Throughout the centre of France, from the Bay of Biscay to Switzerland, there are large plantations, almost forests, of chestnut trees. The poor people, through the autumn and winter, often make two meals daily from chestnuts. The ordinary way of cooking them is to remove the outside shell and blanch them. The blanching is done by throwing the nuts into boiling water, and with a *briquette* rubbing them around the kettle until the inside skin peels off. The *briquette* is composed of two square pieces of wood, 24 to 36 inches long, the angles of which are notched about one foot up; they are joined like shears with a rivet. After the blanching process, a wet cloth is placed in an earthen pot, which is almost filled with raw chestnuts; they are covered with a second wet cloth, and put on the fire to steam. They are eaten with salt and milk. Hot steamed chestnuts are carried round the city streets in baskets or pails; the majority of the working people, who usually have no fire early in the morning, eat them for their breakfast, with or without milk. These nuts are often used as a vegetable, and are exceedingly popular, being found on the tables of the well-to-do and wealthy. They are served not only boiled, but roasted, steamed, puréed, and as dressings for poultry or meats. Chestnuts are made into bread by the mountain peasantry. After the nuts have been blanched they are dried and ground. From this flour a sweet, heavy flat cake is made. It resembles the oat cakes so popular among Scotch peasants. The United States commercial agent at Limoges says that when these nuts are stored they are very apt to heat and ferment, and great care must be taken to prevent this; they are placed in cool, airy bins, so that the air can readily pass through the pile and perfect ventilation be obtained. The walnut tree is very generally grown all over France, but more especially in the central and eastern departments. Walnuts, as an article of food, are losing ground in France because of their scarcity. The trees have been in great demand for timber and furniture-making; nevertheless there are certain sections of the country in which these nuts form a regular article of

diet. The peasants eat them with bread that oftentimes been rubbed with garlic. The health effects are considered good, replacing meat to a large extent. These nuts are also used to adulterate the latter. The prisoners in prisons are, says the commercial agent, often in cracking walnuts and picking out the kernels which are pressed into oil. Almonds are exported from France. The climate of the northern and southern departments of the country are favourably adapted to the growth of them. In the summer, the almond, while the shell is still hard, are soft, green and tender, is sold by the dozen at a hundred in the markets, at from one farthing to one penny halfpenny per dozen, according to the quality of the crop. The meat is white and creamy. As an article of food they are not used as extensively as chestnuts and walnuts. Almond oil is employed for various purposes. Apricot stones are often used with almonds to adulterate the oil. Confectioners and bakers consume large quantities of these nuts, making different kinds of cakes and sweetmeats. Hazelnut trees are only grown for their fruit, although they will flourish in nearly all the departments, the nuts are considered a luxury, and are always high-priced. Hazelnuts are eaten green in the summer, when they are sold at reasonable rates. The exportation from France is important. The pea-nut, so common in the United States, is very rarely eaten roasted in France; nearly all that enter the ports are imported from Spain, Italy, and Africa. The variety is small, uninviting, and very high in price. The taste of these nuts, as a food, is said to be growing. About 200 tons of pea-nuts are imported from the West Coast of Africa, India, and the Malayan Archipelago, and sold in Marseilles and other centres. These are usually bought for the oil which is extracted from them. Pea-nut oil is used for cooking purposes, and adulterated and substitute for olive oil. Many experiments in different parts of Europe have been made as to the nutritive and medicinal qualities of all kinds of nuts, and have advanced views on their use as food, under certain conditions, in special diseases. Nuts contain a special kind of oil especially adapted for lubricating and softening the muscles. Some practitioners claim that the people would be benefited by a more extensive diet. The only evil to be overcome is that the nuts should be thoroughly masticated.

RAMIE CULTIVATION IN KOREA.

The ramie stalk indicates its maturity for good by turning yellow, and the leaves curl inwards at the end. In curing, the bark is loosened with the nail, and is then stripped off with the aid of a

This is done as soon as the stock is cut. Decortication must be delayed, the stems are in water to prevent drying. This stripping is done by the women. The stripped bark is in the shade for several days, and is then made in more or less compact bundles for packing on a pony back. The plant is propagated by transplanting the small rootlets that spring from the main stem. This is done soon after the breaking up of the soil.

Plants may be raised from seed, but the seedling method is preferred, and almost universally used in Korea. The cultivation consists in digging about the plant just enough to keep it free from weeds; deep cultivation is not deemed necessary.

There are three cuttings annually, in June, August, and again in September. Great care has to be exercised in making these cuttings, so as not to injure the young shoots that have sprung up, and on which the next crop depends. Moist, rich loam is the most suitable soil for its cultivation. Stable manure is used as a fertiliser. Warm temperature is the best for the plant. The United States Consul-General in Korea says that there are two kinds of the ramie grown in Korea, but he is unable to state whether they are distinct families, or simply varieties of the same. *Moshi* is the name given to the carelessly cultivated one, and the fibres of this plant produce the silky threads made up into the highly-prized Korean cloth. The other plant, called *sam*, seems to be of growing almost everywhere. It is found in places as a weed, and it will grow on rough hillsides and by water-courses. Neither barrenness of soil nor drought seems to kill it, though, of course, it is susceptible to care and attention. It is used for the coarse fabric worn by the poorer classes in the summer, and for the very extensive mourning dresses of all classes—a veritable "sackcloth." It is used for the outer gowns of both sexes. No woman of any means in Korea is without one or two garments made from moshi, which ranks as a second-rate material, and is almost as pretty as, silk. The *sam* is, however, just as popular among the poor, and is invaluable for the three years' mourning periods that constitute such an important part of every Korean's life. Once started, becomes a permanent crop, easy to grow and care for, and of much value. There are no accurate statistics as to the production of the fibre, but there are supposed to be 12,000,000 inhabitants in Korea, it will be seen, from what has been said, the uses to which the ramie fabric is put, that its production must be considerable. There is no doubt of either fibre or fabric. During the year 1897, an American expert in ramie visited Korea, with a view to a process for the rapid handling of decorticated ramie, which he claimed to be able to turn into the finished silk-like article in two hours. The Koreans were much interested in his proposition to establish a factory in Korea, but declined to pay the large cash outlay required for the use of the secret process. It is probable that the culture of ramie could be increased indefinitely.

Notes on Books.

LANDMARKS IN ENGLISH INDUSTRIAL HISTORY.

By George Townsend Warner. London: Blackie and Son, Limited. 1899.

It is an excellent sign of the tendency of modern education in our larger public schools towards increased breadth of scope to find a Harrow master departing from the ancient lines of historical teaching and producing a book like the present. The study of English history was never very greatly honoured at Harrow. In years gone by it was made the subject of that very perfunctory duty known as the "holiday task," and the time devoted to it was generally a portion of the last day of each holiday, and the first evening after each return. Perhaps things are better now, and it is to be hoped that Mr. Warner will not be content with having produced this excellent textbook, but will induce some of his pupils to study it.

There are very few books dealing with English commercial history. Green touched on the subject, and Professor Cunningham's "Growth of English History and Commerce" is recognised as a standard work on the subject. Many books have of course dealt with the development of commerce, if not with its history, and the history of invention, especially of special branches of invention, has been made the subject of much excellent work. But the field which Mr. Warner has taken for himself may be said to have been quite unoccupied. Nobody—so far as the writer of this note is aware—has previously attempted to sketch, in a fairly popular form, the growth of English industry and trade from the times when Cornwall was known—if it ever was so known—as the Cassiterides, down to the date of the latest labour difficulties. Intimidated perhaps by the enormous mass of detail which would be required for a complete history of English industry, the author has, as his title indicates, endeavoured to depict the chief characteristic, or, as he calls it, landmark of each age, and to show its causes and consequences.

After an introduction and a chapter on the industrial condition which prevailed before the Norman conquest, he gives, under the title of "The Manorial System," an account of land tenure and agriculture in Norman and Plantagenet times. Then comes a chapter on "Towns, and the Beginnings of Town Life," in which the rise and development of the guilds is described, and the general conditions indicated under which craftsmen worked and traders dealt. A chapter on "The Exchequer" shows how the revenue was collected, and how accounts were kept without arithmetic. The next principal landmark is the "Black Death," the effects of which in upsetting the old state of things, and introducing new developments into agriculture and commerce, are hardly realised, except by the few who have made a special study of the time. An account of the woollen industry and of the "mercantile" system leads up to

the times of Elizabeth, and the beginnings of colonial expansion. Then, after a survey of English industries, the origin of banking is described, and its growth. Then comes the growth of Greater Britain, and the trade wars of the 18th century. A single chapter on machinery and power is considered sufficient to describe the results of the introduction of the steam-engine and all the enormous changes consequent thereon. This portion of the book seems somewhat inadequate; indeed, a history of industry would not be ill-proportioned in which the first half was devoted to commerce and industry before the introduction of power, and the second to its later and greater developments. Perhaps some day Mr. Warner may expand this 18th chapter into a volume. There is ample material; indeed, perhaps too much. The remainder of the book deals with modern developments and modern economic theory, the subject being indeed brought down until the present day, in the last chapter on "Modern Conditions: Trade and the Flag."

General Notes.

SIR HENRY DOULTON.—A reredos has been erected in the chapel of St. Thomas's Hospital in memory of Sir Henry Doulton, who was for many years Governor and Almoner of the hospital. The reredos is the work of George Tinworth, and was presented by Sir Henry Doulton's children. It contains three panels—the subject of the centre panel is the Ascension of Christ, that of the second the recognition of the Saviour by Mary after the Resurrection, and that of the third the evidence given to St. Thomas of the Resurrection. The reredos was consecrated on Tuesday last, the 21st inst., by the Bishop of Rochester.

MEETINGS OF THE SOCIETY.

CANTOR LECTURES.

Monday evenings, at 8 o'clock :—

PROF. HENRY R. PROCTER, "Leather Manufacture." Four Lectures.

LECTURE I.—APRIL 17.

Primitive methods—Difficulties of investigation—Sources of raw material—Methods of curing—Anatomical structure of skin—Arrangement of hair-pores—Chemical character of skin and epidermis—Manufacture of gelatine—Soaking and softening of hides and skins preparatory to tanning.

LECTURE II.—APRIL 24.

Removal of hair and wool—The staling process—Bacteriological and chemical actions involved—Liming by lime—Practical methods—Chemical liming process—"Buffalo" method—Pulling—Direct process—Use of alkaline sulphhydrates—Mechanical operations—Deliming process—Chemical and physical considerations—"Down" with acids—Fermentative methods—Tanning—Drenching—Bating and puering.

LECTURE III.—MAY 1.

Physics of tanning—Theory of the pickling process—Mineral tannages—Tawing with alumina—Chrome tanning—Heinzerling process—"Scotch" "two-bath" process—Basic or "one-bath" process—Iron tanning.

LECTURE IV.—MAY 8.

Oil dressing—The chemistry of the process—Combinations of oil and mineral tanning—Various tanning matters—Chemistry of the tannins—Various methods—Combination of vegetable and mineral tanning—Currying—The chemistry of oils used—Theory of the currying process.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MARCH 27...Imperial Institute, South Kensington, 8½ p.m. Mr. Sidney G. P. Coryn, "Living conditions of Canadian Ranch and Prairie."
Cleveland Institute of Engineers, Middle Row, 7½ p.m.
Geographical, University of London, Buntings gardens, W., 8½ p.m.
Institute of Public Health, 20, Hanover-square, 8½ p.m. Mr. W. J. Dibdin, "Sewage Disposal."
Actuaries, Staples-inn Hall, Holborn, 7 p.m.
Medical, 11, Chandos-street, W., 8½ p.m.

TUESDAY, MARCH 28...Medical and Chirurgical, 11, over-square, 8½ p.m.
Civil Engineers, 25, Great George-street, 8 p.m. Mr. Robert Abbott Hadfield, "Iron and Nickel."
Photographic, 12, Hanover-square, W. (Technical Meeting.) Mr. T. Manly, "Printing with Carbon Tissues, a new method of photographic Printing."
Anthropological, 3, Hanover-square, W. 8 p.m.
Colonial Inst., Whitehall-rooms, Whitehall, S.W., 8 p.m. Sir William MacGregor, "New Guinea."

WEDNESDAY, MARCH 29...Aeronautical (at the Home Office), SOCIETY OF ARTS, 8 p.m. Mr. Percival "Andrée's North Polar Expedition: suggestions for future Polar Exploration by Balloon."
British Astronomical, Sion College, Embankment, W.C., 5 p.m.
Mining and Metallurgy, Geological Institute, Jermyn-street, S.W., 6½ p.m. Annual Meeting.
Chemical, Burlington-house, W., 8 p.m. Meeting. President's Address.

March 31, 1899.]

Journal of the Society of Arts.

No. 2,419. VOL. XLVII.

FRIDAY, MARCH 31, 1899.

Communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Proceedings of the Society.

INDIAN SECTION.

Thursday afternoon, March 9, 1899. The Hon. Mr. G. C. M. G., Under-Secretary of State for India, in the chair.

The paper read was—

LEPROSY IN INDIA.

By H. A. ACWORTH, C.I.E.

The statement of objects and reasons appended to the Bengal Bill No. III., of 1895, which ultimately became the Bengal Lepers Act No. V. of 1895, begins with the following words:—

"The expediency of segregating pauper lepers under proper safeguards, and of forbidding lepers generally from exercising certain trades and callings connected with human food, drink, and clothing, was urged by the Leprosy Commission which visited India in 1890-91. Experience in Bombay having shown that these recommendations can be successfully carried into effect, the accompanying Bill has been prepared, &c."

On the 30th July, 1896, a Bill was introduced into the Legislative Council of the Government of India, which became in time the Lepers Act No. III. of 1898. The statement of objects and reasons attached to that Bill opens with these words:—

"The expediency of segregating pauper lepers under suitable safeguards, and of forbidding lepers generally from following certain trades and callings connected with the bodily requirements of human beings, was urged by the Leprosy Commission. . . ."

... The present Bill has been prepared on the lines of the Bengal Act."

On the introduction of the Bill in the Government of India Legislative Council, the mover, Mr. Woodburn, now Sir John Woodburn, Lieutenant-Governor of Bengal, made the following observations:—

"In 1890-91, a Leprosy Commission visited India, and a couple of years later submitted a report to the Government of India, pressing on it very earnestly two questions, the segregation of lepers, and the restraint of lepers in certain callings in which they were brought into immediate contact with the food and clothing of their neighbours. The Government of Bombay had already taken action in that direction, with the help of a very munificent donation from Sir Dinshaw Petit. They constructed in 1890 a lepers' asylum in Bombay. That asylum, I believe, contains accommodation for about 300 lepers, and the result has been to free the city of Bombay from the beggars who extorted alms by the exhibition of their sores. The unfortunate creatures subjected to this dreadful malady have now been removed to a hospital, in which that comfort and attention are given to them to which their pitiable condition gives them a just claim. The Government of Bengal followed that example last year, and passed through their Local Council a Bill for the two purposes I have mentioned; the segregation of lepers, and their prohibition from certain callings."

The object of the writer in making these references is two-fold; first, to point out that the legislation undertaken in the Councils of Bengal, and of the Viceroy, was avowedly based upon recommendations made by the Leprosy Commission; secondly, that both Governments acknowledged that an example set in Bombay had encouraged and induced them to undertake that legislation. Sir John Woodburn's account of the action taken in Bombay is hardly accurate; but the error is one which has no interest except for the present writer, who will be excused, perhaps, for reverting to it further on. It will suffice to say here that the Government of Bombay never erected a leper asylum in Bombay, and that though Sir Dinshaw Petit did offer a lakh of rupees for the purpose, it was never spent.*

Now is it true that the Leprosy Commission recommended the segregation of lepers; meaning, of course, their compulsory segregation? In both Councils their authority was appealed to in justification of legislative measures for the enforcement of a system of compulsion; and the word segregation, as

* The asylum, built in 1890, was at first known as the "Acworth Asylum," and was so styled in Government resolutions. The writer requested (and wrote accordingly to Government) that the name might be changed to the "Matoonga" Asylum, after the suburb in which it was built.

used in these Councils, must clearly be understood in this and no other sense.

Among the definite conclusions at which they arrive, the Leprosy Commissioners say:—

“3.—Though, in a scientific classification of diseases, leprosy must be regarded as contagious, and also inoculable, yet the extent to which it is propagated by these means is exceedingly small.”

If this be so, the writer must confess that he fails to understand on what principle save, perhaps, that of heredity segregation, or voluntary isolation, can be defended as of any value.

Going on to “Practical Suggestions,” the Commissioners say that segregation “may be voluntary or compulsory, and in either instance partial or complete. Complete segregation has never yet been possible.” They then consider the examples set by the Sandwich Islands, and Norway, and go on to say:

“For India, complete compulsory segregation may be considered to be absolutely impracticable. Neither do the conclusions given . . . as to the nature of the disease, justify any recommendation for absolute segregation. The presence of a leper in a healthy community is a source of danger no greater than the presence of an individual suffering from tuberculosis. Both diseases are contagious in an equal and minimal degree. The amount of ulceration which exists in both diseases is to some extent a measure of the danger of contagion.

“It is impossible for the same reasons to advise compulsory partial isolation. Voluntary isolation is, therefore, the only measure left for consideration. Among civilised communities the separation of those suffering from many diseases other than leprosy is encouraged. The voluntary isolation of the leper is, therefore, no exception to this custom. For this reason the Commissioners recommend the adoption of a voluntary isolation as extensive as local circumstances allow. Further, by permitting marriages among lepers, the plan suggested might be the more easily carried out.”

The Commissioners then go on to recommend that the crowding of lepers into large towns should be discouraged, for a variety of general reasons, but not because there is any risk of their diffusing the contagion of leprosy; that municipal bye-laws should be passed, preventing “vagrants suffering from loathsome diseases from begging in or frequenting places of public resort, or using public conveyances;” also that leper asylums should be built near towns, and that the “authorities should have the power of ordering lepers infringing the regulations, either to return to their homes, or enter an asylum.” They also recommend that lepers should be debarred from following

occupations which concern the food, drink, clothing of the people, but guard themselves by adding that they recommend this “apart from the dread of a possible infection.”

“In no case,” say they, “would the Commissioners suggest an Imperial Act, especially directed against lepers as such, for these are far less dangerous to a community than infectious or syphilitic people.”

The writer would here observe that he does not presume to state any opinion of his own on the questions of the hereditary or contagious character or otherwise of leprosy. For information on these points, he goes to the reports of the leaders of medical science; though they, unfortunately, may speak with an uncertain voice. All that the writer, and those who, like him, have been concerned with the question of leprosy in its administrative aspect, look for or are capable of discussing, is a working hypothesis. It was, he believes, Dr. H. Vandyke Carter—*clarum et venerabile nomen*—who spoke of contagion as a “good working hypothesis.” Dr. Vandyke Carter is, nevertheless, for many years a non-contagionist, though the writer is not sure whether in later life the views of that most eminent authority were not modified or changed.

The references which have been made to the report of the Leprosy Commissioners make it abundantly clear that the legislation which has been undertaken in the Bengal Council, at the instance of the Viceroy, would never have been passed without their concurrence, and that to have questioned their views, and their recommendations, in support of it, seems to indicate a misapprehension of their views.

The writer must repeat that if the contagiousness of leprosy may for practical purposes be disregarded, if it is not a “good working hypothesis,” he is at a loss to comprehend why lepers should be singled out as the objects of any of the measures which the Commissioners deem to be justifiable. It seems to him that the Commissioners, however convinced they may have been of the accuracy of their opinions, had not what is commonly called the courage of them. They repudiate the risk of the disease being diffused by contact, and then recommend, or suggest, or suggest, a series of measures which cannot be justified on any other grounds. The words “suggest” are meant to indicate the recognition of the value of isolation, coupled with the whittling away of the value of it by making it voluntary. The Commissioners must have been aware, by the experience gained on the

hat in India voluntary isolation is no isolation at all, and that a voluntary asylum has almost no effect whatever in relieving the streets and public places of a town from the presence of lepers. Dr. G. A. Hansen, in an article in *The Lancet*, in October, 1893, dwells on the contradictory character of this part of the report.

The Committee of the National Leprosy Fund, in commenting on their Commissioners' report, expressed their "entire dissent from the conclusion that segregation was either impracticable or undesirable." "They entertained a precisely opposite opinion," and "would be sorry if the Government of India were encouraged by the report of the Commissioners to refrain from taking the necessary steps in the direction of such segregation of lepers as may be found possible." They then expressed their concurrence in views formerly expressed by Dr. Vandyke Carter, and which favoured the erection of leper asylums, the establishment of leper colonies or villages, in all of which compulsory segregation should be enforced, together with the strict isolation of leprous subjects retained at home at the express wish of their friends.

This last provision has been enforced in Norway since 1885, when a law to that effect was passed at the instance of Dr. Hansen, the Inspector-General of Leprosy, and it illustrates the view of that authority that separate sleeping accommodation, a separate food apparatus, and strict cleanliness of house and person, are "usually isolation enough to prevent the spread of leprosy."*

It is interesting to note that the first name signed to the committee's memorandum is that of George N. Curzon, then Under-Secretary of State for India, and now Viceroy of India. Of the medical men who also signed it, two only failed to append minutes of dissent from the views of the committee as to compulsory segregation. Mr. Jonathan Hutchinson, Sir Dyce Duckworth, Sir Joseph Fayrer, Sir Andrew Clark, Sir Guyer Hunter, Sir James Paget, all dissented from those views.

Such being the array of expert knowledge and talent in favour of the Commissioners' views upon the question of compulsory segregation, is there any likelihood that, circumstances remaining as before, any legislation in that direction would have been yet undertaken in India? The writer is firmly convinced that

there is not;* and that in spite of the minute of the Committee of the National Leprosy Fund, the Governments in India would not have moved if circumstances had remained as before. If, indeed, either the report of the Commissioners or the minutes on it had supplied the necessary stimulus, it may be alleged with some confidence that the Government of Bengal would not have waited for two years, or the Government of India for three years, before dealing with the question. It was the stimulus supplied and the example set in Bombay which were really the parents of legislation at Calcutta and at Simla.

The question of leprosy as an administrative problem had become urgent in the city and presidency of Bombay some considerable time before the death of Father Damien (April, 1889), or the foundation, under the chairmanship of H.R.H. the Prince of Wales, of the National Leprosy Fund (June, 1889), but it was the creation of this fund, and, in particular, the association with it, and the energetic leadership and control, of His Royal Highness, which furnished the momentum, under which a solution of the question was rendered possible. Our great English moralist says:—

"How small of all that human hearts endure,
That part that Kings or laws can cause or cure."

There may be some truth in this, as a general proposition, but it has no correct application to the present question, or to our Kingly Commonwealth of England. On the contrary, it may be confidently asserted that it was to the personal influence and capacity of H.R.H. the Prince of Wales, that we owe it that the question of leprosy in India was made ready and ripened for solution, instead of being allowed to linger on as an unmanageable administrative difficulty for an unknowable series of years.

By the census of 1881, the number of lepers in the Bombay Presidency was 10,095, and in the rest of British India, 108,858, or a total of 118,953. By the census of 1891—which was after the period which the writer is about to consider—there were 10,187 lepers in Bombay, and 94,510 in the rest of British India, to which, since 1881, Upper Burma, with 3,504 lepers, had been added. There was a great diminution in 1891, as compared with the

* The writer says "yet undertaken." He has no doubt, seeing the position he occupied on the Committee of the National Leprosy Fund, that the able and resolute man who is now Viceroy of India would not have waited long after his arrival to initiate a measure for the segregation of lepers.

* Hansen, *Lancet*, October, 1893—"Hansen and Looft on Leprosy," 1895.

figures of 1881, in Bengal and Madras, the numbers being, 76,079 for Bengal, and 11,967 for Madras in 1891, against 92,181 and 14,088 in 1881. In Bombay the numbers had remained nearly the same.

The census figures can only be taken as an approximation to the truth, for there can be little doubt that numbers of persons who were affected only with what is called white leprosy had been included as lepers, and, on the other hand, that some true lepers had escaped enumeration. In the early stages of the disease, true leprosy is often very difficult, and to a layman impossible to detect. The writer has seen many cases in which the only indication of leprosy has been a small patch of discoloration on the skin, very often covered by the clothes. He remembers one case in the Matoonga Asylum, in which the patient was a fine, robust, healthy-looking young woman of the Maratha caste, who showed no sign of the disease, excepting a small light-coloured patch, called by the doctor an anæsthetic patch, high up on the inside of the left thigh. In another case, a female child of six years' old, there was one such patch on one arm, and another on the buttock (right hip). Photographs of the latter case were included among a number which he sent to the Medical Secretary of the National Leprosy Fund. Such cases as these would never have been included among lepers by any census enumerator.

Without going into the classes into which true leprosy is divided, nodular or tuberculous (*lepra tuberculosa*), anæsthetic (*maculo-anæsthetica*), and mixed, if a separate division is now recognised under the title of mixed, the writer would point out that in Western, and he believes in other parts of India, two kinds of so-called leprosy are popularly recognised. One of these is black leprosy, and called in Marathi raktapiti, and the other white leprosy, or kor. The former is true leprosy; the latter, Vandyke Carter says, has "hardly anything in common with true leprosy." . . . "It is included among a group of skin diseases, known as 'kushta.' The leprosy of the Jews was clearly the same as the 'kushta,' of Hindu writings. . . . The expression leprous as snow can only refer to some skin disease, probably 'kor.' It cannot possibly be true leprosy. 'Kor' and 'raktapiti' are totally distinct."* "What is called 'white leprosy,'" says Mr. Jonathan Hutchinson, "is usually

leucoderma, a disease which has no relation true leprosy."

White leprosy, therefore, kor, or leucoderma may be eliminated from consideration altogether. Every measure contemplated effected in India for dealing with leprosy had relation to black leprosy, or raktapiti.

There were several leper asylums in the Bombay Presidency in 1889. There were two in Belgaum, one at Ratnagiri, and one in Trombay, close to Bombay. This was a very small one, accommodating about 20 patients and had been established by the charity of a Parsee gentleman of the All Bless family. There was also at Byculla, in the heart of the city of Bombay, a leper dharmasala, attached to a dharmasala for indigent persons. These were established by Sir Jamsetjee Jeejeebhoy, an endowment provided for a small daily issue of food and money, and in 1889 this dharmasala contained from 150 to 200 lepers from all parts of the Presidency. Dr. Vandyke Carter has noted in 1876, in a report on leprosy in Kattiawar, that it was customary to send bad cases from that province to the leper dharmasala at Byculla.

It may be added that there was a leper ward attached to the Central Jail at Yerrowda near Poona, to which leper criminals, if sentenced to long terms of imprisonment, were sent. These lepers here were isolated, and did not mix with the healthy prisoners. Compulsion, of course, is part of a prison administration, and there was no difficulty in enforcing it at Yerrowda, but the fact that it was enforced showed that where it was possible to resort to it, the necessity for compulsory isolation had already been recognised as a "good working hypothesis." The case was the same in Madras, where a leper ward for criminal lepers had been attached to the leper asylum in that city.

In every part of the city of Bombay leprosy was, in 1889, more or less in evidence, in every stage of the disease, and exhibiting in the public streets every one of its hideous deformities. On the occasions of Hindu festivals they crowded to the temples on the sea-shore, lining the streets in scores and hundreds. They occupied the verandahs and courts of empty houses. They washed and drank from the public taps. They scattered their rags about the shops and markets, and instead of using, like Job, potsherds to scrape themselves with, they used rough stones from the heaps of red metal stacked at the street sides.

For some years a sense of this evil had been growing. In 1883 the Roman Catholic Bishop

* H. Vandyke Carter, Trans. Medical and Physical Society, Bombay, 1871; No. XI., p. 74.

f Bombay had applied to the Government for the grant of one of the old forts of Sion, Jatoonga, Warli, or Sewri, to turn into an asylum for lepers. His request was not complied with, but the Government intimated that they would gladly see an asylum established in Bandora or in Kurla, outside the limits of the city. A year or two afterwards the tiny asylum at Trombay, already referred to, was established, and also the asylum at Ratnagiri. In February, 1888, the Municipal Commissioner Mr., now Sir Charles Ollivant) called on the Health Officer for a report with reference to the leper dharmasala at Byculla. Early in 1888 the Inspector of the Education Department drew the attention of the Government to the fact that a colony of lepers had established themselves in close proximity to some large schools; and, being also a member of the Bombay Municipal Corporation, he brought the matter forward in that body, desiring to know what powers the Health Officer required to deal with the evil.

The Commissioner of Police in June, 1889, reported that lepers were on the increase; that he could not deal with them, because there was no place to which they could be sent; that was useless to place them before the magistrates as vagrants, for the magistrates would not send them to jail; that there were 430 lepers in the city at the last census, and at the time of writing probably twice as many; that Section 424 of the Municipal Act was put into force he could clear the city of them in a few days, supposing there was any place to send them to; and that the necessity of clearing the city of them and isolating them was urgent. The Municipal Commissioner, in sending on his letter, said that the existing provisions of the law were totally inadequate.

In August, 1889, the Government of Bombay directed the Municipal Commissioner to remove the lepers from the place complained of by the Educational Inspector. They added that it was the duty of the Municipality, under Section 424 of the Bombay Municipal Act, to remove persons suffering from dangerous diseases to hospitals or asylums, and if there were no suitable hospitals or asylums in existence they should be provided.

To issue such an order as this from the Secretariat was easy enough; to carry it out was quite another matter. Supposing the estimate of the Police Commissioner as to the number of lepers to be accurate, and that there were 860 requiring removal, it would have cost, on the basis of the expenditure afterwards

incurred at Matoonga, and which was rigidly economical, at least three lakhs of rupees to build an asylum for them, even supposing the land to have been obtained free, and a monthly expenditure of Rs. 8,600, equal at 4 per cent. to a further capital of nearly 26 lakhs, to maintain them. Moreover, the law quoted by Government gave no adequate power to any authority. Section 424 of the City of Bombay Municipal Act, III. of 1888, runs nearly as follows:—

“The Commissioner, or any Police Officer empowered by him in this behalf, may, on a certificate from the Health Officer, or any duly qualified medical practitioner, order the removal of any person suffering from a dangerous disease, and who is without proper lodging or accommodation, or who lodges in a building occupied by more than one family, to a hospital where such diseases are treated.”

This is an extremely valuable provision in its way, and is constantly acted upon in cases of small-pox, cholera, and so on, but its futility in cases of leprosy consists in this, that though it gives power of *removal*, it gives none of *detention*. A person suffering from cholera or small-pox is generally glad to be removed to a hospital, and glad or not, is physically incapable of leaving it until he has recovered; then he is allowed to leave it, and no one tries to detain him. But the case of a leper was quite different. He was as well able to leave the hospital the hour after he was taken there as he was when he came in, and if he wished to do so no one could prevent him. The section was, therefore, useless as applied to lepers, and the orders of Government dead at their birth. The Corporation realised this, and simply “recorded” the order, without attempting to take action on it.

Before matters had reached this stage the foundation of the National Leprosy Fund, and the public action in connection with it of H.R.H. the Prince of Wales, had stirred into movement the *non possumus* of India. In June, 1889, the Supreme Government issued a Resolution on the subject of leprosy, which, together with a draft Bill for dealing with lepers, was circulated to the various provinces for opinion. The main features of this Bill were as follows:—

A leper was defined to be “a person certified by a medical practitioner, having from the local Government general or special authority, to be suffering from leprosy.” The writer may observe in passing, that in his opinion this definition is preferable to that which was subsequently embodied in the

Bengal and Government of India Acts, which became law. The Bill empowered local Governments to establish retreats, to which lepers might voluntarily apply to be admitted for life or a term of years, being liable to punishment if afterwards they escaped from them, and to which vagrant lepers might be sent by magistrates for detention. Provision was made for the inspection and management of these retreats, in which, by a further provision, the sexes were to be separated from each other. Local bodies were empowered to spend money on such retreats, and local Governments were authorised to devote to them any moneys which they held at their disposal for expenditure on hospitals or asylums.

It may be observed here that the Government of the Central Provinces had, in the previous year, asked the Government of India to include powers for the compulsory detention of lepers in the Municipal Bill for those provinces which was at the time before the Supreme Government.

The reports on this draft Bill were on the whole unfavourable to it. Particular stress was laid on the circumstance that it contained no adequate provision for dealing with rich lepers. The Bill was not proceeded with.

In January, 1890, the Government of Bombay laid their hand upon an Act, to which their attention had been drawn some time before by their solicitor, and on the strength of which the asylum at Matoonga was afterwards established. This was Bombay Act VI. of 1867. It does not appear that the Government realised how this Act might be used to supplement or supersede the insufficient coercive provisions of the City of Bombay Municipal Act. The writer thinks that this discovery was left for him to make. But it was useful, and used for other collateral purposes.

The Act is entitled "An Act for the better sanitary regulation of the City of Bombay," and the preamble states that it is intended to have special reference to vessels using the port. It gave Government power to establish by notification sanatoria "for the segregation of persons suffering from any infectious disease dangerous to life," and to notify what diseases should be held to be such for the purposes of the Act.

On 8th January, 1890, the Government issued a notification, declaring "black leprosy" to be an infectious disease dangerous to life, and further declaring the asylums at

Trombay and at Ratnagiri to be sanatoria under the Act. Three weeks later they required of the Police Commissioner of the city that he should deal with the evil, inasmuch as "places had been provided for the treatment of leprosy."

Now the Trombay Asylum would hold comfortably 18 or 20 patients, and at a pinch 25; the Ratnagiri Asylum would hold at the outside 80. Moreover, Ratnagiri was distant 12 miles from Bombay by sea, and was almost inaccessible for a sick person, certainly for a crowd of them, by land. There were, ex hypothesi, at least 800 lepers in Bombay. Even if Ratnagiri could be reached, yet the asylums there and at Trombay would together hold only an eighth of them. The action of the Government opened no way out of the impasse. The Police Commissioner was ordered to make bricks without straw.

At this juncture, Sir Dinshaw Petit offered one lakh of rupees for the erection of a leper asylum, on the conditions that it should be called after his name, and that the Corporation or Government, or both, should equip and maintain it. The Corporation agreed to the terms, but hoped Government would contribute. On 25th March, 1890, the foundation-stone of this asylum was laid at Trombay by an illustrious prince, who was then visiting India and whose early death no long time afterwards threw the whole empire into mourning. Plans and estimates were ordered to be prepared for the accommodation to provide for 1,000 lepers.

It may be observed here that no part of the money has ever been spent, and that the scheme has never advanced from that day to this. It was found, to begin with, that accommodation for 1,000 lepers in buildings sufficiently solid, and, if I may use the word "pukka," to satisfy the Government engineers would cost nearer five lakhs than one, and the necessary funds were not available. When the plans were being considered, and during the pause which ensued on this discovery, the asylum at Matoonga, intended at first as a temporary expedient to bridge over the period till the new asylum at Trombay should be ready, was started, enlarged, and gradually acquired its present permanent character, all for various reasons, among others, the much greater convenience of the situation, has superseded the Trombay scheme altogether.

The writer succeeded to the office of Municipal Commissioner of Bombay on 1st May, 1890. It was by that time becoming very plain that a long time must certainly

lapse before the asylum at Trombay could be built, if ever it was built, and the question of what to do with the lepers of the city was every day more and more pressing.

The writer has no intention of dwelling at any length upon the measures which he took to dispose of the difficulty. It was soon clear to him that the best, indeed the only, course was to elicit from the public charity—that charity which the natives of Her Majesty's Indian Empire always and everywhere so nobly show when the necessity for it has been made clear to them—funds sufficient to provide a temporary home for vagrant lepers, until the expected permanent accommodation was ready.

He would be egotistical, and would interest nobody except himself, to recount the measures he took towards this end. It suffices to say that by a sustained and organised effort funds were raised, funds in the issue considerably exceeding the sum offered to Government by Sir Dinshaw Petit. But the raising of these funds was the least and the easiest portion of the undertaking. Two things presented themselves as difficulties requiring preliminary solution, one the question of maintenance, the other the far greater and wider question of segregation. As regards the first, the writer applied to Government and to the Municipal Corporation to guarantee a certain monthly sum per head of lepers received into the asylum. In each case a generous response was made. Government and the Corporation each agreed to contribute Rs. 10 per head upon the number of 150 lepers, or a joint total of 300. In mentioning this, the writer must needs mention the names of Lord Harris, the Governor of Bombay, and of Mr. Pheroze Shah M. Mehta, now the Hon. Pheroze Shah M. Mehta, C.I.E. Lord Harris was the first, and a very liberal, subscriber to the fund, and though the writer cannot assert, yet he has no doubt, that it was primarily to his influence that he owed the consent of Government to the large contribution they made towards maintenance. He owed a similar debt in the Corporation to Mr. Mehta, and here he has a full knowledge of all that passed, and is able to state that, generously disposed as the Corporation undoubtedly were, yet it was to Mr. Mehta's commanding influence and ability that he is principally indebted for the readiness of their response to his appeal.

The question of segregation seemed for a long time to be an insuperable difficulty. The chief object to be aimed at was the purgation of the city. To this end a voluntary asylum

would have been useless. If lepers were to come and go, the streets would never be clear of them. At all times the majority, on each of the numerous occasions of a festival all of them, would infest the streets as before, begging and exhibiting their deformities. It was absolutely necessary, if any good was to be done, that the real crux of the leper question, which had never yet been grappled with, and on which every scheme had hitherto been wrecked, should be resolutely and decisively faced, and disposed of.

It was clear that in the Municipal Act no help was to be found. After other vain explorations in the arcana of legislative enactments, Act VI. of 1867 (Bombay) was turned to, and after careful study, it seemed to give all the necessary power. Under the third section of the Act, the Consulting Officer of Health, or in his absence, the Health Officer of the port, had the power to remove any vagrant who might be suffering from a disease notified under Section 12, to a sanatorium notified under Section 1; and any person so removed was "*bound to remain there until one of the said Officers of Health certified that he might go abroad without danger to the public.*" Now, over the Health Officer of the port the Municipal Commissioner had no control, but under Section 76 of the Municipal Act the Health Officer of the Municipality was made Consulting Officer of Health for the purposes of Act VI. of 1867. The Health Officer of the Municipality was subordinate to, and was indeed the head of one of the departments under, the Municipal Commissioner. The writer, who filled the latter office, began, therefore, to see his way sufficiently clearly to justify him in proceeding to collect subscriptions. As soon as a certain sum had been realised, building was begun. The site chosen was at the village or suburb of Matoonga, within the limits of the city, but on its further boundary, and near the head of the harbour. Though not far from one of the main roads leading northward out of the city, it was completely concealed from it, and was, in fact, so effectually isolated, that, as the Health Officer observed, it was "*anatomically twenty miles from the city.*" In former days troops had been quartered at the place, and the long high embankments or plinths upon which the barracks had stood were very suitable for the erection of wards, and their existence saved much expense. The ground belonged to the Municipality, and it was not the least of the services of the Corporation to the cause that

they never demurred to its occupation, which the writer had no authority to have effected without their previous concurrence. But in all matters connected with the leper asylum, the Corporation of Bombay have shown a large and noble liberality.

The asylum was at first intended to be of a temporary character, but if it was to resist the monsoon of Bombay, strength was essential. Economy also was a primary requisite. The plans and the character of the structure were the work of the Municipal Chief Engineer, Mr. Rienzi Walton, now one of the Engineering Inspectors of the Local Government Board, without whose talent and energy the buildings could not have been erected so quickly as they were, or on such satisfactory lines. Though at first called temporary, and constructed to a great extent of iron (angle and T irons with brick noggin), so as to be easily removed, they may, as a matter of fact, defy the wear and tear of centuries.

The wards, with all their adjuncts, which now include, besides lavatories, storehouses, dispensary, and so on, a Hindu temple, a Mohammedan mosque, a Roman Catholic church, and a very useful hospital ward (built at the cost of the benevolent Bai Dinbai, widow of Mr. Nusserwanjee M. Petit), cover several acres of ground, and are surrounded by a high fence of barbed wire.

On the 6th November, 1890, sufficient work had been done, though building had only begun on 19th August previous, to provide accommodation for somewhat less than 100 lepers. Those who were concerned with it will not forget that day, the first on which compulsory segregation was applied to lepers in India. The police had received due warning, and the necessary orders had been issued by their Commissioner, whose valuable co-operation had been readily secured. On the morning of the 6th of November, 40 or 50 lepers were brought in by the police from the streets, and conducted to a locality where they were to be inspected by the Health Officer (Surgeon-Major Kirtikar). They were all carefully examined, the necessary certificates were issued, and they were removed in carts (afterwards carefully disinfected) to the Matoonga Asylum. On the next day similar action was taken, and so on, until the available space was filled. As the asylum grew, further removals took place, and when the writer left India in April, 1895, the full number of 300 was rather exceeded; there were about 310 patients in the asylum.

Two sets of prophecies attended the establishment of the Matoonga Asylum; one, that it would be so popular that it would soon be over-crowded; the other, that it would be impossible to coerce the lepers into staying there. Both have proved wide of the truth, though the former is nearer to the facts than the latter.

The asylum became in course of time sufficiently popular to keep it filled, and even a little more than filled. It did happen now and then that a leper seeking admission had to be turned away, but these were occasional cases. Room was always found for lepers sent there by the police. It must be understood that after the first few months the intervention of the police was confined to sending to the asylum casual vagrants arrested for begging, and who would, if they had not been lepers, have been placed before a magistrate.

In its earlier days, the asylum was distinctly unpopular. The wholesale sweeping up of lepers from the streets, and the confinement of the asylum were both resented. The writer was once disposed to attribute the diminished number of lepers in the city, which was disclosed by the census taken in February, 1891, four months after the asylum had started, to an exodus caused by the coercive measures which had been adopted; but though he still thinks there was some ground for that belief, he has since come to the opinion that he exaggerated it, and that though a few lepers may have left Bombay on that account, yet the real fact was that both he himself and all the other authorities of the city at that time had over-estimated the number of lepers within it. He has already referred to the Police Commissioner's estimate that there were at least double as many in 1889 as there were in 1881, and no one put the number at less than 800 to 1,000. But the writer greatly doubts whether 500 would not have been an over-estimate. The writer never thought or said at any time that he believed leprosy to be on the increase in India; but he did believe that with the improvement of communications both by land and sea, the natural gravitation towards a great city, that is, towards a convenient centre for begging, had added to the number of lepers in Bombay itself. He still thinks it had done so, but not to anything like the extent which he at one time supposed to be the case.

The Matoonga Asylum, however, built to contain 300 patients, might reasonably be enlarged so as to contain 500.

For some weeks after the asylum was established, it was thought advisable to keep a

small guard of police there. But in spite of this, and in spite of the fact that it was surrounded by an 8 foot fence of barbed wire, there were several cases of escape from it in the first few weeks, perhaps a dozen from first to last, and there was a good deal of discontent within the asylum. The truth is that confirmed habits of vagrancy are difficult to eradicate, and that lepers, like tramps in this country, prefer a life of freedom and irresponsibility, though it be one in which their sustenance is precarious, to regular habits, and sufficient food and clothing, coupled with restraint, however lightly applied. Perhaps the vagrant leper may often have passed a day or two without a full meal, but then he very often got opium, sweetmeats, and other luxuries, and forgot his sufferings in the enjoyment of them. It is true that when the pinch of privation was severe, large numbers would have voluntarily sought the asylum; but after good feeding for a day or two they would have left it again, and resorted to their former wandering habits. For this reason a voluntary asylum in India will never clear a place of lepers, and as a matter of fact, never has done so. There is, for instance, a most admirable leper asylum at Madras, constructed on the best lines, and managed to perfection; but when the writer visited it (in March, 1891), he found the streets of Madras full of lepers.

One difficulty which was felt at the Matoonga Asylum, when first started, arose from the opium-eating habits of the patients, and though the writer for a short time adhered to the resolve not to allow the issue of opium, he had at last to give way, and small and diminishing quantities were allowed under the strict control of the medical officer. It was found possible to reduce the quantities by degrees, and the habit was gradually almost or altogether eradicated.

Every effort was of course made to render the asylum as comfortable a residence as possible. The diet was on the most liberal scale, the clothing was excellent, tobacco was allowed to both men and women who cared to have it, and the strictest regard was paid to cleanliness. At the same time, every remedy, medical and surgical, by which the misery of the patients could be alleviated, was at their disposal. A medical officer lived on the spot, and he was under the control of a doctor of superior rank and attainments, who daily spent from two to three hours at the asylum. The latter again was under the orders of the Health Officer to the Municipality. The whole

asylum was directly ruled by the Municipal Commissioner.

After a few weeks, it was found possible to remove the police guard; and as the reputation of the asylum grew among those whom it was intended to serve, as they learned how greatly health and comfort were promoted by residence there, and how ample a measure of freedom they might still possess within its wide boundaries, attempts to escape came entirely to an end, and the difficulty of finding room for those who wished to come in was substituted for the difficulty of retaining them there.

All classes of natives were admitted, and there were from time to time a very few Europeans. A question soon arose as to providing for the spiritual requirements of the inmates. The writer did not feel at liberty to do this out of the general funds collected for the erection of the asylum. He, therefore, made special appeals to Hindu, Mohammedan, and Christian gentlemen; and out of the funds by them contributed for the purpose, he built a small Hindu temple, properly fitted up, a small mosque, and a small Roman Catholic church, and suitable arrangements were made for the attendance of priests of the different religions. The writer's action in this respect exposed him to some comment, and he was accused of furthering the cause of idolatry; but for such accusation he cared and cares little. The inmates of the asylum were, without having committed any crime, prisoners for life, and he felt it to be his clear and sacred duty to provide, so far as he could, for all their legitimate requirements; and he thought, and thinks, that the claims of a Hindu or a Mohammedan for a place of worship according to his belief, was a requirement as legitimate as that of a Christian for a church.

Perhaps the most painful feature of the asylum was the large number of children which it contained. These amounted at last to 30 or 40, from five or six years of age upwards. Every species of game and toy that could be devised was provided for them, and added to from time to time; and though education would be of little use to them, it was thought well to occupy their minds by giving them some schooling. A small school was accordingly built; schoolmasters were easily found among the lepers, and four hours' schooling a day, excepting during the holidays, was insisted on. Examinations were periodically held with as much show and circumstance as possible, and public prize-givings, often attended by many of the principal ladies and gentlemen of the city,

succeeded to them. It was easy to raise money for these prizes from the benevolent, and it was contrived, contrary to all sound educational principle, that all the children should receive some prize or other. The last prize-giving which was held before the writer left India, was presided over by the Right Rev. Dr. Mylne, Bishop of Bombay, to whom the writer was greatly indebted, not only for his kindness in consenting to preside but also for the excellent speech which he made to the children in the Marathi language, a feat which not many of the chaplains under him could have emulated.

But for the institution of the school the condition of the children would have been far more miserable than it was. It gave them something to think about, and take a solid and abiding interest in, saved them from brooding, and gave zest to their play hours. The writer considers that if they were kept tolerably happy, it was chiefly the school to which they owed it.

During the years following the establishment of the Matoonga Asylum, the writer had some friendly controversy with the Army Sanitary Commissioners on the question of compulsory segregation; that is to say they condemned it in some of their reports, and he replied to them in his annual Administration Report. It might seem that a layman can be but ill-equipped for such a combat with leaders in the medical profession, but, as before remarked, what the layman has to do is not to solve medical problems, but to seek a hypothesis upon which action may be based, and, believing the problem before him to be one of an administrative character, the writer maintained and preferred his own opinion even to that of the Army Sanitary Commissioners. The latter, in reviewing the sanitary condition of Bombay in 1889-90, dealt with the question of leprosy, and deprecated compulsory segregation, on the grounds that the benefit to the community at large would be small, the expense would be great, and the interference with liberty would cause great injustice. On the last two points a practical administrator is probably a better judge than a medical man; at all events, they are clearly questions for the former. As regards the first, if it is correct, it is difficult, nay, impossible, to understand why voluntary isolation should be recommended by the Leprosy Commission, or any interference with lepers in their trades, even though those trades do concern human food, drink, or clothing. If isolation is *per se*

of value, it cannot matter, medically, whether it is voluntary or compulsory. How the isolation is to be effected does not seem to be a question for the profession. Given isolation as an end to be achieved, the method by which it is to be achieved is a question for administrative, not medical, science. Suppose the Army Sanitary Commissioners to have been in favor of compulsory isolation, would they have thought it part of their function to prescribe to the writer the agency which he was to employ to enforce it, or to dictate whether such agency was to be that of the police or of the Municipality?

The Army Sanitary Commissioners, in a later report, recurred to the subject, and said they had thought, and were still of the opinion, that compulsory segregation would cause much mischief. To this the writer replied in 1890 that the Matoonga Asylum had, at the date of his writing, been in existence for more than thirty years; that it was idle to employ hypotheses when facts were at hand; and that if any mischief had been caused by compulsory segregation, it would be possible to prove it from the example of the Matoonga Asylum. He added that the Bengal Government were then considering a Bill for the compulsory segregation of lepers (the Bill which has since become law), and which had been sent to the writer for comment and opinion by the Bengal Government, and that a fact of that sort, which showed that the responsible administrators of another province believed that an example had been set in Bombay which it was wise to follow was worth a thousand theories to the contrary.

It need hardly now be repeated that the example set at Matoonga has germinated and spread, and that not only have the Bengal Government passed an Act on the subject, but that the Government of India, in direct opposition to the advice of the Leprosy Commission, have passed "an Imperial Act, especially directed against lepers, as such," though the expression "directed against" does not seem a happy one.

A plain and simple narrative has been given of the establishment of the Matoonga Asylum, and it will be seen that it was incorrect to say that that asylum was built by the Government of Bombay, out of funds contributed by Sir Dinshaw Petit. It was built by the writer out of funds collected by him. He claims no credit for having built a leper asylum. Any energetic person in the position he then occupied could have collected money and built an asylum; but such a str-

March 31, 1899.]

if it had been no more than a hospital or one, would have been as useless, considered a means of delivering the city from an insupportable pest, as every other asylum in India at the time was. The real peculiarity which differentiated Matoonga from all other asylums, and which furnished first Bengal, and then the British Government, with an administrative model, was that the principle of compulsion was in it first applied. There had been scores of leper asylums for years all over India, but none of them had brought this great question much nearer to solution. The Matoonga Asylum solved it, and has done so in the teeth of the medical profession. The writer hopes it may be pardoned for saying that he could not peruse Sir J. Woodburn's speech (which he first saw in January last), without some feeling of astonishment; and that he had a right to expect that his services to the country in this connection would not have been so completely forgotten.

Having regard to the fact that from the Matoonga Asylum has sprung the whole leprosy legislation of India, it will not be thought that too much time has been spent on that asylum. The writer wishes now to say a few words on the general question of compulsory segregation, to which India has been committed. The serious fact in connection therewith is that the medical profession is almost unanimously opposed to it. It is almost impossible to deal with the question without some reference to the further question of contagion, with regard to which, however, the writer feels his incapacity, and would decline disputation with a medical man as together *impar congressus*.

The writer may be here allowed to digress for a moment to recount an incident which made at the time a considerable impression on his mind. When the Leprosy Commission first came to Bombay, at which time the Matoonga Asylum had been established, they were courteously called at the Municipal Commissioner's Office, and the writer pointed out to them the Act under which leprosy had been notified as "an infectious disease, dangerous to life." On his calling their attention to the words, one of them asked with a smile, "Who as the bold person who called leprosy an infectious disease?" The only reply that could then be made was that the word infectious must be read in a popular and general sense, as meaning communicable; but the suggestion that leprosy could not, with propriety, be termed infectious, caused a very

uneasy feeling; for, if it could not, the whole fabric of the Matoonga Asylum and its regulations would fall to pieces. Under no other law than this Act was it humanly possible to enforce segregation—it could not be enforced unless leprosy could be notified under the Act—and if leprosy was not an infectious disease, the notification already issued was bad *ab initio*, and all that had been done under it lawless and actionable. The Matoonga Asylum was open to any respectable visitor, and who knew how soon some sharp solicitor might get hold of an aggrieved leper, and bring an action for false imprisonment, on the ground that leprosy was not an infectious disease, and, therefore, not notifiable under Act VI. of 1867? Luckily, nothing came of it, and doubts were dissipated by time.

But is leprosy not an infectious disease? Drs. Hansen and Looft, in their monograph on leprosy, published (at least the translation was) in 1895, seem to use the term "infectious" as synonymous with communicable. That is to say the Norwegian word that they use has been translated "infectious." They say that there is no course open but to assume that leprosy is infectious, that leprosy may be "caught" by inoculation, that as bacilli cannot be destroyed the only thing to do is to prevent "infection," and that this can only be done by isolation.

In a contribution to the "Journal of the National Leprosy Fund," Dr. Beavan Rake (one of the Leprosy Commissioners) speaks of "infected foci." Other instances of the use of the word by medical men may be quoted, sufficient, probably, to justify the use of it in connection with leprosy in an Act of the Legislature.

To what extent the medical world is divided on the question of the contagiousness or otherwise of leprosy, the writer is hardly in a position to judge. It is noticeable that the Leprosy Commissioners, while they discard the theory of hereditary transmission, consider that, scientifically, leprosy must be regarded as contagious, though the extent to which it is propagated by contagion is exceedingly small, and that in the great majority of cases leprosy originates *de novo*, that is, "from a sequence or concurrence of causes and conditions which are related to each other in ways imperfectly known." In referring to this oracular pronouncement, Dr. G. A. Hansen remarks (*Lancet*, October, 1893) that it would have been more straightforward to say at once that it was not known how leprosy originated, than

to pretend to know something about it; and to a plain mind the criticism seems not unfair. The Commissioners further remark that leprosy is not originated by insanitary surroundings, though it is "indirectly influenced" by them as increasing susceptibility to the disease. This again does not seem to take us much further. Of course, a weak man is more easily knocked down than a strong one.

There appears to have been much difference of opinion on the question how far the measures adopted to combat leprosy in the Middle Ages were the real agents in expelling, or almost expelling, the disease from Europe. It has been, no doubt, popularly supposed that the isolation of lepers, which was at one time generally, and often harshly and cruelly, enforced in England and in Europe, was the cause of this successful result; but many, perhaps most, medical authorities seem to think that improved hygienic conditions were in reality responsible for it. Dr. Vandyke Carter, however, concurred in the common and popular view. It is difficult to mention this name without paying a tribute to it. Of all Indian authorities upon leprosy he is surely by far the foremost. It is refreshing and ennobling to read his many contributions to the literature of the question, to study the masterly capacity with which he arrays his facts, the extraordinary acuteness with which he sifts them, the combined clearness and caution of his conclusions, above all, the earnest unwavering persistence with which he strives after truth; never the advocate for a moment of any special fad or theory, firm in his opinions, because they are based on facts and sound deduction, but always ready to yield to wider knowledge and sounder reason, continually striving after the light with a large and liberal recognition of the claims of practice as well as theory. Dr. Vandyke Carter did not believe that hygienic improvement accounted for the decline and practical extirpation of leprosy in the Middle Ages. He says,* in 1871:—"The ban under which lepers were put in Europe had the greatest influence in eradicating the disease—it may be said it was thus stamped out. To mention the old harsh leper laws, except with deprecation, might not be acceptable, yet, if the only alternative to their partial imitation be the hope thus expressed in the report of the late London Committee" (Committee of the Royal College of Physicians, June, 1862), "that a marked change in the

habits of the population of India will en upon the increase of divers industries, the proved cultivation of land, the less frequent recurrence of famines, and the consequent general amelioration of their condition from year to year, and that better food, better clothing, better housing, with greater personal cleanliness, will lead to the abatement of leprosy; then, indeed, the outcome of a most elaborate official inquiry does seem disproportionate." He goes on—"To realise the needs and remedies of India on this subject, some practical acquaintance with the country, which the Committee of the Royal College of Physicians have not enjoyed, is an essential prerequisite." He might well say so. Those of us who have been brought into close contact with leprosy in India—and what district officer or resident in a great town has not?—it seems the merest trifling to argue that we are to wait till the general improvement of the physical condition and sanitary surroundings of more than 300,000,000 of people has expiated the disease.

In 1873, Dr. Vandyke Carter wrote a report on "Leprosy, and Leper Asylums in Norway" in which he says:—"In my opinion the decline of leprosy in Europe was mainly due to segregation, harshly and badly carried out as it was, and there is no essential connection between leprosy and bad sanitation. In Norway there has been no such general improvement in the condition of the people as would account for the decline in leprosy. It is due to asylums and segregation." He continues (and the sentiments expressed are just and noble that the quotation must be allowed), "It is most desirable to remove from the sight of and contact with healthy men, women, and children, the diseased and repulsive leper . . . Familiar contact with a loathsome malady can have but one effect on young and old, when not accompanied, as in an asylum, by constant efforts to palliate the cure. . . . Passive tolerance of frightful disease is surely the work of blunted sympathies, or worse, of reprehensible indifference, failings in the long run which cannot but rest on the community. . . . Much of the difference to suffering, which we often wonder at among the Hindus, is due to persistence in the conditions now hinted at. On the broad grounds of social policy they should be detested with."

The curious point is that when Dr. Vandyke Carter expressed these strong opinions as to the value of segregation he was not a believer

* Transactions, Bombay Medical and Physical Society, No. XL, p. 74.

the diffusion of leprosy by contagion. The radiation between theory and practice in his mind is very striking. As a medical man, he would not go an inch beyond where the evidence led him; but, as a practical adviser of government, he was able to free himself from the trammels of mathematical demonstration. He was the master of logic, not its slave.

At a later date, viz., in 1876, in reporting on leprosy in Kattiawar," he wrote as follows: "Leprosy flourishes, but does not arise under any bad hygienic conditions. I am disposed to admit that leprosy ever arises spontaneously; it can, therefore, only be propagated by contagion, or by hereditary transmission. There is a good deal of negative evidence against contagion. I am disposed to attach more weight to positive evidence. . . . It is not upon the presumption most favourable to the interests of society in general . . . that I speak with great caution and reserve.)"

"Hereditv, as the exclusive agent in the propagation of leprosy does not seem to be entitled to the position once allotted to it." He had been once a powerful advocate of the theory of heredity; his judicial wisdom is exceedingly striking). . . . "In Kattiawar disease persists in the midst of a general prosperity, and in spite of the improvement of the people. . . . My plan is the complete isolation of the leper, and, if possible, his removal to an asylum. . . . I suggest (a) convenient refuges for vagrant lepers who are to be detained in them; (b) similar asylums open to the poor who are not vagrants, and in which they should be compelled to enter; (c) that persons who are willing to provide separate maintenance for their lepers should only be allowed to do so on condition that isolation be effected."

This is almost the same system as has been adopted in Norway, partly before and partly since Dr. Vandyke Carter made these recommendations. It will be convenient now to turn to Norway, which furnishes the best modern evidence as to the value or otherwise of isolation.

The publications of Dr. G. A. Hansen, the Inspector-General of Leper Asylums (or of leprosy—the writer is not sure what the exact meaning is) have already been more than once referred to. He published in October, 1893, a short article in the *Lancet* commenting on the report of the Leprosy Commissioners. In that article he makes nearly the same remark as Vandyke Carter makes when considering the question of contagion, that one bit of positive

evidence is worth a thousand negatives. But without dwelling at this point on Dr. Hansen's opinions, it will be better to look for a moment at his facts and figures. The general truth of the observation that figures may be made to prove anything may be admitted, but facts in the shape of figures nevertheless furnish the best quality of evidence when they are studied with the desire, not to manipulate them in favour of a preconceived theory, but to obtain light from them upon the path of truth.

In a monograph on leprosy, published in 1895 (which has been already referred to) by Drs. Hansen and Looft (the latter being assistant physician at a great hospital) a tabular statement is included, which shows

Year.	Total Lepers at beginning of year.	New cases.	RESULT.					Total at end of year.	Proportion in Asylums to total at beginning of year.
			Died.	Cured.	Emig. gratid.	At home.	In Asylums.		
1856	—	238	—	—	—	2,598	235	2,833	—
1857	2,833	242	293	3	15	2,339	427	2,766	15'07

1889	1,156	27	86	9	12	551	530	1,081	45'04
1890	1,081	10	122	6	2	447	507	954	45'97

year by year from 1856 to 1890 the number of lepers in Norway, the number of new cases, the deductions by death, cure, and emigration, the admissions to asylums, the number remaining at home, and finally the total of lepers in Norway at the end of the year. It is believed

that the statistics are absolutely accurate. As Dr. Hansen says: "Every leper in Norway is known by name." There were 2,833 lepers in Norway at the end of the year 1856, when asylums were first established, and the system of isolation entered on tentatively and imperfectly. At the end of the year 1890, the lepers of Norway were 954; in the year 1894 Dr. Hansen says they were 700.

A study of the Table will show that from the time that the system of isolation was resorted to, partial and incomplete as it was, at all events at first, there has been a steady decrease in the number of lepers in Norway, not absolutely year by year, but practically so. There were only two years, 1858 and 1859, in which the number of lepers exceeded—very slightly—the number of the previous year. In 1858, there were three more than in 1857; in 1859, there were 21 more than in 1858. With these exceptions every year shows a steady decline.

The writer has added a column to this Table, in which he shows for each year the proportion out of the total number of lepers in the country at the beginning of each year, who had been isolated in asylums. It seems to him that this is an useful addition to make. Looking at the absolute figures alone, without taking out their relations to each other, might give an erroneous impression as to the extent to which asylums have been made use of. Thus in

1857	there were	427	lepers in asylums.
1867	"	787	" "
1877	"	629	" "
1887	"	514	" "
1890	"	507	" "

One might conclude from this that the value of isolation was less and less felt by the people, and less and less insisted on by the authorities as time went on, but such a view would be quite erroneous, inasmuch as it would leave out of account the diminishing number of lepers in the country. Thus the proportion of lepers isolated in asylums, to the total number in the country at the beginning of each of the above years, was:—

1857	15·07
1867	29·43
1877	30·63
1887	..	40·47
1890	45·97

A study of the Table will show that from 1857 to 1866 the proportions of lepers in asylums rose rapidly; there was then for some years a pause, and even a slight decline; in

1876, for instance, the proportion was 28·8, against 29·64 in 1866; but there was then a fresh start, and after 1876 the proportion never went back, except very slightly in 1882; the progress was steady and continuous, till at the end of 1890, it had risen to over 50 per cent. The total lepers in the country were 954, of which 507 were in asylums.

The writer was hardly prepared for such a result when he began to extract the proportions. Among a people like the Norwegians, comparatively highly educated and civilized, it was to be expected that the value of isolation would be so fully appreciated that it would be largely enforced at home, without any necessity for resort to an asylum. This had evidently been the case to some extent, but not so much so as to check the growing belief in the value of asylums, not only as places of isolation, but, no doubt, also as places of medical relief. Examining the statistics strictly by district, Drs. Hansen and Looft point out that the decrease in the disease in each district depended on and succeeded to the numbers isolated in asylums. "Where isolation was insufficient or absent, there was little or no decrease, where it was thorough a decrease was invariable." The same thing was shown through each quinquennium (they give the figures for quinquennial periods, which is more satisfactory than taking them yearly, as it reduces the effect of casual causes); as the numbers of lepers remaining in the homes were reduced, so were the "centres of infection" diminished, and the numbers of new cases were continually lessened. To take the same years as have been already quoted, the numbers of new cases were:—

In 1857	242
1867	200
1877	110
1887	47
1890	10

If isolation is of no value what do the facts mean? Dr. Hansen is, of course, a strong contagionist; but the writer has nothing to say on his own account on that point. He will once more, however, quote the views of a great authority against contagion, Dr. Vandyke Carter. He says in his report on Leprosy in Norway:—"There has been such general improvement in the condition of the people of Norway as would account for the decrease of leprosy. It is due to asylums and segregation. . . . The detention of lepers in asylums leads to the diminution of the disease outside asylums. This can only arise in

er, by the abstraction along with the of some injurious influence appertaining itself. . . . Asylums in Norway were first ished under the belief that leprosy was tary, but whether transmissible by here- or contagion, asylums are equally use-

This was written in 1873, when the er of lepers in Norway was still over Had Dr. Vandyke Carter seen the s now before us, he would have been even strongly convinced. During the first 17 from 1857-1873, the number of lepers way was reduced by about 500; during xt 17 years it was reduced by more than

Leprosy Commissioners, quoting Dr. Collins (*Lancet*, May 17th, 1890), e to agree with him that "to attribute cline of leprosy in Norway to compulsory on is entirely erroneous. . . . I met lepers . . . going about their usual ons." This seems to the writer to be trifling. It is not contended by any one complete system of compulsory isolation

Had that been the case, probably Dr. n would say that leprosy would have stamped out years ago, and that it is eradicated only slowly and gradually, e isolation is only partial. Dr. Collins tes the decline to the material improve- of the people, which Dr. Vandyke Carter . The writer is unable to comprehend r. Collins's theory can be made to square gures and facts. They seem to him to conclusively in the other direction. If in e had had the facts of Norway, and the ence gained in that country before him, i of knowing nothing about them, the would have had a lighter heart in under- the responsibility of compulsory segre- in the Matoonga Asylum.

Hansen says, "Our statistics clearly strate that this result" (decrease in r of lepers) "has been brought about by on." The writer is unable to see what eduction from them is possible.

ppears that in Norway it was vagrant only that in former days were compelled r an asylum. But in 1885, a law was s, at the instance of Dr. Hansen, provid- at every leper who chose to live at home have his own room, bedding, and eat- paratus, and have his clothes separately s. If he was unable to ensure these tions (and every leper was known by and was under the eye of the physician t district), he was to be compelled to

enter an asylum. The proportion of lepers in asylums rose very rapidly for some years after 1885, no doubt in consequence of this law.

There is one column in the tabular state- ment relating to Norway appended to this paper which will cause most laymen a good deal of surprise; that is the column headed "cured," which shows that 208 persons have been cured of leprosy between 1856 and 1890. The writer had always supposed the disease to be incurable. Drs. Hansen and Looft say, however: "Patients usually die before the disease has run its course. But in the maculo-anæsthetic form, the cure of the leprosy is almost invariably the result. What remains, however, after the cure of leprosy is very different. We have . . . usually only a miserable rudiment of a human being, with more or less paralysed and deformed hands and feet, with unclosable eyes, of which the lower part of the cornea is opaque, and from which the tears run down over his cheeks, and with paralysed facial muscles, unable to close the mouth, so that the saliva constantly dribbles from it. Such cases may, however, live long and reach great ages, if such is an advantage." The leprosy is cured, but it leaves an animated, partially animated, corpse behind it. This awful picture, which is one only of many others equally awful which might be drawn of the results of leprosy, indicates where the justification really lies for speaking of the disease as an "Imperial danger." The phrase was much condemned when first used, as an unjustifiable exaggeration, and in so far as it was meant to convey that leprosy was dangerously on the increase, it was no doubt rightly condemned. But in its intensity and its fearful effects upon the human frame, though not in its wide diffusion, the disease may justly be spoken of as an Imperial danger.

The Governments of Bengal and of India, in legislating on this subject, made no reference to Norway, but appealed to the advice of the Leprosy Commissioners and the example of Bombay in justification of their action. But Norway seems to furnish as strong a case as a legislator need ask for of the value of isolation. And the Commissioners, after accumulating reasons to prove that isolation is of no use, and quoting authorities in support of that view, end by recommending it. It is true they do so in a half-hearted way. They deprecate compulsory, they advise voluntary isolation. But isolation is isolation, whether compulsory or voluntary, and seems to be justifiable only on the ground that the leper, to use Vandyke

Carter's words, carries about with him some noxious influence "appertaining to himself." If this is so, the isolation ought to be as complete as it can be made, having regard to all the circumstances which should be considered in fixing a limit to it.

Voluntary isolation in India may be pronounced to be impracticable and useless. Neither intelligent appreciation of its advantages, nor a sense of obligation to society can be expected where education and anything resembling a high standard of civilisation are so meagrely diffused. Nor would it be possible, the area and population of the country being so vast as they are, that the watchful scrutiny of the medical man, which has been found so valuable in Norway, should be generally effective. The only resource, therefore, which is open to Government in India is to make isolation compulsory, if it is to be resorted to at all. This is what has now been done, the application of compulsion being confined to vagrant, or as they are called in the India Act of 1898, as well as the Bengal Act V. of 1895, "pauper lepers."

Both Acts contain definitions of the terms "leper" and "pauper leper." A leper is defined to be a person suffering "from any variety of leprosy, in whom the process of ulceration has commenced." In the draft Bill circulated by the Government of India in 1889, a leper was defined to be a "person certified . . . to be suffering from leprosy." The writer has already remarked that he prefers the latter definition. When the Bengal Bill was sent to him for opinion, he submitted his reasons for preferring it, but his views were not in accordance with those of the medical advisers of the Government of Bengal, and afterwards of the Government of India, and they did not prevail. But he thought then, and continues to think now, that practical inconvenience may be caused by the narrower definition, which confines the term leper to persons in whom the process of ulceration has commenced. It may perhaps be true that the leper does not carry about "any noxious influence appertaining to himself," except when ulcers exist. But the writer's experience in Matoonga teaches him that on admission to an asylum where the patient is properly housed, clothed, fed, and medically treated, ulcers, unless very far advanced, generally close up. They re-appear, no doubt, but often not for months. If the leper is discharged, as no longer belonging to the statutory class of lepers, as soon as his ulcers are closed up, he will go

out to beg again, the ulcers will spread, and if re-open, he will again become the medium of the "noxious influence" spoken of by Vandyke Carter, and all the trouble and expense of arresting him and re-conveying him to the asylum will have to be gone through a second time—or, indeed, for all the writer knows to the contrary, it may have to be gone through a dozen times. As soon as he is exposed to the unhealthy conditions of a vagrant leper, ulcers will re-appear. As soon as he comes again under the palliative influence of an asylum, they will close, and thus he will continually be oscillating between the outside and the asylum, until the disease is so advanced as to resist all palliative treatment.

It is true that the definition objecting to classes every man as a leper in whom ulceration has "commenced;" and it may be replied that once ulceration has been discovered, the patient is to be regarded as a leper for the remainder of his life; that a subsequent discharge of the ulcers does not dispose of them, but that they once existed; and that a claim for discharge on that ground could not be maintained.

It is to be observed, however, that the power of inspection provided for by the Act is not to be exercised, and no doubt is expected to be exercised, the power, and no doubt is expected to be exercised, the power, of discharging from an asylum a leper who "can be released without hazard or inconvenience to the community." (Section 10 and Form E, Schedule to Act III. of 1895.) Ex-hypothesi a leper is not a source of danger or inconvenience to the community unless the process of ulceration has commenced. If it has then, can he be detained if it has ceased?

But supposing the above objection to be invalid on the ground suggested, the writer would still venture to think that to require a leper to be confined within the limits expressed by the definition is inexpedient, for a leper may, and probably will, go free long after the process of ulceration has commenced, because, if it is known to be a leper, it may not be discovered or known that he is an ulcerated leper. The very danger against which the law is intended to guard is allowed to have a wider operation than was at all necessary.

It must be here added that to require a vagrant leper, in whatever stage of the disease, to be admitted into a properly constituted asylum such as that at Matoonga, is an act of kindness to the leper as well as to the community; at least, such is the writer's firm opinion. If the inevitable interference with liberty" (Army Sanitary Commissioners) amounted to a hardship

weighed against the immense advantages to accompany it, it would be another thing for her. But the writer is convinced, and asks from an intimate experience, that it is not the case. If the anxious and regard to the comfort and happiness, moral and mental, of the patients, which is to be paid, and no doubt in all asylums the Act, will be paid, is maintained, effects of it will almost without exception every few days after admission, prefer the life to the life without. If this be so, the moral objection to making prisoners of innocent men (and the case cannot be more strongly stated than in these words) disappears entirely.

The writer may, of course, be wrong in the effects it takes of the possible consequences of the fining section of the Act. Time will tell, and he can only regret that he has so few opportunities or possibilities of watching its operation.

Another point in which the Act III. of 1898 is practically the same as the Bengal Act of 1895) differs from the draft Bill of 1895 is that it contains no provision for the segregation of the sexes.

In 1890, laymen at large no doubt believed in the heredity of leprosy. The writer most probably did when, in the ensuing year, he visited the sexes at Matoonga. But he must admit that if he were establishing an asylum now, he would be in a difficulty on that point. He does not in the least believe in the heredity of leprosy as a "working disease," that is to say, in the hereditary transmission of the disease. But this belief or opinion does not exhaust the question of segregation or the reverse. There can be no doubt that if married lepers are allowed to live together, and lepers in an asylum are allowed to marry, the amenities of such an arrangement will be greatly increased. All objections, it is true, seems to show that lepers are prolific; still some children will be born to them; and if contagion be under any circumstances possible, the close intercourse between parents and children, particularly between mothers and infants, will vastly increase the effects of it. It is true that orphanages or mothers' homes can be instituted, to which the offspring of leper parents interned in an asylum may be ultimately conveyed, but it is not possible to separate the mother from her nursing infant. For some years, probably, the child and the mother must continue to live together in the most intimate associa-

tion, and the chances are perhaps at least considerable, that under these circumstances, the child will become a leper, particularly when its other surroundings in a leper asylum are considered. This consideration furnishes an argument, though by no means a conclusive one, in favour of segregating the sexes. The advantages and disadvantages on both sides have to be carefully weighed, and, of course, were carefully weighed by the Government of India before it determined to exclude from the Act of 1898 the provision for sexual isolation which the earlier Bill had contained. All that the writer wishes to point out is that the question is not disposed of by a repudiation of the theory of the hereditary transmission of leprosy.

The Act of 1898 contains a certain number of restrictive provisions which debar a leper from preparing or selling food, drink, or clothing, from bathing or washing in the public wells or tanks, and from using public conveyances. Under the City of Bombay Municipal Act of 1888 a considerable advance had already been made in this direction. Persons suffering from contagious diseases are debarred (Section 38 of that Act) from using public wells, tanks, standpipes, &c., by Section 428 from using public conveyances, and the Municipal Commissioner, under Section 410, and others, possesses considerable power of control over the sale of articles of food. But the Municipality will, no doubt, find it to their interest, if they have not already done so, to move the Local Government to supplement the provisions of the existing law by notifications imposing further and more precise restrictions, such as it is empowered to issue under Section 9 of the Lepers Act.

There is one other point to which the writer would wish to refer. Dr. Hansen's law of 1885, under which lepers not wishing to enter an asylum, are compelled to give guarantees for efficient isolation at home, has been already referred to. This provision makes the law in Norway complete by embracing every class of lepers, the rich and poor alike. Nothing of the sort has yet been attempted in India. It would be very desirable to do it if possible; but is it possible? Independently of the extent of the country and population, the extreme difficulty and delicacy of any inquisitorial law which invades domestic privacy, are very serious obstacles. It is true that the public opinion of the country would be on the side of Government if any such attempt were made. The people of India do believe in the segregation of lepers. Possibly, as time goes on, it may be

practicable to make, with extreme care and caution, some advance in this direction, to collect valid statistics as to the existence of leprosy among the rich and influential, and by the aid more of the doctor than the magistrate, to inculcate, if not enforce, that degree of isolation which the great authorities of Norway deem to be sufficient to combat and resist the danger of contagion. When this has been done, the work of the statesman and legislator will be as complete, very nearly, as they can make it.

Some years must pass before the candid observer in search of truth will be in any position to judge of the value of the coercive action which has now been applied to Her Majesty's Indian Empire, and it will be for a future generation to discover and appraise its full benefit. The writer has no more doubt, not only that the measures which have been taken are wise and beneficent in themselves, but that they are the sure and certain prelude to the final extirpation of leprosy, than he has of the movements of the planets round the sun. He has already had occasion to remark—and he hopes he may be excused for repeating it, and with some pain—that his personal services in the cause have been as completely forgotten as if they had never been; but he believes that the future historian of India will, in the category of India's debt to England, place these measures for dealing with leprosy in the same rank as those by which Suttee and Thuggee were suppressed. But that historian will never know, for those who could have told him will have passed away, that the wise and humane policy by which the most awful of human diseases was conquered and swept away was born, its feasibility proved, and its efficacy established, in a little institution known as the Matoonga Asylum.

DISCUSSION.

The CHAIRMAN said they must all have been deeply interested in this paper. It was quite evident that, after mature consideration, the Government of Bengal and the Supreme Government of India had adopted the recommendations which Mr. Acworth was the first to bring into practice, viz., the segregation of lepers. He had thus very powerfully contributed to the solution of a very difficult problem. On the other hand, all who had heard the paper would recognise that there was a very strong opinion in the opposite direction, and he hoped they would have the advantage of hearing from some of the medical men present an expression of their opinion.

Dr. PHINEAS S. ABRAHAM, M.D. (Honorary Special Committee, National Leprosy Fund), had listened with great interest to this paper and could testify to the fact that when Mr. Acworth started the Matoonga Asylum his work was not ignored, because a notice upon the subject appeared in the "Journal of the Leprosy Committee," publication was still looked upon as one of the authorities on the subject. It was very curious to notice the apathy in this country and amongst the men and governments of the British colonies on this subject. This was illustrated at the Berlin International Conference some time ago, which was initiated by some scientific men in Berlin, who sent invitations to the governments of all the British colonies. The conference was attended by 250 delegates from all parts of the world, but he himself was not a representative of England, India, or the Colonies. Very important investigations were then carried forward, and Mr. Acworth's conclusions were mainly borne out by the medical authorities. It was very satisfactory to have for the first time from Mr. Acworth the full history of the Matoonga institution, about which there had been much confusion, but he could not understand how that the authorities had not up to the present time given Mr. Acworth the full credit he deserved. With regard to the etiology of leprosy, the question of contagion that was hardly the proper place for a discussion; it was a very difficult question, and any one who thought the question open lay in a nutshell and was easily settled simply because that he had not worked much at the subject. He regretted to say they did not yet know how the poison of leprosy entered the system, but the general impression amongst medical men now was that it was a microbe whose presence could be demonstrated in well-developed leprosy tissues. How that microbe gained entrance was not yet settled. Mr. Hutchinson would no doubt explain his view was that it entered the body with food; many believed that that was possible, but his own belief was that the poison might enter in as many ways as that of tubercle. They knew by observation and experiment on animals that the poison of tubercle could gain entrance through the skin, by inoculation into the lungs, and through the stomach, and he had no *à priori* reason why the leprosy poison should do the same. But there was this difference between the two, that you could prove these facts with regard to tubercle, but it had not yet been done in the case of leprosy, and in spite of Mr. Acworth's observations they could not say that infection had been proved. Although he (Dr. Abraham) was in the bacillary theory he was met with facts which he could not get over. First, his experiments had failed to inoculate leprosy on animals or on human beings. Professor Hutchinson inoculated 15 or 20 medical students and none with leprosy and not one of them developed the disease. Similar experiments had been conducted

by Danielssen, and in some of the islands of the Grecian Archipelago, with the same results. The attempt at inoculation had been tried, but had failed, except in one possible instance in 1811. There there was a convict going to be pardoned on condition that he submitted to inoculation with leprosy, and a year afterwards he had developed the disease, which, at first sight, was inconclusive; but, unfortunately for the theory, he died, and it was ascertained that this man's son, his brother, and other members of his family were lepers, and he came to be a strict where leprosy was prevalent. Knowlton did, how long the incubation period was, and how long the disease might have been in his system before he was inoculated. Another fact which Knowlton laid great stress on was this. There were a certain number of lepers in England, and at the Berlin Conference he (Dr. Abraham) laid a great deal of trouble to get up the subject, and with great difficulty he was able to show between 50 and 60 cases within the last 10 years. Of course, there must have been some cases which were not traced, and, altogether, there probably have been about 100 cases; but there is no reason to suppose that there had been any more in the late years. Ever since there had been so much communication with India and the colonies, there had been cases of leprosy in England, but, with the exception of one case—which might be doubted, though he did not doubt about it himself—every case in England had acquired the disease in India or in one of the colonies, and it had never appeared on any individual in the United Kingdom who had not been born and lived in a leprosy district. In this one case, a man came from India with his brother, and his brother took it, but that was the only case he knew of. If leprosy were as infectious as some people imagined, how was it that it never spread in this country, where no measures were taken against it? Cases were traced to hospitals and treated and attended by doctors and nurses, placed in the same beds, and, as the other patients, there being no measures taken at isolation. There were cases now in England which he knew personally, many of whom were not just like other people. The public did not know of it, or there might be another scare, such as there was some years ago with regard to a case which was mentioned by H.R.H. the Prince of Wales at a public-house, in which a leper was seen sitting and selling meat in one of the public markets. Knowlton admitted that absolute segregation was not worth the effort, as the slighter cases were difficult of isolation, in fact, quite impossible, except by skilled hands. A child might have a spot on the arm, and leprosy might not become obvious to an ordinary observer for many years, but, nevertheless, the child was a leper. In all leprosy countries there are numbers of these cases which were not traced, and the patients were healthy in other respects, and were able to work, and an attempt at compulsory

segregation of such persons would not be tolerated. It could be done in a partial way, as was done in Norway, but it was only partial. He was there in 1888, three years after the compulsory clauses were introduced, and saw cases of leprosy walking about the streets. The doors of the asylum were not locked, the inmates could go out, and the doctor in charge of one institution told him they allowed the inmates to go out and walk about, but did not like them to go to churches or crowded places, otherwise they were practically at liberty. With regard to the isolation in their own homes, which Dr. Hausen laid stress on, they knew it was impossible to insist on people, who were perfectly free, in such a country as Norway, being strictly isolated in every way. At the same time he admitted that this partial isolation had had a very good effect in calling attention to the subject, and also directly in diminishing the disease; and Mr. Acworth had done a great service in showing the possibility of doing this in India. But when they saw the riots which ensued when the Government enforced certain sanitary measures in connection with such a malignant disease as plague, it struck him at once how much more trouble there would be if any stringent measures were attempted with regard to leprosy. At the Cape an attempt was made to send all lepers to Robben Island, and the result was that the people hid their lepers, great difficulties arose, there was a danger of riot, and a few years ago it became quite a political question. The compulsory clauses had now been modified, and lepers were allowed to remain in their own homes, with a certain amount of isolation and notification. It seemed to him that was the proper way of dealing with the question. Of course, those who went about begging and showing their sores should be compulsorily isolated, and the others should be isolated as much as possible. In his opinion the Government of India had been wise in passing their Act of 1896, and, he believed, that this could not have been done had not the possibility of carrying out such measures in India been demonstrated by Mr. Acworth.

Sir STEUART COLVIN BAYLEY, K.C.S.I., C.I.E., here took the chair in place of Lord ONSLOW, who was obliged to leave.

Mr. JONATHAN HUTCHINSON, F.R.C.S., F.R.S., said:—None of us can, I feel sure, fail to give to the author of the important paper which we have just heard, our hearty applause for the humanity of motive and energy of action which it displays. Without doubt, he has set an excellent example and accomplished a very beneficent work. To admit this, and to admit it thankfully and without stint, is still very far from signifying acceptance of his conclusions. Seldom indeed has, I think, a better example of counting chickens before they are hatched been afforded, than that given in some of his latter paragraphs. Mr. Acworth feels confident that he has commenced the

extermination of leprosy from India, but he has not offered us the slightest proof that he has done anything towards diminishing it. What he aimed at doing, was to remove conspicuous lepers from the streets of Bombay, and this he has accomplished partly by straining a legal enactment beyond its scope, but chiefly by bringing into play the living law of kindness. He built a leper house, and made its inmates comfortable and happy, and thus, as he has repeatedly told us, he attracted to it even more than it could accommodate. If, in addition to this, he fenced it with barbed wire, and employed the police to apprehend vagrant lepers found in the streets, it is yet absurd to call his place compulsory isolation in the sense meant by the sanitarians. His measures were, indeed, directed to the concealment of the leper from sight, rather than extirpation of the disease. For the latter object, the leper who lives at home must, according to the theories of the contagionist, be sought out and forcibly removed from those whom his presence endangers. To take into custody those only who obtrude themselves in the public streets, is to crop off a few of the shoots of a shrub, whilst leaving its roots undisturbed. The "segregation" which Mr. Acworth accomplished was kindly and judicious, the measures at which I have hinted are, if not necessary for the public, cruel in the extreme to the individual. I do not believe that they are necessary, nor that however rigidly carried out, they would exercise the slightest influence upon the prevalence of leprosy. They would leave its cause wholly untouched. In saying this, let me say again that what Mr. Acworth did has my approval; I dissent only from his assertions as to what he thinks he was doing. There is no inconsistency in being an advocate for leper-asylums, and, at the same time, a disbeliever in contagion. I am a Christian Socialist enough to hold that it is the duty of the State to provide for the maintenance and comfort of all who by misfortune are disabled from earning their own living, and I see nothing at all unjust in a community declaring that it will not permit loathsome exhibitions of disease in its streets. In these respects the leper, and the victim of any other disabling malady, should be treated alike. In most parts of Mr. Acworth's paper there is a tone of most judicious moderation, and a very evident desire to avoid exaggerations. This is shown in his statements of the number of lepers in India and in Bombay, and in some of his references to the fallacies of statistics. We may thank him for not having attempted to construct any statistics of his own; and if he has been—as I think he has—misled by those sent us from Norway, it is not a matter for surprise. Permit me to say a few words about these, with the object of showing that they do not prove what they are supposed to do. Leprosy at one time prevailed extensively all over Europe, including the British Isles. In the latter it lingered last in the Shetlands. It disappeared from amongst us by slow degrees, *pari passu* with the advance of

agriculture, and it is not more than a century the last case occurred in the Shetlands. In the period of its decline it attracted but little notice, and all measures of isolation ceased to be resorted to. Now when it died out in our northern islands, it lingered on the opposite coast of Norway and Iceland. The parts of Norway in which it was chiefly those on the west coast, with Lofoten and Molde for their centres—the homes of the fishing industry, and the homes, in another sense, of a population steeped in poverty and almost without agricultural land. They had participated but little in the general advance in social conditions in more favoured regions, and they were still dependent upon fish as food. Yet there is no reason to believe that for long leprosy has been slowly declining in Norway. That it has declined markedly in the last fifty years we may thankfully say. Norway has become a pleasure-ground for the rich, and wealth and comfort have increased, and under those conditions have prevailed before which in other temperate countries professing the same religion, leprosy has always yielded ground. To claim the recent diminution of the disease in Norway attributable to segregation is to ignore the experience of other countries. Leprosy was common in New Zealand during the early period of our colonisation, but with the advance of agriculture and the introduction of fishing it has disappeared, without any whatever from attempts at segregation. As to segregation in Norway, the truth is that it is a case of very recent introduction, and only of a partial extent. The disease was rapidly communicated before the new law was enacted, and at that time lepers were frequently to be seen in the streets of Bergen. When the new law was passed, it was necessary to provide any additional accommodation for what existed was quite enough. It is not plausibly held that the new law has been coincident with the decline of the malady, but that to boast of its results is to fly on the coach-wheel. Mr. Acworth holds that to him it appears the "merest trifling" that the 300,000,000 of India's population is to be put to the test for the extirpation of leprosy, until it is brought about by "the general improvement of physical and sanitary surroundings." Surely it is not to remind him that if such improvement means to that end, he will have to wait. The forces of nature are inexorable, and we shall do well to wait them patiently, and not to rush in ignorant and useless expedients. Leprosy has disappeared from a thousand of its old-world haunts, and it is so under the influence of precisely those changes which we are now told it is the "merest trifling" to wait for. I hope soon to show that even in India to them it is not necessary to wait in vain, but that there are measures which may be adopted promptly and with great hope of success. The most barbarous in the extreme have been those which in the past have been resorted to

n of leprosy. Permit me to record my—a conviction resulting from a lifelong subject—that those measures have never d in the least to the end desired, and that as meanwhile been slowly brought about by influences which are now spoken of so dis- . I will now try to show that the extirpa- rosy by natural measures—by such, I mean, removing its cause—is not perhaps so hope- re have imagined. The data do exist which ble us to form a confident opinion as to the ts cause, and it is not one which is irrem- . If these data, the non-medical mind is well capable of judging as the trained and it is much to be desired that the ublic should look at the facts for itself- oes not require much medical knowledge to the bearing of some of the facts, which I mention. Leprosy is identically the same , Norway, the Sandwich Islands, the East Indies. Inference: that it has nothing to do with race or climate. Leprosy affects s well as the poor, and may develop itself ans who go to live in leprosy districts, and army officer or the missionary precisely the use as in the poorest native. Inference: it cessary connection with poverty or personal Leprosy prevails extensively in some places, tance the Sandwich Islands, in which as od clothing and climate, no sort of hardship leper asylums, the doctors, nurses, and ever contract the disease. Inference: it is gious. When lepers are imported into where the disease does not prevail as, for in- om Norway into the United States, r communicate the disease to others. : It is not contagious. In further on of the last proposition it may be t no year passes without the introduction and of a certain number of lepers (English- ho have developed the disease abroad). In the nature of the malady is carefully cond they mix with their friends without any recutations. No single instance of any of contagion has occurred. Dr. Abraham ly referred sufficiently to a single case which in Ireland. It is a solitary one, and doubt. I have on the table before me a which I have endeavoured to mark the t present the homes of leprosy. The lessons globe are most instructive, but I must not o speak of them excepting in the most rms. You will find that there are black the seaboard of almost all well-populated . The chief exceptions are parts of Europe, h Islands, and the United States. At many pots marked, however, there are but few t more perhaps than might be counted on hands. These few have, in most such had their representatives for many genera- nd although no segregation, as a rule, is

attempted, their number does not increase. I ask does this look like contagion? In many other places, however—Japan, China, the Malay Peninsula, India, Ceylon, the West Indies, parts of South America, the Sandwich Islands—I have been obliged to use the brush very freely. In most of these places, however, although the number is large there is reason to believe that it is either stationary or declining. Were it capable of spreading by contagion we should—since the precautions taken are in most places of the weakest possible kind—expect it to attain universal prevalence. Surely it does not need a medical education in order to see that a disease which affects half-a-dozen people at fifty different places on the shores of the Baltic, another half-a-dozen in New Brunswick, and a few more in Crete, and which never spreads, has far closer analogy with a dietetic disease such as gout than with a contagious one like small-pox. Just as gout prevails in certain districts among certain classes and certain families and does not spread, so it is with leprosy. The legitimate inference is that both are dietetic diseases, and the legitimate hope is that as gout is yielding before tea, coffee, and temperance, so will leprosy yield before the substitution of cereals, potatoes and flesh food for salted fish. Another argument of greater cogency is, I think, fairly obtainable from examination of the leprosy globe now before us, when it is explained that in nearly all the places where the disease prevails now it had done so from time immemorial. It is not the fact that European intercourse introduced leprosy to aboriginal populations, as has been the case with many other maladies. Everywhere we found it there already, and everywhere the same. Go where you will—Japan, China, Borneo, Sumatra, New Zealand, the East and West Indies, everywhere, provided you keep near the coast and amongst races which have learned the art of fishing—and there you will find reason to believe that leprosy has existed from the most ancient times. Quite recently, in the Fiji Islands, “Leprosy Stones” regarded with superstitious reverence have been found in many districts (Dr. Corney). I do not see why it should be held to demand the acumen of a physician to determine the bearing of this remarkable fact. If a disease is found to be one to which the whole human race when residing in certain districts and adopting certain habits has from all times been liable to suffer, and if that disease is found to prevail independently in many countries, islands, as well as continents, which through long ages have had no communication with each other, does it not follow that it is a malady capable, so to speak, of spontaneous origin? Is it not proved almost to demonstration that it cannot owe its origin to contagion, but must rather take its rise in some usage common to the human family? No usage can I affirm be suggested which does not concern an article of food. In this matter I am half inclined to make appeal to the intelligence of the public against the prepossessions of my own profession. I shall be

told by the latter that it is absurd to compare leprosy with gout, because in the one there is a bacillus and in the other none, and that where a bacillus is present the malady can be none other than contagious. The medical mind is at present engrossed by the study of microscopic organisms, and is dazzled by the flood of new light which has dawned upon us respecting them. In a little time we shall see more clearly, and I much mistake if we shall not then come to recognise that these organisms are themselves fed by food, and in many diseases their development denotes only a stage in the causation. To say that because bacilli are present therefore a disease must be contagious and contagious only (whether it be done in case of tuberculosis or of leprosy) is, I cannot but think, to go far beyond what has been proved. Mr. Acworth would possibly call it having regard for logic. I would myself rather say that it is a lapse of logic, since it rushes to an inference before it has been ascertained that the premises are true. The bacillus may be in latent forms ubiquitous, and may take its energy and its special form of development from the food with which it is supplied. There is nothing that I know of that has been proved in reference to the life history of these organisms to disprove such an hypothesis, and very much in its favour. For the present, however, it will probably be caviare to most zealous bacteriologists, and for that reason I venture to hint that intelligent lookers-on are entitled to form their own opinions. That I may, if possible, avoid the risk of being tedious let me hasten to aver my own conclusions. The chief of them is this, that if a malady has been proved to be almost universally prevalent, to pay no regard to climate or to race, to riches or to poverty, and to be at the same time neither hereditary nor for practical purposes contagious, there is but one inference possible, and that is that it must be caused by some article of food. I defy anyone to accept these propositions and to arrive at any other explanation of the facts. My next conclusion is that there is but one article of food which can be plausibly suspected as the cause of leprosy and that is *uncooked fish*. Again, I defy anyone accepting the food hypothesis to mention any other article. Just as we may be quite sure that it is no telluric or climatic influence which causes leprosy, because the disease prevails in districts which vary widely as to these; so we may be sure that it is neither flesh of pigs, rancid butter, or any kind of vegetable, for we find leprosy amongst people who vary exceedingly as to their use of all these. On the other hand, as regards uncooked fish, the evidence is *prima facie* overwhelming. In almost every district where leprosy prevails, fish has been suspected. The disease prevailed in aboriginal communities, and in times when fish was extensively used, it still prevails in large fishing centres and along sea-coasts. Excepting under special conditions, it is unknown in inland districts. One of the most recent writers on the subject (Mr. Ehlers), speaking of its present distribution in Europe, has used the expression, "it forms,

roughly speaking, a ring round the continent which has disappeared from numberless places simultaneously with the progress of agriculture and the substitution of other forms of food for fish. It rose into its highest point when the supremacy of the Catholic Church, with its numerous fish fasts, reached its height (in the time of Hildebrand), and declined with a low state of agriculture. In its decline, it is true, before the days of the Reformation, but the rate of decline was apparently helped by that event. It still appears, as Europe is concerned, has a great prevalence for Catholic communities. It did not pass from the Greek Church into the interior of Russia, and does not occur there now, for that Church forbids the use of fish as well as of flesh on its fast days. In the West, it has increased largely in the Sandwich Islands and at the Cape, and at each place coincident with the establishment of a company for salting and curing fish. The fish hypothesis covers well, I think, the facts as to the prevalence of leprosy in all parts of the world with the exception of certain districts. In many the evidence in its support is very strong indeed. Respecting certain inland districts which suffer, I well know that I shall find that fish is not there to be had, and that the unobtainable religion of the race forbids its use. To this I am able to reply that the hypothesis which has been given me by those who have resided in those districts has been most correct, and that I have been assured by many who are in good right to give opinions, that nowhere is fish-food inaccessible; that amongst no people is there a religious prohibition wholly availing to exclude the use of fish; further, that the statements made by natives as to their dietetic habits, are absolutely untrustworthy. The fish theory does not imply a large consumption of fish but rather the use of it—it may be in small quantities—but in very deleterious form. In the use I do not believe that any district of the world or race in India is wholly exempt. Further, I have added that the degree of prevalence is almost in direct ratio with what is probable in this respect. Dr. Vandyke Carter, because, as Mr. Acworth has said, "eulogistically, his practice and his opinion are not consistent, it has been said that he was the slave of logic and not its slave." I am not satisfied that it is not to see that there is something epigrammatic in this expression, but I am too dull to appreciate its force. Most willingly would I be, if I were the slave of logic, and deeply should I respect the correctness of my opinions if I could not but practice upon them. The leprosy question has been debated by all others suffered from this masterful and illogical thought. Surely it is not in accordance with either logic or common sense to go on asserting that the disease spreads by contagion, when the evidence is overwhelming in the opposite direction. No one can act as if the disease were in some direct connection with poverty and neglect, when it has been

and cleanly suffer in precisely the same. Nor is it logical to go on repeating, and report by reference to authorities, statements which have been refuted over and over again by facts. I understand by logic the application and reasoning processes to the subject in although it is very certain that nothing "hematological demonstration" can be attained which we are now dealing, yet I feel sure who are weak enough to let their prejudices and sessions override the conclusions derived from a careful investigation of facts, will never see the truth. My own theory as regards the leprosy is that it is a malady closely allied to tuberculosis. Its bacillus is one that can hardly be distinguished from that of tubercle, and the two differ only at more points than one. It might be termed "fish-eaters' tuberculosis," such a name being allowed to imply that the bacillus of leprosy is in the leper modified by fish-food. My theory I would suggest is an inexpensive one, and is not in any way curtail the food of the community. It would be simply to prevail upon those in leprosy districts never to partake of partially decomposed fish. At the same time, that no one should be spared to diffuse information, and to change of habits in this matter it is very desirable that leper asylums should be founded in every district where there are lepers. It should, however, be understood that they are for the benefit of the community, not for the extermination of leprosy. To what they will have any efficacy in the latter matter it would be to base such suggestion on the creed that disease spreads by contagion is to proceed on a hypothesis, and can only lead to disappointment. The true friends of the leper are those who earnestly seek to discover its cause and to remove it. In conclusion, I have but to repeat what was said at the outset, that I feel most grateful to the author of the paper for a most praiseworthy example of benevolence, whilst, at the same time, I agree with him in thinking that the measures which would produce the results he anticipates. Let us have leper homes, but let us do as much as possible from resort to the police—"barbed wire," and conduct them rather on the plea of the farmer who tethers his flock by their gates, let us make the homes comfortable and attractive, and poor creatures will gladly resort to them. Any plan which proposes to deal with leprosy as a venereal disease and to enforce isolation on that account, I must contend, the strenuous opinion of all who are well informed as to the subject. On the other hand, legislation which is well warranted which should restrain as much as possible human consumption," the fabrication of certain articles of fish-food now common in India. It would be justified on the ground that it would strike at the real cause of leprosy, and in time, together with the need for leper homes.

Mr. H. M. BIRDWOOD, C.S.I., said that there were not many present who would refuse their sympathies to Mr. Acworth in the circumstances narrated by him, or would blame him for placing before them the facts relating to the establishment of the Matoonga Asylum, near Bombay, which had been so strangely misapprehended in the Governor-General's Council, on the occasion of the introduction of the Lepers Bill in July, 1896. No one would, of course, think of suggesting that Sir John Woodburn was for a moment aware that he had not correctly realised all the facts of the case, and no one more than himself would regret the mistakes as to matters of fact into which he had been unwittingly led. But none the less must it have been an invidious and unpleasant task for Mr. Acworth to correct those mistakes—seeing how closely his own name and official reputation had been associated with the establishment and success of the asylum—and the thanks of the meeting were due to him for explaining so fully and clearly the history of an institution which had already justified its existence, for it had solved a most difficult problem which had troubled some of the best minds in India, and had made it possible for the Government of India to inaugurate a course of legislation which might prove to be of untold benefit to the people of India. Mr. Acworth was perfectly correct in saying that the Matoonga Asylum was not constructed by the Bombay Government, and that the munificent offer by Sir Dinshaw Manekji Petit of a lakh of rupees for another hospital was never taken advantage of for the Matoonga Asylum, as supposed by Sir John Woodburn. The facts were well known in Bombay, and had indeed been set forth in detail in a valuable Blue-book issued by the Government of India in 1896. From his own personal knowledge, he (Mr. Birdwood) could say that the necessity for remedial action had become apparent about ten years ago, at a time when the increasing wealth of Bombay and the charitable disposition of its citizens had attracted many mendicants, including large numbers of vagrant lepers. The consequent condition of the public streets and thoroughfares was graphically described in a letter from Lady Thompson, which appeared in the *Times of India* in June, 1899, under the signature "A," in terms not very different from those used by Mr. Acworth. The letter was prompted by warm sympathy for the homeless, penniless, and friendless lepers, whose miserable state was in such constant evidence, and also by an earnest desire to protect the public from a threatened danger. The writer pleaded for funds for a temporary home for the sufferers, pending the completion of Sir Dinshaw Petit's proposed asylum, and promised a subscription of Rs. 500 for that object. It was that letter, Mr. Birdwood believed, which set Mr. Acworth on further enquiry. He at once decided that a temporary home must be provided by private enterprise, without waiting for further action from any official body; and with characteristic energy he took immediate steps for forming an influential committee of the foremost citizens of

Bombay, which held its first meeting in Sir Dinshaw's house. His efforts were so far successful that, by May, 1892, the committee had collected nearly Rs. 100,000. But so early as in August, 1890, work was commenced on the requisite buildings from designs prepared by Mr. Rienzi Walton, the executive engineer of the Municipality, and by June, 1891, the buildings were ready for the accommodation of 300 patients. Towards the cost of these buildings no contribution was received from the Government of Bombay, though, at the very outset, an impulse was given to the collection of funds by a prompt personal contribution of Rs. 1,000 from the Governor of Bombay, Lord Harris, who thus showed his interest and sympathy in the movement; and he would have been present at the meeting if his presence had not been necessary elsewhere on important duty. It was undoubtedly a courageous act on Mr. Acworth's part, in the conflicting state of scientific opinion as to the advantages, or even the possibility of segregation, thus to start an institution in which the segregation of lepers was to be compulsory. He was not indeed without the warrant of strong scientific opinion in support of the action taken by him. He had acknowledged his indebtedness to the guidance of Dr. Vandyke Carter, whose preponderating influence had also been felt in the discussions of the Committee of the National Leprosy Fund. Dr. Bidie, of Madras, was on the same side; and so, among others, were Dr. Stephen, the Sanitary Commissioner of the Panjab, and the Public Health Committee of Calcutta. Dr. Bidie pointed out, in an important contribution to the Blue-book already referred to, that leprosy had appeared in certain countries for the first time only after the arrival of lepers from other countries. Thus leprosy was introduced into Australia by Chinese lepers; into South Africa by Kafirs; into South America by the early Portuguese colonists; into the West India Islands by negroes; into the United States of America by Chinese and Norwegians; and into Canada by Norwegians. In Norway itself the compulsory segregation of lepers had apparently resulted in the reduction of 20 per cent. of the leper population in 20 years; and Dr. Bidie also expressed the opinion that the direct result of restrictive measures in Great Britain was the extinction of leprosy, though that result might also have been due, to some extent, to other causes; improved hygienic conditions, and a higher standard of personal comfort having in time fortified the people against attack. There would then appear to have been some ground for accepting the direct communicability of leprosy as "a good working hypothesis" for a civil administrator, on which to base measures of reform; but Mr. Acworth was the first to put the question to a practical test, under the authority which he held to be given him by a local Municipal Act; and his action had now been endorsed by the Indian Legislature, after a full and careful consideration of the opinion of the Leprosy Commissioners, as recorded in their able report, of the members of the committee of

the National Leprosy Fund, and of member experienced staff of civil and medical officers of India. No doubt this action had in view of administrative considerations, not on strictly medical grounds; but there could be no question that the inmates of the Matoon had benefited in health; and their state was better now than at any previous time. It had been difficult, except at first, and for a short time, to detain the patients within bounds. Even in the most anxious moments, Mr. Acworth had never resorted to such stringent measures as had commenced in a former age, to the authorities of the Asylum at Greenside, near Edinburgh. The rules of that asylum—as stated in Dr. Bidie's report—were forbidden, on pain of instant death, to receive visitors; and a gallows was erected outside the hospital to show that the authorities were in earnest! Mr. Acworth was content with milder methods; and had his reward in witnessing the complete success of his plans for the "purgative" City of Bombay, and in the knowledge that the unfortunate lepers, whose welfare he had undertaken to be in the enjoyment of comforts to which, for all their lives, till then, been strangers. The relative measures adopted hitherto were not extreme caution; but that was only in the present state of our knowledge of leprosy. (Mr. Birdwood) hoped that the time would come when leper farms, which had been strongly commended by competent advisers, would be established in selected districts throughout India, suffering from black leprosy, ought to be taken from large towns. Employment on agriculture and horticulture could not fail to improve the health, and to cheer their last years, so far as was possible. Leper farms were said to have succeeded in Cyprus and elsewhere; and it was a satisfactory fact to know that the question of their establishment in India had been engaging the attention of the Government. But whatever further measures were to be developed, Mr. Acworth should be assured that the good work done by him in Bombay would soon be forgotten. He was one of a successful class of Administrative officers, drawn from the ranks of the Indian Civil Service, who had filled with success the position of Municipal Commissioner of Bombay, and had helped to bring the Municipality to the forefront of municipal institutions in Bombay. Mr. Acworth would certainly, in reference to the work done by him in Bombay, be the first to make the proud boast that, among the servants of the Government of all grades and departments in British India, he was "five hundred good as he." Still to be allowed to fall the privilege of accomplishing a special work of beneficence, the value of which could not be estimated too highly. It was as fine a work as had been done in the last ten years, signalised by some of these years had been by noble efforts in contest with famine and pestilence. He (Mr. Birdwood) was glad to be there to testify to the

ENDISH BOYLE, K.C.M.G. (Government British Guiana), said he was not there as a specialist or as an experienced officer of the Indian Service, but merely as a humble representative of the Government. The more he heard of this great subject the more he saw of it, the more certain he was how to deal with it was a question at present in the power of any man to decide, whether he was a member of the Royal College of Surgeons or the Sanitary Institute. He was quite sure they had got to the bottom of it, and he feared they were not for a long while to come. His experience in connection with some of the West Indian Colonies and more recently with the colony of British Guiana here there were not only negroes, Portuguese, Chinese, but a considerable number of Europeans, though that colony was larger than the whole of the British Isles, it had a population of only 100,000 of whom more than a third, 108,000, were coolies. During 1897-8 they dealt with 1,000 of course, there were many more, but they were isolated, being nearly 2 per 1,000 population. What would be thought in other Colonies where there were a similar proportion of lepers in a population of 4,500,000; and if provision had to be made for hospitals or asylums for 9,000 leper patients? Would they look at things somewhat differently? He did not suppose that many present would think what a terrible scourge leprosy was, and how necessary it was to do all they could to prevent bad cases mixing freely with the ordinary population. They had heard something about the disease being completely hidden, and that there were a few lepers in England whom no one could see; but what was to be done with a poor fellow who could scarcely be called a human being, and who so horribly afflicted by the disease that you could not hide him? Either you must lock him up in a hospital where everyone who came near him know what he was suffering from. He had not seen such a case in England, but he had seen hundreds of such cases in the Colonies. He could not say anything on the subject as to whether segregation would stop it or the isolation of these poor people in asylums, but they would be looked after and attended to as they would not be elsewhere, and where the rest of the world's people would be led as easily as possible, and it was essential in every colonial government. The Hon. Member had referred to the apathy of the Government with regard to the Berlin Conference, but he could assure him that the only reason why the Government was not represented was lack of interest. What he had heard that day, and what he had heard from the medical staff in the colony, how they came to the conviction that if the members of the Conference came back with honour they did not wish to do so with peace, so far as controversy was concerned, for they did not seem to have decided who was right and who was wrong. He would say, however, that coming from a colony where there were people from almost every country in the

world, the Government of which was as benign and considerate as possible, when lepers were found exposing themselves to the detriment of the community, it had been thought necessary to isolate them, and he hoped that would continue.

The CHAIRMAN proposed a cordial vote of thanks to Mr. Acworth.

The vote of thanks having been carried unanimously,

Mr. ACWORTH, in reply, said that he wished to reiterate, in reference to the remarks of Dr. Phineas Abraham and Mr. Jonathan Hutchinson, that he was not an advocate of the theory of contagion. He had no theory of his own as to the origin of leprosy; but he thought that the right measures for dealing with it were those which would be adopted if that theory was the true one. He must repel the imputation that he was disposed to scoff at sanitary science. On the contrary, he had been an apostle of it in Bombay for many years. But when he was told, as by the College of Physicians in 1862, that it was the duty of the Indian authorities to sit with folded hands in the presence of an intolerable pest, philosophically waiting until, in the lapse of centuries, sanitary science had remoulded the habits of 300,000,000 of people, then he said and he maintained that this was to trifle with the question in the name of sanitary science. Dr. V. Carter had, in effect, said the same thing. His eulogy of Dr. Carter as the master of logic and not its slave had been condemned, but yet the idea conveyed was a trite one. What he meant to say was that that great physician was able to survey the question with the eye of a statesman, as well as with the eye of a doctor; that he was able to realise that human affairs are not governed by pure reason; that impulse, passion, prejudice, sentiment, imagination, have to be taken into account, conditions of the mind which are not governed by logic. Our system of government in India was an utterly indefensible one on logical grounds, but was there anyone in that room who doubted its excellence? Mr. Acworth concluded by expressing his acknowledgments to the Earl of Onslow for taking the chair on that occasion, and to Dr. Abraham, Mr. Hutchinson, and the other eminent men who had done him the honour to think his paper worthy of discussion. However much they might disagree with him, he was not the less grateful to them for their presence.

Professor W. J. SIMPSON, M.D., writes:—I wish to add my testimony to the splendid work done by Mr. Acworth. I took a special interest in leprosy in India, and I well remember that it was due to his influence and energy that a magnificent leper asylum was established on the outskirts of Bombay, that powers were put in force for the compulsory segregation of wandering and vagrant lepers, and that the streets and markets of the city were cleared of a loathsome

and dangerous nuisance. I am accordingly surprised to hear to-day from the paper read that the Bill of 1896 should have been introduced by such a speech as has been mentioned, and that no credit was given to Mr. Acworth, the Municipal Commissioner of Bombay. I did not notice it at the time. I had the advantage of going over the Matoonga Asylum when the arrangements were completed and in full working order, and I had no difficulty in concluding that perhaps, with the exception of the excellent leper asylum near Colombo, in Ceylon, it was the finest in the East, and that everything was done to ameliorate the hard lot of the lepers, and make their lives as comfortable as possible. Thoroughly in sympathy with those who hold the views that leprosy in the towns of India can only be efficiently dealt with by compulsory segregation, I was anxious to see erected on the outskirts of Calcutta a leper asylum established on similar lines to those of Bombay and Ceylon. But progress in some things is slower in the capital of the Indian Empire than in the first city of India, and it took several years to get the first important point decided, and this only after a special note was addressed by me to the Bengal Government in 1893, on the subject that compulsory segregation was absolutely necessary in any new asylum that might be built for Calcutta, and it took several years more to decide on a suitable site. Before my departure from Calcutta plans for the new asylum had been begun, but I fear plague in India has distracted attention from the leper, for I have not heard of the buildings having been completed. There was an old asylum in Calcutta, which admirably illustrated the disadvantages and evils of an asylum near dwelling-houses, and worked on the voluntary system. The asylum was in one of the best residential quarters of the native town, and was the source of frequent complaints from the neighbours, who were subjected to much annoyance by the constant passing to and fro of the lepers; but this grievance was small compared with the fact that the lepers' sores attracted to the asylum a plague of flies, which used to invade the neighbouring houses and alight on the food. The voluntary system, moreover, was of no practical use for the purposes of detention. The lepers would be put into the asylum one day and would be out the next, and the majority used the asylum only as a shelter for the night. With this voluntary system, the same results were to be seen in Calcutta as in Bombay before the compulsory system was introduced. The streets, markets, bazaars, doors of the rich men during feasts, marriages and festivals, and the approaches and entrances to the principal temples were thronged with lepers; wherever begging and the soliciting of alms could be profitably carried on there would the lepers gather exhibiting their hideous deformities with the object of exciting pity. Alms were given to them partly from pity but mainly through fear of the leper coming too near, for the natives of India, notwithstanding any views held to the con-

trary in this country, have a wholesome fear of the leper and of his disease. I have been opposed to voluntary segregation however advantageous it may be in theory, but breaks down in practice. The Leprosy Commission in advocating voluntary isolation, had no practical experience of the subject; and, after a careful perusal of their report, I have, like Mr. Acworth, been inclined to understand on what grounds they recommended compulsory segregation because they came to the conclusion that leprosy is not hereditary nor contagious, but arose de novo, and that the virus was widely distributed throughout the country. I attribute this extraordinary conclusion, which is contrary to the experiences of all those countries who have given special attention to the subject, to the fact that the Commission spent too much in the limited time at their disposal instead of visiting the whole of India, and examining different parts, 2,500 lepers, out of a reputed population of 105,000, or less than 3 per cent., they examined and studied the disease in some of the worst parts of the country, I believe they would have arrived at a different conclusion. One of the Commission visited Burdwan, which is one of the worst parts of the country, remained two days, and saw 23 cases out of a population of less than $\frac{1}{2}$ per cent. Chamba, which, according to the last census, contained 20 to 30 lepers out of a population of 100,000, was not visited at all. Attention should have been concentrated on such places as Ellichy, where the leprosy population increased in twenty years from 5 to 16 per 1,000; Goalpara, which increased from 7 to 19 per 1,000; Manbhum, which increased from 5 to 12 per 1,000; and Pooree, which increased from 3 to 15 per 1,000. This increase is very small if it be remembered that the life of a leper is only nine to twelve years, and that, consequently, the average number of lepers in the country, years, 70 or 80 per cent. of these would die annually, therefore, a maintenance of the average number requires a fresh supply of lepers equal to that rate, to replace those removed by death; while the increase in the ratio indicates a much larger proportion of fresh increase of the disease, and this is intensified by the fact that the birth-rate among lepers is very low. Notwithstanding Dr. Abraham's views, I am inclined to think that all that is positively known regarding leprosy is against the conclusions of the Commission. Dr. Vandyke Carter, in his report, showed that out of 1,564 lepers, into whose family history he had made inquiries, 64 had a father affected in the direct line, that is in father, mother, or father's parents; over 14 per cent. in the collateral line, that is among the uncles and aunts; and 21 per cent. in the co-equal line, *i.e.*, among brothers and sisters. This positive information in no way favours the view that the virus is widely scattered throughout the country; on the contrary, it indicates that the virus has a very marked character, and has a very intimate relationship with family life. This investigation was made before Hansen's discovery of the bacillus, and before the relative rôle and importance of which heredity and communicability play

of leprosy, was differentiated. It is now conceded that heredity does not play a very important part in the production of the disease, and, in these circumstances, the facts brought out by Carter, as to family disposition, points to transmissibility by close and sustained intercourse. This is supported by facts in another direction. I have again instances have occurred of a young man living in a village or house where there was a leprosy, and sooner or later forming a focus or centre of infection to the villagers and members of the household. As it has been stated that no case of leprosy of the disease has been experimentally produced, I will mention one accidental experiment, which shows that the disease is inoculable. It is recorded by Dr. Tache, of New Brunswick, in which a young man was inoculated from the shoulder of a woman whom he helped to carry to her home. "The day was hot, and, on a sudden, liquid began to ooze out through a joint of the shoulder of the shoulders of one of the carriers. This, combined with the heat and the pressure of the edge, produced an abrasion of the skin of the young man. The contact of the liquid with the surface lasted a part of the time of the protraction of the whole length of the service, as well as only on his way home that the young man shed his sore shoulder and changed his name."

Some months after, that man, whose name had always been robust, began to feel the symptoms. In a short time the symptoms of leprosy appeared, and he died of the disease a few years after the occurrence. There had not been a case of leprosy in the family, whose ancestry is traced for several generations back; in fact, the disease was not yet known as leprosy, being called "the disease" in the locality and among those who lived there. He was the fourth case in that place, the first being the woman spoken of, the husband of the woman, in the ancestry of whom there had never been any trace of the disease; the second in that locality was the sister of the young man. Both Chinese and Indians believe in the transmissibility of leprosy, and this is no new doctrine. It was held years ago in India at a high civilisation and enlightenment. Susruta, an Indian physician, sums up the observations on leprosy, which are just as applicable to-day as they were then, as follows:—(1) "Women and men whose blood and seminal fluids corrupted from (not of the white kind) get their offspring diseased." (2) "The diseases named below are transmitted from one person to another by sexual intercourse, by touch, by taking meals in the same house, by sleeping in the same bed and sitting on the same seat, by putting on the same garment, by wearing the same garlands, and by using the same ointment—leprosy, fever, consumption, mania, and small-pox of different kinds." A fact has been expressed that compulsory segregation would reduce rioting similar to that which happened

when plague patients were segregated. This apprehension is based on a misapprehension of the nature of the two diseases, and the point of view from which they are looked at by the people in general. Segregation of lepers is on a totally different footing with segregation of plague patients. Leprosy is a chronic disease, loathsome in its nature, and a general object of dread. The family, as a rule, soon get tired of the patient and are glad to get rid of the lepers—in fact, he or she as often as not becomes a wandering outcast. Plague is an acute and very fatal disease; its effects are sudden, and the patient is removed to hospital at a time when the emotions of grief are most acute, and the friends are swayed by their feelings. As so many who are taken to hospital die, it appears to the Indian mind, as it would to the poorer classes of other countries, that there is a direct connection between segregating their relations in a hospital and their death, and it is easy to understand in their excited frame of mind the revolt against segregation of plague patients. No such fears need be entertained regarding the segregation of lepers; and if the lepers are treated kindly in the asylums, and everything done for their comfort, remembering they are there, not as prisoners, but as unfortunates for whom every care should be taken, I believe compulsory segregation will do much good, especially, if after the removal of the leper to the asylum, the house in which the leper lived is thoroughly disinfected, or, if a hut, is burnt down.

Obituary.

JEREMIAH HEAD.—Mr. Head, the eminent consulting engineer, died at Hastings on the 10th inst., at the age of 64. He was articled to the celebrated Robert Stephenson, and early took a prominent position as a mechanical engineer. In 1865 he inaugurated the Cleveland Institution of Engineers. He built the Newport Rolling Mills, and from 1867 to 1874 these works were carried out on the industrial co-partnership principle. He was one of the original members of the Iron and Steel Institute, and in 1875 was elected a member of the Institution of Civil Engineers. In 1885 and 1886 he was President of the Institution of Mechanical Engineers. He read papers on Iron Ores and Manganese Ores before the Iron and Steel Institute, and last month he read a paper before the Institution of Civil Engineers on the Iron Deposits of Lake Superior. Mr. Head was elected a member of the Society of Arts in 1873.

G. W. LEITNER, LL.D.—The distinguished Orientalist, Dr. Gottlieb Wilhelm Leitner, died from pneumonia at Bonn, on the 22nd inst. He was born at Pest, on October 14, 1840, and at the early age of fifteen was appointed (1855) first-class

interpreter to the British Commissariat during the Russian War, with the rank of full colonel. In 1866, Dr. Leitner made a special investigation of the languages and races of Dardistan. In 1874, he read a paper before the Indian Section of the Society of Arts entitled, "Account of the Races of Dardistan." In the following year he was elected an honorary corresponding member of the Society. He was for many years Principal of the Lahore Government College, with which the Delhi College was incorporated, and he was the first Registrar of the Punjab University. In May, 1884, he read before the Indian Section a paper entitled, "Thoughts Suggested by the Past and Present Condition of Indigenous Education in India." Besides these papers, he was a frequent contributor to the *Journal*, and a constant attendant at the meetings when papers were read which dealt with subjects connected with the scenes of his travels and his special studies. On leaving India he settled in England, and founded the Oriental Institute at Woking. He was a voluminous author, and for some years edited the *Asiatic Quarterly Review*.

Notes on Books.

THE LONDON WATER SUPPLY. By Arthur Shadwell, M.B. London: Longmans, Green and Co. 1899.

The aim of Mr. Shadwell's book is to vindicate the claims of the Thames as a sufficient source of supply for London for many years to come, and consequently to show that no reason exists for the promotion of a scheme for obtaining a supply of water for London from Wales. It is therefore, to a large extent, avowedly polemic, but it gives a very clear statement of the present condition of the question, and may be usefully studied by those who desire information about it.

It comprises a brief history of the origin and development of the water supply of London, a full account of the present supply, a consideration of the difficulties which arose last year in consequence of the drought, and the partial failure of water supply in East London, and a full discussion of the two schemes for extending London water supply—one advocated by the London County Council, and involving the provision of water from the Welsh mountains; the other proposed by the water companies, and involving the construction of large additional reservoirs near Staines, for the storage of Thames water.

Although, as above mentioned, the whole book is avowedly the work of an advocate, and the statements must be looked upon as *ex parte*, there are some points which are very clearly enforced—prominent among these is the excellence of the present

water supply of London (and it would be well who have not paid any special attention to the facts, would convince themselves of this point) another is the sufficiency of the Thames as a supply for very many years to come under all conditions of the increase of population.

THE WATER SUPPLY OF SUSSEX. By Whitaker, F.R.S., and Clement Reid

This is the first of a series of publications of the Geological Survey propose to publish on the supply of the English counties, and in this respect by Sir Archibald Geikie, the Director-General. A request is made that all those possessed of information, such as details of the strata, or of the results of sinking wells, would forward the same to the Geological Survey Office, a portion of its being used in future issues. The present portion of the pamphlet gives an outline of the geology of Sussex—so far as it relates to the water supply—the rest is principally an account of the sections in the county.

MEETINGS OF THE SOCIETY

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

APRIL 12.—"Telephones." By JOHN A. W. H. PREECE, C.B., F.R.S., will preside.

APRIL 19.—"London's Water Supply." By WALTER HUNTER, M.Inst.C.E.

APRIL 26.—"Coal Supplies." By T. BROWN.

MAY 3.—"Wireless Telegraphy." By W. H. PREECE, C.B., F.R.S.

MAY 10.—"Fruit Growing in Kent." By E. BUNYARD.

MAY 17.—"Trade Marks." By J. E. JACKSON.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

APRIL 27.—"Judicial Reform in Egypt." By JOHN SCOTT, K.C.M.G., D.C.L., Deputy Advocate-General, and late Judicial Adviser to H.H. The Khedive. The LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock:—

APRIL 18.—"Inlaying." By STEPHEN LOCK.

Mr. Lock's paper on "Domestic Furniture" announced for this evening has been unfortunately postponed.

Journal of the Society of Arts.

No. 2,420. VOL. XLVII.

FRIDAY, APRIL 7, 1899.

Communications for the Society should be addressed to
Secretary, John-street, Adelphi, London, W.C.

Proceedings of the Society.

REIGN & COLONIAL SECTION.

Tuesday afternoon, March 21, 1897; J. M. LEAN, M.P., in the chair.
The paper read was—

COMMERCIAL DEVELOPMENT OF GERMANY.

BY C. ROZENRAAD, F.S.S.

At a time when the commercial struggle of nations is more acute than ever, when each is striving to secure the largest possible share of the world's trade, it is of the highest importance that England should follow intently her rivals and competitors are doing; for though Great Britain, with her extensive home and colonial trade and navigation, her organised monetary and banking systems, still marching at the head of the great commercial nations of the globe, other nations are not idle; indeed, some of them have made marvellous progress in every direction. This is especially the case with Germany, which, thanks to the zeal, energy, knowledge, and toughness of her business men, occupies an important place in the world's trade, forcing on England a continual struggle everywhere. Indeed, it is not too much to say that Germany has become one of England's greatest commercial rivals.

It is not the first time that the Germans have taken a leading part in commerce. Already, in the Middle Ages, German commerce manifested its strength, not only in Germany itself, but also in foreign countries, where the big central cities of Germany had created commercial offices or Hanses, who had obtained, from the Sovereign or Government where they were constituted, numerous privileges. At these German Hanses were in direct and almost exclusive relations with the towns which they created them, but, little by little, they

joined into one confederacy, forming a defensive and offensive league for the maintenance of peace, the administration of justice, the extension of trade, the regulation of questions of customs and the rate of exchange, representing, in a word, a powerful body. This Hanseatic League owed its origin to the imperfection of the political and social institutions of Germany in the Middle Ages and to the insecurity of trade and navigation in Northern Europe. As international relations gradually improved and Europe attained a higher degree of civilisation, the utility of such a confederacy was less felt, and after four centuries of fluctuating prosperity, after having exercised a considerable influence on the commerce of Europe, they could no longer compete either with Holland, which had succeeded in attracting a large share of their business, or with England, which then had already secured a position of great importance, and had permanently become one of the principal commercial nations. The League was, therefore, dissolved in 1641. The history of the Hanses and that of the powerful Hansa towns, Hamburg, Bremen, Lübeck, and other cities, is one of the most interesting pages of the history of the commerce of the world, showing that, even in those days, the German merchants were already men of energy, of enterprising spirit, and endowed with great business capacity; but the same history shows also that already at that time there existed in Germany a party strongly in favour of Protectionism; that, as in the present day, there were then numerous adherents to commercial restrictions, and absolutism in economical doctrines, the application of which paralysed the development of international commerce, and often gave rise to rivalry between the various German States and towns.

So that, suffering as they did from want of united action, none of the German States or commercial towns ever succeeded in recovering their former brilliant position, and it is only since 1871, when the battle of Sedan ended the dominating position of France in Europe and opened the way for the federation of the different German States into one Empire, that Germany has come again to the front, in a marked manner.

Then the great German who was placed at the head of the affairs of his country showed clearly by his entire policy, that the mainspring of his actions was not only to make Germany strong and powerful, but also to secure for her an important portion

of the world's trade. After having provided a constitution for the United German Empire, to the whole of which he applied the Zollverein, he enforced universal conscription, placed the railways in the hands of the Government, introduced uniform weights, measures, and coins for the whole of Germany. In a word, Otto von Bismarck laid the foundation of the future great German Empire, and, by his wise measures, enabled Germany to compete on the field of international commerce.

Realising that gold is the precious metal, *par excellence*, in the settlement of all international transactions, that England with her gold standard and sound banking policy had become the principal gold and money market of the world, Bismarck created and accepted the presidency of the Imperial Bank of Germany, after having replaced the gulden, banco-mark, thaler and louis d'or thaler, by the reichsmark. He saw how England, by establishing numerous banks and branches in her colonies and in Africa, Asia, China, South and North America, had secured greater facilities for her trade, how bills on England and English acceptances were everywhere readily taken, so he induced his countrymen to establish German banking institutions in foreign parts, especially in countries beyond the sea, to make the German reichsmark and German bills of exchange familiar everywhere, and to secure to the German banks the commission, interest, and profit arising from exchange operations, hitherto paid to English banks, with the result that German banks are founded in the Argentine Republic, Brazil, Chili, and other countries. It had likewise not escaped the great Chancellor, that a well-organised consular corps can contribute materially to enlighten and to extend national trade, and under his able directions, and under those of his coadjutors, an elite class of men was formed, who, abroad, zealously promote the interests of Germany. Bismarck saw that in England and France, the *haute finance* always supports the Government in all that is necessary to advance the welfare and prosperity of the country; so he secured the counsel and advice of the leading bankers of Germany, especially that of the Berlin agent of the first banking house in the world. He observed how the great statesmen in England and France always valued the co-operation of capable men, and so he consulted the first German authority on monetary matters, Ludwig Bamberger, although the latter became his political opponent; he obtained the support of Delbruck, whose know-

ledge was invaluable in questions of treaties of commerce; of Stephan, who, in 1874, created the first postal union of the world, and of Bismarck, who gave Germany an almost perfect postal and telegraph service. Bismarck realised the value of the numerous steam lines which connect England with all parts of the world, so he encouraged the construction of German steamships, obtained subsidies for German steamship companies to all parts of the globe, and his ships soon vied with English steamers in comfort, discipline, and speed. Last, but not least, he recognised that free trade was the foundation of England's wealth and prosperity, and the Iron Chancellor became a Free-trader and succeeded in abolishing all import duties with the exception of a few fiscal charges. And Europe looks full of admiration to the German people with feelings of gratitude to the man whose indomitable will enabled him to carry out his schemes for the firm establishment of the greatness of Germany.

Just as under the strong government of Richelieu, Mazarin, and Colbert, France prospered; just as under Oliver Cromwell, England had a period of great prosperity; just as under the sway of Napoleon II, the commerce and industry of France were in a flourishing state; so under Bismarck's rule, Berlin became one of the principal financial centres of the world, showing again that business prospers in a country ruled by a strong political government. Under this strong hand which had unified and made Germany, German trade and industry developed in all directions.

But the Germans were carried away by their great prosperity. Intoxicated by their recent success, led away by the French war contribution of five milliards of francs, they founded numerous companies and industrial undertakings lacking a solid basis; and, usually the case in times of great expansion of trade and industry, overproduction and overtrading provoked in Germany, first, a decline in prices, and, finally, a severe recession. This was but a repetition of what occurred in England in 1847, 1857, and 1866, when, owing to the disastrous results of overtrading, the Government was compelled to suspend the Bank Act.

And Germany began to look for artificial remedies. Industry, always prone to protection, asserted itself; it demanded import duties not so much as a measure of protection against foreign competition, because Germany already occupied an important position in international

ers, but in order to enforce higher prices, when the German markets were flooded with American and Russian wheat, Bismarck yielded to the representatives of industry and agriculture, who insisted upon Protectionism and the days of free trade in Germany were over. In 1879, the first protectionist tariff was adopted; the imports of foreign iron, coal, and grain were checked, and both Hamburg and Bremen, hitherto free ports, were brought into the German Zollverein. It soon became manifest, however, that, as in every case wherever Protectionism is applied, one tariff is never sufficient; others are to follow. The industrial tariff was imposed between 1881 and 1883, and the import duty on corn was raised successively in 1883 and 1887.

Now, the history of commerce teaches us that Protectionism always fetters international trade, always leads to retaliation, and is only repeated itself again in this case. The increasing duty on grain had the effect of checking, if not of stopping altogether, the export to Germany of the principal article of Russian production—wheat. And so Russia retaliated by imposing a heavy import duty on Germany's principal articles of production—iron and steel.

And gradually the relations between the great Powers became less friendly. The Franco-Russian war was followed by the expulsion by the Prussian Government of the Poles, who worked their iron factories and harbours near the frontiers. Russia retaliated by imposing regulations tending to restrict the rights of foreigners to acquire property in Russia. In a word, the struggle between the two great Northern Powers became fiercer and fiercer, till the German Government attempted a great *coup* to undermine the credit of the enemy, and, by the decree of November 10th, 1887, the Imperial Government of Germany declined to make any further advances on Russian securities. From a financial, and from a political standpoint, the significance of the decree was of the highest importance. For it must not be forgotten that Bismarck was not only Imperial Chancellor, but also President of the Imperial Government of Germany, and the refusal to advance money on the securities of a country with which Germany still continued to be, officially, on friendly terms, could certainly not have been effected without his knowledge, or without his consent.

Small causes sometimes have great results. The introduction of Protectionism in Germany

gave rise to the tariff war, afterwards to the financial war with Russia, which, in its turn, led to the political and financial alliance between Russia and France—an alliance which, to a great extent, helped Russia to place her finances and her monetary system on a sounder basis, and enabled her to become a dominating Power, not only on the Continent, but also in Central Asia, and to follow in the Far East, the policy with which we are all acquainted.

As you see, Protectionism has been the main cause of important international events, the consequences of which cannot be foreseen even at this juncture; whilst in Germany itself the further development of Protectionism went hand-in-hand with the progress of Socialism. In vain, did the Government propose measures for promoting the welfare of the working man and the improvement of his lot. Gradually, the situation became more and more critical, and although Bismarck succeeded in maintaining his prestige as regards foreign politics, his domestic policy did not meet with the same appreciation as formerly, either from Crown or from Nation. His fall became merely a question of days, of hours, till at last the faithful servant of Monarch and Fatherland had to disappear from the political arena. He may have committed many errors, but to him belongs the honour of having laid the foundation of the present mighty German Empire as a political and commercial nation.

The work of the greatest statesman of our century was continued by his successor, Caprivi, but under much more moderate commercial and fiscal conditions. The political alliance with Austria and Italy concluded by Bismarck made it possible for his successor to complete it by a commercial alliance with both countries. On the 6th December, 1891, a commercial treaty, based upon lower tariffs, was concluded between Germany and Austria. It was followed on February 1st, 1892, by similar treaties with Italy, Switzerland, Belgium, and Servia, whilst a treaty of commerce and navigation was entered into with Roumania on the 1st January, 1894. These treaties may not be the ideal of what commercial treaties should be, but nevertheless they prove that an end has been put to the sharp protectionist policy followed hitherto by Germany, that more moderate ideas have gained the upper hand there. These treaties being concluded for a term of twelve years will safeguard trade against further tariff variations, at least for that period.

But it was not only with allies and friendly

nations that Caprivi concluded commercial treaties. He did so even with Germany's antagonist, Russia. On the 8th March, 1894, he entered into a commercial treaty with the Government of the Tsar, thereby putting an end to the tariff war with Russia, cancelling also the decree of the Imperial Bank of Germany of the 10th November, 1887, which prohibited advances on Russian securities. So that a more moderate commercial policy healed the wounds inflicted by extreme Protectionism, the amicable relations between the two great Northern Empires were restored, and Berlin once again participated, in a marked manner, in the important Russian financial operations, connected with the abolition of the forced currency in that country.

And the favourable results which have followed the more moderate commercial policy inaugurated by Germany, became more evident. Her influence and commerce developed in all directions. In industry, she became a power; in chemical and electric industries, the Germans are gradually taking the lead. German banks abroad (the Brazilian Bank for Germany, with a capital of 10,000,000 marks, is represented in Rio de Janeiro, San Paolo, Santos, &c.; the Deutsche Uebersee Bank, with a capital of 20,000,000 marks, has offices in Buenos Ayres, Valparaiso, &c.; the Bank of Chili and Germany, with a capital of 10,000,000 marks, is also established in Valparaiso; whilst the German Asiatic Bank, with a capital of 15,000,000 marks, is represented in Shanghai, Tientsin, and Calcutta) contribute, with success, to the promotion of German trade abroad, earning satisfactory dividends for their shareholders.

In Italy, immediately after the disastrous crisis in 1893, which caused 44 banks and banking-houses to suspend payment, the German *haute banque*, together with their friends in Austria and Switzerland, founded two banking institutions—in Milan, the Banca Commerciale; in Genoa, the Credito Italiano, both of which render important services to Italian trade and industry.

Germany, however, is not only represented abroad by banks, but also by her surplus population, which is increasing by nearly 1 per cent. every year. The total population now exceeds 54,000,000, as against 42,500,000 in 1874. Germany sends her sons, fully equipped with the knowledge of foreign languages, to all parts of the world, some as clerks and commercial travellers, others as technical officials and engineers, endeavouring

to create new markets and to develop trade between the Fatherland and foreign countries. Everywhere we find Germans and German houses, while German capital is invested in many foreign enterprises. The Kenek Assian Railway was built entirely with German capital, whilst Germany is largely interested in the Netherland South African Railway Company, in the Brazilian Railway Oeste de Minas, and others. Germany is besides busily engaged in Turkey, covering that country with a network of railways. In Russia, Germany has found a large field for her energies, especially in connection with the building of the Siberian Railway, which, when completed, will shorten the voyage for both passengers and goods from Western Europe to China and Japan, and, as the new route traverses Germany from one end to the other, the German railways will reap increased receipts from passengers and goods, without even counting the very important mail traffic between England and the Far East, which now goes *viâ* the Suez Canal, and which, by the new route, *viâ* Germany, will also yield considerable advantages to that empire.

According to official figures, nearly 140,000,000 marks of German capital are engaged in Guatemala, of which half is in plantations; in Mexico, nearly 400,000,000; in Venezuela, nearly 200,000,000; in Brazil, nearly 650,000,000, of which the greater part has been invested in industrial and land enterprises; in Chili, the German capital employed is estimated at 28,000,000, chiefly invested in saltpetre mines; in Africa, 100,000,000 marks. These investments represent more than 1,500,000,000 of marks, whilst the total amount of German capital employed in foreign stocks is estimated at many millions more.

But the great development of trade and industry, the great progress in every domain, and especially the importance the Berlin Bourse has attained as an international market, were a thorn in the side of the Agrarian party, which succeeded in getting a law passed by which Stock Exchange transactions and time-bargains were hampered, in many cases rendered impossible, and by this the German grain market was disorganised.

Whereas commerce in England is regarded as the greatest of all political interests, in Germany the reactionary party attempted to impede as much as possible the further extension of speculative transactions, of commerce, and of industry.

But the German Agrarians have been foiled,

tor Bourse, commerce, and industry combined energetically to oppose such a short-sighted policy. and the very obstacles they experience spur them on to greater activity. The aim of Germany to acquire a large portion of the world's trade remained the same.

The statistics of recent years prove how active German trade and industry have been. From 1872 to 1897 the trade increased 60 per cent., and 30 per cent. between 1881 and 1897. The larger part of this increase is due to the shipping trade, being about 65 per cent. of the total.

In 1898 the commercial advance, far from being reduced, has increased in large proportions. This development will be seen from the following figures :—

Year.	IMPORTS.	
	In tons.	In 1,000 marks.
1894	32,022,502	4,285,333
1895	32,536,976	4,246,111
1896	36,410,257	4,557,951
1897	40,162,317	4,864,644
1898	42,718,075	5,477,648
EXPORTS.		
1894	22,833,715	3,051,480
1895	23,829,658	3,424,076
1896	25,719,876	3,753,822
1897	28,019,949	3,786,241
1898	30,086,228	4,001,746

Or less imports and exports of gold and silver :—

	IMPORTS.		EXPORTS.	
	In 1,000 marks.		In 1,000 marks.	
1896	4,307,163	3,525,130	3,525,130	3,525,130
1897	4,680,697	3,634,975	3,634,975	3,634,975
1898	5,118,529	3,746,628	3,746,628	3,746,628

Compared with other countries, Germany as indeed made great progress, as will be seen by the figures in Table I., p. 448.

This development is all the more remarkable as Germany had, like many other nations, to struggle against the Protectionist system applied by several countries. It is partly due to the many export unions (*Ausfuhrvereine*), whose principal object is to promote foreign trade. Especially the Export Union of Saxony is to be mentioned. Established in May, 1885, with only 200 members, paying an annual subscription of 20 marks each, that union has now thousands of members sending out travelling commissions, circulars in five languages, spending between 1886 and 1895 1,000 marks to investigate trade prospects in Venezuela, Ecuador, Peru, Bolivia, Chili, Mexico, Canada, Cuba, &c. In Berlin many corporations and newspapers are working in the same direction, for instance to quote only a few:—The Centralverein, for commercial

geography and promotion of foreign trade ; the Deutsche Colonialverein, with 250 agents in London, Antwerp, and other important commercial markets. In a word, by constant efforts, by continued study and investigation, Germany endeavours to extend her trade in every respect. The commercial struggle between the nations is now so acute, that the efforts of one single firm are not sufficient, they all work together, publishing illustrated almanacs, giving every detail of home products, the addresses of the firms who export them, and readily complying with the requirements of the foreign customers, whether in quality or mode of packing the goods, selling not in marks, but in the currency of the customer, trying in every way to please the client and to facilitate the buying of German goods.

But all these efforts would probably not have had the great results shown by the constant increase in Germany's exports mentioned before, had German commerce not found in Hamburg a most suitable place for the concentration of the export trade. The old Hanse town, with her international trade established centuries ago, with her branches and agents in every country, with her extensive shipping business, is really the principal commercial German town, the principal German market, and no efforts are spared by the Hamburg merchants to maintain that position. Since joining the Zollverein, Hamburg has not only spent more than 300,000,000 marks on improvements in the harbour, but the steam lines connecting that port with all parts of the globe, are constantly increasing, with the result that Hamburg is now the first port on the Continent, ranking immediately after London. The shipping trade of that port for 1898, compared with the three former years, is as follows :—

	Entered.		Cleared.	
	Ships.	Tonnage.	Ships.	Tonnage.
1898	12,523	7,355,000	12,532	7,393,000
1897	11,173	6,708,000	11,299	6,852,000
1896	10,477	6,445,000	10,371	6,300,000
1895	9,443	6,254,000	9,446	6,280,000

We must not forget Bremen, whose new harbour accommodation, costing 100 millions of marks, has contributed immensely to the development of her shipping trade. Besides, by the practical organisation of her cotton exchange, Bremen is now the first cotton market on the Continent, the second in Europe. The American crop last season was 11,500,000 bales, of which not less than 1,709,000 were sent to Bremen.

TABLE I.—INCREASE IN GERMAN TRADE COMPARED WITH THAT OF GREAT BRITAIN, THE UNITED STATES, FRANCE, ITALY, AND AUSTRO-HUNGARY, 1897-8.

IMPORTS.					
Country.	1897.		1898.		Increase or Decrease.
Great Britain		£451,029,000		£470,518,000	+ £19,489,000
Germany	M. 4,864,644,000	£243,232,200	M. 5,477,648,000	£273,882,400	+ £30,650,200
United States	\$ 742,595,000	£148,519,000	\$ 633,665,000	£126,733,000	- £21,786,000
France	Frs.3,956,027,000	£158,241,080	Frs.4,376,195,000	£175,047,800	+ £16,806,720
Italy.....	Frs.1,191,598,770	£ 44,133,287	Frs.1,413,335,346	£ 52,345,753	+ £ 8,212,466
Austria-Hungary	Fl. 755,300,000	£ 62,941,666	Fl. 830,900,000	£ 69,241,666	+ £ 6,300,000

EXPORTS.					
Country.	1897.		1898.		Increase or Decrease.
Great Britain		£234,220,000		£233,391,000	- £ 829,000
Germany	M. 3,786,241,000	£189,312,050	M. 4,001,746,000	£200,087,300	+ £10,775,250
United States	\$ 1,099,709,000	£219,941,800	\$ 1,254,925,000	£250,985,000	+ £31,043,200
France	Frs.3,597,952,000	£143,918,080	Frs.3,593,167,000	£140,125,680	- £ 3,792,400
Italy.....	Frs.1,091,734,230	£ 40,434,601	Frs.1,203,560,304	£ 44,576,640	+ £ 4,141,999
Austria-Hungary	Fl. 766,200,000	£ 63,850,000	Fl. 808,800,000	£ 67,400,000	+ £ 3,550,000

In view of all these important results, one cannot help deploring the tendency in the German Parliament, and also amongst several industrial firms, towards Protectionism, which leads them to form syndicates, even in articles of first necessity—for instance, in coals, for which a powerful syndicate has been formed in Westphalia, with a view to control the market and raise prices at every opportunity, or whenever foreign competition is not felt. But these reprehensible manœuvres have met with the retribution they justly deserved. The manufacturers of Twenthe—the Lancashire of Holland—resenting the often arbitrary increase in price of Westphalian coal, have decided once for all to shake off the yoke of the above syndicate by acquiring coal mines in Preston, and forming, at Newcastle-on-Tyne, the Preston Coal Company (Limited), with a capital of £650,000. This company will work the mines and dispose of the coal, principally in Holland. The loss of such an important and regular customer as Twenthe is naturally very detrimental to the interests of the syndicate, but the sharp rebuke thus inflicted by the friends of Free Trade on the knights of Protectionism, is well deserved, and has had the result of benefiting England, and of drawing still closer the already excellent commercial relations between the two sole champions of Free Trade in Europe—England and Holland.

But whatever may be said against the

formation of syndicates in articles of first necessity, the development of German trade is undeniable, and the result obtained is not only a brilliant proof of the activity of the German nation, but it also shows how Germany has been well advised in renouncing the trade protectionism of Bismarck during the last few years of his Government, and following a more moderate commercial policy. A country which, as Germany, whose annual exports exceed £200,000,000, cannot be exposed to frequent modifications in foreign tariffs must have stability, at least, for some time in the custom duties, and be sure that the different markets do not escape them. Therefore, Germany acted in its own interest in concluding the different treaties of commerce mentioned before. But, as in the time of the Hanseatic League, the Protectionists, far from acknowledging how much a more moderate commercial policy has contributed to the development of German commerce, are continually on the alert, trying, at every opportunity, to influence public opinion towards Protectionism. And this in view of the decision which must be taken before long on the subject of the renewal of the trade treaty of commerce signed in 1892. It is to be feared that the attempts of the Agrarians will give rise to lively discussions in Parliament, but no doubt the good sense of the German nation will finally prevail, and the continuation of a commercial policy so beneficial to Germany will

isted upon. England has every interest watching the agitations of the Agrarian, which favours extreme Protectionism, only because if, against all expectations, Agrarians succeeded, the development of an international commerce would be checked, but also because the treaty of Commerce of May 30, 1865, between England and Germany, has really ceased to be operative on July 31, 1898, it having been denounced by England on July 30, 1897, in support of the commercial policy inaugurated in April, 1897, in Canada. As you are aware, the Canadian Government passed a Bill providing for the following reductions on import duties:—From the passing of the Bill until June 30, 1898, a reduction of $12\frac{1}{2}$ per cent., and from July 1, 1898, a reduction of 25 per cent. on goods, but few stated exceptions, imported into Canada from any country whose tariff admits the products of Canada on terms, on the whole, as favourable to Canada as the terms of the present reduced tariff.

It followed, that, as Great Britain admits Canadian goods free, the reduction applied automatically to imports into Canada from the other country. But the commercial treaties concluded by Great Britain in 1862 with Prussia, and in 1865 with Prussia and the Zollverein, stipulate that goods imported from Prussia and Germany into the British Colonies, shall not be subject to higher or other duties than goods imported into the said colonies from Great Britain. The question arose, therefore, whether owing to these stipulations the reduction in the Canadian tariff should not at once be applied to imports from Belgium and Germany, without any corresponding reduction on their part of the duties at present imposed on imports into Canada.

In order to remove all misunderstanding, Great Britain denounced the said treaties as from the 31st July, 1898. But while, by this measure, every obstacle was removed which heretofore prevented the English Colonies from freely accepting whatever fiscal treatment they might choose to apply to imports from the mother country, the commercial relations between Great Britain and Germany would have become, from the 31st July, 1898, uncontrolled by treaty. In view of the important commercial relations existing between the two countries, it would have been detrimental to both of them. On this side of the question did not escape the Governments of the two countries, and as there was scarcely time to arrive at a final understanding on the subject of a new treaty of

commerce, it was stipulated on the 11th June, 1898, that, while continuing negotiations in favour of a new treaty of commerce, Germany would grant up to the 30th July, 1899, to England, all the advantages which are granted by the German Empire to the subjects and products of the most favoured nation, while Germany is, at present, in Great Britain, and in all British possessions (with the exception of Canada), subjected to the lowest customs tariff rates.

In a word, a prolongation of the treaty of 1865 is temporarily secured, and, until a final treaty is concluded, it will be well to take into account the Protectionist tendency of a great number of the members of the German Parliament, although, as I have said before, there is no doubt that, in view of the conciliatory and open spirit which underlies the relations of the Governments of the two nations, a final understanding will be arrived at on the existing basis, and this time, we hope, not for a short period. Germany has every interest to come to an understanding, as England is one of Germany's best clients, buying much more from Germany than Germany does from England.

In 1895, Germany exported to England only £27 millions; in 1896, £27·6 millions; in 1897, £26 millions; and in 1898, over £28½ millions; while England exported to Germany £20½ millions in 1895, £22·2 millions in 1896, £21·6 millions in 1897, and £22·5 millions in 1898.

Taking these figures alone, it would appear that England is constantly a debtor to Germany, but we enter here on a question very difficult to solve—the balance of trade. Nothing is so difficult as to strike this balance. To come to a right conclusion, the figures of imports and exports are not conclusive. The bank commissions, interests, insurance premiums, freights, arbitrage in foreign stocks, coupons, and many other statistics must be taken into account. These are uncertain quantities, and make it difficult to arrive at anything like reliable results.

The only barometer which, to a certain extent, can guide us on this subject is, and will always be, the rate of exchange, and it is certainly remarkable that, notwithstanding the above figures, and the fact that the rate of discount of the Imperial Bank of Germany and that of the open market have been, in 1898, nearly constantly above the official and market rate in London, the rate of exchange on London in Berlin has neither in 1898, nor in 1899, gone down, one single day, to the point

at which it would have been possible to send, with profit, gold from England to Germany. On the contrary, the rate of exchange on London in Berlin has several times even reached a point at which gold exports from Germany to England would have been possible. In January, 1898, the lowest quotation (for eight days) of the rate of exchange on London in Berlin was 20·375, in February, 20·42; in March, 20·45; in April, 20·49; in May, 20·445. During the latter two months the rate of exchange even reached the point for the export of gold from Berlin to London, the highest quotation being 20·53 and 20·53½; in June, the quotation was again 20·375; in July, 20·37; in August, 20·395; in September, 20·30; in October, 20·37; in November and December, 20·40. At no time, therefore, did the rate of exchange permit of the export, with profit, of gold to Berlin, although several times Germany sold large amounts of foreign securities, notably Italian stocks, mostly purchased by France on the signing of the treaty of commerce with Italy, sales which were settled principally in the international *valuta par excellence*: bills and cheques on London.

The continuance of a rate of exchange adverse to Germany may be partly due to the fact that the Deutsch - Asiatische Bank, representing the leading German banks, took up one half of the 4½ per cent. Chinese loan of £16,000,000 (the other half being taken up by the Hong-kong and Shanghai Banking Corporation), and partly to larger imports of food stuffs, to meet the wants of the ever-increasing German population, and of raw materials to cope with the great development of industry.

As we have seen above, the total imports for 1898 attained the imposing figure of £273,882,400 (5,477,648,000 marks), exceeding the exports (£200,087,300, or 4,001,746,000 marks) by £73,795,100 (1,475,902,000 marks).

This great excess of imports over exports should not give rise to any surprise or uneasiness. Just as the millions and millions of pounds received by England for freights, interests, commissions, and for the construction of ships for foreign account, &c., enable her to make up the difference between the exports and imports, and to pay for the food, she must import for her population, and for the raw materials used in her home industry, so Germany also receives with her extensive shipping, banking, and industrial business, large remittances from abroad in the form of freights, commissions, interests, &c. The money spent by the

foreigners who frequent her watering places, study at her universities is also an important item. Besides, the interest and dividend on the many millions of foreign securities in Germany must also be taken into account.

There is not, therefore, the slightest reason for alarm. The situation of England and Germany is, on this point, identical and perfectly safe, on condition, of course, that we continue to increase their national labour and neglect nothing to increase their exports. To-day, China must emerge from its Eastern lethargy, and will have to answer the call of Europe, inviting her to open the country to progress and civilisation. To-day America is yielding more and more her treasures to energetic and enterprising countries, England and Germany. These two great commercial nations have, in those regions, a vast field for their activity and energy, and enough to occupy their industry and commerce for many years and far from competing with each other. Governments of the two nations have found, and, no doubt, will find in the future, many opportunities to work together, in perfect agreement, in the interest of their commerce, and in the interest of peace, justice, and civilisation. Germany agrees entirely with the policy of England, who, concentrating her efforts to maintain her own trade, claims only to share any advantage obtained by any other nation just as any other nation is free to share in any advantage obtained by England. This policy of England, equitable and just, and of a nature to give great results, corresponds entirely to Germany's own views.

The German Government is, therefore, giving its entire support to the policy followed by England in the Far East, where the British Kiao-Tchaou was occupied after the murder of the German missionaries in the province of Shantung, and a squadron sent, under the command of Prince Henry; and, as we have seen above, half of the Chinese loan of £16,000,000 was taken with England. In a word, England has seen the wisdom of securing the interest of her commerce and industry on a firm footing in China and of maintaining and enlarging her influence in those regions. German industry requires the Chinese market all the more, now that the United States, which formerly were such good clients of Germany

* According to a statement made by Count von Posadowski, Secretary of State for the Interior, in the Reichstag, February 11th, 1899, in 1890 American imports from Germany amounted to \$39 millions, in 1896 to \$34 millions, in 1897 to \$111 millions, an exceptional increase due to the special circumstance of the sugar trade, but in 1898 imports from

7, 1899.]

mercial situation of that country, will try
ke a large share in the trade of the Far

Thanks to the enterprising spirit of her
ren, thanks to the tenacity of her efforts,
any has already made great progress in
direction, and everything indicates that
will try in the interest of her commerce
industry to extend her operations in these
tries where there is yet so much to be
 , where there is room for everyone.
ng the last thirty years, Germany has
ed no effort to increase her production,
h exceeds now the amount she can absorb
elf, and, therefore, she is obliged to find
markets.

It to protect these markets, to give courage
energy, to defend eventually the interests

had declined to \$70 millions. In 1890 American exports
rmany had reached the value of \$86 millions, in the
ial year of 1898 they had increased to \$155 millions. The
e of America's trade with Germany in favour of
s had in 1890 been \$13 millions; her balance of trade
our of exports to Germany has now reached \$85 millions.

of those of her sons who, in these distant
lands, work to extend national commerce, a
powerful navy is necessary, and Germany
neglects nothing in that direction. Especially
the Emperor William has devoted all his
energy, talent, and firmness, to endow Ger-
many with a strong navy. The struggle in
this direction with the German Parliament
never discouraged him, nor turned him from
his design, and whatever obstacle arises will
be overcome by the energetic efforts of the
man who wishes the commercial greatness of
his country, who sees to what extent Germany
has already succeeded, and who feels what an
immense future is in store for her.

This is clearly shown by his speech delivered
at Kiel on the 16th December, 1897, when his
brother Henry was starting for China at the
head of the German squadron, when he said:—

“ Under the protecting banner of our German
ships of war, our commerce, the German
merchant and German vessels must now
obtain those rights which the foreigner
concedes to all nations. Our commerce is
indeed no new creation. The Hanseatic
League was in olden times one of the
mightiest enterprises that the world ever saw.
The German towns were once able to fit out
fleets, such as had never been seen before.
But the League decayed, and inevitably
declined, because one of the two conditions
of its maintenance was lacking—the Imperial
protection. The first preliminary condition,
the German Empire, has been created. The
second condition is also present. German
commerce flourishes and develops, and it can
only develop in prosperity and safety when it
feels safe under the Imperial power. Imperial
power means naval power, and naval power
and Imperial power are implicitly dependent
on each other; the one cannot exist without
the other.”

Besides, it is not only Germany who increases
her navy, everywhere we see the same thing.
To all commercial nations a strong navy is of
vital importance. For Germany, the increase
of her navy will cost about £20 millions (400
millions of marks), extending over a number of
years.

The construction of these ships has, of
course, contributed to the activity of Germany's
industry, already so busy. This is amply
proved by the movement of the iron trade:—

The imports amounted in tons to:—

In 1898.	In 1897.	In 1896.	In 1895.
523,807	against 564,745	421,426	258,227

The exports amounted in tons to :—

In 1898.	In 1897.	In 1896.	In 1895.
1,626,130	against 1,392,953	1,518,620	1,527,894

That is to say that the exports of 1898 exceeded those of 1897 by 233,177 tons, or nearly 77 per cent. It will be seen from these figures how favourable the situation of the iron industry is, which is due to the active demand for machinery, the construction of railways, and also to the demands of electricity, the development of which is increasing more and more in Germany.

Indeed, one can safely maintain that in electricity Germany is at the head of all nations. According to the "Bulletin de l'Office du Travail," the length and the number of cars of electric rail and tramway lines in Europe was as follows :—

	Length in kilometres.		Number of cars.	
	1897.	1898.	1897.	1898.
Germany ..	642·69	1,138·20	1,631	2,493
France ..	279·56	396·80	432	664
Great Britain and Ireland	127·45	157·20	195	252
Italy	115·65	132·70	289	316
Austria-Hungary	83·89	160·50	194	243

The German banks naturally found in the development of commerce and industry a vast field for their activity. Their issues amounted to :—

In Millions of Marks.				
1894.	1895.	1896.	1897.	1898.
1,419	1,374	2,088	2,013	2,697

of which—

In Millions of Marks.					
1894.	1895.	1896.	1897.	1898.	
268	389	535	668	1,002	were in various stocks.
203	43	34	25	146	„ German Loans.
189	73	333	167	326	„ Foreign Loans.
95	229	307	283	477	„ Industrial Shares.

These are big figures, and it would be rash to say that all these issues were successful. Here it will be well to remember the words of the great French financier, Isaac Pereire : "Souscrire n'est pas placer et placer n'est pas classer."

But, on the other hand, it must not be forgotten, that the extensive development which commerce and industry has taken in Germany, has greatly benefited the German people. Many fortunes have been made, and from the middle classes these fortunes have spread rapidly to the working classes.

Already in 1893 the well-known German professor, Schmoller, declared before the investigation committee of the Bourse that, working on official statistics, he found that

the German nation saves every year between 2,000 and 2,500 millions of marks, of which 1,000 millions were invested in stocks, since 1893 the general wealth has greatly increased, as is proved by the official statistics showing, that during the last three years the income and value of property in Germany increased nearly three milliards of marks, by the ever-increasing receipts of the savings banks, which in 1893 were only 798 millions in 1895 already 981 millions, in 1896, 1,039 millions in 1897, 1,082 millions of marks.

These and other statistics show clearly that the purchasing power of the German nation has largely increased. Besides, the conversion of German and Foreign Government stocks induced the greater part of the public not satisfied with the moderate interest offered to desert this sound department of the Bourse and to take up industrial shares, thinking against the greater risk attending these shares there was, on the other hand, a chance of dividends and higher quotations.

In a word, these considerations and the increase of wealth contributed much to the success of many of the issues. But this success would never have been as great had it not been for the law of the 22nd June, 1896, on Bourse transactions, prohibiting all time-transactions in industrial stocks. The Agrarian party was always jealous of the importance of the Bourse, and of the quickness with which fortunes were made, thought that by this a terrible blow would be dealt to the German banks and bankers who made such large profits out of the flotation of new companies, issues of loans, &c. The contrary happened. In fact, as will be seen from the above figures, and those that are given further on, never had so many flotations of new companies been more numerous in Germany; never was banking business so active there.

Then, since the prohibition of time-transactions in industrial shares, the banks found employment for their capital by facilitating the cash bargains of the public, who, under the prosperous conditions of the industry had not escaped, and who subscribed with even eagerness to the issues of the banks. Generally these institutions only introduced to their clients good sound business. In Germany, not only is the law on Bourse transactions stringent, but no issue can be placed unless the prospectus has been approved by the Bourse Committee, which is composed of the *élite* of the bankers and bank managers.

The banks had also to procure mon

lustrial concerns so busily engaged in building new ships, and numerous railways in Turkey, China, and other countries. As a result, they had in many cases to advance money on stocks subscribed by the public, although nearly every bank raised its discount, money was continually in great demand, necessitating a repeated rise in the rate of discount of the Imperial Bank of Germany. On the 9th of April, 1898, that rate was raised from 3 to 4 per cent., on the 10th of October from 4 to 5 per cent., on the 10th of November from 5 to 5½ per cent., and on the 11th of November to 6 per cent. Only since the foundation of the bank, in 1875, has the discount been as high (in 1877 and 1878) but the bank had no choice. For owing to face large demands for discount, the rate had several times exceeded the maximum rate fixed by law for the uncovered circulation of bank-notes, and the gold reserve had fallen to 500 million marks, on the 30th of September, 1898, to 250 million marks, on the 7th of October to 100 millions and it was only by heavy purchases of gold on the English market, that the reserve was, on the 15th of December, brought up to 575 million marks.

The London and Paris markets, of course, were affected with interest the situation in Germany, and the continued development of her commerce and industry. The success which crowned the energetic efforts of the German people aroused, in some quarters, feelings of jealousy, but a discount rate of 6 per cent., as well as a rate of exchange constantly against the German, showed clearly enough that the German currency was advancing a little too quickly, when some of the German banks began to raise their rate, on a rather large scale, three months' ago, on London and Paris, certain English banks hesitated to discount these bills. Remembering how in 1866 bills drawn against London and cheese were readily discounted at 10 per cent., while the discount of bankers' bills declined even at 10 per cent., the English banks showed themselves unwilling to discount bills of paper refused by the Imperial Bank of Germany itself. Indeed, the Imperial Bank of Germany only admits for discount paper bills arising from purchases or sales of goods, bills of exchange, or drawn against bills of lading, insurances, &c., but does not admit bills based on credit alone, bills which are not admitted in Germany "Finanzwechsel."

These drawings were not, however, extraordinary, as it was only natural that the German banks, so skilled in matters of arbitrage,

and finance, should take advantage of the difference between the high rate of discount applied in Germany, and the much lower rates in London, Paris, &c., especially at a time when, the rate of exchange on foreign countries in Berlin being very high, the risk of losing on the exchange was reduced to a minimum. Nobody can dispute that the English money market, which, to a great extent, owes its position of being the first monetary market in the world to the application of sound business principles, that this market, so brilliantly represented here this evening by several of its most influential members, has a perfect right to insist upon exercising its own discretion as to what paper it shall discount; but it is to be regretted, especially at a moment when the situation in Berlin was already uneasy, that rumours were put in circulation concerning certain German banks and concerning the situation of the German markets which were without the slightest foundation. Indeed, as soon as it was known in Berlin that London looked with disfavour on bills which, as I have explained before, had only been drawn to take advantage of the difference in the rate of discount, when at the same time it was thought that the rise in the rate of discount of the Bank of France, on the 20th October, 1898, from 2 to 3 per cent. might be a warning not to encourage too many negotiations in the said Finanzwechsel, the German banks did not hesitate a minute to redeem their drafts immediately, giving in this manner another proof how liquid and strong they were, and how wrong people were in speaking of difficulties on the Berlin market, whose position was perhaps tight for a moment on account of the great demand for money, especially at the end of the year, but which has always been perfectly able to meet its liabilities. Indeed, it is not too much to say that the strong desire which characterises in every country all members of the Stock Exchange and banking business to fulfil their engagements punctually, exists to the highest degree in Germany, where the sense of commercial honour is cultivated by every merchant.

But the policy followed by the English and the French banks concerning the German drawings has been an excellent lesson to the German banks to rely only on their own resources, and not to issue any more bills based on credit alone, the creation of which might give rise to wrong interpretations, and to limit their operations to figures more in keeping with their available resources.

TABLE II.—POSITION OF THE SEVEN LEADING BANKS IN BERLIN AT THE END OF 1898.
(In Millions of Marks.)

	Capital	Reserve.	Debtors.	Creditors	Deposits.	Acceptances.	Gross Profits.		Profits on current banking business.			Profits on Stocks, Syndicates, &c.			
							1898.	1897.	1898.	1897.	1896.	1898.	1897.	1896.

The balance-sheets for 1898 of the leading German banks clearly prove that there is not the slightest reason to be alarmed about the situation in Berlin (Table II.).

Of course, these balance-sheets show that active business has been in 1898, how largely in commerce and industry, as well as the public have had to appeal to the banks; but they show also, that the situation is perfectly normal, perfectly safe, and that the banks have found in satisfactory dividends, and in several cases in higher dividends than those of 1897, the reward for their skill and energy.

While on this subject we must not overlook the very different way in which English and German banks are working. Where the former almost limit their transactions to current banking business, strictly speaking, and, by the application of sound financial principles, inspire that confidence without which no bank can exist (and more especially banks which receive millions and millions on deposit) the German banks not only do current banking and arbitrage business on a large scale, but contribute also to the development of commerce and industry by financing the different industrial, railway, shipping, and other concerns forming syndicates to take over Government and other bonds. In a word, their mode of working differs in more ways than one, from that of the English banks. Both systems, if applied with prudence and skill, have given however, excellent results, and while the English banks cannot be too highly praised for the way in which they conduct their business, the Berlin banks, of more recent origin, having their energetic efforts been very useful to German commerce and industry, contributing, in a large measure, to the expansion of German trade and so making Berlin one of the leading financial markets.

But while the deposits in the English banks continually increase, attaining now nearly 100 millions of pounds, the figures shown by the German banks are far behind. The total deposits at the German banks were in 1890, only 39 millions (760 millions marks); in 1891, 39.6 millions (792 millions of marks); in 1892, 39.45 millions (789 millions of marks); in 1893, 39.9 millions (798 millions of marks); in 1894, 48.5 millions (970 millions of marks); in 1895, 49.5 millions (981 millions of marks); in 1896, 51.9 millions (1,038 millions of marks); and in 1897, 54 millions (1,080 millions marks). For 1898 the total deposits of the seven leading German banks were 179.7 millions (3,800 millions of marks). And

the Deutsche Bank, so well represented on the London market, figures with 6·08 millions (millions of marks). At one moment it decided that this establishment intended to transfer its deposit department to a special company, with a capital of 60 millions of (£3 millions). In order to carry out this scheme, the share capital of the bank was increased by 30 millions of marks from 180 millions of marks.

Although nothing definite has been decided yet, it is highly probable that in the future the Deutsche Bank will have to increase its capital, and, in any case, many of the German banks have decided to do so. The Berliner Handelsgesellschaft intends to increase its capital by 10 millions, the Dresdner Bank by 20 millions, the A. Schaaffhausenscher Bankverein by 25 millions; in a word, the augmentation of the capital of many other banks to the extent of, roughly speaking, millions of marks is contemplated. These augmentations of capital may, to a certain extent, be justified by the great expansion of German trade, but it should not be forgotten that one of the main factors which has contributed to that development is the successful policy constantly followed by the Emperor and the German Government; although there is, at present, no reason to suppose that any political complication which might force Germany to interfere may arise, the political horizon is not altogether cloudless, and the Berlin banks would do wisely not to go too far, inasmuch as money shows again everywhere a certain tendency to rise in value, especially in Germany, where, after a certain time at the beginning of the year, rates are generally harder.

ready—and we are only at the end of the year—the official rate of discount in Germany is $4\frac{1}{2}$ per cent., and if business continues to be as active as it is now, we may soon see higher rates. Since 1895 the value of money has constantly increased in Germany. For the year the average rate of discount was 3 per cent., for 1896 3·65 per cent., for 1897 4 per cent., for 1898 4·26 per cent., and on the 10th November, 1898, till the 14th January, 1899, Germany was suffering under a rate of 6 per cent., a rate which was reduced on the 14th January, 1899, to 5 per cent., and on the 20th February, 1899, to $4\frac{1}{2}$ per cent. In 1898 the Imperial Bank of Germany was allowed to exceed 16 times the legal maximum of uncovered circulation of bank-notes, but only 9 times in 1897, and 6 times in 1896.

That legal maximum was, when the Imperial Bank was created on the 14th of March, 1875, fixed at 250 millions of marks, on condition that whenever any of the other 32 banks of issue (entitled to issue 135 millions of marks), renounced such right, it should be transferred to the Imperial Bank of Germany. Twenty-five of those banks having renounced their right of issue, the Imperial Bank of Germany was authorised to issue uncovered notes up to 293·4 millions of marks. Every amount issued by the bank in excess of that limit, is subject to a Government tax of 5 per cent. This system differs entirely from that applied by the Bank of England, as, according to the Bank Act of 1844, the Bank of England must hold gold for every banknote issued beyond the legal maximum (now £16,800,000), whilst the Imperial Bank of Germany can issue any amount of notes beyond the legal maximum, provided the bank pays to the Government a tax of 5 per cent. In Germany, this system is called the *indirecte contingentirung* whilst the English system is called the *directe contingentirung*.

But since the creation of the Imperial Bank of Germany, in 1875, trade and commerce have developed in a remarkable manner. In 1875, Germany's population was only $42\frac{1}{2}$ millions of inhabitants; it now exceeds 54 millions. Her exports were then $2\frac{1}{2}$ milliards of marks; now 4 milliards. The railway system measured then only 28,000 kilometres; now 47,000. The railway goods traffic was in 1875 only 90 millions of tons; now 222 millions. In a word, every branch of industry, commerce, and shipping, has immensely increased, whereas the amount regarding the issue by the first institution of the country of uncovered paper currency, beyond the legal figure, is still the same. A Bill has, therefore, been introduced in Parliament raising the maximum of the uncovered paper circulation of the Bank, free of tax, to 400 millions of marks. The same Bill proposes also to raise the capital of the Bank from 120 millions to 150 millions of marks. While in France and in other countries the capital of the institution having the right to issue banknotes is considered merely as a reserve (the Bank of France, according to its Articles of Association, has no right to employ its capital or reserve for its current business, but must invest it in French Rentes), the Imperial Bank of Germany has not invested its capital in Government stocks, but uses it in current business. Therefore, by the increase of its capital by 30 millions of marks, and

of the maximum of the uncovered paper circulation, free of tax, from 293·4 millions to 400 millions, the Bank will be in a much stronger position, and better able to grant on a larger scale than before, the facilities required by trade and industry, and to extend the scope of the valuable services rendered during the last 25 years.

The discussions concerning the new German Bank Act have again shown that the Protectionist party is always in the field, trying to make of the Imperial Bank of Germany a State Bank, but their efforts up to now, have been in vain and will probably be in vain, for the majority of Parliament, representing the general feeling of the country, have already refused to listen to proposals so contrary to the interests of the nation and to modify the present state of things. The Imperial Bank of Germany, so ably managed by men of great experience and talent, has worked too well on the present system, for the efforts of the Protectionist party to have the slightest chance of success in Parliament. Some modifications in the capital or in the Government share of the profits may be introduced, but there is not the slightest doubt that the Imperial Bank of Germany will continue to work on the existing system.

I have now reached the end of my task, and it remains for me to thank you for the kind and undivided attention with which you have followed me. I have tried to bring before you the progress and commercial development of a country in which I have lived several years, where I have been able to study the economic, financial and monetary position, where I have seen how much is done to make Germany one of the greatest commercial nations of the world. It is obvious, that each of the subjects treated deserves a further and more detailed examination, but I have already taxed your patience to excess, troubling you with many figures. Yet I have tried to bring some interesting matters before you, in as popular and clear a manner as I could. And if I have succeeded, in showing that Germany is a rival not to be despised, if I have succeeded in inducing you to work with all energy and skill in the interest of England's trade, I shall consider myself fully rewarded for the time and pains I have bestowed upon my task. With the great energy and perseverance of the English nation, with the sound business principles and strong spirit of self-reliance which they constantly display, I am convinced that Great Britain

will not be distanced by any nation, in many, many years, that country of perfect freedom will continue to be at the head of the commercial nations of the world—will be faithful to her trade policy, that is to the policy of Free Trade, which has so benefited her people, and which, in the future, will prove to be the best commercial

policy. But to maintain that position, she must neglect no opportunities, she should devote her energy to extend her share in the world's trade. For trade and commerce are the primary interests of the nations. They may differ in languages, laws, customs, history, traditions, but all, however, have but one common ultimate object in view; all are animated by the same ambition; all turn every force at their command into one and the same direction—the acquisition of wealth and power, through trade and commerce. And that nation whose trade and commerce are most extensive and widespread is the nation whose wealth and power are the greatest, which will do most for the human race, carrying civilisation, justice, and freedom to the uttermost parts of the globe.

DISCUSSION.

The CHAIRMAN said it was always a pleasure to listen to a man who was a thorough master of his subject, and he was sure they would agree with him in thanking Mr. Rozenraad for the paper which he had read—a paper of the most comprehensive and exhaustive kind, which had given a complete picture of the present commercial position of Germany and which had explained, in a most lucid manner, the causes of what was a very remarkable feature in the industrial and commercial progress of to-day, namely, the very great progress which Germany had made in the international trade of the world. He quite agreed with Mr. Rozenraad that a very great deal depended upon the principle of freedom by which Germany had been animated in pushing forward her trade, and he quite shared the opinion that England need not feel the least of jealousy at the progress of Germany. He saw in the newspapers remarks comparing the progress made by one nation or another, and suggesting that England was on the decline because other nations were advancing, but that was a very narrow and improper way of looking at a subject of this kind. He further thought that other nations advanced in prosperity the more they grew in wealth, the better it was for this country, as they became more valuable customers of England, and every day as Germany improved in position so would she become a better customer of Great Britain. Now, not only freedom

necessary for Germany's improvement, but were other virtues which she had developed of years. What a different man the German of was from the German whom some remembered 50 years ago—a citizen of a small Prin- or State, with nothing to excite his of emulation, with no great spirit of patriotism ing his heart for the great nation to which onged. The wars from the year 1860 to 1871 nged all that. A successful war, which d a nation to unity and strength, developed all inliet features of the inhabitants. They rel their self-respect, were nerved to great ises, and carried on with a hope and spirit of y, and a determination to succeed that was n to them before. That was what had d the German character from what it was 40 or s ago. He quite agreed with Mr. Rozenraad ermany's commercial development had been markable, especially in ocean-going steamers, y of them were of an exceptional character, re carrying a constantly increasing trade. Nor only that Germany had prospered at home, for e going to distant possessions would find that a merchants and bankers were prospering there. was a great German club, for instance, not a Manchester but in Calcutta, under the flag. Germans under the British flag were g on trade in India, South Africa, and else- . This was one reason why the two nations live happily together, and should make them ine to do the best they could to promote the of the world. He believed that the era which ad just passed through in the last 10 or 15 the era of international suspicions and hatreds, nstant dread of war—was now drawing to a and that they might hope for a better time maments would be reduced and good feeling n the various countries would prevail. There ie feature of German progress which had not ommonly noticed. In England, a great deal en done in railway enterprise, but they had had any of the enormous physical obstacles as existed in the case of other nations; ad not had thousands of miles of desert erse or lofty mountains to level or pierce unnels. One of the most curious features lem life was that Continental nations had oed railway enterprise in a very remarkable and a degree which had hitherto been un- in England. The building of great Continental s which was now going on, and the levelling y mountains was something new in the of railways. He would give an illustra- of what they might accomplish in Europe . When he was in the South of France a time ago, he noticed there was a very invasion of Germans into that part of the y, and also into the north of Italy, and upon inquiry he found that the Germans poured in ge numbers every year. Now what was the

reason of that? It was simply on account of the Alps having been pierced by numerous tunnels, or crossed by railways, Italy being no longer shut out from Germany by an impassable barrier. At one time goods could only reach Italy from London by a long sea voyage, but now that the Alps had been traversed in half-a-dozen different directions this was not the case. The result was that the two nations had been brought more closely together, and a great interchange of trade had sprung up. In some of the Foreign Office despatches from our consuls in Italy, the usual lamentation was made about the decline of British merchants. The fact was that the British merchant was not less wanting in enterprise, but the German had been brought nearer than he was before, and was so able to send his goods through the Alps at a cheaper rate than the English merchant could hope to do. When at Lucerne he compared the statistics of people who passed through, and he found that the number engaged in business was greater than those on pleasure. The very same thing was being done over the whole of Asia by the construction of these railways. Germany and Russia were taking the initiative in that part of the world, and England had lost ground by not seeing what an enormous field for new enterprise was being opened in Asia. They had concentrated too much attention on Africa in recent years. Beyond Egypt and South Africa, he did not see any great prospect of wonderful new markets which people expected to find in the illimitable regions of unproductive country inhabited by warlike tribes. There were far more fruitful fields in Asia, which had been left uncultivated, and which the Germans and Russians had seen the possibility of turning to advantage. Some years ago, Lord Salisbury called attention to the necessity of looking at large maps, but the world had become very much smaller since those days. When Lord Salisbury spoke Moscow was thousands of miles distant from Pekin, but it was now within a few days' journey. The opening of the railways across Asia would have as much influence upon the development of trade as the opening of the Suez Canal had. In conclusion, he proposed a hearty vote of thanks to Mr. Rozenraad.

BARON VON LINDENFELS (Consul-General for the German Empire) said he must congratulate Mr. Rozenraad upon the complete manner in which he had dealt with this subject. Nothing was more useful for forming a proper opinion upon the subject than the frank and impartial criticisms given by an outsider whose knowledge of the subject could not be doubted, and this gave a good guarantee that it had been treated with impartiality and fairness. He was convinced that German commerce was in a steady state of development. It was not a development that need give rise to any serious apprehensions to England, whose commerce and industry was at all times in such a high state of development that it could compete with other countries. Germany, as a

young commercial nation, would have more trouble and more difficulty in competing with England than with other nations. There was no doubt there would be a great deal of competition in the future between these two countries, but their interests were, to a great extent, much the same, as both exported the same products to different markets. But there was no reason why this competition should not be a friendly one. The United States had great chances of enormous commercial development, whilst Germany, which had already reached certain limits with regard to population and the like, could not easily make much further progress. He could see no reason why there should be any jealousy between the two countries in the future; and, for his own part, he hoped that the friendly relations which had hitherto subsisted would continue to the benefit of both countries.

Mr. HERMANN SCHMIDT said he had been much struck with the remarks in the paper upon the advancement of Germany, and the figures brought forward plainly showed that in spite of the system of Protection which Mr. Rozenraad had criticised, the progress of the country had been most remarkable. The fact was that Germany had never been Protectionist except in self-defence. When the great fall in prices took place, there were only two ways of meeting the difficulty, and in order to check the effect of the fall, Germany was obliged to take up with Protection. When it had served its purpose the Protection system was relaxed. Germany had not passed through the years of commercial depression through which England had passed, and which led a few years ago to so many great failures, culminating in the Baring collapse. It was owing to the wise precautions which the German Government took in counteracting the effect of the fall in prices that that country had been able to progress commercially without interruption. It was not that it had progressed in consequence of Protection, but it was through the protective system being introduced at a time when the fall in prices took place, with the result that they had been able to ward off many of the evil effects of the fall. The banking system in Germany was not quite analogous to that in England, though to say the German banks were not as safe as English ones was going beyond the mark. The banks in Germany were conducted by men of very great commercial experience.

Mr. H. GERLICH (Commercial Attaché, German Embassy), after expressing his thanks to Mr. Rozenraad for his admirable paper, said there was one point with which he did not quite agree, and that was upon the subject of Protection. He believed in Protection, and it appeared to him that this belief was spreading rapidly even in England. In England it had taken only a less offensive name, and was called a countervailing duty. He did not want, however, to discuss the questions of Protection and Free Trade. Every country had to select the policy which it thought the

most suitable to itself. If Germany went better with Protection, and England found that Free Trade was more favourable to her, no one had to interfere. He only could wish that both countries should make rapid progress in prosperity. That a country developed its resources, the better it would be for its customers to trade with it. He was confident that if Germany and England worked together the result would be increased prosperity of both.

Mr. C. W. STOKES said that he hoped the paper would make allowance for him if he differed from the author of the admirable paper, and from the other speakers, in their praise of so-called Free Trade, inasmuch as the trade he had been devoted to was dependent upon — silk manufacturing — practically ruined by the unfair competition commonly erroneously called Free Trade. He considered that the primary duty of the Government of a country was to ensure that the consuming power of a nation should support the producers of the nation, but that England exposed the consuming power of the British Empire to foreign competition on equal terms, whilst British producers were handicapped by protective duties almost prohibitory, and could not share the roseate views of the future of the United Kingdom expressed by the Chairman. The universal application of machinery throughout the world, and the protective duties of countries, involved inevitable over-production, which would be very serious to the United Kingdom if it were to be open ports.

Sir CHARLES MALCOLM KENNEDY, K.C.B., said he wished to add his appreciation of the paper, but he would not further dwell upon points which had already been adverted to. There were two or three matters on which he would like to say a few words. In the first place, it seemed to him that the historical and political aspect of the question of the commercial development of Germany had been well stated by Mr. Rozenraad; but there was one point which had special importance, and which was often overlooked in this country, and that was the bearing of international commercial relations had on our domestic questions. These engagements were of special importance, they afforded stability to trade, and, in countries whose political systems differed from ours, they afforded weight to all foreign trade relations. A point of great importance to which Mr. Rozenraad had alluded was the varying relations between German agriculture and trade interests. This arrangement opened out a wide field of economic operation, which was very important, and which might with advantage be followed by those who read the paper in the *Journal*, and who studied the relations of these two great national interests. Then, with reference to the action of syndicates, to which Mr. Rozenraad had alluded, was not an unmixed benefit, the Continental practice of combined action on the part of man-

was of great importance. That was shown in national exhibitions abroad. Foreign industries together in putting forward what was a collective exhibit; and by that means advanced their own trade and national industry, while they avoided the waste of energy and money which was occasioned by single and uncoordinated action on these occasions. Again, he thought they must acknowledge the very beneficial effect of German official action in commercial matters. These matters were treated in a systematic manner by the German Government Departments, and what was wanted in this country, namely, a special commercial intelligence department, and matters as these were well looked after by the Government in Germany, Belgium, and other Continental countries. In this connection he would ask the person who followed up the subject to give their attention to a recent Foreign Office report on Germany, No. 490, of the miscellaneous series. As this was the last meeting of the Colonial Section for the year, he might, perhaps, be permitted to say that he thought the members owed a debt of gratitude to Mr. Digby, the new Secretary of the Section, who had been instrumental in providing four excellent papers.

A vote of thanks was put and carried unanimously.

P. DE JERSEY GRUT writes:—Mr. Rozenraad's valuable and interesting paper appeared to be influenced by the fact that though Germany's exports to Britain are greater than her imports from Great Britain by several millions of pounds sterling annually, the rate of exchange, as between Berlin and London, is always in favour of the latter place. He points out the difficulties of the question of the "balance of trade" (on which our forefathers held erroneous views), and suggests that the explanation of the above-mentioned apparent inconsistency is to be found in commissions, interests, freight, &c. This is, however, a much simpler explanation. It is not that the "balance of trade" as between Germany and the British Isles is in favour of the former country, but when the "balance of trade" is considered between Germany and the British Empire as a whole, the boot is on the other leg. In the year 1896, German exports to the British Isles amounted to 715,000,000 marks; her imports to 614,000,000 marks. But her exports to Germany and Australia amounted to only 78,000,000 marks, while her imports from those countries were valued at a value than 270,000,000 marks. It is true that in the case of Canada she imported only 3,000,000 marks and exported 15,000,000 marks worth. On a comparison of all the imports and exports, as between the British Empire, the balance in favour of the British Empire was about 125,000,000 of marks. Now the balance of trade as between Germany and the Indian

and Colonial members of the British Empire is settled by exchange operations that run to earth at London. Hence it will be seen that it is not to be wondered at that the rate of exchange is practically always in favour of London, and against Berlin. Mr. Rozenraad makes a comparison between the deposits of the English and German Banks, the former amounting to nearly £800,000,000 sterling, while the latter only amount to £54,000,000 sterling. A still more striking contrast can be afforded by mentioning the Australian local bank deposits, which amount to £100,000,000 sterling. It is remarkable that a new country, with only 4,500,000 inhabitants, should have nearly double the amount of bank deposits that an old and really wealthy country like Germany, with 52,000,000 inhabitants, has. Also, that the seven leading German banks have, all told, only the same amount of deposits that one Australian bank—the Bank of New South Wales—has. It would be interesting if, on some future occasion, Mr. Rozenraad would give his views as to the causes of the relative smallness of the bank deposits in the Continental European countries.

Miscellaneous.

LEADLESS GLAZES.

The joint report of Professor Thorpe and Professor Oliver to the Home Secretary on the subject of the employment of compounds of lead in the manufacture of pottery, and their influence upon the health of the workpeople, have been issued as a Blue-book, and the following abstract of its contents is extracted from an article in *The Times*:—

Besides visiting factories of earthenware and china at Stoke, Hanley, Burslem, and other places in the Pottery District, Professors Thorpe and Oliver have visited, either singly or together, the leading manufacturing factories on the Continent, including those at Delft, La Louvière, Maastricht, Copenhagen, Stockholm, Dresden, and the Royal Prussian Porcelain Works at Charlottenburg. Special reports on these visits by Professor Thorpe are appended to the joint report, and the Blue-book also contains a report by Professor Thorpe of experiments on substitutes for raw lead conducted in the Government Laboratory, and a statement, for purposes of comparison, of the special rules for the manufacture of pottery in force in England, and the regulations observed in foreign countries.

The report, which is dated February 21, states at the outset that since the inquiry of 1893, very little of an effective character has been done, or even attempted, to remedy the evil of lead-poisoning, and from the figures given it appears that of the total male workers, in the year 1898, 4.9 per cent. became "leaded," while of the female workers, the proportion is as high as 12.4 per cent. With regard to

obviating the use of lead in glazes, inquiry at first showed that only in a few cases were the results of experiments satisfactory, although in the case of white and cream-coloured ware (as distinct from the use of glazes in conjunction with colours), there ought to be little difficulty in the application of a leadless glaze. In the last six months, however, many successful attempts to substitute a leadless glaze have been made by the manufacturers, and the authors of the report say they "have no doubt whatever that leadless glazes, of sufficient brilliancy, covering power, and durability, and adapted to all kinds of table, domestic, and sanitary ware, are now within the reach of the manufacturer," and that this fact is now becoming admitted in the trade. If, however, the use of lead compounds in glazes is still to be permitted, the report states that much may be done to minimise their evil effects, and that no practical difficulties would result to the trade from the general substitution of "fritted" for "raw" lead. The substitution of a "simple" silicate, where it has been effected, has been attended with advantage so far as plumbism is concerned, though cases of poisoning from it are not unknown.

With regard to the workpeople the report, besides advocating the exclusion of women from certain parts of the work—except where leadless glazes are used—suggests the adoption of expedients to avoid the absorption of lead by the skin in the process of dipping. In foreign factories either the dippers are provided with indiarubber gloves up to the elbow or else the articles to be dipped are held by tongs, while in England the dippers' hands and arms are immersed in the glazing material. Indiarubber gloves have been tried, and though they have not found favour in the Pottery District, a return of them is advised by Professors Thorpe and Oliver.

The report expresses strong dissent from the doubts which have been expressed in some quarters as to the greater susceptibility of women and young persons to the evil effects of the metal; and points out that in certain potteries and lead works in Belgium and in Paris women are not allowed in any circumstances to work in the factories, owing to the recognised destructive effect of lead-poisoning on the power of child-bearing. While not recommending the complete abolition of even married female labour in the potteries, Professors Thorpe and Oliver make definite proposals as to the restriction of female labour, a subject which they acknowledge to have been one of the most difficult problems of the inquiry. The report concludes as follows:—

"The conclusions at which we arrive from the inquiries we have instituted at home and abroad, and from the observations and experiments we have made, are—

"That by far the greater amount of earthenware of the class already specified can be glazed without the use of lead in any form. It has been demonstrated, without the slightest doubt, that the ware so made is in no respects inferior to that coated with

lead-glaze. There seems no reason, therefore, in the manufacture of this class of goods the use of which should still continue to be exposed to the evil of the use of lead-glaze entails.

"There are, however, certain branches of the pottery industry in which it would be more difficult to dispense with the use of lead compounds. But there is no reason why, in these cases, the lead so employed should not be in the form of a fritted double-lead compound. Such a compound, if properly made, is but little attacked by even strong hydrochloric, acetic, or sulphuric acid. There can be little doubt that, if leadless glazes were used, the employment of such a compound instead of lead-glaze in its use could be ensured—would greatly diminish the evil of lead-poisoning.

"The use of raw lead as an ingredient of a glaze material, or as an ingredient of colours which are to be subsequently fired, should be absolutely prohibited.

"As it would be very difficult to ensure that an innocuous lead-glaze shall be employed, we are of opinion that young persons and women should be excluded from employment as dippers, assistants, ware-cleaners after dippers, and glaze-placers in factories where lead-glaze is used, and that the adult male dippers, dippers' assistants, ware-cleaners, and glaze-placers should be subjected to systematic medical inspection.

"In the 1893 report the medical member of the committee expressed the opinion that 'many of the factories are wholly, or in part, unfit in a sanitary point of view for occupation,' and they suggested 'that there should be some authority to close the premises whatever part of them is condemned, on the same principle as dwellings are declared uninhabitable.' We share this opinion and we concur in the recommendation. Certain of the factories we have inspected in the last stages of dilapidation, and it appears to be well-nigh impossible to introduce into them the re-arrangements or additions as are required by amended special rules."

TEA CULTIVATION IN NATAL

The picking season in Natal generally commences early in September, and goes on till about the middle of the following May. The months of June, July, and August are taken up with digging and manuring the land, and pruning the plants. The tea is picked by the coolies, mule carts in different gangs collect the leaf. Men and women are employed in the picking process. The tea leaf is taken down to the factory, where it is "weighed in." When weighed, it is spread out thinly on frames covered with hessian, for the purpose of "withering," in a temperature of 80° to 90°. The United States Consul General at Cape Town says that, in the course of twelve hours, the leaf has become pliable, soft, and produces the same sensation to the

silk handkerchief. The leaf is then passed through shoots into the machine room, where it is called "1;" the object of this process being to break the juice cells in the leaf, and to give the leaf that "crisp" twist characteristic of the tea seen in ordinary commerce. When the rolling is finished, the sappy, green mass is sent down into the cooling chamber where it is spread out and submitted to the action of steam at a temperature of from 60° to 70°. This is the final stage in the manufacture of tea. The eye of an experienced manager is required to see that the fermentation is arrested at the exact time, or the tea will lose quality, and would acquire an undesirable character. The rolled leaf is then passed to drying, on which it is spread out thinly and submitted to a temperature of about 250°, the excessive heat being removed by fermentation, and taking all moisture out of it. The now manufactured article is sent on to the sorting department, where the different grades of tea, such as Pekoe, Flowery Pekoe, Pekoe Souchong, and dust, are separated by machinery, which consists of a huge, revolving screen cylinder, the meshes gradually getting larger towards the outer edge, so that the dust falls from the separating machine and the Souchong last. It may be observed that the smallest leaves on the twig, when picked, are the finest tea. The tea is then put into air-driers where it is allowed to remain from two or three months to mature. After this it goes to the packing department, where it is put into packets or boxes for the trade.

RECEIPTS OF PARIS THEATRES IN 1898.—The annual return showing the gross receipts of the principal places of amusement in Paris has just been issued by the Director of the General Administration of Public Assistance in France. The largest amount realised during the period comprised between 1850 and 1898 was in 1889, the Exhibition year, when the receipts amounted to £1,292,000, but with the exception of this year, 1898 showed the largest receipts of any, these amounting to £1,246,000. In 1878, also an exhibition year, the amount realised was £1,226,000, and the lowest amount realised in any one year of the series was, as may be easily understood, in 1871, when only £228,000 were received. Taking the amounts received at each establishment last year, it is found that the Opera, as usual, heads the list with £119,232; then comes the Porte St. Martin with £87,796; and the Comedie Française with £78,088. The Folies Bergère realised £52,748; the Opéra Comique, £48,516; the Vaudeville, £47,564; the Variétés, £44,940; the Nouveau Cirque, £35,580; the Gaité, £34,920; the Nouveautés, £29,160; the Scala, £28,588; the Gymnase, £28,280; the Casino de Paris, £27,948; Olympia, £26,920; the Châtelet, £24,596; the Palais Royal, £23,812; and the Ambigu, £22,456. The Conservatoire concerts yielded £9,048; the Colonne concerts, £7,328, and the Lamoureux concerts, £6,760.

General Notes.

POLITAN VAGRANCY.—Another great plague, owing to Her Majesty's Consul in Naples, is to be feared from the streets of that city. Begging is abolished. Italy has no "Poor-law," and no provision made for beggars at the so-called "ospizio di Mendicita" has never been efficacious. Mendicants, if they give trouble to the authorities, are put there for a few days at most, and then let out and allowed to begin again. The city has many mendicant charities, and if these were harmoniously administered, a great part of the really deserving indigent population would be provided for, were it not that every Italian has a rooted aversion to being kept inside a hospital of any kind. The municipality proposes to attend to the worst cases (such as deformities, blind, &c.) among such charitable institutions as are available, and to calculate to take care of them, and to provide for the others by a subsidy of 10,000 lire (£400) annually. Taking each pauper at the moderate estimated cost of 20 lire (16s.) per month, 10,000 lire would provide for 42, a mere drop in the ocean of Italian vagrancy.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

APRIL 12.—"Telephones." By JOHN GAVEY. W. H. PREECE, C.B., F.R.S., will preside.

APRIL 19.—"London's Water Supply." By WALTER HUNTER, M.Inst.C.E.

APRIL 26.—"Coal Supplies." By T. FORSTER BROWN.

MAY 3.—"Aerial Telegraphy." By W. H. PREECE, C.B., F.R.S.

MAY 10.—"Fruit Growing in Kent." By GEORGE BUNYARD.

MAY 17.—"The Law of Trade Marks." By J. E. EVANS-JACKSON.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

APRIL 27.—"Judicial Reform in Egypt." By Sir JOHN SCOTT, K.C.M.G., D.C.L., Deputy Judge Advocate-General, and late Judicial Adviser to H.H. The Khedive. The LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., will preside.

MAY 11.—“The Revenue System and Administration of Rajputana.” By MICHAEL FRANCIS O'DWYER, I.C.S., Settlement Commissioner, Alwar and Bhurtpore. Colonel GEORGE HERBERT TREVOR, C.S.I., will preside.

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock :—

APRIL 18.—“Inlaying.” By STEPHEN WEBB.

MAY 2.—“Maiolica.” By WILLIAM BURTON.

MAY 16.—“The Artistic Treatment of Picture Frames.” By J. HUNTER DONALDSON.

MAY 30.—“Wrought Iron Signs.” By J. STARKIE GARDNER, F.G.S.

CANTOR LECTURES.

Monday evenings, at 8 o'clock :—

PROF. HENRY R. PROCTER, F.I.C., “Leather Manufacture.” Four Lectures.

LECTURE I.—APRIL 17.

Primitive methods—Difficulties of investigation—Sources of raw material—Methods of curing—Anatomical structure of skin—Arrangement of hair-pores—Chemical character of skin and epidermis—Manufacture of gelatine—Soaking and softening of hides and skins preparatory to tanning.

LECTURE II.—APRIL 24.

Removal of hair and wool—The staling process—Bacteriological and chemical actions involved—Depilation by lime—Practical methods—Chemistry of liming process—“Buffalo” method—Pullman's indirect process—Use of alkaline sulphhydrates—Realgar—Mechanical operations—Deliming processes—Chemical and physical considerations—“Pulling down” with acids—Fermentative methods—The brandrench—Bating and puering.

LECTURE III.—MAY 1.

Physics of tanning—Theory of the pickling process—Mineral tannages—Tawing with alumina salts—Chrome tanning—Heinzerling process—Schultz or “two-bath” process—Basic or “one-bath” process—Iron tanning.

LECTURE IV.—MAY 8.

Oil dressing—The chemistry of the process—Combinations of oil and mineral tanning—Vegetable tanning matters—Chemistry of the tannins—Practical methods—Combination of vegetable and mineral tanning—Currying—The chemistry of oils and fats used—Theory of the currying process.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, APRIL 10...Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Mr. E. T. Hall, “Sanitary Building Construction.”

Engineers, in the Theatre of the United Institution, Whitehall, S.W., 7½ p.m. Ewart C. Amos, “Machine Tools.”

Chemical Industry (London Section), Bureau, W., 8 p.m. Dr. J. T. W. Threlkeld, “The Industrial Technical Treatment of and of British Colonial Wines.”

British Architects, 9, Conduit-street, W., 8 p.m. “The Application of Colour to Interior Decoration in Relief.”

Medical, 11, Chandos-street, W., 8½ p.m. Victoria Institute, 8, Adelphi-terrace, W.C. Mr. T. G. Pinches, “Babylonian Deities.”

TUESDAY, APRIL 11...Royal Institution, Albemarle-street, W., 3 p.m. Prof. J. Cossar Ewart, “Zebra-Hybrids.” (Lecture I.)

Medical and Chirurgical, 20, Hanover-square, W., 8 p.m.

Civil Engineers, 25, Great George-street, W., 8 p.m. 1. Discussion on paper by Mr. Hadfield, “Alloys of Iron and Nickel.” James Murray Dobson, “Buenos Aires Works.”

Photographic, 12, Hanover-square, W., 8 p.m. Mr. E. W. Maunder, “The Correct Exposure given to Photographs of the Corona.”

Colonial Inst., Whitehall-rooms, Whitehall, S.W., 8 p.m. Sir William Robinson, “The Capabilities and Prominent Products.”

Pharmaceutical, 17, Bloomsbury-square, W.C., 8 p.m.

WEDNESDAY, APRIL 12...SOCIETY OF ARTS, JOHN RUSSELL BUILDING, W.C., 8 p.m. Mr. Gavey, “Telephones.”

Geological, Burlington-house, W., 8 p.m. W. J. Sollas, (a) “Fossils in the Upper Devonian of the Ural Mountains.” (I. Silurian Echinoidea; Ophiuroidea); (b) “The Occurrence of Spicules in the Carboniferous Limestone of the Ural Mountains.” 2. Mr. C. T. Clough and Dr. H. Pollard, “Spinel and Fürsterite from the Ural Mountains.”

Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Miss Alice Ravenhill, “Practical Hygiene in Elementary Schools.”

Royal Society of Literature, 20, Hanover-square, W., 1 p.m.

THURSDAY, APRIL 18...Antiquaries, Burlington-house, W., 8½ p.m.

Society for the Encouragement of Fine Arts, Conduit-street, W., 8 p.m. Mrs. Philip Noyes, “Some Goldsmiths and their Work.”

Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Mr. W. C. Tyndale, “House Drainage.”

Royal Institution, Albemarle-street, W., 8 p.m. Prof. Dewar, “The Atmosphere.” (Lecture I.)

Electrical Engineers, 25, Great George-street, W., 8 p.m. 1. Discussion on paper by Mrs. Ayrton, “Hissing of the Electric Arc.” 2. Messrs. Duddell and E. W. Marchant, “Experiment on Alternating Current Arcs by aid of Oscillographs.”

Mathematical, 22, Albemarle-street, W., 8 p.m.

FRIDAY, APRIL 14...Royal Institution, Albemarle-street, W., 5 p.m. Weekly Meeting. 9 p.m. Prof. Rucker, “Earth Currents and Electric Tides.”

Astronomical, Burlington-house, W., 8 p.m. Junior Engineering, Westminster-palace, S.W., 8 p.m. Mr. H. C. Reid, “Piles and Drivings.”

Philological, University College, W.C., 8 p.m. Clinical, 20, Hanover-square, W., 8½ p.m.

SATURDAY, APRIL 15...Royal Institution, Albemarle-street, W., 3 p.m. Mr. Louis Dyer, “Machine Tools.” (Lecture I.)

Journal of the Society of Arts.

No. 2,421. Vol. XLVII.

FRIDAY, APRIL 14, 1899.

Communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Proceedings of the Society.

XVTEENTH ORDINARY MEETING.

Tuesday, April 12, 1899; W. H. E. C.B., F.R.S., in the chair.

The following candidates were proposed for members of the Society:—

Thomas Henry, Avonmore, Dudley-park-road, Letchworth, Herts. Green.

C. Foster, Sheepcote-road, Harrow.

William John, Finchley and Hornsey-lane, Finchley, N.

John Henry Neville, 34, Devonshire-place, W., London, W. 1, 6, Leadenhall-street, E.C.

John Horatio Haliburton, 5, The Cam, Southbourne, Southsea, N.

John J. R., J.P., Calder-green, Bantyre, N.B.

Arthur Dingwall Fordyce, A 24, Exchange, London, W. 1, 1, Pool.

Charles, 39, Victoria-street, S.W.

John E. Montague, 162, Romford-road, Stratford, E.

Montagu, Bonsor Gold Mining Company, East London, Rhodesia.

John William Alexander, 13, Prospect-hill, Broomfield, Hamstow, Essex.

John Annesley, Lieut.-General Arthur Lyttelton, Lyttelton, Weybridge, Surrey.

John James, Alexander Marshall, 1, Bon Accord, Aberdeen.

Alfred, 4, Orient-terrace, Manor-road, Liscard, Wirral, Cheshire.

Carl, 35, Hill-street, Mayfair, W.

Mrs., 40, Thurloe-square, S.W.

Adolphus, 4, East India avenue, E.C.

John Charles Thomas, Madras, India.

Major John Alfred, Rangoon, Burma.

The following candidates were balloted for and elected members of the Society:—

Ernest, Hermann L., 55, Redcross-street, London, E.C.

Henry Archibald, Somersall-hall, Chester.

John Julius Charles, 82, Piccadilly, W.

The paper read was—

TELEPHONES.

By JOHN GAVEY.

GENERAL.

The invention of the speaking telephone, which was the outcome of the labours of Page, Reis, Graham Bell, Edison, Hughes, and numerous successive inventors, has entirely modified the means of rapid and accurate inter-communication, not only within limited areas, but between cities and towns many hundreds of miles apart, and this method of communication, which is proving such a rival to the older form of telegraphy, has aroused such widespread interest that your Council have thought it desirable that a paper on the subject of Telephones and Telephone Exchanges should be laid before you.

THE TELEPHONE RECEIVER.

Although many forms of receiving telephones of varying degrees of merit have been designed,

FIG. 1.

BELL'S TELEPHONE.

it is only necessary here to refer to the first perfect articulating telephone that was practically used, namely, that invented by Graham Bell. It may be said that not the least remarkable feature of this invention is the fact that since its introduction, in the year 1877, beyond the mere perfection in its manufacture, it has been found impossible to effect any material improvement in the type of instrument then introduced, when used as a receiver. At the present time the original drawings or diagrams, prepared for the first public lecture on the Bell Telephone, still serve for purposes of illustration.

A very brief description only of this receiver is necessary. Bell's telephone, as now used, comprises a permanent magnet, preferably of the horse-shoe type, with a small coil of insulated wire surrounding each pole piece. Opposite these pole pieces is placed a thin diaphragm of soft iron which is set in vibration when undulating or vibrating currents traverse the coils. This telephone can serve both as a transmitter and as a receiver, but in practice it is now used only for the latter purpose. Fig. 1 illustrates its present form.

THE TELEPHONE TRANSMITTER.

The modern telephone transmitter is based on the discoveries of Hughes and Edison, of the fact that loose or imperfect contacts, preferably of carbon, when subjected to vibrations, vary their resistance to the passage of an electrical current, and that within certain limits this variation bears a direct relation to the amplitude and to the frequency of the disturbing vibrations. Thus, musical or articulate sounds, producing sonorous vibrations in the air, impinge upon a diaphragm and set it in vibration, and if this diaphragm press upon or set in movement loose contacts of a suitable character, a corresponding variation arises in the resistance of the circuit of which these contacts form part, and a current of electricity traversing the circuit can be made to describe precisely the same curves as those due to the sound waves. It is the function of the receiver to convert these electrical curves into mechanical vibrations, and thus to reproduce actual sound.

The action of speaking by telephone thus involves a number of successive transformations of energy. The sound waves, which impinge on the diaphragm of the transmitter, set up mechanical vibrations, which give rise to electrical undulations. These undulating currents traverse the connecting wires, causing

variations in the magnetic field of the receiving telephone, and setting up vibrations of the diaphragm similar to those which originate the disturbance. In this manner musical speech are reproduced.

Innumerable forms of carbon microphones have been devised. In some cases particles of hard carbon rest loosely in sockets formed by carbon blocks attached to the diaphragm of the transmitter; in one form—still generally used with single wire circuits—a button of carbon rests against the diaphragm, the most effective transmitter consists of small granules of carbon enclosed between two carbon discs, one of which is fixed, and the other free to vibrate. Fig. 2 illustrates the form at present used by the Post Office. The design of a transmitter care must be taken to provide against the vibrations of the diaphragm causing an actual break of the circuit, which gives rise to disagreeable sounds, and renders speech inarticulate. The two former types of transmitter are subject to this defect should the speaker shout or approach too closely to the telephone, but with the latter it is possible to speak close to the transmitter, and with considerable force, without rupture of the circuit, so that it is well adapted, not only for intercommunication on short lines, but also for use on long trunk circuits.

FIG. 2.

DECKERT'S GRANULAR TRANSMITTER.

The various types of receivers and transmitters are fully described in the text, so that it is not necessary to refer to them in large at the present moment.

* These two blocks have been kindly lent to me by Longman and Co.

THE CIRCUIT.

When the telephone was introduced as a local instrument it was discovered that it was by far the most delicate detector of vibrating or vibratory currents that had been placed in the hands of the scientific investigator or the practical electrician. When limited to a single wire, the circuit of which was completed through the earth, and which in proximity to other circuits similarly laid up, innumerable noises were heard when the neighbouring wires were worked. Carrying secondary currents, some due to leakage, some to electro-static, and some to electro-magnetic induction, were attracted by the adjacent working currents, so that if these were used for telegraphic purposes buzzing and frizzling sounds were heard on the telephones, of such intensity as to render speech impossible. On the other hand, if the neighbouring circuits were used inductively, and were in excess of a certain amount, the conversation held on one circuit could be heard on all the neighbouring circuits. To avoid, however, two wires were used to form a complete metallic circuit, and when they were placed in regard to all neighbouring wires at the same average distance between any one of them and the two former was the same throughout, then the electro-motive force due to induction in one of the wires of the circuit was equal to and opposed to that in the other, so that disturbing currents circulated, there was no leakage from earth, and a silent circuit was formed, in which nothing interfered with telegraphic speech.

Early as 1881, when the first Post-office telephone exchange was opened, the Department erected metallic circuits, and this policy has been adhered to throughout. Most of the telegraph administrations and companies throughout Europe and America, however, started with single-wire circuits, and this is one of the principal causes of the dissatisfaction which has long since become a complaint of the members of the public who have felt with the telephone service. To reduce the overhearing between neighbouring single-wire circuits, it was found necessary to use somewhat imperfect transmitters, which only admitted of good communication when the users spoke in gentle tones, and even then the circuits were noisy, inefficient, and unsatisfactory. In justice, however, to those who started on these lines, it must be said that in the early days of telegraphic exchange work there was no form of insulated wire thoroughly adapted for use for underground purposes, and it was practically

impossible to erect aerial wires in the enormous numbers that soon became necessary to provide metallic circuits for the large Exchanges that rapidly arose. Gutta-percha and india-rubber insulated wires were very costly, they took up much space, and their static capacity was so high that the limit of distinct speech was soon reached.

The invention of paper insulated air space multiple cables has led to a revolution in telegraphic practice. They are relatively cheap, they take little space, a conduit that would hardly hold 80 gutta-percha wires will accommodate 408 wires insulated with paper, and the static capacity of the latter is but one-fourth that of the former, which practically means a fourfold increase in the range of speech when underground circuits are in use. Specimens of these cables are exhibited.

All European and American administrations and companies have availed themselves of this new form of underground cable, and at present about three-fourths of the Exchange service in these countries is provided by means of complete metallic loops. Their use is being rapidly extended, so that within a relatively short period the single-wire telephone exchange circuit will be a thing of the past.

It may, however, be well to refer to the fact that for long distance speech, over trunk lines connecting distant places, we are still practically restricted to the use of open wires, for the relatively high static capacity, and the considerable electrical resistance of the small conductors used in these paper cables, although not very detrimental on short lines, would render speech over long distances utterly impracticable under present conditions.

THE SWITCH.

The history of the modern switchboard in its elementary form extends back to the early days of telegraphy, for the most serious problem which has confronted telephone engineers, namely, the ready method of placing a large number of subscribers in rapid and simultaneous intercourse with one another, arose in a minor degree when public telegraphs were first inaugurated. It was obviously impossible to erect wires between every two individual towns throughout any country, and in order to avoid re-transmission of messages at intermediate points, *i.e.*, the writing down of a message received at B, from Station A on one wire, and the sending of it to Station C on another wire, a system was devised by means of which all the circuits in a central office were

terminated on a series of brass bars fixed horizontally on a suitable base, and a second series of similar bars was fixed at right angles to and insulated from the former. The two lots of bars were pierced with holes and provided with pegs, and it was possible to make direct connection between any two of the horizontal bars on which the telegraph circuits were connected by inserting pegs through these into one and the same vertical bar. An old-type switch is exhibited.

This was termed an Umschalter switch, but it gradually fell into disuse, as it was soon found to be more speedy and more economical to transmit the messages by writing them down at one instrument and handing them to another operator to send over the second instrument, rather than to wait till both the circuits were free and ready to be connected through direct.

In the year 1864, the Universal Private Telegraph Company re-introduced the use of these switches for providing connection between subscribers to their private-wire telegraph system so as to place them in direct communication with each other, and what was virtually a telegraph exchange was established by them. The system was subsequently extended by the Post-office to several towns in Great Britain.

On the establishment of the first telephone exchanges in this country the Edison Company started with a switch of the fixed bar and plug type just referred to, whilst the Bell Company introduced a board in which flexible cords, connected to plugs, were used for joining through the circuits. This was the direct progenitor of the modern system of switching.

A telephone switching installation comprises the following apparatus at the Exchange:—

1. *An Indicator*, by means of which the attention of the operator is called when a subscriber desires to communicate.

2. *A Jack*, or switch spring, to which a subscriber's line wires are connected.

3. *Plugs*, for insertion in the jacks, and connecting cords, containing conductors, by means of which connection is established between any two subscribers.

4. *Speaking and Ringing Keys* and other subsidiary apparatus, the use of which appears in the description of a modern switchboard. Specimens of each class of instrument are exhibited.

Each subscriber is, of course, provided with a complete telephone, an electric bell, by means of which he can be called, and some

means of actuating the Exchange indicator (1) when he desires to communicate.

The operation of telephone switching in small Exchanges is a simple one. When the operator has received the call, she inserts one plug of a connecting cord into the corresponding jack, and by depressing a special key brings her telephone into the circuit. She ascertains the requirement, inserts a second plug of the cord into the jack of the subscriber who is wanted, depresses a ringing key which actuates the bell of the second subscriber, and the latter, on answering, connects himself in communication with his correspondent. The apparatus is exhibited. The calling up of the Exchange has been effected in various ways. In one, the most common, subscribers are provided with a small magnetic machine, set in motion by a cranked handle. The turning of this handle drops the Exchange indicator. In others, primary batteries have been used.

Again, a system known as the "Lawrence" or "Call wire" system has been tried. In this an independent circuit extends from the Exchange to a certain number of subscribers, each call circuit serving from 40 to 60 persons. It terminates in a telephone at the Exchange at which an operator is listening continually. To obtain attention a subscriber depresses a special key on his local telephone, which switches it into the call circuit, and if not speaking, he makes his wants known to another subscriber by using the call circuit; the former waits his turn. The operator, on hearing his requirements, makes the necessary connections as before, the subscriber releases the "Call key," and his telephone is then cut out of the call circuit and restored to the speaking circuit, on which he listens till he hears his correspondent answer.

Finally, in the Post-office, a system has been designed, under the instructions of Mr. Proctor, by which the removal of the telephone from its suspending hook actuated the indicator at the Exchange, and this method has now been adopted, and, with certain modifications, which will be described later—it promises to become the standard type of working in the United States.

When the conversation is finished, the reverse operations are performed. If the call is originated by ringing, a brief ring is repeated and this drops a second indicator shutter which is bridged in the connecting cords, and which is an instruction to the operator to connect the two circuits. With the "Call

14, 1899.]
 n, instructions to sever the connection conveyed on the call wire, and finally, with post-office system, the restoration of the line to the hook sends an automatic signal to the Exchange, which indicates the end of the conversation.

where a special operation, is necessary to sever the severance of a connection, much difficulty occasionally arises through a subscriber omitting to ring or call off; under these conditions, other subscribers who wish to speak to either of the two who are engaged through are told that he is engaged, which much discontent and trouble have arisen from this cause. The advantage of a system which abolishes this special operation and substitutes an automatic signal on the hanging of the telephone is obvious.

As long as Exchanges were of limited size, the simple types of switching readily met all requirements; but as the number of subscribers increased, and the switchboards grew to such dimensions that several operators had to be employed, a difficulty arose in making connections between circuits beyond the reach of a single operator. This was at first met by providing what are termed office circuits between each operator and all subscribers; but as the system became more extensive, the number of these junctions and the difficulty of manipulation increased to such an extent as to render this method of working impossible.

To meet this difficulty, the multiple board was designed. This board is divided into sections usually of such a size as to provide space for seating three operators, and on each section are the local jacks and indicators of a number of subscribers, varying from 200 upwards, according to the average number of calls dealt with daily. In addition, however, to these local jacks and indicators, all the circuits of the whole of the remainder of the subscribers to the Exchange are attached to a number of jacks fixed on the upper panels of the board, so that each operator is in a position to connect any one of the local subscribers, whose calls she is responsible, directly to either subscriber on the Exchange. It is, however, evident that before a subscriber could be connected to a local section is joined through to another subscriber, it is necessary to ascertain that the latter is not connected through another section of the board to a third subscriber, and this is ascertained in a very instantaneous manner. On the face of each jack is a metallic socket, and resting on this socket is

one of the springs of the jack itself. These springs and sockets are so connected that on the insertion of a plug into a subscriber's jack, at any section of the board, the socket spring is moved into contact with a stud that connects a battery with the whole of the sockets of the jacks which serve that particular circuit. If a subscriber who is wanted is engaged, the fact is indicated to any operator in the Exchange by a click in her telephone when she touches, with the tip of the plug to which her telephone is for the time being connected, the socket of his jack on her section. If she hears no click, she assumes that the subscriber is disengaged, and connects him through to the calling subscriber.

The early types of multiple boards were extremely costly, and they were subject to many defects which led to the introduction of other systems which were designed to cheapen the service and to improve the working. This again put the advocates of the multiple system on their mettle, with the result that the modern multiple board, as at present manufactured, appears to meet, within its capacity, most of the requirements of a thoroughly efficient telephone system.

I propose to describe briefly the latest form of multiple board, designed by the Western Electric Company, which embodies the most recent developments of American practice.

First, the Post-office system of automatic "calling" by the removal of the telephone from its hook, and automatic "clearing" by the restoration have been adopted: but the progress of modern discovery has placed at the command of telephone experts improved methods of which they have availed themselves. Thus, small electric glow-lamps, worked by relays, have been substituted for the necessarily somewhat cumbersome drop indicators previously used in most Exchanges. These glow-lamps can be placed in any position, vertical or horizontal, and they take up such little space that they can be fixed in the exact localities in which their indications are most readily observed, instead of having to be placed, as in the older boards, at a considerable distance from the jacks and cords with which they are worked. Thus there is no need for hesitation or thought on the part of the operator, whilst trying to connect in her mind a distant signal with the particular operation to be performed, for each lamp indicator is in immediate proximity to the jack or plug, as the case may be, which has to be used.

Under each subscriber's local jack at the

Exchange is placed one of these glow-lamps, which is normally dark, but which acts as the subscriber's calling signal. On the keyboard, and close to each of the connecting cords and plugs, are two similar lamps, the use of which is indicated in the following description of the *modus operandi*:—

On the removal of the subscriber's telephone from the hook the calling lamp immediately under his jack at the Exchange lights, and the operator, without a moment's hesitation, inserts a disengaged plug into the jack. The insertion of this plug extinguishes the "calling lamp," and the operator presses the speaking key forward and simply says, "Number." On receipt of the reply from the calling subscriber the second plug of the pair is used, in the first place, to test the line on the multiple of the subscriber wanted, and then, if the latter be disengaged, for insertion in that subscriber's jack. This action lights the lamp nearest the operator on the keyboard. She reverses the speaking key for a brief interval, and this has the effect of ringing the bell of the subscriber wanted. On his removing the telephone from its hook the front lamp is extinguished, the two subscribers are in correspondence, and the operator is made aware, by the lamps ceasing to glow, of the fact that her work for the time being is complete. Should either subscriber hang up his telephone, as is sometimes done while searching for information, one only of the keyboard lamps lights, but no notice is taken of this, unless it should remain in that position for an undue period. When, however, the conversation is really finished, and both subscribers restore their telephones, both keyboard lamps light, and this is an absolute signal to withdraw the connecting plugs, which action is followed by the extinction of the keyboard lamps. If the subscriber wanted is engaged or fails to answer, the operator says to the originating subscriber, either "busy" or "does not answer," and on the latter restoring his telephone, the lamp on the keyboard furthest from the operator lights, and she withdraws the plug. It will be observed that the speaking in the course of manipulation is reduced to a minimum. When there is nothing to prevent an immediate connection, only one word is uttered by the operator, and this is increased to two when the connection cannot be made. Switches illustrating the series of operations are exhibited in work.

One great advantage of the automatic method of signalling, whether Post-office or

Western Electric, is the fact that it maintains the line under a constant test; for should a fault arise on the wires at any time, the switches give warning of the fact by indicating a condition which no answer can be obtained. A line is at once dispatched to remedy the defect before a subscriber has learnt that any error is wrong.

In the Western Electric system also individual primary batteries at each subscriber's office are replaced by central station batteries at the Exchange, which are used for speaking and signalling purposes. The process of replacing primary by secondary batteries at all large telegraph offices in the country has been in progress for some years, and these batteries also have been in use on the Department's trunk lines for automatic signalling purposes for a considerable period, but their use for speaking purposes also is a promising innovation.

Of course, various types of modern switches exist, most of which have some advantages to recommend their use, but I have thought the description of the above type will have particular interest as being the outcome of the general experience in the United States, which may be termed the home of telephony.

If the capacity of a multiple switch were unlimited, and the telephoning of large numbers could be effected by concentrating the terminals of the circuits in one Exchange, the problem would be easily met by the use of a switch of the above, or of some similar type. Unfortunately, the number of subscribers which could with advantage be served on one switch is limited, the largest now in use providing for 10,000 subscribers. The limit is caused by various causes. The range of an open switch reach is not great, and it is obviously unwise to extend the multiple jacks beyond heretofore limits. There is also a limit to reduction in size effected in the size of jacks, so that it is not possible to crowd more than a certain number within a given space. There are also other objections to which specific reference need not be made, but the result is that to deal with a large number of subscribers it is necessary to establish several Exchanges, and these are connected together by junction circuits. These circuits are virtually the equivalent, in a certain degree, of the trunk circuits connecting larger cities and towns, and they are almost universally worked by means of automatic signals, but a detailed description of the methods in use would scarcely have sufficient interest to justify further explanation here.

will be interesting to quote certain figures relative to the Central Exchange belonging to the French Government in Paris. It is at present fitted for 15,000 subscribers, and to provide for this number no less than 100 jacks are joined up. To connect these in the interior of the building, there are 118 miles of 40-wire cable, giving an aggregate of 4,760 miles of wire in the switch-room. These wires are cut and jointed to the jacks at intervals of about 12 inches, and this has involved the making of 2,500,000 soldered joints. I mention these figures because it works in the same fashion to under-estimate the work in constructing a modern telephone system. I take an analogy. It is a simple matter to provide the catering for a single establishment, but there are few problems of greater magnitude than the provisioning of an army of 100,000 men. In the same way, any telegraph electrician can run up a few score miles and connect them to a switch, but when the wires grow from scores to thousands, and the area of thousands, spread over an area of some

hundreds of square miles, the problem becomes as intricate as that involved in any other type of heavy electrical engineering.

The telephone trunk service of Great Britain, in other words, the system which provides intercommunication between the principal towns in the country, was fully described in a paper I had the honour of reading before the Institution of Electrical Engineers, in November, 1896, and there has been no material modification in the methods then described. On the 31st March, 1898, the Post-office plant comprised 56,373 miles of wire at work, and in course of construction, and 269 towns were connected with trunk circuits, by means of which any one of them could be placed in direct connection with any of the others. The system is being rapidly extended.

The following Table, which shows the mileage of the telegraphic and telephonic systems throughout the world at the end of the year 1898, will be of interest. It is compiled from official documents supplied to the Bureau International de Berne.

APPROXIMATE MILEAGE OF THE TELEGRAPHIC AND TELEPHONIC SYSTEMS OF THE WORLD, JANUARY, 1899.

	LINES.				WIRE.			
	Telegraph Lines.		Telephone Lines of States and Private Companies.	Totals.	Telegraph Lines.		Telephone Lines of States and Private Companies.	Totals.
	State Administrations and Private Companies.	Railway Companies.			State Administrations and Private Companies.	Railway Companies.		
	Miles.	Miles.	Miles.	Miles.	Miles.	Miles.	Miles.	
<i>Countries subject to the International Telegraphic Convention:—</i>								
American	490,200	179,570	169,300	839,070	1,604,300	623,200	852,800	3,080,300
European	167,300	64,620	14,290	246,410	406,100	205,300	119,230	730,630
<i>Countries not subject to the Convention:—</i>								
America—								
Western Union Co. ..	233,000	233,000	1,003,400	1,003,400
Postal Telegraph Co. ..	18,640	18,640	108,730	108,730
Other offices	248,500	186,400	434,900	..	745,600	2,175,000	2,920,600
America	15,533	9,300	3,107	27,940	29,820	27,960	31,070	88,850

<i>Submarine Cable Companies</i>	167,800	167,800	169,600	169,600
	1,117,526	529,950	382,417	2,029,893	3,396,510	1,685,940	3,202,950	8,285,400

Finally, I may venture to say that it is almost impossible to predict the future of the telephone. There is room for unlimited growth,

and great as have been the developments of the ordinary methods of telegraphy, they are probably destined to be entirely eclipsed by

the telephone which may before long be the principal channel through which both business and social intercourse of the country will be carried on.

DISCUSSION.

The CHAIRMAN said this had been an absolutely practical paper; there was nothing in it controversial, and it had shown very well that the chief characteristic of the telephone was its simplicity. When he brought the first telephone to this country from America, in 1877, and described it to the British Association at Plymouth, he summed up the whole matter in two words, which had been repeated over and over again, by saying that its chief merit was its "ridiculous simplicity." Another point worthy of notice was this; that however much the use of the telephone in this country had been retarded, there had been no obstacle to the improvement in its working; nearly all the steps in its progress had emanated from this country, and other countries, particularly America, had flattered them most sincerely by copying them in many particulars. Still, they could not blink the fact that for some reason the telephone in England was eminently unpopular. Why this was so he could not say; perhaps some light might be thrown on the question in the discussion, but he might suggest that one great reason was ignorance—ignorance of the construction and working of the telephone, of the appliances used to make it serviceable, and of the intricate and exacting duties which had to be discharged by the operators, who were generally, if not universally, young ladies. Mr. Gavey was a most experienced experimenter; for twenty-one years he had been his (the Chairman's) right hand, and had experimented with telegraphs and telephones in every form and shape, and yet, when he came to read his own paper, and to show the operations of a simple instrument, he had partially failed. If this were so, surely some consideration ought to be shown to those young ladies who were doing their very best to serve the public, but who, he feared, had often to listen to very impolite remarks. Mr. Gavey had not mentioned one interesting fact, viz., that in consequence of improvements originated by the Post-office, and now adopted all over the world, the use of automatic signalling had put an end to the use of that phrase which used to be so frequent and so annoying—"Have you finished?" Those in London who used the telephone a good deal, were still sometimes vexed by this question being asked, but when the automatic system would be introduced they would hear it no more. He could not help calling special attention to the immense growth of the telephone system. It was something to have lived in an age when they had seen the growth of electricity from childhood to manhood. As he had already said, he brought the first telephone across the Atlantic; he

saw it before a single Exchange existed in America for there were not more than two or three circuits at work when he was sent over to the Postmaster-General of the day to inquire into the merits of this instrument. That was only in 1878, and now there were nearly 4,000,000 miles of wire employed for telephones, and the total number of miles of wire used in telegraphy was about 8,000,000. Even in one single Exchange in Paris, 2,500,000 joints had to be made to complete the work. This all showed that those who carried out this work were the convenience of the public should receive special consideration. An engineer had been defined as one who applied the great forces of nature to the wants and wishes of mankind, and he ventured to think that there was no branch of engineering which had done more to make life comfortable and convenient than that connected with electric telegraph and telephones.

Mr. J. E. KINGSBURY said he had listened to the paper with very much pleasure, and was pleased to note the remark that the work connected with telephones was entitled to stand on a level with any other branch of electric engineering. The time to which they were indebted to American countries had been referred to, but he might point out that America was also indebted to England in many points. It was within his knowledge that the cable work between London and Birmingham had attracted a good deal of attention from American engineers who had carefully investigated it, and who, he was sure, would be willing to give full credit to the originators of the system. This cable work was quite a pioneer class, and would probably alter and change the conditions of long line working.

Mr. DANE SINCLAIR said all who were familiar with telephone work must have listened to the paper with great pleasure. To him it had been a treat, because the exposition had been so simple and yet so complete, and he must congratulate both the author and his audience. Mr. Gavey had led them from theory to practice, and from the old practice to the very latest developments. After dealing shortly with the instrument itself, he came to a part which required most attention, the signalling arrangements, and on that matter he had brought them thoroughly up to date. As the Chairman said, the arrangements seemed very simple as simple as the instrument before them appeared when they thought of what a large Exchange in New York or London is like, they would recognise that what was in principle simple enough, must become extremely intricate. Last year he was in the States, and saw this new system of lamps and a common battery was much taken with it, but was not sure that the points had been considered which were necessary to make it suitable to a place like London. For instance, if one of the subscribers had two or

phones in his office, how would you ensure that the one was put in circuit when he was called up the Exchange? Apart from this difficulty, he thought the lamp was a great advance on the more mechanical systems previously in use. There was nothing to make it excessively costly, and he had no doubt that those who had charge of the telephone business would gladly introduce anything which rendered the service more speedy and efficient.

STANLEY FLINT said he would endeavour to come answer to the question of the Chairman, that the telephone was unpopular. They had been in an ideal system, but what they suffered from London was a very inefficient system. As a member for some years, he might say that he often had a difficulty in getting in connection with other members, and was inconvenienced by being cut off in the middle of a conversation. If the system were more efficient, there would be more subscribers, and the charges were very high—much higher than in most Continental countries. The constant question "you finished?" was very annoying, but it was worse to be suddenly cut off even if you answered.

A. O. GRANGER said he was a user of the telephone on the other side of the water, and should be glad if any explanation could be given of the different rates which prevailed in different places. He used the telephone in Canada, and in two places in the United States. In Philadelphia they paid 150 dollars for one telephone; in Montreal 40 dollars; and in Greenville, a little town in Georgia, of under 100 inhabitants, they only paid 18 dollars. Generally when an article came largely into use it was cheapened, but in the case of telephones the reverse was the case, the highest rate being charged in the largest towns.

THE CHAIRMAN said he would leave Mr. Gavey, who had recently visited the States, to reply to the question if he could, but with regard to the main objection as to the inefficiency of the system in operation in London, it was only right to point out that the instrument exhibited that evening was the latest development, which had only been perfected within the last few months, and it was quite possible for a private company, or even a Government department, to replace or renew their apparatus every year to meet the wishes of an exacting public.

He might say that of all the systems he had inspected, the very worst—from an expert's point of view—was that adopted by the German Government in Berlin; and yet, in spite of that, there was not a town in the world where telephony was so successful. He did not say the London system was perfect though he had inspected Exchanges in London which were absolutely perfect according to the knowledge and experience of that time, and yet the public were dissatisfied, and said the system was inefficient.

He had over and over again pointed out that the chief source of inefficiency in the telephone service lay with the users, and it was the same with nearly all branches of the public service, such as telegraphs and railways. If an exacting public did not get everything absolutely up to date, they were dissatisfied and grumbled. Anyone who was dissatisfied should not write to the papers and complain, but go to the nearest Exchange and ask to be shown the working of the system; the more they understood it the better would they be able to use their own telephone, and the better they would be pleased with the service. He would conclude by proposing a hearty vote of thanks to Mr. Gavey.

The vote of thanks having been carried unanimously,

Mr. GAVEY, in reply, said the newly designed method of automatic working which he had exhibited had only recently been introduced, and at present the demand on the manufacturers was so great that, huge as their factories were in New York and Chicago, they were doubling them in size in order to meet the American demand alone. At the large Exchanges they were fitting them up as rapidly as possible, and he believed in this country the National Telephone Company would soon have one fitted up in Bristol. With reference to Mr. Sinclair's question, curiously enough, there was more difficulty where a subscriber had two telephones in his office than if he had twenty. In many of the large buildings which were so frequent in American cities there was a private wire exchange in the structure itself, to which all the offices were connected. In St. Louis, when a company erected a large building they provided a private wire exchange, and put a telephone in every office, the use of which was included in the rent. Every tenant could communicate free of charge with everybody in the building. That private exchange was connected with the Central Exchange, and those who wanted to speak through the Central Exchange, could do so on paying a toll for each call. With a system of that kind, the signalling was very simple; junction circuits were provided between the private wire exchange and the Central Exchange. Where a subscriber had two telephones alone, he believed a method of signalling at both stations from the central batteries was now being evolved by the inventors, and he was told there was every hope of arriving at a satisfactory solution of the problem shortly. With reference to the question of rates in the United States and Canada respectively, he was not prepared to give a very definite reply. In the United States, at all events, the master patents which controlled the telephones were in the hands of one large company, and until the last few years it was the practice to charge "flat rates," which meant the same system as was in vogue here—an annual payment which gave the right to unlimited user. For various reasons very high flat rates were charged, and the result was that the number of

subscribers was somewhat limited, but in order to meet the demand of smaller users the various companies in most of the cities introduced what was termed the toll system. Under that they charged a moderate rate—say £20—per annum, which gave the right to six or seven hundred conversations, with an extra charge for each call beyond that number. The result of that was very wonderful. He was told that one company in New York alone had 6,000 additional subscribers in one year. He should imagine that in all probability the charge in Philadelphia was a “flat rate,” and in Charlesville a “toll rate.”

Mr. GRANGER said it was a “flat rate” there also.

Mr. GAVEY said in that case he could not explain how such a difference arose.

Miscellaneous.

TECHNICAL EDUCATION IN GERMANY.

German merchants and manufacturers are alive to the importance of increasing the efficiency of the mechanics and artisans, and of improving the quality of their goods. According to the United States Consul at Hanover, they appear to be resolved that “Made in Germany” shall no longer pass as a term of opprobrium, but be a synonym of excellent materials and good workmanship. A meeting took place recently in Hanover, which is likely to exercise a very important influence in this direction. It was in the nature of a conference, under Governmental sanction and direction, to discuss German trade and manufacturing interests, and to devise plans for their extension and improvement. It was held at the instance of the Prussian Minister of Trade and Commerce, and was presided over by the Oberregierungs President of the Province of Hanover, Count Stolberg. Representatives of the Government from Berlin, the highest officials of the Hanoverian provincial and municipal administrations, leading manufacturers and business men, delegates from the Chamber of Commerce, the manual training and artistic trade schools, and from the working men’s trade unions, attended and took part in the deliberations. As a result of the conference, it was unanimously resolved:—1. To establish at once in the city of Hanover advanced lecture courses, in which artisans and apprentices in all trades shall have an opportunity to complete their mechanical education, and be instructed by experts how to install and manage a model workshop, and work and use machines and tools to the greatest advantage. Instruction will also be given in book-keeping, the making and rendering of accounts, the making of estimates of the cost of work and materials, how to conduct business corres-

pondence, drawing, and other practical branches. 2. The supervision and control of the said lecture courses shall be under the direction of a commission composed of representatives from the Imperial, provincial, and municipal administrations, the Chamber of Commerce, the manual and art schools, and from the trade unions. 3. The first course of lectures will be for cabinet-makers, locksmiths, shoemakers, and tailors. Those for other trades will follow. 4. A fee for tuition will be exacted from mechanics able to pay, but those unable to pay will be instructed free. Funds for the payment of the tuition of the poor will be provided by the Hanover provincial and municipal Governments. 5. Only mechanics and apprentices will be admitted to the classes whose theoretical and practical knowledge is such as to give promise of success as students. The Commission has power in all cases to decide as to qualification of applicants for admission. 6. Teachers are to be selected by the Commission, and confirmed by the Minister of Trade and Commerce. 7. The cost of the establishment and maintenance of the lectures is to be supplied by the General Government, and that of the province and city of Hanover, together with the trades unions, the Chamber of Commerce, and others interested therein. 8. It is further intended that great care shall be used in teaching apprentices how to obtain the most practical advantages from the knowledge obtained by them in the classes. To this end, the creation of working-men’s co-operative societies is to be urged. 9. A permanent exhibition of all power machines and tools used in the small trades is to be established in the Gewerte Halle (Industrial Hall) in Hanover. The machines exhibited there are to be worked by competent mechanics, who, on request, will exhibit their uses and management to all inquirers. In connection with the machine exhibition, there will also be established an exhibition of sample products, in process of manufacture, as well as finished. 10. In order to enable small manufacturers and tradesmen to purchase their raw materials at wholesale prices, and to facilitate the sale of their products, the formation of co-operative stores is to be encouraged. Consul Anderson has been informed that the establishment of these courses of lectures to mechanics is the initial move in a general plan to be in all the main labour centres of Germany, dependent upon the success of this experiment.

Obituary.

THOMAS ALLEN REED.—Mr. Reed, the well-known shorthand writer and reporter, who had held the office of Examiner for Shorthand in the Society of Arts Examinations since 1888, died on the 29th March, at his residence, Rusholme, Surbiton. He was born at Watchet, Somersetshire, on April 6th,

1826, and in early life was associated with the late Sir Isaac Pitman, the inventor of phonography, in the promulgation of that system of shorthand. Fifty years ago, Mr. Reed established an agency called the Metropolitan Reporting Agency, for the purpose of supplying the Press with reports of all public proceedings, and he presided over it until his last illness. He was a past President of the Shorthand Society, and the chief organiser and chairman of the committee of the first International Shorthand Congress, held in London in 1887, in celebration of the tercentenary of the art. He was the author of several works on shorthand, and adapted phonography to the French language, publishing a work on the subject in 1882.

General Notes.

THE BREWING INDUSTRY IN GERMANY.—According to a German trade review, it appears that during the year 1897-98, in the 8,055 breweries of Germany proper, exclusive of Bavaria, Wurtemberg, Baden, and Alsace-Lorraine, there were brewed altogether 916,000,000 gallons of beer, the revenue derived from the taxation of which amounted to £1,869,000. In Bavaria the 6,364 breweries produced a total of 351,000,000 gallons, on which was paid £1,780,000. In Wurtemberg the 6,285 breweries produced 90,000,000 gallons, and paid into the exchequer £467,000. In Baden the 946 breweries, with their output of 60,000,000 gallons, paid a Government tax of £326,000. In Alsace-Lorraine the 127 breweries showed an output of 21,230,000 gallons, and paid into the exchequer £157,000.

WOOD PAVING.—The *Vie Scientifique* reports that trials are being made in Paris with the kari wood for street paving, instead of the pitch pine or Norwegian fir generally employed. Kari is a hard and heavy wood, of close grain and greasy appearance, that has considerable analogy with teak, while, like that wood, it withstands damp and wear. Resembling mahogany in colour, though of far closer grain, kari flourishes in tropical regions, and large quantities are found in the forests of Australia. It is brought to Europe at the bottom of vessels' holds as ballast, and in Paris it is sold, sawn into blocks ready for laying, at the rate of 124 francs per cubic metre (£3 16s. 3½d. per cubic yard).

ELECTRICAL EXHIBITION AT BRUSSELS.—An exhibition of the domestic applications of electricity is announced to open on 1st June this year, in the new Hôtel des Téléphones, Brussels, and to remain open at least a month, but not longer than six weeks. Not only Belgians, but all who have a representative in Belgium are free to exhibit, and the electric current will be supplied gratis by the Brussels municipality. The exhibition, which is due to the initiative of M. Banneux, Director of the Telegraph Administration,

will be held under the auspices of the Belgian Society of Electricians, and under the patronage of the King of the Belgians, while Prince Albert of Belgium is Honorary President. Further particulars may be obtained from the Secretary of the Executive Committee, 18, Rue Melsens, Brussels.

PHILADELPHIA COMMERCIAL EXHIBITION.—The Department of Science and Art has received, through the Foreign Office, from Her Majesty's Ambassador at Washington, a copy of a joint resolution by the Senate and House of Representatives of the United States of America, to the following effect, respecting the Commercial Exhibition to be held at Philadelphia this year. Exhibitors will not be restricted by the Acts of Congress, prohibiting the importation of foreigners, from bringing into the United States, under contract, foreign labourers for the purpose of preparing for and making their exhibits under the regulations prescribed, provided that no alien shall enter the United States under contract to perform labour except by express permission, naming such alien, of the Secretary of the Treasury; and any such alien who may remain in the United States for more than three months after the close of the Exhibition shall be subject to the penalties applicable to aliens coming in violation of the alien contract-labour law.

WINE AND CIDER PRODUCTION IN FRANCE.—The yield of wines in France in 1898 amounted to 710,211,898 gallons, being a decrease of 1,503,986 gallons as compared with 1897. The average yield per hectare (2½ acres) from the 4,266,282 acres of vines in the various departments of France amounted to 418 gallons, which is 22 gallons less than in 1897, and inferior by 154 gallons to the yield in 1896. The yield in the department of the Herault averaged nearly 800 gallons (of a value of about 9d. per gallon), and in the department of the Gironde to only 366 gallons (of a value of about 1s. 6d. per gallon), while in the Champagne country, the average yield was 570 gallons, valued at about 2s. 11d. per gallon. The production of wine from dried raisins amounted to 2,835,470 gallons, as compared with 9,931,284 gallons in 1897. The yield of cider in 1898 amounted to 234,023,592 gallons, while the yield for the previous ten years averaged 289,485,152 gallons. Practically, all the cider is consumed in the country, as the quantity exported in 1898 amounted to only 393,426 gallons. There is, however, a small export trade in cider apples. Last year, owing to the bad crop, it amounted to only £6,622, which is £31,757 less than in 1897.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

APRIL 19.—“London's Water Supply.” By WALTER HUNTER, M.Inst.C.E. WM. WHITAKER, P.G.S., F.R.S., will preside.

APRIL 26.—“Coal Supplies.” By T. FORSTER BROWN. W. BOYD DAWKINS, F.R.S., will preside.

MAY 3.—“Aerial Telegraphy.” By W. H. PREECE, C.B., F.R.S.

MAY 10.—“Fruit Growing in Kent.” By GEORGE BUNYARD. SIR GEORGE BIRDWOOD, K.C.I.E., C.S.I., will preside.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock :—

APRIL 27.—“Judicial Reform in Egypt.” By Sir JOHN SCOTT, K.C.M.G., D.C.L., Deputy Judge Advocate-General, and late Judicial Adviser to H.H. The Khedive. The LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock :—

APRIL 18.—“Inlaying.” By STEPHEN WEBB. JOHN SPARKES will preside.

MAY 2.—“Maiolica.” By WILLIAM BURTON.

MAY 16.—“The Artistic Treatment of Picture Frames.” By J. HUNTER DONALDSON.

MAY 30.—“The Revival of Tradesmen's Signs.” By J. STARKIE GARDNER, F.G.S.

CANTOR LECTURES.

Monday evenings, at 8 o'clock :—

PROF. HENRY R. PROCTER, F.I.C., “Leather Manufacture.” Four Lectures.

LECTURE I.—APRIL 17.

Primitive methods—Difficulties of investigation—Sources of raw material—Methods of curing—Anatomical structure of skin—Arrangement of hair-pores—Chemical character of skin and epidermis—Manufacture of gelatine—Soaking and softening of hides and skins preparatory to tanning.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, APRIL 17.. SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Cantor Lectures.) Prof. Henry R. Procter, “Leather Manufacture.” (Lecture I.)

Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Dr. G. Reid, “Sanitary Appliances.”

Victoria Institute, 8, Adelphi-terrace, W.C., 4½ p.m. Prof. Hull, “Sub-oceanic Terraces and River Valleys.”

TUESDAY, APRIL 18.. SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Applied Art Section.) Mr. Stephen Webb, “Inlaying.”

Royal Institution, Albemarle-street W., 3 p.m. Prof. J. Cossar Ewart, “Zebras and Zebra-Hybrids.” (Lecture II.)

Civil Engineers, 25, Great George-street, S.W., 8 p.m. Mr. James Murray Dobson, “Buenos Aires Harbour Works.”

Statistical, in the Theatre of the United Service Institution, Whitehall, S.W., 5 p.m. Mr. George Martineau, “The Statistical Aspect of the Sugar Question.”

Pathological, 20, Hanover-square, W., 8½ p.m.

Photographic, 12, Hanover-square, W., 8 p.m. Photo-mechanical Meeting. “Apparatus for Half-tone Process Work.”

Zoological, 3, Hanover-square, W., 8½ p.m. 1. Mr. C. W. Andrews, “The Extinct Birds of Patagonia.

—1. The Skull and Skeleton of *Phororhacos inflatus*, Ameghino.” 2. Staff-Surgeon P. W. Bassett-Smith, “A Systematic Description of Parasitic Copepoda found on Fishes, with an Enumeration of the known Species.” 3. Mr. W. E. de Winton, “The Species of *Canidae* found on the Continent of Africa.”

Asiatic, 22, Albemarle-street, W. 4 p.m

WEDNESDAY, APRIL 19.. SOCIETY OF ARTS, John-street, W.C., 8 p.m. Mr. Walter Hunter, “London's Water Supply.”

Meteorological, 25, Great George-street, S.W., 7½ p.m. 1. Mr. Henry Mellish, “Soil Temperature.” 2. Major-Gen. H. Schaw, “Some Phenomena connected with the Vertical Circulation of the Atmosphere.”

Microscopical, 25, Hanover-square, W., 8 p.m. Prof. Lionel S. Bale, “The Bioplasm of Man and the Higher Animals, and its Influence in Tissue Formation, Action, and Metabolism—a Microscopical Study.”

Archaeological Association, 32, Sackville-street, W., 8 p.m.

Patent Agents, 19, Southampton-buildings, W.C., 7½ p.m. 1. Mr. J. W. Gordon, “King James' Book of Bounty.” 2. Mr. J. C. Chapman, “Some Aspects of Disconformity and the Judicial Functions of the Patent-office in regard to same, and other matters.”

Mining and Metallurgy, Geological Museum, Jermyn-street, S.W., 8 p.m. 1. Presidential Address. 2. Mr. C. W. Merrill, “Notes on the Alleged Shortage in Cyanide Bullion.” 3. Mr. Henry F. Collins, “The Chemical Reactions involved in the Amalgamation of Silver Ores.”

THURSDAY, APRIL 20. Royal, Burlington-house, W., 8 p.m. Antiquaries, Burlington-house, W., 8½ p.m.

Linnean, Burlington-house, W., 8 p.m. 1. Mr. H. W. H. Pearson, “The Botany of the Ceylon Patanas.” 2. Prof. A. J. Anderson, “Imitation as a source of Anomalies.” 3. Rev. O. Pickard Cambridge, “List of British and Irish Spiders.”

Chemical, Burlington-house, W., 8 p.m.

Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Mr. J. W. Clarke, “Details of Plumbers' Work.”

Royal Institution, Albemarle-street, W., 3 p.m. Prof. Dewar, “The Atmosphere.” (Lecture II.)

Civil Engineers, 25, Great George-street, S.W., 8 p.m. (James Forrest Lecture) Prof. J. A. Ewing, “Magnetism.”

Historical, 28, Jermyn-street, S.W., 8½ p.m.

FRIDAY, APRIL 14. Royal Institution, Albemarle-street, W., 8 p.m. Weekly Meeting. 9 p.m. Dr. F. W. Pott, “Structure of the Brain in Relation of its Functions.”

Quekett Microscopical Club, 20, Hanover-square, W.C., 8 p.m.

Physical, Chemical Society's Rooms, Burlington-house, 5 p.m. 1. Mr. C. S. Whitehead, “The Effect of a Solid Conducting Sphere in a Variable Magnetic Field on the Magnetic Induction at a Point Outside.” 2. Mr. R. A. Lehfeldt, “Demonstration of Richards's Method of Standardising Thermometers.”

SATURDAY, APRIL 22. Botanic, Inner Circle, Regent's-park, N.W., 3¼ p.m.

Royal Institution, Albemarle-street, W., 3 p.m. Mr. Louis Dyer, “Machiavelli.” (Lecture II.)

Journal of the Society of Arts.

No. 2,422. VOL. XLVII.

FRIDAY, APRIL 21, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

CANTOR LECTURES.

Professor HENRY R. PROCTER, F.I.C., delivered the first lecture of his course on "Leather Manufacture," on Monday evening, 17th instant.

The lectures will be published in the *Journal* during the summer recess.

UNION OF INSTITUTIONS.

The following Institution has been received into union with the Society since the last announcement:—

St. Bride Foundation Institute, Bride-lane, Fleet-street, E.C.

APPLIED ART SECTION.

Tuesday, April 19, 1899; JOHN SPARKES in the chair. The paper read was "Intarsia or Inlaying," by STEPHEN WEBB.

The paper and report of the discussion will be printed in the next number of the *Journal*.

Proceedings of the Society.

SEVENTEENTH ORDINARY MEETING.

Wednesday, April 19, 1899; WILLIAM WHITAKER, P.G.S., F.R.S., in the chair.

The following candidates were proposed for election as members of the Society:—

Greene, Frank Arnold, 22, Martin's-lane, Cannon-street, E.C.

Hall, John Slocombe, 45, Chatsworth-road, Brondesbury, N.W.

Molloy, Harry J., care of Messrs. W. Watson and Co., 7, Waterloo-place, S.W.

Pakenham-Mahon, Captain Henry, D.L., 35, St. George's - road, Eccelston - square, S.W., and Stokestown, Ireland.

Wiseman, William Thomas, Cromwell-house, 160, Stockwell-park-road, S.W.

The following candidates were balloted for and duly elected members of the Society:—

Lehmann, Charles Theodore, Moorside, Ealing, W.

Locke, Cyril L. C., St. Neots, Eversley, Winchfield.

Phillips, Lionel, 33, Grosvenor-square, W.

Piper, John Edwin, LL.B., 16, Middleton-road, New Wandsworth, S.W.

Polak, Joseph Henry, 28, Grosvenor-road, Highbury New-park, N.

Reid, Arthur H., P.O. Box 120, Cape Town, South Africa.

Whittow, Thomas, 35, Oxford-gardens, W.

The paper read was—

LONDON WATER SUPPLY.

BY WALTER HUNTER, M.INST.C.E.

A constant and plentiful supply of pure water is necessary for the sustenance, health, and comfort of every community. The water supply of large cities has consequently demanded the attention of the most civilised nations which have existed in the past ages of the world. Notably, the Romans are renowned for the aqueducts which they constructed for the supply of water centuries ago, and water for irrigation and other purposes has for ages been stored in tanks by the natives of India.

The history of water supply, as practised in different parts of the world, would be an interesting and fascinating theme to pursue, but the water supply of London, which I have been asked by the Council of the Society of Arts to describe, forms in itself so large a subject that I feel it necessary, without further preface, to enter upon the special subject which brings us together to-night.

It is, however, interesting to note that for two centuries after the Conquest, London obtained a sufficient supply of water partly from the rivers and streams which passed through it, and partly from wells sunk into the sands and gravels above the London Clay. Holywell, Clerk's Well (Clerkenwell), and St. Clement's Well (near Clement's-inn), are mentioned by Fitzstephen as those "of most note." In 1236, the Magistrates purchased from Gilbert Sandford the liberty to convey the waters of the Tyburn from Paddington in leaden pipes to the City, and a great conduit of lead, castel-

lated with stone, was begun in Eastcheap in 1285. Various other conduits were built in the 14th and 15th centuries, some for the water of the Thames, from which also the inhabitants were supplied by the City Company of Water-bearers, who brought it in leather panniers slung on horses.

In 1582, a great step in advance was taken by Peter Moris, a Dutchman, who erected a *forcier*, on an arch of London-bridge, to convey the Thames water into the houses in the east end of the City as far as Gracechurch-street; in 1594, another was erected near Broken Wharf for West Cheap, Fleet-street, and the district round St. Paul's; and in 1610, a third at Aldersgate, without the gate. Moris, who obtained the lease of an arch of London-bridge for 500 years, at a rental of 10s. per annum, and two years later the use of another arch, erected for his purpose very ingenious machinery; and the works continued until 1701 in possession of his family, who, after amassing large wealth, sold the lease to a company for £30,000.

This company ultimately occupied four arches, and continued until 1822, when the works were removed just before the demolition of old London-bridge, and the property was sold to the New River Company.

Dr. Sisley, in his interesting and accurate book upon the London water supply, recently published, gives an excellent account of the early history of the supply, and describes the state of the London-bridge Waterworks Company in the beginning of this century, as follows:—

“The quantity of water supplied by the Company in 1610 was estimated at something between 3,000,000 and 4,000,000 gallons daily, and the water-wheels worked for about twenty hours each day. When the tide was very low less water was raised by water-power, and the necessary quantity was made up by working a steam-engine. The superintendent of the Company gave a somewhat depressing account of the state of business in the year 1821. They had at that time a very “strong enemy” against them, which had taken away many of their customers. ‘They were in a state of pauperism, and much to be pitied.’ The ‘strong enemy’ was the New River Company, which had the power of raising water higher than the London-bridge Company could possibly do. The new fashion of building high houses was disastrous to the Company, because cisterns and water-closets were placed at an unreasonable distance above the ground in the new buildings. The distributing pipes used by the Company were made of wood, and they had not money enough to replace them by iron ones. They were unable to supply the water at a higher level than

the second story of a house. The superintendent of the Company would not admit that the water supplied was of a bad quality, and he said that in many instances distillers took it in preference to any other, but he said he never thought of drinking it in the condition in which it was supplied. The ebb tides, he admitted, brought down a considerable quantity of soil from the rivers which ran into the Thames, and the water was frequently foul, but after it had stood in a cistern for twenty-four hours it became ‘finer than any other water that could be produced.’ For his own supply the superintendent had two large cisterns, and by drawing out the water alternately every other day he had ‘as clear water as could be imagined.’ The rates charged for supplying the tenants of the London-bridge Waterworks varied, according to the amount supplied, from a minimum of less than £1 to a maximum of over £20 per annum. The total number of customers was a little over 10,000, and sixty-eight public buildings were supplied. The method of arranging as to the price charged to customers was that the surveyor first examined the premises closely, and reported to the superintendent what he thought the consumption was likely to be, and the size of the service-pipe. The price was then fixed, and if in the course of time it was found that the consumption was more or less than had been estimated, an abatement or increase in the sum charged was made, according to the circumstances of the case. Brewers, stable-keepers, and some other tradesmen were subject to an extra charge. The amount of water considered necessary for a daily supply to a house was one butt, and any quantity above that was considered ‘extra service.’

“With regard to the ultimate failure of the London-bridge Waterworks, it may be said to have been due not so much to complaints as to the quality of the water supplied as to the fact that the New River Company were able to supply water at a higher pressure, which enabled them to force it to the upper storeys of the London houses.”

The Corporation of the City of London obtained an Act to convey water from Hertfordshire to the City, in 1606, and a supplemental Act in the following year, but failed to avail themselves of their provisions. The works contemplated under these Acts, were undertaken in 1609 by Hugh Myddelton, who, when his funds became exhausted in 1612, received the necessary money from King James I., on condition that he should share in the profits. This was the commencement of the prosperous enterprise since known as the New River Company. The Chelsea Company was founded in 1721, the Vauxhall Company in 1805, the West Middlesex and East London Companies in 1806, the Kent in 1810, the Grand Junction in 1811, and the Southwark in 1822.

The history of all these companies reveals

the fact that the municipal and local authorities were unwilling to undertake the risk of supplying London with water, leaving it to be carried out by private enterprise, which in this way, as in so many other ways, has proved itself to be the great factor in promoting the material interests of the country. This fact is apt to be forgotten or hidden from view by the apostles of the new school of Socialistic doctrinaires, who seek to repress individuality and depreciate self-interest, which, when properly regulated, has nevertheless been one of the most powerful motives for the advancement of mankind.

Having thus briefly traced the history of the London water supply, let us turn to the consideration of its extent in the present day. The subject appears to divide itself naturally into six heads :—

1. The area and population to be supplied.
2. The quantity of water supplied.
3. The sources of supply and the quantity taken from each source.
4. The works for the storage, filtration, and distribution of the water by the companies for the supply of their several districts.
5. The quality of the water.
6. The supply in the future.

1.—THE AREA AND POPULATION SUPPLIED, OR WHICH MUST EVENTUALLY BE SUPPLIED.

The area supplied by the eight metropolitan water companies under their Parliamentary powers is generally known under the name of Water London, and has a total area of 620 square miles. It extends from Amwell (near Hertford) in the north, to Croydon in the south, and from Hampton in the west, to Ilford in the east. Its population in 1891 was about 5,237,000, and is now estimated at about 5,800,000, having increased from 958,863 at the beginning of the century.

Water London contains within it the administrative County of London, and is co-extensive with the area called Registration London by the General Register office with the addition of the hamlet of Penge.

Greater London is the area included within the Metropolitan and City Police districts. It includes all parishes wholly situate within a circle of 15 miles radius from Charing-cross, and all parishes of which any part is included within a circle of 12 miles radius from the same centre. Its total area is 701 square miles, and its population in 1891 was 5,633,332.

It is this area and population, with the addition of the area and population of Water London which lies outside it, which Lord Balfour's Commission took into consideration when framing their valuable and exhaustive report in 1892-3. But perhaps the best idea of the gigantic problem of the London Water Supply can be obtained by the knowledge that the population to be supplied is equal to the aggregate population of the following cities and towns in the United Kingdom—viz., Glasgow, Birmingham, Liverpool, Manchester, Salford, Edinburgh, Dublin, Belfast, Leeds, Sheffield, Aberdeen, Dundee, Bath, Bristol, Southampton, Northampton, Nottingham, Newcastle, Bradford, Cardiff, Swansea, Blackburn, Halifax, Derby, and Brighton. Such a fact speaks for itself without comment.

The supply to Water London is given mainly by the eight metropolitan water companies, viz., the Chelsea, East London, Grand Junction, Lambeth, Kent, New River, Southwark and Vauxhall, and West Middlesex Companies.

In addition, outside the Parliamentary districts of these companies and wholly or partly within the area of greater London, the following ten water companies and local authorities give supplies :—

The Barnet District Gas and Water Company.

The Central Middlesex Water Company (Alperton and Sudbury).

The Colne Valley Company.

The East Surrey Company.

The Epsom Local Board.

The Rickmansworth Company.

The South West Suburban Company.

The Sutton Company.

The Uxbridge Local Board.

The West Surrey Company.

Such being the area and population supplied we proceed to consider the quantity of water supplied.

2.—THE QUANTITY OF WATER SUPPLIED.

As the quantity supplied by these smaller bodies was estimated by Mr. Balfour's Commission to be not more than 10,000,000 gallons daily, we propose to neglect them and to confine our attention to the eight metropolitan water companies.

The average daily quantity of water supplied in 1897 by the eight metropolitan water companies, the population supplied, and the average daily supply per head, are given in the following Table :—

Company.	Populat'on suppl.ed.	Average daily supply (in gallons).	Average daily supply (per head).	Sources.
East London	1,261,732	41,036,906	32 52	Lea, Thames, and wells.
New River	1,176,363	35,974,488	30·58	Lea, wells, and springs.
Southwark and Vauxhall.....	809,320	33,767,401	41·72	Thames and wells.
Lambeth	666,981	23,688,305	35·51	Thames.
West Middlesex	601,509	20,337,019	41·72	„
Kent	512,412	15,482,056	29·94	Wells.
Grand Junction	398,396	19,532,580	49·03	Thames.
Chelsea	276,691	12,283,789	44·32	„
Totals.....	5,703,404	202,102,544	35·43	—

Total supply, 1897—73,767,428,465 gallons.

3.—THE SOURCES OF SUPPLY.

The sources of supply are:—(a) The Thames and the gravel beds adjacent to the river; (b) The Lea and springs in the Lea Valley; (c) Thirty-two wells in the chalk formation.

In 1897 the average daily quantities supplied from these sources were as follows:—

	Gallons.	Per-centage of whole supply.
From the Thames.....	112,178,641	55·51
From the Lea.....	55,292,863	27·36
From springs and wells..	34,488,016	17·06
Hampstead and Highgate ponds (non-domestic).	143,024	0·07
Total.....	202,102,544	100·00

Having thus given the leading facts of the water supply of London, we proceed to the consideration of our fourth division of the subject.

4.—THE DISTRICTS OF THE SEVERAL COMPANIES AND THE ARRANGEMENT OF THEIR WORKS FOR STORAGE, FILTRATION, AND DISTRIBUTION.

THE NEW RIVER COMPANY.

The New River company was incorporated by Royal Charter in the reign of King James I, the Charter prohibiting any interference with the New River, or the bringing to the cities of London and Westminster and the borough of Southwark, water from any place whatsoever without the license of the New River Company. The powers of the company have since been altered by Acts of Parliament passed at different times.

The company's district of supply includes the City of London (with a few exceptions in

Bishopsgate and Aldgate, supplied by East London Company), Edmonton, Enfield, Hornsey, Tottenham, in Middlesex; and, in Hertfordshire, Broxbourne, Cheshunt, Great and Little Amwell, Hoddesdon, St. Margarets, Ware, Wormley, and St. John's without the Borough of Hertford.

It should, however, be noted that in Middlesex the District Councils of Enfield and Tottenham have independent sources of supply, while very few supplies are given to the parishes in the county of Hertford. This district is coloured red upon the cartoon, which clearly shows its general extent and boundaries.

The average population supplied in 1897 was 1,176,363, the average daily supply being 35,974,488 gallons.

The New River Company derive their principal supply from the Lea, the intake being situated between Hertford and Ware Locks. Under the River Lea Water Act of 1855 a quantity of about 5,400,000 gallons daily is reserved for the navigation, and as much as be necessary in addition to keep up the head of water in each level of the river.

The New River Company have a preferential right to take 22,500,000, and the East London Company to take 22,500,000. When these demands are satisfied the two companies are empowered *pari passu* to take all the remaining flow of the stream. A balance gauge has been constructed at the intake which regulates the quantity taken by the New River Company to 22,500,000 gallons a day, the quantity to which under arrangement with the East London Company, the company at present limit their supply.

The New River is about 26 miles long, and commences at the Chadwell Springs between Hertford and Ware, being shortly joined by an

artificial cut bringing the supply from the River Lea. It runs through Broxbourne, Cheshunt, Enfield, and Southgate to Hornsey, thence to Stoke Newington, where the principal works of the company are situate, and finishes at the New River Head, Clerkenwell. At intervals between Chadwell Spring and Hornsey are the following wells, with pumping machinery for raising water from the subterranean reservoirs in the chalk into the river channel: — Broadmead well, above Ware; Amwell-end well, at Ware; Amwell-hill well, below Ware; Amwell-marsh well, between Ware and St. Margaret's; Rye Common well, at St. Margaret's; Hoddesdon well; Broxbourne well; Turnford well, between Broxbourne and Cheshunt; Cheshunt well; Hoelane well, above Enfield; White Webbs well, at Enfield; Highfield well, at Edmonton; Campsbourne well at Hornsey; Betstile well, at New Southgate.

The New River Company have also deep wells at Hampstead-heath, at Hampstead-road, and at Bush-hill-park, Edmonton, but these wells have no pumping machinery.

In addition to the above sources of supply, the New River Company will have the right to take 11½ million gallons daily from the Thames when the Staines Reservoir Works are completed.

The company have at Cheshunt two storage reservoirs, with a joint capacity of 39,000,000 gallons, which can be filled from the adjoining well.

At Hornsey, 7,000,000 gallons daily pass from the river through subsiding and storage reservoirs, with a total available capacity of 8,500,000 gallons, into eight filter beds having a total filtering area of 5¼ acres, whence the water is pumped to service reservoirs at Crouch-hill, Bourne-hill, Maiden-lane, and Hornsey-lane. From Hornsey the river flows to Stoke Newington, where the principal works of the company are situated. The water flows through two subsiding and storage reservoirs with a total available capacity of 90,000,000 gallons on to nine filter beds with a total area of nine acres, whence a daily average of about 19,000,000 gallons is pumped by one compound Worthington and six compound beam pumping engines to the service reservoirs at Crouch-hill and Maiden-lane for distribution into the town district of the company.

The remainder of the water travels on to the end of the channel at the New River Head, Clerkenwell, where it passes through a subsiding reservoir on to three filter beds, with a

total area of 2¼ acres, from which about 6,000,000 gallons daily are raised to a service reservoir in Claremont-square.

The capacities and levels at the full water lines of the various reservoirs are as follows:—

	Capacity in Gallons.	Feet above O.D.
Claremont-square	3,500,000	139'00
Crouch-hill	12,000,000	195'50
Bourne-hill	1,500,000	195'50
Maiden-lane.....	15,000,000	232'00
Hornsey-lane	3,000,000	348'20
Southgate	1,000,000	308'00
Highgate	1,000,000	432'50
Hampstead	500,000	446'20
Total	35,500,000	

At three of the reservoirs there are stand-pipes, by pumping into which water can be supplied to further heights as under:—

	Feet above O.D.
Claremont-square	185'00
Highgate	481'80
Hampstead.....	486'30

There are also at Hampstead and Highgate, ponds having a total available capacity of 29,000,000 gallons, from which separate pipes supply street watering posts and other non-domestic services.

This company are also constructing works at Hanworth and laying a 36-inch main to convey to their district the 11½ million gallons of daily supply which will be available from Staines. These works are being designed and are under the direction of Mr. J. Francis, M.Inst.C.E.,

THE EAST LONDON WATER WORKS CO.

The East London Water Works Company was established in 1808 and authorised to purchase two existing waterworks, one situate at Shadwell, started in 1669, the other at West Ham, started in 1747. The company constructed settling reservoirs at Old Ford, with an area of about 11 acres, which were supplied from the River Lea within tidal influences. A service reservoir was also constructed at Mile-end with the necessary pumping machinery. In 1829 the company purchased the Hackney Waterworks and Lea-bridge Mills, and obtained an Act to enable them to remove their intake from Old Ford to Lea-bridge, whence the water was brought to the Old Ford reservoirs by an open conduit and thence pumped for use. In 1852 and 1853 the company's district was defined, and authority was obtained to make a new cut in connection with the

River Lea, for improving the quality of the water, to construct large impounding reservoirs at Walthamstow and filter beds at Lea-bridge, and to make an intercepting cut on the western side of the Lea from Tottenham to beyond Ponders End for the purpose of preventing polluted water from entering the river above the company's intake. In 1852 and 1862 Acts were passed for increasing the capital of the company. In 1867 an Act was passed enabling the company to construct a covered service reservoir in Finsbury-park, and to establish works at Sunbury and Hanworth with the necessary engines and main to convey 10,000,000 gallons a day from the Thames to the company's district. In the same year a separate Act gave powers to increase the number of reservoirs at Walthamstow and filter beds at Lea-bridge, to fill up the open reservoirs at Old Ford, and to cease using the open canal communicating with the open reservoirs and the works at Lea-bridge. In 1881 and 1886 Acts were passed for increasing the capital, and in the latter Act the company took power to sink wells and to construct further works to guard against pollution above their intake. The works at Old Ford were finally abandoned early in 1892.

The places and parishes in which the East London Company are by their Acts authorised to supply water are as follows:—*

Middlesex.—Whitechapel, Mile End Old Town, Mile End New Town, Spitalfields, Bishopsgate, Artillery Ground, Aldgate, St. George's East, Shadwell, Limehouse, Wapping, Ratcliff, St. Luke Old-street, Stoke Newington, Bow, Bromley, Stepney, Poplar, Bethnal-green, Shoreditch, Hackney, Tottenham, Old Ford, Homerton, Clapton, Kingsland, Shacklewell, Holloway, Stamford-hill, Dalston.

Essex.—West Ham, East Ham, Low Leyton, Leytonstone, Leyton, Walthamstow, Waltham Abbey, Waltham Cross, Ilford, Stratford, Romford, Dagenham, Wanstead, Woodford, Chigwell, Loughton, Chingford, Barking.

SOURCES OF SUPPLY.

The company takes its supply of water from four separate sources.

(1) From the River Lea, the intakes being at Enfield Lock and Ponders End.

(2) From deep wells in the chalk at Walthamstow, Chingford, Lea-bridge, and Waltham Abbey. Three additional wells are

being sunk at Rammey Marsh, Ponders End, and Barking.

(3) From the River Thames at Sunbury.

(4) From springs at Hanworth.

The company's works are 10 in number, situate at Lea-bridge, Walthamstow, Chingford-hill, Woodford, Buckhurst-hill, Hornsey Wood, Sunbury, Hanworth, Waltham Abbey, High Beach.

Lea-bridge.—The water flows from the reservoirs at Walthamstow in an open channel $1\frac{1}{4}$ miles long to the filter beds, of which there are 25, with a total area of 24 acres. The filtered water is pumped into the district by 10 engines and 4 turbines, with an aggregate horse-power of 2,710. There is a deep well in the chalk whence water is pumped by an engine of 250 horse-power. The chief offices of the engineering department, stores, testing and workshops, are at this station.

Walthamstow.—At this station are 10 storage reservoirs, with a total capacity of 1,215,000,000 gallons. The reservoirs are fed from the Lea at Enfield Lock and Ponders End, the two conduits joining a short distance above Chingford Mill. Three reservoirs are high level and three low level. The former receive their supply from the head and the latter from the tail of Chingford Mill. Powers were taken by the Act of 1897 to construct additional reservoirs of 1,000,000,000 gallons capacity, and the company are promoting a Bill in the present Parliamentary Session for about 5,000,000,000 gallons of additional storage and other works at a total cost of £1,500,000. At this station a well has been sunk into the chalk whence water is pumped by a 250 horse-power engine, which a 350 horse-power engine pumps eastward to Hagger-lane and westward to Hornsey Wood reservoirs.

Chingford Mill.—Here are two wells, from one of which the water is pumped by turbines to Woodford under a pressure of 230 feet, while a quadruple expansion engine pumps the water from the other well.

Woodford.—These works comprise two covered service reservoirs of a joint capacity of 3,000,000 gallons, the head water level being 171 above O.D. and two engines each of 60 horse-power for pumping to the higher districts.

Buckhurst-hill.—A water tower of 70,000 gallons, with an altitude of 328 above O.D. was erected in 1879 and a service reservoir containing 7,000,000 gallons has recently been completed.

Hornsey Wood.—This reservoir is situated

* Appendix to Report of Royal Commission, 1892-3, page 9.

in Finsbury-park, has 5,000,000 gallons capacity, and is connected with the Thames supply and with the Lea-bridge works. Its height is 142 feet above O.D.

Sunbury.—The intake is in the county of Surrey in an eyot in the Thames above Sunbury Lock. Two engines, of 75 horse-power each, pump the unfiltered water to Hanworth, about two miles.

Hanworth.—The unfiltered water from Sunbury is delivered into an open reservoir containing about 5,000,000 gallons, whence it flows on to 6 filter beds having a joint area of 5 acres, and from the filters into 2 covered reservoirs, having a joint capacity of 2,500,000 gallons. Underground water is obtained from gravel beds in which collecting tunnels have been driven. Five engines, of 630 total horse-power, force the water over a tall stand-pipe, and through about 19 miles of 36-inch main to the Horsey Wood reservoir in Finsbury-park, whence it gravitates over the company's western district.

Waltham Abbey.—A deep well has here been sunk into the chalk, whence the water is pumped by triple-expansion engines to the surface of the ground, and thence to the High Beach reservoir.

High Beach Reservoir.—The reservoir, which can be filled either from Waltham Abbey or from Woodford, is situate in Epping Forest, near to the King's Oak. Its capacity is 2,500,000 gallons, its altitude 371 feet above O.D., and it supplies the company's high-level district in Essex.

The East London now supply more water than any of the other London companies, their average daily supply, in 1897, being 41,036,906 gallons distributed to a population numbering 1,261,732.

Mr. W. B. Bryan, M.Inst.C.E., is the engineer to the company.

THE WEST MIDDLESEX WATER WORKS.

The company was incorporated in 1806 by Act of Parliament, which empowered them to supply with water the parishes of St. Paul's, Hammersmith; All Saints', Fulham; St. Mary Abbott's, Kensington; St. Nicholas', Chiswick, with other parishes in the county of Middlesex, and also certain parishes in the county of Surrey, to which, however, the company did not give any supply. By a further Act of 1810 the limits of supply were enlarged, and by another Act of 1856 the district was extended to the parishes of St. John's, Hampstead;

Hendon; Willesden, a small portion of Acton, all in Middlesex.

DESCRIPTIVE SUMMARY OF THE WORKS.

The intake of the company from the Thames is at Hampton, where there are a pair of engines, 900 horse-power, capable of delivering 32,000,000 gallons per day, and one engine of 400 horse-power, capable of delivering 24,000,000 gallons per day into the subsiding reservoirs at Barnes, a distance of nine miles, through two 36-inch cast-iron mains.

At Barnes there are seven subsiding reservoirs with a total available capacity of 397,000,000 gallons—four of which have recently been constructed upon the recommendation and to the designs of Mr. Hervey, M.Inst.C.E., the company's engineer—and eleven filter beds, having a filtering area of four acres, are in course of construction. The water is filtered through a stratum of washed sand 2 feet 9 inches thick, superposed upon a stratum of various sized stones, 1 foot in thickness.

At Hammersmith, the station on the Middlesex side of the Thames, the water is pumped for the supply of the whole district. The water gravitates from Barnes to the engine wells through a channel 8 feet in diameter, which has recently been constructed under the bed of the river.

The engine-power available is 1,605 horse-power, capable of pumping 30,000,000 gallons daily. Nearly the whole of the district is supplied by direct pumping, by means of three 30-inch mains, two 21-inch mains, one 14-inch main, and one 10-inch main. Three service reservoirs are also supplied from Hammersmith at Kensington, Barrow-hill, and Willesden. The higher parts of the country district are supplied by pumping a second time at Barrow-hill and Willesden.

At Barrow-hill the available engine-power is 180 horse-power, capable of pumping 6,000,000 gallons per day, by means of three trunk mains, two 15-inch, and one 16-inch in diameter. The service reservoirs supplied from Barrow-hill are at Kiddepore and Shoot-up-hill. At Willesden the available engine-power is 84 horse-power, capable of pumping 4,000,000 gallons daily, by means of a main 16 inches in diameter, running to the service reservoir at Shoot-up-hill.

The situation, capacity, and elevation of the service reservoirs are as follows:—

	Height above Ordinance Datum.	Capacity in Gallons.
Kensington, Campden-hill..	120	3,672,000
Barrow-hill, by Primrose-hill	190	4,750,000
Willesden, Harlesden	190	2,500,000
Shoot-up-hill, Mill-lane, by Edgware-road	257	6,000,000
Kiddepore, Platt's-lane, by Finchley-road	323	2,500,000
Total.....		19,422,000

The above filtered-water reservoirs are all covered. All engines and trunk pumping mains are in duplicate. The total quantity of water that may be drawn from the River Thames, by agreement with the Thames Conservancy, is 24,500,000 gallons per day, to which will be added a further supply of 11½ million gallons daily when the Staines Reservoir Works are completed.

The average daily supply in 1897 was 20,337,019 gallons, distributed to a population of 601,509.

THE GRAND JUNCTION WATER WORKS COMPANY.

The company was incorporated by Act of Parliament in 1811, which transferred to the company Parliamentary powers for supplying certain western districts of the metropolis, under the Act granted to the Grand Junction Canal Company in 1798. The original works were situated at Paddington, and the supply was taken from the canal till 1826, when the source of supply was removed to the River Thames at Chelsea. In 1835, the intake was removed to the works at Kew-bridge. In 1852, the company's source of supply was removed to its present position at Hampton.

Area of Supply.—The company's area of supply includes the parishes of Paddington, Kensington, Marylebone, St. George's, Hanover-square, St. James, Westminster, Hammersmith, Brentford, Ealing, Chiswick, Acton, Hanwell, Isleworth, Twickenham, Teddington, Hampton, Hampton Wick, Hampton Court, Bushey-park, Whitton, Hanworth, and Heston, all in the county of Middlesex.

DESCRIPTION OF WORKS.

The works are situated in the Hampton and Sunbury parishes, Middlesex, upon the north side of the Thames, at Kew-bridge, at Campden-hill, and at Ealing. The intakes from the River Thames are at Hampton.

The old intake, constructed in 1853, is situated opposite Platt's Eyot, about a quarter

of a mile above Hampton Church, and consists of two 36-inch pipes with sluices. This intake delivers water direct into the low-level filters for the supply of the country districts, and to the "bull engines," which formerly pumped the water to Kew, but are now held in reserve for use upon emergency.

The new intake is situated about one mile higher up the river, upon an islet opposite Kenton Court, where a chamber, commanded by sluices, and protected by a grating, has been built, and is connected by 30-inch pipes to a chamber on the north bank of the river. The top of these chambers is raised to a level above the level of the highest recorded flood. From the second chamber the water is conveyed by two 36-inch pipes, laid under the Lower Sunbury-road, to the wells of the low lift pumping-engines, about half a mile distant.

Gravel Beds.—In a 10-acre field immediately opposite the new intake, but upon the north side of the lower Sunbury-road, the gravel beds form a natural filter, from which the water is drawn through 24-inch drain pipes with open joints connected with the third line of pipes 30 inches in diameter laid along the lower Sunbury-road to the works, and these can also be connected direct to the river. A channel has been formed in the centre of the field, through which the land can be charged with water from the river when desirable. The bottom of the channel is constructed as a filter, the sand of which can be removed and washed when necessary. These gravel beds are treated by the company, and recognised by the Water Examiner as practically an addition to their storage resources.

The works at Hampton consist of a storage and subsidence reservoir, having a capacity of 45,000,000 gallons. A large proportion of the supply from the river is pumped into this reservoir, whence it is drawn off through two water towers provided with sluices, so that the water may be drawn off from the surface whatever may be its level. The total area of filters at Hampton is 15¼ acres. The filters are generally constructed as shown by the type diagram upon the wall. The filtering material consists of washed sand, 3 feet in thickness, resting upon gravel and stones 2 feet thick, gradually increasing in size towards the bottom of the filter. As the stones in the gravel found upon the works were not sufficiently large, the concrete bottom of the filter has 2-inch drain pipes, 1 yard apart, laid over it, which run to the collecting main in the centre. The water is delivered into the filters by a bell-mouthed

pipe, just above the top sand level. It flows over the surface of the sand to the depth of about 5 feet, and passes through the sand and the gravel into the collecting drain, running along the centre of the filter bed, whence it is delivered through cast-iron pipes to the engine wells. Valves are provided for regulating the supply and delivery of the water, so that the water shall pass through the filtering medium at a rate not exceeding a maximum of $2\frac{1}{2}$ gallons per square foot of filtered surface per hour.

The country district is supplied from the Hampton Works by a pair of compound beam engines and a "Davy" engine, to which a vertical triple expansion engine is now being added. The water is pumped through one 30-inch and one 12-inch main running through New Hampton into the Twickenham-road, along which the 30-inch main proceeds past the Kew Works to which it has two connections. It then supplies part of Shepherd's-bush, and is finally connected into the Campden-hill reservoir. The 12-inch main after diverging through Twickenham, follows the same course to Turnham-green, whence it passes through Goldhawk-road and Uxbridge-road, and finishes in Ladbroke-grove by a connection to the Kew 30-inch main.

Kew-bridge Works.—The water is pumped from Hampton to Kew through two 33-inch mains, one running along the Twickenham-road, through Isleworth to Kew-bridge, the other through New Hampton past Hospital-bridge, and through Whitton and Isleworth to Kew-bridge, which it enters at the back of the works. This latter main will also be used for the supply of the western part of the district as the population increases.

At the Kew-bridge Works there are:—One upper reservoir, 8,500,000 capacity; one lower reservoir, 5,000,000 capacity; eight filter beds, $8\frac{3}{4}$ acres area; one filter water reservoir (covered), 2,500,000 capacity.

From the Kew-bridge Works, the town district is supplied by two 30-inch mains, one running almost due east through Turnham-green and Bedford-park, along Uxbridge-road (with a branch to Campden-hill and Oxford-street) terminaring near Poland-street. The other 30-inch main turns up Gunnersbury-lane (whence there is a 30-inch main to Ealing Reservoir), Acton, Ladbroke-grove, Notting-hill-gate, Grand Junction-road, and finishes in the Edgware-road, where it is connected with a 24-inch main, supplied from Campden-hill.

Engines.—There are 8 pumping engines

at these works, having a pumping capacity of about 26,000,000 gallons in 24 hours.

Ealing Works.—At Ealing, upon the top of Hanger-hill, the company possess a service reservoir for filtered water, having a top water level of 205 feet above O.D., and having a capacity of 3,000,000 gallons, and a large storage reservoir containing 50,000,000 gallons, having its top water level 193.5 feet above O.D. For the supply of the higher part of the neighbourhood a water tower with cast-iron tank on the top, having a top water level of 265 feet above O.D., has been erected.

Campden-hill Works.—At these works there are 3 filtered water storage reservoirs, having a total capacity of 18,000,000 gallons, and 3 pumping engines capable of raising about 20,000,060 gallons daily into a standpipe to a level of 270 feet above O.D. The supply of the high level district of the company is given from these works.

Powers of Supply.—The company has statutory powers to take from the Thames any water that is required for the purpose of their district. Under the agreements of 1852 and 1886 with the Thames Conservancy these powers are at present exercised to an extent not exceeding 24,500,000 gallons daily. When the Staines Reservoirs Works are completed the company will have an additional supply of $11\frac{2}{3}$ million gallons daily. The average quantity of water supplied daily in 1897 was 19,532,580 gallons to a population of 398,390.

CHELSEA WATER WORKS COMPANY.

The company's intake is situated at West Molesey in the county of Surrey, on the south bank of the Thames, the Thames being the only source of supply. The works consist of of the intake, pumping power equal to 35,000,000 gallons, and four reservoirs whence it is delivered to the Surbiton Works by gravitation. These reservoirs have a total capacity of 140,000,000 gallons, but are now being enlarged to contain 189,000,000 gallons, under the direction and to the design of Mr. R. Hack, M.Inst.C.E. The water is delivered from Molesey to Surbiton through two 36-inch mains. The works at Surbiton contain eight acres of filtering area and pumping power equal to 22,000,000 gallons in 24 hours, which allows of a large margin of reserve for any contingency. From Surbiton the filtered water is pumped to Putney-heath through three mains, one of 30-inch diameter for the whole distance, one 30-inch reduced to 24-inch on the top of Kingston-hill, and one

15-inch main. The storage capacity of the filtered water reservoir at Putney-heath is 11,000,000 gallons, which capacity is being doubled by works now under construction. The top water level reservoirs are 175 feet above O.D., which can be increased to 197 feet above O.D. by pumping over a standpipe.

Distributing Mains.—From the service reservoirs on Putney-heath there are five trunk lines of distributing mains. These mains, of which three are of 30-inch diameter, and two of 15-inch, cross Putney-heath and enter the main road at the top of Putney-hill. At this point they are reduced in diameter to 24-inch and 12-inch respectively, and passing down Putney-hill cross the South-Western Railway by an aqueduct bridge, and the Thames beneath the footways of Putney-bridge. From the north end of Putney-bridge three 24-inch, one 18-inch, and two 12-inch mains distribute the water over the whole of the district of the company.

District of Supply.—The Chelsea Company's district of supply is situated wholly within the metropolis, consisting of an area of five square miles, extending from Charing-cross to the "Crabtree," Fulham, and bounded by the River Thames on the south, and on the north-east and north-west by the Grand Junction, New River, and West Middlesex Companies. The population supplied was 276,691 in 1897, and the average daily quantity of water supplied was 12,079,000 gallons.

The company have power to abstract 22,000,000 gallons of water daily from the Thames, which gives a large surplus beyond that required for the present supply of the district. It is estimated that the eventual maximum daily supply when the company's district is entirely built over will not exceed 17,500,000 gallons.

LAMBETH WATER WORKS COMPANY.

The area of supply of this company consists of the parishes of Thames Ditton, Esher, Long Ditton, Kingston, Putney, Malden, Morden, Wimbledon, Merton, Morden, Tooting Graveney, Clapham, Wandsworth, Battersea, Streatham, Croydon, Newington Butts, Newington, Bermondsey, Camberwell, Lambeth, Horselydown, St. Saviour's, St. George-the-Martyr, Christchurch, St. Olave, St. Thomas, the Clink Liberty in Southwark, and such parts of Beckenham and Lewisham as lie on the western side of the River Ravensbourne.

Works.—The principal intake of the com-

pany from the Thames is at West Molesey, where there are a pair of pumping engines of 100 horse-power and a pair of engines working two centrifugal pumps, the total engine-power being capable of pumping 42,500,000 gallons per day into the subsiding reservoirs or into the conduit hereafter mentioned, as occasion may require. The present storage capacity of the reservoirs is 125,000,000 gallons, which is now being increased to 465,500,000 gallons, by the advice and to the designs of Mr. T. F. Parkes, M.Inst.C.E. The company have powers to take 24,500,000 gallons daily from the Thames, while an additional quantity of spring water can be obtained from under the land at the Molesey Works to the extent of from 6,000,000 to 8,000,000 gallons daily. From the reservoirs the water flows by gravitation, a distance of $3\frac{1}{2}$ miles to the filtration works and main pumping station at Ditton, through two means of communication: (1) a brick conduit of oval shape 5 ft. 9 in. high and 4 ft. 9 in. wide, with intervals of cast-iron pipes 54 in. in diameter, and (2) an iron pipe 36 in. in diameter. There is also an intake at Ditton, but this is only used when from special causes the intake at Molesey is not available.

Ditton Works.—At Ditton, about one-third of the unfiltered water is delivered on to four low level filter beds, and the remainder into a suction reservoir at the same level. Three engines of a total capacity of 280 horse-power, lift the water from the suction reservoir into a reservoir serving 8 filter beds 16 feet higher than those referred to. The two reservoirs contain together 3,000,000 gallons. There are in all 12 filter beds containing a filtering area in the aggregate of $12\frac{1}{2}$ acres. The filtering material is composed of 3 feet of washed sand and $3\frac{1}{2}$ feet of fine and coarse gravel.

From Ditton the bulk of the water is pumped through three mains, each 30 in. in diameter, a distance of 10 miles into two reservoirs at Brixton, the remainder being pumped into a reservoir at Coombe through two mains each 12 in. in diameter which also serve as distributing mains. The reservoir at Coombe supplies by gravitation the districts of Esher and East and West Molesey through two mains, each 10 in. in diameter. Kingston is also supplied by these pumping mains. The total engine-power available at Ditton is 150 horse-power for the Coombe reservoir, and 1,660 horse-power for the reservoirs at Brixton, and 330 horse-power for Coombe and Brixton alternatively. These engines are capable of

pumping, approximately, 3,000,000, 7,000,000, and 39,000,000 gallons per day respectively.

From the Brixton Works water is supplied by gravitation into the town district, the whole of which is on constant service through four trunk mains, respectively 24, 20, 18, and 12 inches in diameter, while the water for the country district is pumped from the station by 10 engines of 1,005 horse-power into service reservoirs, through 9 trunk mains, which also serve as distributing mains. The water is distributed from these reservoirs through 15 leading mains, varying from 10 to 18 inches in diameter.

The service reservoirs for the supply of the country district are as follows:—

	Height above O.D.	Capacity in gallons.
Coombe (1 reservoir)	180 ..	1,150,000
„ (standpipe)	220 ..	—
Brixton (2 reservoirs)	115 ..	12,000
Streatham (2 reservoirs) . .	198 ..	7,500,000
Selhurst (1 reservoir)	218 ..	2,500,000
„ (standpipe)	230 ..	—
Norwood (1 reservoir) ..	315 ..	5,000,000
Rock Hill (1 reservoir) ..	372 ..	} 6,150,000
„ (tank)	387 ..	
„ (standpipe) ..	412 ..	
		28,765,000

The average quantity of water supplied in 1897 was 23,688,305 gallons daily to a population of 666,981.

SOUTHWARK AND VAUXHALL WATER WORKS COMPANY.

The Vauxhall Company was founded in 1805, and the Southwark Company in 1822, the two companies being amalgamated under the name of the Southwark and Vauxhall Company, in 1846. The supply was originally obtained from the River Thames at Battersea, but under the Act of 1852, the intake was removed to Hampton. Under their statutory powers there is no limit to the quantity of water which the company may take from the Thames, but the amount is restricted by agreement with the Thames Conservancy to a quantity of 24,500,000 gallons through their intake at Hampton. In 1897, however, the company obtained temporary powers to take an additional quantity of 20,500,000 gallons daily from the Thames, which were made permanent by an Act passed in 1898; conditionally upon their constructing the storage reservoirs proposed under that Act, and with the restriction that the water may only be taken from the surplus above 285,000,000 gallons flowing at

Penton Hook Weir. When these works are completed the company will therefore have powers to take 45,000,000 gallons daily permanently from the Thames.

In addition to the above sources of supply the company obtained Parliamentary sanction in 1884 to purchase lands, sink wells, and construct the necessary works to supply water therefrom. The first well was sunk at Streatham, and from this a quantity between 2,000,000 and 2,500,000 gallons daily has been regularly obtained. since July 1st, 1895. At Merton the work of sinking another well is in progress, while further wells are under contemplation.

Districts of the Company.—The districts supplied by the company comprise part of Southwark, portions of Lambeth and Peckham, and the whole of Battersea, and also includes Ham, Petersham, Kew, East Sheen, Sheen, Roehampton, Mortlake, Barnes, Putney, and such parts of the parish of Wimbledon as are above the 100 feet Ordnance contour. The company also supply Richmond to a considerable extent with water in bulk, under the agreement incorporated with the Companies Act of 1897.

Works.—The present works of the company are at Hampton, Battersea, Nunhead, Wandsworth, Forest-hill, Streatham, Raynes-park (site of proposed works) Honor Oak.

Reservoirs and Wells.—At Hampton there are three storage reservoirs with a total capacity of 390,000,000 gallons. The company also possess natural filtration works in the gravel at this station with an area of 39¾ acres. The number of filters in use is nine, having an area of 9¼ acres; an additional area of about 7 acres will probably be completed during the present year. The filtering material consists of 3 feet of sand, 1 foot of hoggin, 9 inches of fine gravel, and 9 inches of coarse gravel.

Engines with 26,000,000 gallons daily capacity pump the water to Nunhead or into the district, engines in duplicate of 16,000,000 gallons capacity lift the water obtained from the natural filtration works, two pairs of single-acting quadruple expansion high-speed engines, driving centrifugal pumps with 20,000,000 gallons daily capacity, raise water rom the river to fill the reservoirs, and three inverted direct-acting Cornish engines of the “Bull” type with 23,000,000 gallons daily capacity pump the unfiltered water to the Battersea works.

Three sets of triple expansion rotative pumping engines with direct-acting pumps are now in course of erection.

Battersea Works.—The unfiltered water

delivered by the 36-inch main from the intake of the works at Hampton is received at Battersea into three reservoirs having a total capacity of 46,000,000 gallons, which then pass through the filters, of which there are 11½ acres, and is distributed by six Cornish engines, having a total capacity of 31,500,000 gallons daily.

Nunhead.—The works at Nunhead consist of four reservoirs, two with a top water level of 168 feet above O.D., each having a capacity of 6,000,000 gallons, and two with a top water level of 200 feet above O.D., each having a capacity of 3,000,000 gallons. Those reservoirs supply by gravitation a portion of the eastern part of the district, and also a portion of the Peckham and Dulwich districts. The engines are single acting, of the Cornish type, of 7,000,000 gallons capacity per day. A preliminary boring has been sunk at these works which struck the chalk at a depth of 167 feet.

Wandsworth.—The works at Wandsworth contain two pairs of direct acting quadruple expansion rotative engines capable of pumping 9,000,000 gallons daily to the high level districts and reservoirs at Forest Hill. These engines draw their supply from the 30-inch main from Hampton.

Forest Hill.—At Forest Hill there are two reservoirs, each having a capacity of 500,000 gallons with a top water level of 140 feet above O.D.

Streatham.—The works at Streatham consist of two pairs of 3 cylinder triple expansion engines with lift and pressure pumps delivering about 2,500,000 gallons daily against a head of 200 feet.

The average daily supply of the company in 1898 was 32,743,058 gallons; the estimated average population was 816,894.

Mr. J. W. Restler, M.Inst.C.E., is the engineer to the company.

KENT WATER WORKS COMPANY.

The company, incorporated by Special Act in 1809 and extended under subsequent Acts of 1811, 1852, 1864, 1877, and 1888, now supply water within an area of 178 square miles, comprising many rural districts in Kent.

The population supplied was estimated to be at the end of 1897, 519,340, the number of supplies being 86,390. The average day's quantity supplied in 1897 was 15,482,053 gallons, or at the rate of 29¾ gallons per head of the population. About 93½ per cent. of the supplies are on the constant service.

Sources of Supply.—The supply of water

throughout the company's area is obtained entirely, with one exception, from the chalk strata between the north downs and the Thames by means of deep wells and borings, situated as follows:—

	Wells.
Deptford (chalk).....	3
Plumstead „	1
Crayford „	3
Shortlands „	2
Farnborough „	2
Wilmington „	2
Westerham (green sand)	1
	—
	14

A second well has been sunk in the chalk at the Wilmington pumping station, largely augmenting the yield of water there. The company are now sinking, and have nearly completed, another well in the chalk, in the parish of Southfleet, near Gravesend, and a second well, also in the chalk, at Kent Gate, in the parish of West Wickham. The pumping stations are 8 in number, situated on the sites of the wells. At Deptford there are 6 pumping engines, with a total capacity of 25,170,000 gallons in 24 hours, supplying reservoirs at Deptford, New Cross, Greenwich-park, and Woolwich-common. At Plumstead, a rotative pumping-engine will pump 1,296,000 gallons in 24 hours, supplying reservoirs at Plumstead-common.

At Shortlands are two Cornish engines, with a total capacity of 2,750,000 gallons daily, supplying Chislehurst. At Crayford 3 pumping engines, with a total capacity of 4,500,000 gallons, supply Woolwich Common and Eltham. At Dover-road a pair of horizontal rotative engines can pump 364,000 gallons in 24 hours for the extra lift to Shooter's Hill. At Farnborough are 4 pumping engines, with a total capacity of about 5,128,000 gallons in 24 hours, supplying Farnborough, Knockholt, Constitution Hill, and West Wickham. At Wilmington a pair of compound rotative pumping engines, with lift and force pumps, can deliver 8,000,000 gallons daily to Eltham. At Westerham there is a water wheel with pump which supplies 250,000 gallons daily to Westerham. Mr. W. Morris, M.Inst.C.E., is the engineer to the company.

STAINES RESERVOIRS WORKS.

The evidence given before Lord Balfour's Commission in 1892 showed that whereas an average daily flow of 1,350,000,000 gallons was passing down the river, only 90,000,000 gallons were being taken for water supply. It therefore

appeared evident to me that if some of the superabundant water was stored when the river was running with a high flow, it could be used for water supply when the river was running at its minimum flow, which the Thames Conservancy consider should be 200,000,000 gallons daily at Teddington Weir. Having explained the principle of the scheme to my colleagues on the Grand Junction Waterworks Board, they instructed their engineer, the late Mr. A. Fraser, M.Inst.C.E., to co-operate with me in the matter. We went carefully into the question, and presented a report to the Royal Commission, who approved the scheme. Difficulties arose in regard to its execution, but eventually in 1895 the New River Company, West Middlesex Company, and Grand Junction Company, instructed Mr. R. E. Middleton, M.Inst.C.E. and myself to prepare a scheme for Parliament. Certain modifications in the design of the works were suggested by Mr. Middleton, in the desirability of which I concurred. The Staines Reservoirs Act was passed in the Session of 1896. By it a Joint Committee, consisting of nine members, three from each company, were constituted, with powers to carry out the works, which are now being constructed to the designs and under the superintendence of Mr. Middleton and myself. The contract is let to Messrs. John Aird and Sons.

The works consist of two large reservoirs, having a total capacity of 3,300,000,000 gallons situated about half a mile to the north-east of the town of Staines. The intake from the Thames is situated on the Middlesex bank of the river, about 300 yards above Bell Weir; at this point sluices and a sluice house are being constructed, the intake being protected by screens. The first length of the conduit for about 350 yards is covered, but after passing the Colne Brook it continues as an open conduit to the engine-house, up to which point it has a capacity of 147,000,000 gallons daily, with a fall of about 9 inches per mile. The pumping machinery will consist of five triple expansion surface-condensing Worthington pumping engines, one being a spare engine, each capable of delivering 16,000,000 gallons daily into the reservoirs. The steam will be provided by six Babcock and Willcox boilers, one a spare boiler, the working pressure being 150 lbs. per square inch. The water will be delivered into the reservoirs through two riveted steel mains, each 6 ft. 3 in. in diameter, joining into a steel pipe 8 ft. 8 in. internal diameter, near the reservoirs, from which branch pipes of the same diameter will be

taken down through a tunnel constructed in the clay, and connected to the water tower near the corner of each reservoir, where the western and central embankment joins. The tunnels and water towers will be constructed of Portland cement concrete; the former lined and the latter faced with blue bricks. The stand pipes for discharging water from the reservoirs will be of cast-iron, 5 ft. internal diameter, having 48-inch and 36-inch sluice valves to enable the water to be drawn off at any desired level. From the bottom of each stand pipe a cast iron pipe, 4 ft. in diameter, will convey the water through the tunnel and across the New Stanwell road to a basin 50 ft. in diameter, in which a weir will be constructed for the purpose of aeration, and over which the water will be delivered into the conduit, which will rejoin the main conduit a little to the east of the pumping station. The reservoirs are being constructed with earthen banks, excavated from the interior area of the reservoirs. In the centre of these banks a puddle wall is being constructed down into the solid clay, thus forming a perfectly tight reservoir. The clay for the puddle wall is being excavated within the area of the reservoirs below the top stratum of gravel, which varies from 14 ft. to 35 ft. in thickness.

From the engine-house the conduit reduced in section follows the line shown upon the map, passes at the back of the East London Waterworks at Hanworth, at which point it will deliver water to the new works of the New River Company, and finishes in a reservoir of 30,000,000 gallons capacity at Hampton, whence the water will be delivered into the works of the West Middlesex and Grand Junction Companies.

Under the Staines Reservoirs Act the Joint Committee have power to supply 35,000,000 gallons daily to the Joint Companies, or 45,000,000 gallons daily under emergency by consent of the Local Government Board. The maximum quantity allowed to be taken from the river for supply and for filling the reservoirs is restricted to 100,000,000 gallons in 24 hours, but this quantity must be taken out of the surplus water above a flow of 265,000,000 gallons daily at Bell Weir.

SOUTHWARK AND VAUXHALL COMPANY'S STORAGE SCHEME.

Under this Company's Act of 1898, the company are about to construct at Molesey, under the advice of their engineer, Mr.

Restler, storage reservoirs of 1,070,000,000 gallons capacity, which, when completed, will give them the right to take the additional quantity of 20,500,000 gallons from the river before referred to.

TOTAL SUPPLY AUTHORISED FROM THE THAMES.

From the foregoing descriptions, it will be seen that the total quantities of water which the companies have power to take daily from the Thames upon the completion of the storage works now being constructed are as follows :—

	Million gallons daily.
Chelsea Company	22
East London Company	10
Grand Junction Company	24·5
Lambeth Company	24·5
Southwark & Vauxhall Company ..	24·5
Ditto under storage scheme	20·5
West Middlesex Company	24·5
Staines Reservoirs Joint Committee ..	35
Total	185½

STORAGE FOR THE RIVER LEA.

The East London Water Works Company have, under the advice of their engineer, Mr. Bryan, constructed large additional reservoirs and have deposited a Bill seeking powers for still larger works, which, it is hoped, will be passed in the present Parliamentary session.

Total number of supplies, December, 1898,	871,949
Miles of water-pipes	5,254½
Total horse-power	26,723
Area of filtration (acres)	129½

5.—THE QUALITY OF THE WATER.

From the foregoing description of the companies' works, it will be gathered that the purification of the water supply to London is effected by sedimentation and by sand filtration. The question, whether the present supply was adequate in quality was definitely referred to Lord Balfour's Commission, which gave a verdict upon this issue in the following terms (see paragraph 178 of the Report of Royal Commission, Metropolitan Water Supply, 1892, 1893) :—

"We are strongly of opinion that the water, as supplied to the consumers in London, is of a very high standard of excellence and purity, and that it is suitable in quality for all household purposes. We are well aware that a certain prejudice exists against the use of drinking water derived from the Thames and the Lea, because these rivers are liable to pollution, however perfect the subsequent purifi-

cation, even by natural and artificial means may be ; but having regard to the experience of London during the last thirty years and to the evidence given to us on the subject we do not believe that any danger exists of the spread of disease by the use of this water, provided that there is adequate storage and that the water is efficiently filtered before delivery to the consumers."

The water supplied by the companies is daily analysed and bacterially examined on behalf of the companies by two eminent chemists, Sir W. Crookes, F.R.S., and Professor Dewar, F.R.S. Analyses are also made on behalf of the Local Government Board by Sir E. Frankland, F.R.S., who, at the request of the Associated Metropolitan Waterworks Companies, extends his examination to the chemical and bacterioscopic condition of the raw river waters at the intakes of the various companies and to the bacteriology of the water as it issues from the filter beds.

In regard to the results of the chemical analysis and of the physical and bacterioscopic examination of the water supplied during the year 1897, Sir E. Frankland reported as follows, under the date of January 31, 1898 :—

"In the following Table are recorded the results of observations respecting the freedom from turbidity or otherwise of the various waters, and, for the purpose of comparison, the results of my first observations in 1868 are also included :—

Companies.	Number of occasions when--							
	Clear and transparent.		Slightly turbid.		Turbid.		Very turbid.	
	1868	1897	1868	1897	1868	1897	1868	1897
THAMES.								
Chelsea	7	12	2	0	1	0	2	0
West Middlesex ...	12	12	0	0	0	0	0	0
Southwark	1	12	5	0	4	0	2	0
Grand Junction ...	9	12	2	0	1	0	0	0
Lambeth	6	12	1	0	2	0	3	0
LEA.								
New River	10	12	2	0	0	0	0	0
East London	3	12	8	8	1	0	0	0
DEEP WELLS.								
Kent	8	12	3	0	1	0	0	0
Colne Valley	—	11	—	1	—	0	—	0
East London	—	4	—	8	—	0	—	0

"This Table strikingly exhibits the great improvement which the water companies who draw their supplies from rivers have effected in filtration since I first began these examinations for turbidity in 1868. In that year seven samples were so turbid as to be highly repulsive in appearance, nine were turbid, and no less than twenty slightly turbid ; whereas during the year 1897 no sample of filtered water was turbid in the slightest degree. On the other hand, nine

samples of deep-well water, which does not usually require filtration, were slightly turbid, owing, in all probability, to disturbance by the pumping machinery.

"The purest water in nature contains abundance of suspended matter; indeed, the beautiful blue colour of the purest Swiss lakes and of the Mediterranean is due to these very fine suspended matters, which require years to subside, and which no sand filter will remove, but which may be extracted in the chemist's laboratory to some extent, though not completely by filtration through specially prepared paper. This fine suspended matter, which is, of course, always present in the most efficiently filtered London waters, is under all ordinary circumstances absolutely invisible to the eye. The water is clear, bright, and transparent, but if a decanter of it be placed in a dark room, and a ray of sunlight or electric light allowed to fall upon it, the water will be seen to be full of suspended particles, which no sand or other practical filter is capable of removing, but which are partially arrested by a hard paper filter supported by a glass funnel. The amount of this suspended matter in the efficiently filtered river water supplied to the metropolis rarely, if ever, exceeds 0.0002 grain in a tumbler-full; and, therefore, in order to imbibe a single grain, it would be necessary for the consumer to drink no less than 5,000 tumblers full of the water. Such excessively minute quantities of matter, which is presumably harmless, may safely be neglected; indeed, it is impossible, practically, to obtain water free from it."

In regard to the bacterioscopic examination, Sir E. Frankland wrote in the same Report:—

"The standard of 100 microbes per cubic centimetre, as an indication of efficient bacterial filtration, adopted by Doctor Koch and myself, is, of course, purely arbitrary. I consider it is a sufficient, but not unduly, severe test to apply to the filtration of the river-derived supplies of the London water companies; but I desire it to be distinctly understood that the infraction of this standard does not throw suspicion upon the wholesomeness of the water."

Sir E. Frankland further wrote in the second Report:—

"These results of the bacterioscopic examination of the unfiltered waters used by the metropolitan companies are very instructive; they again show the remarkable effect of storage in reducing the number of bacteria. Thus, in March last, whilst the Thames at the intakes of the companies drawing their supplies from that river contained 50,560 microbes per cubic centimetre, the Chelsea Company, with ten days' storage, were supplying their filters with water containing only 580 microbes in the same volume. Again, in February, the East London Company, with twenty days' storage, kept the number down to 1,050 per cubic centimetre, although 44,600 per cubic centimetre were passing the intake at Angel-road."

In the same Report Sir E. Frankland gave the following particulars of the bacterial condition of the water issuing from the filtering beds of the various metropolitan companies, during the year 1897, compared with the raw material dealt with by these companies:—

Company.	Aver. percentage of microbes removed.
Chelsea	98.96
East London	99.24
Grand Junction	98.46
Lambeth	99.50
New River	99.09
Southwark and Vauxhall	97.72
West Middlesex	99.40

The Reports of Sir W. Crookes and Professor Dewar, as to the quality of the water, are equally satisfactory, and it is interesting to note the following extracts from their Report of October 14th, 1897:—

"In order to prevent any misapprehension in the public mind with regard to our monthly report on the quality of the London water, it may be advisable to repeat that the Water Companies in no way interfere with our position as absolutely independent scientific authorities. Further, they have no information antecedent to publication, as to what will appear in our report. Our communications with the companies are chiefly confined to calling their immediate attention to the least anomaly appearing in the character or the quality of the filtered water; our chief aim being to advise the engineers of the works as to the efficiency of storage and filtration.

"*There is no city in the world where such minute and incessant care is taken daily and almost hourly to detect and report on the slightest deviation from the purity in its water supply.* Apart from the daily bacteriological examination of the clear water wells of the company, we frequently make specific tests for the presence of pathogenic organisms. If any other than a negative result had been obtained the fact would have been recorded."

It will, I think, be conceded that the above Reports are eminently satisfactory.

But the strongest practical proof, in my opinion, of the excellence of the London water supply is to be found in the record of the Vital Statistics of the Metropolis. It will, I think, be conceded that no large city would have a death-rate of 18.2 (the death-rate of London for 1897) unless it possessed a water supply of excellent quality.

Before proceeding to the last head of this paper, it is desirable to mention that a comparison between the cost of the water supply in London (a comparison worked out for a number of towns by Doctor Powle, Mr. Asquith, and Mr. Alexander) as compared with the

charge made in Liverpool, Manchester, Sawford, Birkenhead, Brighton, Bolton, Bristol, Derby, Oldham, Stockton, and Newcastle, shows results which are very clearly stated by Mr. Arthur Shadwell in his recently-issued book upon the London Water Supply, in which he writes as follows:—

“The highest charge in London on the 10 per cent. valuation, that of the Lambeth Company, is appreciably lower than the provincial average, and the London average is no less than 40 per cent. lower. On the £20 valuation it is 32 per cent. lower, on the £30 valuation it is 26 per cent. lower, and on the £50 valuation 11 per cent. lower; only, when we come to premises rated at £100 and upwards, are the London charges higher than the provincial average. In other words, by the system of graduated water rates imposed by the London companies the rich pay for the poor. This is notably the case with the two companies who supply the great area of poverty, namely, the East London and the Southwark and Vauxhall. In fact these two companies, and especially the East London, supply their poorest customers at a loss, which is made good by the higher charges on the more heavily rated houses. Under municipal authority the rates would necessarily be equalised, and the poor would have to forego the advantage they now enjoy. This fact, which is studiously kept out of sight by progressive politicians, is worthy the attention of the poorer classes, in whose interests municipalisation is ostensibly advocated.”

6.—THE SUPPLY IN THE FUTURE.

Soon after the first London County Council was constituted, in 1889, it appointed a committee to consider the question of London water supply. After some inquiries and other proceedings, the Council requested the Government to issue a Royal Commission to inquire into the London water supply. Eventually, a Commission was appointed in March, 1892, consisting of Lord Balfour of Burleigh, Chairman; Sir George B. Bruce, Civil Engineer; Sir A. Geikie, Director-General of the Geological Survey; Professor Dewar; Mr. T. H. Hill and Mr. J. Mansergh, both engineers of large experience in connection with water supply; and Dr. W. Ogle. The Commissioners subsequently appointed Mr. R. E. Middleton, M.Inst.C.E., as an Assistant Commissioner for the purpose of making investigation into doubtful questions raised in the course of inquiry. The terms of reference were as follows:—

“Whether, taking into consideration the growth of the population of the metropolis and the districts within the limits of the metropolitan water works companies, and also the needs of the localities not supplied by any metropolitan companies, but within

the watersheds of the Thames and the Lea, the present sources of supply of these companies are adequate in quantity and quality, and, if inadequate, whether such supply, as may be required, can be obtained within the watersheds referred to, having due regard to the claims of the districts outside the metropolis, but within those watersheds, or will have to be obtained outside the watersheds of the Thames and the Lea.”

Any one reading this reference must see that four distinct issues were raised:—

1. Whether the present sources of supply are adequate in quantity.
2. Whether they are adequate in quality.
3. Whether such supply as may be required can be obtained within the watersheds referred to; or
4. Whether it will have to be obtained outside the watersheds of the Thames and the Lea.

The Commission sat forty-five days and took evidence from ninety-two witnesses, including the engineers and other officials of the County Council and the water companies. The conservators of the Rivers Thames and Lea, gave records of the flow of these rivers. The rainfall was treated by Mr. C. J. Symonds, F.R.S. and other meteorologists. Independent engineering and geological evidence was given by Sir F. Bramwell, Mr. T. Hawksley, Mr. Deacon, Professor Boyd-Dawkins and Mr. W. Whitaker.

Upon the question of quality, evidence was given by Sir E. Frankland, Sir W. Crookes, Dr. Odling, Dr. R. Lankester, Dr. Klein, Dr. Sims Woodhead, and others.

The Commission took into their purview the period of forty years, and basing their estimate upon the decennial increase between 1881 and 1891, arrived at an aggregate of the population in 1931 of 11¼ millions in the area, the water requirements of which were to be considered—viz., 845 square miles.

Taking the needs of this population at 35 gallons per head per day, the average daily quantity required in 1931 was found by the Commission (paragraph 70) to be 391,717,690 gallons. Adding 6 per cent. to provide for increased demand in hot weather and in times of frost, the Commissioners estimated the maximum daily provision required in 1931 at 415,219,752 gallons.

To meet this demand the Commission arrived at the conclusion that if adequate storage were provided for the Thames and the Lea, the following quantity of water would be available:—

	Million gallons per day.
From the River Thames	300
„ „ Lea	30½
„ wells in the Lee valley	40
„ the Kent Company's district	27½
	420

Sufficient, at 35 gallons per head per day, for a population of 12,000,000.

The above figures, adduced by the Commission, show, in reply to the first and third heads of reference, that the present sources of supply are adequate in quantity, and that such supply as may be required can be obtained within the watershed for the Thames and Lea. I have already dealt with the issue raised under the second head of reference, and shown the finding of the Commission to be that the water supply is “of a very high standard of excellence and purity, and that it is suitable in quality for all domestic purposes.”

Inquiry into the fourth head of reference was rendered unnecessary because the Commission had found that sufficient water can be obtained from the present sources of supply to cover the requirements of London for the forty years which they took into consideration.

It might have been expected, after the valuable and exhaustive report of Lord Balfour's Commission, that the question of the London water supply might have been allowed to follow the recommendations of the Commission for many years to come. Such, however, was not the opinion of the County Council. They had asked for the Commission, apparently, in the hope and expectation that they would curse the companies, and, “Behold they had blessed them altogether.”

In 1894 the Council instructed their engineer to report “on the site and yield of other sources of water supply, and as to the method which might be adopted for considering and supplying water to London with estimates of cost.” Sir Alexander Binnie's report, dated June 8th, 1894, describes a scheme for constructing large storage reservoirs for impounding the waters of the rivers Usk and Wye, and several tributaries, and bringing the water so collected to London by two aqueducts about 160 miles in length. The quantity of water to be provided from a catchment area of 488 square miles, with a rainfall varying from 45 to 70 inches per annum, was 415,000,000 gallons a day, to be delivered into reservoirs at Elstree and Binstead, at a total cost of £38,772,000. Sir Alexander Binnie proposed to construct the works in two instalments, the first to bring

182,000,000 gallons daily to Elstree, at a cost of £17,500,000, to be supplemented by the Edw with 18,000,000 gallons additional, or a total of 200,000,000 gallons daily, at a cost of £18,095,250.

The second instalment to be made at a later date would complete the total supply of 415,000,000 gallons daily, at a total cost of £38,772,280, as before stated. If to this quantity be added 67,000,000 gallons daily available water from chalk wells near London, a total supply of 482,000,000 gallons daily would be obtained, sufficient for the wants of a population of 13,800,000, or down to the year 1943.

Fortified with this report the County Council have opposed all legislation based upon the report of Lord Balfour's Commission. Their opposition had previously caused the defeat of the East London Company's Bill of 1893, and by postponing works which the engineer of that company declared to be necessary, had directly contributed to the scarcity of water in East London in 1895 and 1896. The Council have since opposed storage schemes brought in by the separate companies, the Staines Reservoir Companies promoted by the West Middlesex, Grand Junction, and the New River Companies in 1896, and the storage reservoirs proposed by the Southwark and Vauxhall Company in 1898. These schemes have, however, received Parliamentary sanction. The County Council have, moreover, opposed before the present Royal Commission the scheme brought forward to safeguard the supply of every district of the metropolis by making suitable connections between the works of the companies.

In 1897, the Government constituted a Royal Commission, with Lord Llandaff as chairman, to inquire, “whether it is desirable, in the interests of the ratepayers and water consumers in the districts of supply of the metropolitan water companies, that the companies shall be acquired and managed either (a) by one authority, or (b) by several authorities, and, if so, what should be such authority or authorities,” and other subsidiary questions.

This reference has indirectly raised the question, whether the policy of the County Council to bring water from Wales, or that of the companies to develop the present sources of supply, is the more advantageous to the ratepayers and consumers.

Notwithstanding the fact that the question of the metropolitan supply was being considered by the Commission, the County Council

have endeavoured to forestall any recommendations which it may make by promoting Bills in the present Session of Parliament for the purchase of the companies' undertakings, and for carrying out the first portion of their Welsh scheme, as proposed by Sir Alexander Binnie, but slightly modified in accordance with the suggestions made by Sir B. Baker and Mr. Deacon in a report which they have given to the Council upon a reference made to them. Judging by this report, and by the evidence given before the Royal Commission, the County Council appear to have abandoned their original statement, that London water is clarified sewage, unfit for potable purposes, as they are content to accept as a permanent supply the 185,500,000 gallons daily, which the companies now have powers to take from the Thames.

Now, in considering the policies of the County Council and of the companies, it must be remembered:—First, that, as previously shown, the water, as supplied to London, is “of a very high standard of excellence and purity, and suitable in quality for all household purposes.”

Further, the late Mr. Hawksley showed from the health statistics of many towns in England that those which are supplied by river water are generally more healthy than those supplied from a mountain source.

That, secondly, it must also be remembered that the total supply to be obtained under the Welsh scheme is 415,000,000 gallons daily, which, upon the usual proportion, would give about 553,000,000 gallons daily as the total yield of the reservoirs.

On the other hand, the Thames possesses an average flow of 1,300,000,000 gallons daily upon a cycle of years.

It seems absurd, therefore, to leave a larger and equally good supply, obtainable close to London, for another supply from a distant source, unless and until the expense of developing the larger becomes greater than that which would be incurred in utilising the smaller and distant supply. For see what would happen. After exhausting the capacity of the Welsh supply it would be necessary to revert to the present sources, which the promoters of the distant scheme now affect to despise.

The question therefore resolves itself into the comparative cost of the two schemes. It would be impossible for me in the time at my disposal this evening to present to you all the figures and estimates which my friends, Sir Alexander Binnie on the one side and Mr. R. E.

Middleton on the other, have, with marked ability and untiring industry, laid before the Royal Commission. Their views can be read at length in the minutes of evidence taken before the Commission. I purpose, therefore, to lay before you the figures at which, after mature consideration, I have myself arrived, which have the advantage of lying between those for which the two engineers referred to are responsible. My results, however, are much nearer Mr. Middleton's than Sir Alexander Binnie's, as they are based upon the same estimates of the Welsh scheme by analogy with the cost of the Thirlmere works for Manchester, the Vyrnwy works for Liverpool, and the Elan works now being constructed for Birmingham. Until the surveys, drawings, and bills of quantity are prepared, the land scheduled and detailed prices worked out, I am of opinion, with Mr. Middleton, that the estimate by analogy with the cost of works carried out by some of the ablest engineers of the day, is by far the more reliable method of arriving at the cost of the Welsh works.

In regard to the Thames scheme the case is different. We know the exact price of the present works as let to the contractors; we know the prices paid for the land, and the working of an estimate is perfectly simple and must be accurate.

In making the comparison between the cost of the two schemes, I have endeavoured to hold the balance equally and fairly between them, the result being shown in the following Table:—

Summary of Cost of Welsh and Thames Schemes at 1916, 1920, and 1936, the dates at which further supplies will be required.

WELSH SCHEME.

Estimates W. H. 1 and 2.

By analogy from cost of Thirlmere, Vyrnwy, and Elan Valley Works.

First quantity, 121 million gallons daily supply, 1916 or 1920.

Second quantity, 93 million gallons daily supply, 1936

Daily supply.	Cost of works.	Interest during construction.	Capitalised pumping charges.	Total.
million galls.	£	£	£	£
121	29,600,551	3,199,150	87,747	21,878,44
93	12,112,314	1,092,888	85,515	13,290,71
	£32,712,865	£4,283,038	£173,262	£37,169,16

THAMES SCHEME.

Estimates W. H. 2 and 3.

Under conditions of 1898, minimum flow 100 million gallons at Teddington.

First quantity, 121.5 million gallons daily supply, 1920.

Second quantity, 93 " " " 1936.

Daily supply.	Cost of works.	Interest during construction.	Capitalised pumping charges.	Total.
million galls.	£	£	£	£
121.5	4,483,000	559,717	2,992,537	8,035,254
93	4,309,670	543,190	2,610,997	7,463,857
	<u>£8,792,670</u>	<u>£1,102,987</u>	<u>£5,603,534</u>	<u>£15,499,111</u>

THAMES SCHEME.

Estimates W. H. 6 and 7.

Under conditions of 1898, minimum flow 200 million gallons at Teddington.

First quantity, 121.5 million gallons daily supply, 1916.

Second quantity, 93 " " " 1936.

Daily supply.	Cost of works.	Interest during construction.	Capitalised pumping charges.	Total.
million galls.	£	£	£	£
121.5	6,773,930	1,404,719	2,741,026	10,919,675
93	5,039,920	632,933	2,680,278	8,353,131
	<u>£11,813,850</u>	<u>£2,037,652</u>	<u>£5,421,304</u>	<u>£19,272,806</u>

THAMES SCHEME.

Estimates W. H. 8 and 9.

Under conditions of 1893, minimum flow 200 million gallons at Teddington.

First quantity, 121.5 million gallons daily supply, 1916.

Second quantity, 93 " " " 1936.

Daily supply.	Cost of works.	Interest during construction.	Capitalised pumping charges.	Total.
million galls.	£	£	£	£
121.5	5,349,710	943,673	2,732,808	9,017,251
93	5,248,790	674,235	5,687,204	8,610,229
	<u>£10,598,500</u>	<u>£1,617,908</u>	<u>£8,420,072</u>	<u>£17,627,480</u>

It is fair to say that the Thames estimate, and under the conditions of 1898, would be slightly increased, as the estimates were made in November, and would in no way alter the estimate under the conditions of 1893.

It will be seen from the above Table that the cost of the Welsh scheme for the supply of the same quantities of 121.5 and 93 million gallons daily, will be in round figures from 2 to 2½ times the cost of the supply of the same quantity by the Thames scheme, dependent upon the minimum flow fixed at Teddington.

The above quantities added to the 185½ million gallons already authorised, provided for a total quantity of 400 million gallons daily being taken from the Thames, sufficient

with the water available from the Lea and wells in the chalk for the supply of the metropolis to the year 1948, supposing that the population should in the meantime increase in accordance with the figures accepted by the Balfour Commission. There will therefore be no necessity even to consider any question of increased draught from the Thames or the provision of water from an outside source, for at any rate the next forty years. It is possible, and, indeed probable, as has already happened, that the population will not increase in anything like the same rate as in the decade from 1881 to 1891. The adaptability of the Thames scheme to meet such a contingency is one of its most valuable features. The storage reservoirs contemplated under it need only be constructed as the actual increase in the population renders them necessary. Should the population increase at a slower rate than estimated, the work could be retarded until they are actually required. On the other hand the larger part of the expenditure upon a supply from distant sources must be incurred at the outset and may eventually be found to have been undertaken upon too large a scale, laying unnecessary financial burdens upon the ratepayers and water consumers. I would remind you that there is no record in ancient or modern times of a city containing 12,000,000 inhabitants.

It is impossible within the scope of a paper like the present to enter into all the arguments for and against the purchase of the companies' undertakings by the County Council, and it is no doubt undesirable to discuss this question in detail at the present moment when the whole subject is being considered by the present Royal Commission. It is, however, necessary to remember that any purchase to be fair must take into consideration prospective, as well as present, profits and liabilities, and therefore cannot be a source of profit to the purchaser. And further, that the County Council are pledged to the Welsh scheme, which, as has been shown, must result in heavy additional expense as compared with the development of the present source of supply. In addition the County Council will have to provide a sinking fund to pay off the capital sum within a certain fixed period which will entail heavy addition at cost upon the water consumers of the present and next two generations for the benefit of posterity. The foundation of the greatness of Britain is private enterprise. The reward which successful enterprise brings is the great incentive to

the ablest men of each generation to apply their powers to advance the general knowledge and add to the comfort, convenience, and happiness of mankind.

Municipalisation tends to discourage private enterprise, and to fasten the socialistic ideas now popular with a certain school of politicians, the triumph of which will, in my opinion, be the commencement of the decadence of England.

On these grounds I am opposed to the municipalisation of the water companies unless a clear gain to the community is to be the result.

I believe that I have shown that the policy of the London County Council will result in a heavy loss to the consumers and ratepayers. Therefore, I am of opinion that the adoption of that policy would be detrimental to the public interest.

On the other hand, the water companies have shown by the excellent manner in which they have fulfilled their obligations, by their joint action this year in combining to secure the supply of every district of the metropolis, and by the declaration of their readiness to be under all circumstances responsible for the provision of an ample and satisfactory supply of water, that they are worthy of the position which they hold, and that they deserve the continued confidence of the community.

I desire, in conclusion, to express my thanks to my colleagues, the engineers of the companies, for the information and drawings which they have furnished to me, and to Mr. Mansergh, V.P.Inst.C.E., for kindly lending some of the lantern slides which have been shown upon the screen. My acknowledgments are also due to Dr. Sisley and Mr. Arthur Shadwell for their excellent books on "The London Water Supply" from which I have given quotations in this paper.

DISCUSSION.

The CHAIRMAN said the word water implied a cooling drink, but curiously enough when the word "supply" was added to it, people generally get warm, and if you prefaced this by the word London, the temperature rose almost to boiling point. The question of the London water supply generally gave rise to hot discussion; but after all it was a good thing for great questions like that to be well fought out, for there was no way of arriving at the truth so certain as a thorough discussion, especially in scientific and engineering matters. But however different their views might be as to the means, the

object of all, whether the advocates of municipal management or of private enterprise, was to get a good supply of water for London. It was sometimes said that the London County Council or some other Corporation wanted to confiscate private property; but whether they wanted to or not, he was quite sure they would not succeed, for Parliament would never hand over a company which was doing its work properly to a Corporation without making the Corporation pay uncommonly well for the bargain. If a trading company was not doing its duty to the public, of course it was another matter altogether. Again, it was said on the other hand, that a company was only a trading body, and its prime interest was the profit of the shareholders; assuming that to be so, no company could succeed which supplied a bad article. Even the warmest advocates of municipal control would allow that in this country companies had done their work uncommonly well; and certainly in one thing the London water companies had done well. They had taken good care to have the best engineers they could get, and they had been very well served by those engineers. The London water supply was peculiar in this respect that he did not think there was any other part of the kingdom in which it would be possible to get a supply for a large city like London, right in the middle of a river valley. No one would attempt to get such a supply from the Severn, or any of the other large rivers. The Thames happened to be a good river, where you could get intakes at all events not very much polluted, if at all. Of course there was always a risk of pollution to some extent, and the London water companies would have that risk, but they were not simply water-getting companies, they were manufacturers: they had to treat the water to deprive it of any harmful properties it might have, and to send it out in a proper state for consumption. From that point of view the effects they produced were very wonderful, effects which were never dreamed of when sand filter beds were first thought of. It was now known that the surface layers of sand on which a slight organic film formed actually purified the water bacteriologically and destroyed the most injurious contents. The paper divided itself into two heads, first, the historical portion, which might have been treated at much greater length had time allowed; and, secondly, it dealt with more controversial matter—what water should be got and whom it should be got by. Those were subjects he would leave the meeting to discuss; he had always avoided them, because he was a man of peace, but he hoped they would be taken up by others. It was certain that a great city like London could not get on without a good water supply, and the larger the supply you required the more difficulty there was, and the difficulty increased at a greater rate than the quantity. Large expenditure therefore must be faced, whether by companies or by public authorities. Those who opposed the companies would probably allow that they had done their best to improve the supply.

That they had made mistakes went without saying; they were but human, but when the mistakes were pointed out they did their best to set them right. It seemed a curious thing to him that there should be eight different companies supplying London, and he should like to see them joined up. He was told there were great difficulties in the way, and no doubt there were; the companies were constituted under different Acts. They had different organisations, and different methods of work; but if they could join together there would be a great economy in many ways. In the first place, there would be a saving in mains; in many streets there were two independent sets of mains, and perhaps three in some; and there was a story that in one he inhabitants for several years got their water from one company and paid rates to another. Another peculiarity of the London supply was the variety of the sources from which it was derived. He did not refer to the Thames and the Lea, which were for practical purposes two parts of the same river, but a much larger quantity than most people were aware of was obtained from wells—quite enough to supply any other town in the kingdom. The Kent Company obtained its whole supply from wells, but the New River and the East London both got a good deal, and the Southwark and Vauxhall a certain amount from wells. Many other companies had tried experiments, for which as a geologist he was very grateful, with regard to getting water from great depths. They were mostly futile as far as regards very deep supply, but they obtained a good deal of water at intermediate depths which had sometimes repaid the cost, and they had given scientific men a deal of information which they would not otherwise have had, and which may prove of great economic value.

Mr. J. W. RESTLER (Southwark and Vauxhall Co.) said there was one point which he thought might have been even more emphasized. It had been held out to the ratepayers that there would be a great saving to them if the water companies were transferred to the London County Council, but as had been pointed out any purchase would have to be made on the basis of the present and prospective value, so that any future profits would be discounted. On the other hand, if the companies were left alone, part of the future profits must come back to the ratepayers after 10 per cent. was earned, which was now practically obtained by all the companies. Any extraordinary expenditure, however, for new sources of supply, or additional reservoirs, would have to be paid for out of the pockets of the shareholders.

Mr. R. F. WHEELER asked how it was there was such a famine in the East-end of London last year if the supply of water was as abundant as the author indicated.

The CHAIRMAN said he had rather to complain of Mr. Hunter for not including the Croydon Water Works in one of his lists, because they were

rather proud of them. He also thought the New River began not at Chadwell Spring, but a little higher up. He could say a good deal about Chadwell Spring, which, when he last saw it, looked very different to what had been shown in the photograph. He saw it in company with Mr. Francis last autumn, when it was at its driest, and he was surprised to find it so dry, even with that extreme drought. It was a hole 20 ft. deep, and though it was not really dry, it had fallen below the level at which it overflowed. No living person had ever seen it so low. The New River Company did not know what the bottom of it was like, and he was rather glad they had the opportunity to clean it out. Although a chalk spring, it was very cloudy, there being hills all round of drift gravel, sand, and loam, and no doubt some of the finer particles were brought in very quickly after rain, as was the case with other springs in that part of Herts. It generally yielded 3,000,000 or 4,000,000 gallons a day to the New River. He should also rather take exception to the statement in the paper quoted from Mr. Shadwell, that if the municipal authorities took over the supply the rates must necessarily be equalised. He did not see that it was at all necessary; corporations were just as likely to have vagaries in the matter of rates as water companies. Mr. Hunter also referred to the exhaustive report of Lord Balfour's Commission, but he did not think that was quite a correct term, because there had been another Commission since, and probably there would be another again. They had been going on from time to time all his life, and he expected they would continue. The late Mr. Thomas Hawksley had remarked that towns supplied by river water were generally more healthy than those supplied from mountain sources, but it did not necessary follow that that was the effect of the water. Health statistics were very difficult to deal with, but it might well be that most of the towns supplied from upland sources were manufacturing towns in the north in which the population was not so healthy as towns in the south which were supplied from rivers. He was sorry the water companies did not propose the junction scheme earlier, but no doubt it was a step in the right direction. It would prevent such a thing as happened last year when the company which wanted the largest supply ran short. He did not think the term water famine was quite accurate, because the supply at the lowest was at the rate of 25 gallons per head per day, which in many places would be an ample supply. He could not help thinking that a lot of water was wasted in London, and that there might be a good deal of saving which would make the available supply go much further than it now did. Where the waste occurred, he did not know, but it was worse probably in the poorer districts where the people could not be made to understand the value of water, and the care which ought to be exercised not to waste it. In future, those who had more than they wanted would be able to supply those who had less. That

was the principle adopted in rating, the richer parts helped the poorer, and on the whole it was right that it should be so. The Chelsea Company had power to take more than they would ever want, as their district could not increase, and the population might even decrease. It was to be hoped that these steps would get rid of any such temporary differences as occurred last year, which were very unlikely to occur again, at any rate, for a long time, for the circumstances were most exceptional, not in London only, but in many other places, where the question of restricting the supply had to be considered.

Mr. HUNTER, in reply, said there was no doubt the shortness of the East London supply last year—which, after all, was a very good supply—was due to the unprecedented drought. The rainfall was $2\frac{1}{2}$ inches less than in any year of the 82 during which records had been kept at Greenwich. It deceived not only ordinary engineers, but the engineer of the London County Council, for he said, in 1897 or 1898, that he considered the East London Company had plenty of storage. They could only judge of the present and future by past experience, and it would be very uneconomical to allow a greater margin than appeared sufficient. Now, the companies themselves proposed to link up their various works in the way which commended itself to the Commission, and were now spending over £100,000 upon it, from which the shareholders could not get 1d. of dividend, simply with the view of inspiring confidence in the consumers, and to show that the companies did really intend to safeguard the water supply of all parts of the metropolis. No one was more anxious to fulfil the obligations laid upon them than the directors and officials of the water companies, because they knew that in so doing they were serving the best interests of the companies themselves. With about 870,000 consumers, the serious complaints might be reckoned on the ten fingers, which he thought spoke volumes for the efficiency of the administration. The statistics, and the evidence of entirely independent witnesses, showed how they had succeeded in giving an admirable supply as regards quality; the quantity had been ample hitherto, and now that the whole of the districts were to be linked together, it would be ample in the future.

The CHAIRMAN then proposed a vote of thanks to Mr. Hunter, which was carried unanimously, and the meeting adjourned.

Miscellaneous.

THE VANILLA BEAN IN MEXICO.

The State of Vera Cruz has been considered the home of the vanilla, but recent developments show that vanilla can be cultivated in the State of Tabasco and on the Isthmus of Tehuantepec. The true home

of the vanilla, where it flourishes the best in its wild state, is a narrow strip about 30 miles wide, 5 miles from the coast, and 90 miles long. The upper end of this strip is about 50 miles south of Tampico, and extends along the coast 90 miles towards the city of Vera Cruz, the bottoms along the Tuxpan, Casonez, and Nautla rivers, and the creeks contiguous, constitute the richer parts. Here the cultivated varieties yield most without artificial fecundation, either on account of the number of wild bees in the locality or by self-pollination, which some claim as impossible. The United States Consul at Tuxpan says that artificial fecundation must be practised in order to produce the beans in commercial quantities. The vanilla plant is a vine of a bright green colour, with a smooth, waxy, transparent bark. It has a thick, waxy-looking leaf, light-green in colour, 6 to 9 inches long, $1\frac{1}{2}$ to 2 inches wide, and sharply pointed. The vine reaches out tendrils which cling tightly to its tree support, but do not, as some believe, draw nourishment from the tree. The best time to set out the vines, or rather cuttings, is in April or May. The cuttings are the vines divided into lengths, usually $2\frac{1}{2}$ to 3 feet long. Some of these can be cut in two according to the number of joints. Two to three joints are sufficient to put under the ground, with the same number of joints above ground. The joints are easy to propagate, in fact they are hard to kill if kept from being bruised. A cutting can be kept in the house on a dry shelf, and will live for months with scarcely any apparent change. In making a vanilla plantation much depends upon the selection of location. The first thing is to have the plantation where the pilfering of the beans while ripening can be prevented. A vanilla plantation need not be large; a few acres, with care and proper fecundation, will soon produce excellent results from a monetary point of view. Patient care and attention at the proper time is the chief secret of success. The vine requires rich soil, heat, ventilation, shade, and moisture. Rich pockets of land along the creeks and river bottoms are best. A profusion of wild vines of all kinds growing into a jungle, with abundant loose soil affording ventilation at the roots, is the best proof of the adaptability of the land. The land should be free from sand on account of drought, and free from clay, which would cause the vines to rot during the rainy season. There should be plenty of small trees, at the feet of which the vines can be planted. Trees which have smooth bark, and which never shed their bark or leaves, and grow to be no longer than 2 to 4 inches in diameter and from 7 to 10 feet high, are best for this purpose. Usually a variety of such grow on all wild lands, and any of them are good if the trunk of the tree be smooth, with plenty of sap. A small orange tree affords a good trunk for vanilla to grow to. If, while clearing the land, there be not enough of such trees found already growing, to plant the desired number of vine (there should be from 1,500 to 2,000 vines to the acre) enough should be planted, selecting the kinds that

make the most rapid growth, which exist in abundance, and are destroyed by the thousands in nearly every new clearing of land. The ground should be kept clean from weeds. All undergrowth should be thrown around the vines to decay, and serve as manure for the roots. The ground around the roots should not be disturbed. One or two vines should be planted to each tree, and tied at first to the trunk with some flat, flexible band, such as strips of cocoanut leaves or plantain fibre. Round cord should not be used, as it is liable to cut and injure the green, succulent stem of the vine. Live stock are never permitted on a vanilla plantation. The stems and roots of the vine are disturbed as little as possible. The vine needs no cutting or pruning, and all other wild vines are cut out and kept from choking the vanilla vines. The trees should be topped to prevent too high a growth, so that the flowers can be reached from the ground. Light and ventilation beneath, shade from the sun above, rest and plenty of moisture—but free from standing surface water—are the prime requisites for the growth of vanilla vines. One peculiarity of the vine, is that after three or four years planting, the stem will rot off at the roots, and continue to rot three to four feet up the vine, while the top looks green and flourishing. In the meantime, from above where it is going to rot, it shoots out fine little rootlets like threads, and continues them to the ground. So delicate are these threads running along the trunk of the tree, and so prominent the rotted-off end of the stem, that it gives the vine the appearance of living independent of the earth, thus giving rise to the theory that it is an air plant. It will sustain itself in a severed state, but to make material growth and fruitage it must connect it e'f with mother earth. The new vine will commence bearing the third year from planting, and full crops may be expected the fifth year. A vine will bear from 15 to 45 beans a year. Some vines have been known to produce as much as 65 beans at one time. Twenty beans to a vine is a good average. Rarely do those who grow the beans cure and market their crops. Some buy the green beans and make a business of curing and exporting them. Consul Jones says that judging from the way they all get rich at the business, and the difference between the price at which they buy the green bean and the price at which they sell the cured, there must be more profit in the curing than in the growing. Still, in view of the price of vanilla, and the demand for it all over the world, there are large profits for both parties. Wild lands suitable for vanilla can be bought for from £1 to £2 per acre. There are vanilla-producing plantations in the vicinity of Papantla that could not be bought for £100 per acre. Various estimates have been furnished as to the cost per acre of converting wild lands into vanilla-producing plantations. Approximately, £17 an acre is correct, which is very moderate for so profitable a plant. The greater part of the vanilla in the district of Tuxpan is grown about Papantla, much of which is

exported from Vera Cruz, it being easier to reach Vera Cruz by water than Tuxpan by land. The two busy seasons of the year are during the pollenation months—March, April, and May, and the gathering months—November, December, and part of January. During the balance of the year the plantation should have absolute rest, other than keeping down the weeds and undergrowth. Many of the beans are gathered in October, sometimes before they reach their growth, by those who see an opportunity of gathering them unknown to the owner, or by the owner, for fear of losing them, because he has not his vines where he can watch them. Beans gathered too soon are woody and inferior in quality, lacking the oil that furnishes the flavour. Good ripe beans lose but little of their weight while curing; 5 lbs. of green beans will weigh 4½ lbs. when cured. The quality and flavour are increased by allowing them to mature and by the proper curing. The curing is principally done by Spaniards who have followed this business. The process adopted is slow and laborious. The secret is to evaporate the water while retaining the oil, and to take care not to injure the flower. Vanilla is principally exported from Mexico to the United States—about £400,000 worth annually.

General Notes.

THE ELECTRIC LIGHT AT THE SOCIETY'S HOUSE.—Arrangements have been made to connect the Society's electric installation with the street mains, and therefore the machinery and apparatus used since the electric light was first installed in the Society's house in 1883 are now no longer required. It is proposed to offer them in the first instance to any member of the Society who may be contemplating an electric installation in the country. Particulars of the apparatus available will be found in the advertising columns of the *Journal*.

ST. PETERSBURGH HORTICULTURAL EXHIBITION.—Further information respecting this third International Exhibition of Horticulture, to be opened at St. Petersburg, has been received from the Science and Art Department. A second supplement to the programme of the Exhibition has been published, which contains a supplementary list of prizes, with a list of the Foreign delegates, and the constitution of the Foreign Section of the Exhibition.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

APRIL 26.—“Coal Supplies.” By T. FORSTER BROWN. W. BOYD DAWKINS, F.R.S., will preside.

MAY 3.—“Ætheric Telegraphy.” By W. H. PREECE, C.B., F.R.S.

MAY 10.—“Fruit Growing in Kent.” By GEORGE BUNYARD. SIR GEORGE BIRDWOOD, K.C.I.E., C.S.I., will preside.

MAY 17.—“The Law of Trade Marks.” By J. E. EVANS-JACKSON.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock :—

APRIL 27.—“Judicial Reform in Egypt.” By Sir JOHN SCOTT, K.C.M.G., D.C.L., Deputy Judge Advocate-General, and late Judicial Adviser to H.H. The Khedive. The LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., will preside.

MAY 11.—“The Revenue System and Administration of Rajputana.” By MICHAEL FRANCIS O'DWYER, I.C.S., Settlement Commissioner, Alwar and Bhurtore. Colonel GEORGE HERBERT TREVOR, C.S.I., will preside.

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal. The EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock :—

MAY 2.—Mr. Burton's paper on “Maiolica,” announced for this evening, is unavoidably postponed.

MAY 16.—“The Artistic Treatment of Picture Frames.” By I. HUNTER DONALDSON.

MAY 30.—“The Revival of Tradesmen's Signs.” By J. STARKIE GARDNER, F.G.S.

CANTOR LECTURES.

Monday evenings, at 8 o'clock :—

PROF. HENRY R. PROCTER, F.I.C., “Leather Manufacture.” Four Lectures.

LECTURE II.—APRIL 24.

Removal of hair and wool—The staling process—Bacteriological and chemical actions involved—Depilation by lime—Practical methods—Chemistry of liming process—“Buffalo” method—Pullman's indirect process—Use of alkaline sulphhydrates—Realgar—Mechanical operations—Deliming processes—Chemical and physical considerations—“Pulling down” with acids—Fermentative methods—The bran drench—Bating and puering.

LECTURE III.—MAY 1.

Physics of tanning—Theory of the pickling process—Mineral tannages—Tawing with alumina salts—Chrome tanning—Heinzerling process—Schultz or “two-bath” process—Basic or “one-bath” process—Iron tanning.

LECTURE IV.—MAY 8.

Oil dressing—The chemistry of the process—Combinations of oil and mineral tanning—Vegetable tanning matters—Chemistry of the tannins—Practical methods—Combination of vegetable and mineral tanning—Currying—The chemistry of oils and fats used—Theory of the currying process.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, APRIL 24...SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Cantor Lectures.) Prof. Henry R. Procter, “Leather Manufacture.” (Lecture II.)
 Chemical Industry (London Section), Burlington-house, W., 8 p.m. Mr. George Beilby, “The Relations of the Society to Chemical Engineering and to Industrial Research.”
 Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Mr. C. Jones, “Scavenging Disposal of House Refuse, &c.”
 Geographical, University of London, Burlington-gardens, W., 8½ p.m.
 Actuaries, Staples-inn Hall, Holborn, 7 p.m.
 Medical, 11, Chandos-street, W., 8½ p.m.
 Antiquaries, Burlington-house, W., 2 p.m. Annual Meeting.
- TUESDAY, APRIL 25...Royal Institution, Albemarle-street, W., 3 p.m. Prof. J. Cossar Ewart, “Zebras and Zebra-Hybrids.” (Lecture III.)
 Medical and Chirurgical, 20, Hanover-square, 8½ p.m.
 Civil Engineers, 25, Great George-street, S.W., 8 p.m. Annual General Meeting.
 Photographic, 12, Hanover-square, W., 8 p.m. Mr. Thomas Bolas, “A Demonstration of the Making of Glass Diaphragms—thin to Newton's “very black” stages.”

 Mechanical Engineers, Storey's-gate, St. James's-park, S.W., 7½ p.m. Mr. H. G. Oldham, “Evaporation Condensers.”
 Clinical, 20, Hanover-square, W., 8½ p.m.
 Zoological, 3, Hanover-square, W., 4 p.m. Annual General Meeting.
- SATURDAY, APRIL 29...Royal Institution, Albemarle-street, W., 3 p.m. Mr. Louis Dyer, “Machiavelli.” (Lecture III.)

Journal of the Society of Arts.

No. 2,423. VOL. XLVII.

FRIDAY, APRIL 28, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

CANTOR LECTURES.

On Monday evening, 24th instant, Professor HENRY R. PROCTER, F.I.C., delivered the second lecture of his course on "Leather Manufacture."

The lectures will be published in the *Journal* during the summer recess.

INDIAN SECTION.

Thursday, April 27, 1899; the LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., in the chair.

The paper read was on "Judicial Reform in Egypt," by SIR JOHN SCOTT, K.C.M.G., D.C.L., Deputy Judge Advocate-General, and late Judicial Adviser to H.H. the Khedive.

The paper and report of the discussion will be published in a future number of the *Journal*.

PRACTICAL EXAMINATIONS IN MUSIC.

The Practical Examinations in Vocal and Instrumental Music will be conducted by Mr. John Farmer, Balliol College, Oxford, and Director of the Harrow Music School, Examiner, and Mr. Ernest Walker, M.A., Mus.Doc., Oxon, and Mr. Burnham Horner, Assistant Examiners, at the House of the Society, and will commence on Monday, 26th June.

The last day for receiving applications is Saturday, 12th May.

Particulars can be obtained on application to the Secretary.

Proceedings of the Society.

APPLIED ART SECTION.

Tuesday, April 19, 1899; JOHN SPARKES in the chair.

The CHAIRMAN, in opening the meeting, said that he regretted to have to announce that Mr. Webb was too unwell to attend the meeting, and that the paper would therefore be read by the Secretary of the Section.

The paper read was—

INTARSIA.

BY STEPHEN WEBB.

Intarsia, or inlays of wood, ivory, &c., one of the most interesting of the so-called "minor" arts, has probably suffered more both from its neglect and from its abuse than any other method of decoration. At its best—kept within its proper limitations—no more delightful form of decoration was ever devised. One must, however, be confronted with a bad example in order to be able to realise how bad it can become at its worst.

Probably every existing form of art or craftsmanship has at some period of its development suffered through the ultra-cleverness of its exponents. In painting, at the present time technique (especially in France) is worshipped for its own sake, and what we think should be only regarded as a means of expression is set before the student as the end to be attained. Intarsia, like every other art, is at its best when most itself, but, except in the earliest periods of its development, its students and makers were never able to resist the temptation to wander out of their proper limits in imitation of other arts. The reasons of the very earliest designers and craftsmen for keeping simple and pure in their designs and patterns did them little credit, as they were probably merely mechanical reasons, and arose out of the difficulty of producing elaborate work by the only methods known to them at that time.

To a designer who has taken the thing up in the right spirit, and who has gone to the trouble of making himself even tolerably well acquainted with the resources of the craft, it would appear incredible that any one should consider it necessary to go outside its proper limitations in order to imitate any of the sister arts. The materials are so beautiful in themselves, so infinitely varied, and so adaptable to his purpose, that, assuming him to possess even a

small measure of artistic instinct, his work is really half done to his hand before he draws or cuts a line. The decorative problems which present themselves to the worker in intarsia for solution are few as compared with those of the painter or sculptor. For example, he has not to concern himself with surface technique at all. Tone, harmony, and, in a limited degree, the sense of values, he must certainly cultivate. He must also be able to draw a line or combination of lines which *may* be ingenious if you like, but *must* be delicate and graceful; vigorous withal, and in proper relation to any masses which he may introduce into his design.

He must thoroughly understand the value of contrast in line and surface form, but these matters, though a stumbling block to the amateur, are the opportunities of the competent designer and craftsman—if by good hap the designer is in a position to be the craftsman also. The most charming possibilities of broken colour lie ready to his hand to be merely selected by him, and introduced into his design; and yet, with these and other advantages peculiar to work in this kind, the whole history of the art, so far as I can follow it, except in the earliest times, is a story of perverted ingenuity, the story of an art degraded more than any other by the perverseness and want of taste of its votaries. Surely in no other art has the clever, sometimes exquisitely clever, craftsman suffered so many things from the bad or perverted taste of the designer. Whether the craftsman has been his own designer or has worked from the drawings of another, is all one; and it makes one marvel to find the most consummate technical skill so frequently associated with that which is worst in taste and in composition.

I do not know the precise date at which the use of veneer for furniture became general, but I have little doubt that what may be termed the "fatal facility," which this afforded to the craftsman, must have suggested the over-elaboration which had been practically impossible through the limitations imposed by the earlier methods. The earliest examples of inlaid work, viz., those in which the ground is cut away and the pattern inserted into the solid wood will nearly always be found to be good of their kind. The work, from its nature, could only be done at the cost of much time and labour, and this, doubtless, suggested to the executant the necessity for the elimination of everything from the design which was not absolutely necessary to the development of the

motive, a condition of things which always makes for good decorative art in any material.

I doubt not that the early workers in intarsia often wrought, as the old builders are said to have sometimes builded "better than they knew."

With the introduction of veneers or skins of wood came a complete change. The economical necessity for the reticence hitherto observed was removed, the smallest details could be introduced into a design with comparatively little difficulty or cost. Wooden pictures began to replace the former pure and appropriate decoration. All reserve was apparently thrown aside, and the tarsatoir of the period revelled in the representation of temples, gardens, figures in extravagant costumes with wooden bodies and sometimes ivory heads or faces, and so the triumph of craftsmanship and the decadence of design may be followed through their various developments. In these the artist appears to have done his best (or worst) to outdo his predecessor or contemporary worker in the extravagant use of forms, proper only to the painter or picture maker, till it touched what was, perhaps, its highest point of absurdity in the wooden representation of whole towns, castles, &c. We see these illustrated in the German work of the 18th century on panels used chiefly for the interior decoration of cabinets.

The French work of the 18th century is every whit as extravagant as that of Germany in another way. There is a small table in the Jones collection at the South Kensington Museum, the top of which is decorated with "Boule work (metal and ivory). In the plan of the decoration a band is used into which—and on which are introduced figures in the costume of the period—curiously scalloped cloths, tassels, foliated forms, pateræ, Caryatides—monkeys, squirrels, swags of flowers, baskets of flowers, masks, birds (cranes), dogs, festoons formed of petals or husks, cornucopias, and probably a few other properties more or less material to the scheme. If this kind of thing was ever worth doing (a matter about which I am hardly prepared to speak here), an excuse for it would surely be found in this table, which, as a piece of craftsmanship, apart from its design, is certainly one of the finest existing examples of this kind of work.

Personally, I have never been able to get up any enthusiasm for metal inlay for furniture. It is frequently very gorgeous, nearly always extravagant in design, seldom beautiful, and

even if one has the fortune to get a beautiful design, it is generally difficult to bring it into harmony with any colour scheme which may have been adopted for the decoration of the room.

Moreover, it is not easy to cut, though that is perhaps more a matter of time than difficulty, and it is apt to leave the ground when laid—which is a much more serious matter.

These are only mechanical difficulties. The chief trouble, and one which I confess I have never overcome to my own satisfaction, is in the selection of wood of a colour and texture which shall at the same time contrast agreeably with the metal surfaces and harmonise both with the metal pattern and the ordinary colours used in the decoration of a modern room. May I venture to recommend this problem to the notice of any of my *confrères* who have the requisite leisure and experience to attempt its solution. The thing has never been done yet.

In studying French—and indeed all other marquetry work of nearly every period—the superiority of the workmanship to the design is still constantly in evidence. In nearly every important example which remains, it is plain that the executant, so far from being guided by the designer, has been led out of his way, the obvious result being a deplorable waste of skilful craftsmanship.

Curiously enough this want of taste shown in the selection of forms suitable to the embellishment of furniture, is sometimes, and indeed often, found combined, in the same cabinet, with what one would fain believe to be evidence, that the designer had the colour scheme perfectly, and could select the woods suitable for his purpose, with the certainty of getting the effect which he had in his mind. But the almost inevitable introduction of these little bits of ivory again gives one pause, makes one doubtful whether the harmony of colour in the woods was not accidental, or the effect of time, as it would seem impossible that a designer, who had sufficient knowledge of the conditions necessary to produce so good a colour harmony in the woods, could deliberately bring himself to introduce anything so obviously disturbing to the whole scheme as these little bits of ivory always are.

It is not until the close of the 14th, or beginning of the 15th, century that we find intarsia used for the decoration of large surfaces, nor, indeed, till then, does it appear to have been taken seriously into the consideration of artists or its possibilities recognised. Then we hear

that Brunelleschi and Paolo Uccello gave lessons in perspective and tarsia to architects and others, of which Masaccio, in his paintings, and Benedetto da Majano, in his inlaid works, availed themselves.

There are certainly to be found examples of the craft in the small ivory boxes, ornamented with inlay of various coloured woods, manufactured chiefly at Venice in the 14th century.

According to Vasari, one of the greatest names in the art is that of Fra Giovanni da Verona, who, in place of the dark and light woods of two or three tints only, used by the Majani, gave artificial colours to his wood inlay by means of waters, coloured infusions, and penetrating oils. To obtain brilliant high lights he was accustomed to use delicate slips of willow. F. Vincenzo dalle Vacche is mentioned by Morrelli in his *Notizia* as excellent in such work, particularly in the church of San Benedetto at Padua. Fra Raffaello da Brescia, of Monte Oliveto, ornamented the choir of San Michele. Sabba Castiglione, in his "Ricordi overo Ammaestramenti" (1562), given in Digby Wyatt's essay on the subject, in "The Industrial Arts of the 19th century," mention the Legnaghi as good artists in this manner, and he speaks of the Dominican monk, Fra Damiano da Bergamo, the most celebrated of the 16th century followers of the art. "But above all, those who can obtain them, decorate their mansions with the works, rather divine than human, of Fra Damiano . . . who excelled not only in perspective, like those other worthy masters (Fra Giovanni and Legnaghi), but in landscapes, in backgrounds, and what is yet more—in figures, and who effected in wood as much as the great Apelles did with his pencil. I even think that the colours of these woods are more vivid, brilliant, and beautiful than those used by painters, so that these excellent works may be considered as a new style of painting without colour, a thing much to be wondered at. And what adds to the marvel is that though these works are executed with inlaid pieces, the eye cannot, even by the greatest exertion, detect the joints." Thus the worthy Messer Sabba Castiglione.

The colouring in this case was produced by chemical fluids, with the aid of burnt in shadows. Damiano's best work, in which he was assisted by Fra Antonio Asinello, of the same monastic order, are not in colour, but are assisted in their effect by burnt shadows.

Other works of his are mentioned by Lanzi, as in the Dominican Church at Bergamo, and in San

Pietro da Casinensi, Perugia. Gian Francesco Capo di Ferro is spoken of as working, also at Bergamo.

Other works in this manner are to be seen at the Certosa, Pavia, in the choir executed by Bartolommeo de Pola in 1486; in the choir of the Cathedral at Siena, by Fra Giovanni da Verona; in the Sacristies of San Miniato al Monte and Santa Croce at Florence, and in the Sala del Gambia at Perugia, the last being signed with the name of Marc Antonio Meretelli. The tarsia work of artificially coloured woods which Sabba Castiglione so eulogises is not to be found in any of the above-named works, and although the practice clearly originated in Italy it reached its ultimate development in France and Flanders.

Probably the inlay which in its character most nearly approaches that of the Italian Damiano is the modern French work, so much of which is sent over to England in and for the decoration of pianofortes, &c.

It has nearly all the faults so conspicuous in Damiano, and where the modern Frenchman has missed any of the weaknesses apparent in the work of the Italian he has more than made up for it by those which he has invented for himself. Here is evident the same struggle to obtain the effect of painting, and an equal anxiety to conceal the joints which divide the various pieces of highly coloured woods introduced into the design. Indeed the French critic of marquetry in these days makes this joining the test for good or bad work, and were a panel of intarsia submitted to his judgment in which the mark of a saw could be seen the work would be at once condemned as bad though it exhibited all the finer qualities of design and cutting.

The experience of the writer is that the joinings of the various kinds of wood used in a design should not only not be concealed, but that they should be dealt with as frankly as possible, and that their utilisation in the design contributes almost more than anything else towards giving the work its character as intarsia or marquetry. It is true that the arrangement of the various pieces of veneer in a manner which will make the work of the cutter practicable and easy, and secure an artistic line for the joinings at the same time, calls for the exercise of some ingenuity, but this, though irksome and troublesome at first, soon becomes a habit with the designer for intarsia, or, at least, soon would do so if he understood its value. In nearly every example of modern work in which shading (generally

produced by hot sand) has been resorted to, it has been abused. If the wood be properly selected, shading is rarely necessary, and if it is done at all it should be done by an artist. It can never be safely left to a merely mechanical cutter of marquetry, even though he works from the most carefully finished drawing. In the hands of an artist, very beautiful effects may be obtained by this process, the same kind of wood being made to yield quite a number of varying shades of colour of a low but rich tone, and that without any sacrifice of what, for lack of a better term, I must call the transparent quality, so characteristic of all good marquetry work. Overstaining and the abuse of shading is destructive of this, one of the most valuable and distinctive qualities in inlays of wood.

Ivory has always been a favourite material with workers in tarsia, and in the hands of an experienced designer, very charming things may be done with it. There is, however, no material suitable for tarsia which requires so much care and experience in its use. It is ineffective in light coloured woods, and in the darker ordinary woods such as ebony, stained mahogany or rosewood, under polish, the contrast of colour is so great that the ivory must be used very sparingly, in other words the designer must invent for his panel or border a pattern or design which, while containing very few elements, shall convey the idea of a satisfactory furnishing or filling (always a difficult problem for the designer to solve in any material). In work intended for many other processes and materials, every artist has, at times, to consider the advisability of some such treatment as this, but it is seldom that he finds it so absolutely indispensable to the success of his work as in the application of design to the inlay of ivory for furniture. This kind of work is improved very much by age (the effect of light chiefly) even under polish. The ivory is sometimes stained in order to bring its colour more into harmony with a dark wood ground, but it is never quite satisfactory, and no one who had seen much old ivory in tarsia could be deceived by it.

There are conditions possible where—particularly in the decoration of furniture—the advantages are nearly all on the side of intarsia as compared with carving or modelling. The amount of time wasted for instance on very small carvings in dark-coloured woods intended to be used in furniture is incredible. The colour of wood, such as mahogany, walnut, &c., makes it impossible to see small

carved detail in the various and varying conditions of light, which usually obtain in a living room, and when, as so frequently happens, rosewood or some other strongly-marked wood is used for this purpose, the markings in the wood are so much stronger than the shadows by which the small carved forms are expressed that their effect is destroyed, and the result must always be confusion and waste of time.

Very small detail, especially in carvings, is introduced much more frequently than is necessary in furniture, as in architecture, and its introduction may usually be taken as indicative of some confusion in the mind of the designer or architect between smallness and delicacy. This idea, that scale or minuteness of detail must somehow be related to refinement or delicacy, absurd as it would appear to be to an artist, must really be very common to the designers of houses and furniture, or we should not see so much skilful labour and valuable time wasted in such useless productions. In this, as in other matters, it is only the thought or design in the thing which really counts; no amount of mere slavish though skilful labour undirected can possibly result in anything but disappointment, and there must be a very plentiful lack of direction in some of the places where modern furniture is decorated. If small carved details must be introduced into the external decoration of furniture they can only be certainly effective when plain and light coloured wood is used, such as box, pear tree, &c., or quite black wood such as ebony (which has generally to be made black artificially), materials which have but little marking to disturb the surfaces and lines of the carving.

Undoubtedly, the colour of these would render them in many cases unsuitable for the decoration of furniture, as they are apt to prove disturbing to the quiet colour effect, generally associated with a living room.

It is here that inlay for the surface decorations can be made so useful in the solution of a difficult problem, when it is done with judgment and taste. However quiet it may be kept in tone and in good hands it is always quiet; however rich and varied in colour, it can always be seen, as it does not depend on the light for its due effect, either in the same degree or in the same manner in which carving depends on it. I am not making general comparison between the advantages severally of carving and marquetry for the purposes of decoration, nor do I wish it to be for a moment

supposed that I think marquetry can ever supersede carving for general purposes, even if the thing were desirable.

This is merely a protest against the grievous waste of time and of skilful, and frequently artistic, labour caused by architects and designers through their inability to grasp beforehand the idea of the modifications which will be brought about in the effect of their work by the conditions under which it will be seen. The decoration on small pilasters and capitals as applied to furniture and carved in these woods, is rarely seen at all, except on a rough and disturbed surface. Still more rarely can enough of the motive or details be made out to awaken any interest in it.

Assuming that about the same quantity of detail is introduced—(which is usually the case)—the carving on a pilaster 3 ft. by 9 in. can be done as quickly, and at no more—probably less—cost than the same design 1 ft. 6 in. by 4½, namely, half the size. There is no question of delicacy or refinement in this relation.

The inferior carver will inevitably give you a coarse and clumsy rendering of the small design, if you trust him with it. From an artist you will just as surely get a suggestion of—refinement and delicacy pervading all the work in the large panel—though each man works from the same drawing or even the same model. Moreover in the larger carving one is much more independent of the markings in the wood, by reason of the fact that the sinkings and shadows are deeper and stronger, and so in a measure, control the disturbing colour.

Apart from the question of cost which is always in favour of tarsia, there is this essential difference between the two methods, that while carving must always depend in a large measure on the direction of the light for its effect as carving (you can destroy the effect of carving which is in low relief at any time by a direct front light), the use of inlay makes the direction from which the light enters the room a matter of no moment—so long as the light reaches the object decorated.

I cannot close this paper without some reference to the practice so prevalent among writers on art, and especially applied art, of comparing the conditions under which the work was produced two or three hundred years past, with the conditions which obtain in our time. By no conceivable combination of circumstances can we ever get back to the conditions under which those workers produced their work, and although the productions of the writers above mentioned are frequently pleasant reading they

are rarely helpful, and indeed we—as artists or craftsmen—have but little concern with them, we must accept matters as we find them and do our best under the changed conditions. Moreover it is so easy to write in that way. The contrasts between the prevailing conditions and those of the past are so sharp—the change so complete—that a writer in this kind, possessed of only very ordinary ability, can hardly fail to be at least picturesque. We are so frequently told by poetical writers on art that a designer should, wherever practicable, carry out his design himself in the material for which it is intended. No artist who has a design in which a really fine idea is embodied need be told this; he would probably be but too glad of the opportunity to do this assuming that he had ever had the chance to obtain the requisite knowledge and skill in craftsmanship. His ideas are the children of his mind born not without travail—and, when it becomes necessary to hand them over to strangers for their material development, he does not part from them without a pang.

The modern designer, though he be really a master of his own branch of art in all its details, must needs leave a good many of those details to other and more mechanical hands.

[Mr. Webb sent some fine specimens of ivory inlay work for exhibition.]

DISCUSSION.

Mr. LEWIS DAY said they must all greatly regret Mr. Webb's absence, because it was always delightful to hear a workman talk about his work, still it was very interesting merely to hear read what he had written, and he could only say that he endorsed it cordially, and especially the concluding remarks about the absurdity of modern faddists who wanted them all to go back to the year 1. He thought those men did more harm to art than they knew, and it was good to hear a workman like Mr. Webb say what all workmen felt.

Mr. PHILIP H. NEWMAN said he felt in much the same position as Mr. Day, except that he did not come with any idea of questioning what the author said but to learn something about marquetry of which he knew nothing whatever. This paper had cleared up all his doubts and misgivings as to what marquetry ought to be. They must all regret Mr. Webb's absence and the cause of it.

Mr. PHENÉ SPIERS said he knew nothing of inlaying, and his recollections of what he had seen in

Italy was rather faint, but he remembered looking at some of those marvellous examples referred to in the Italian choir stalls without any idea that they could be reproduced. The perspective of some of the interiors was marvellous, but he did not know that it could be recommended for imitation. The specimens exhibited were very beautiful, but he thought the effect produced was a little monotonous; there was too much detail. He had seen specimens of inlay in which the style was broader, the design being made up of larger masses. This was too much like lace work or a wall-paper pattern. He had seen some modern marquetry which was about the best class of work one could find anywhere, namely, the chapel which Burges decorated at Worcester College, Oxford. In that chapel you would find more modern ideas of decoration than anywhere else he knew of. The chapel was built at the end of the 17th century, and when Sir Gilbert Scott was asked what should be done with it, he said they had better pull it down and build a Gothic one; however, they did not like to do that, and eventually applied to William Burges, who advised them not to destroy it but to decorate it as it was, and the results were most wonderfully beautiful throughout the whole building. In the pavement in front of the altar and every other portion of the building he brought in perfect specimens of modern craftsmanship, and he could only recommend students and workmen to go and see it

Mr. W. AUMONIER said the paper was very interesting, but he could not help thinking that in the specimens of ivory inlay exhibited, Mr. Webb had gone a little in the direction which he had condemned, as there was too strong a contrast and a want of harmony of colour. There was a beautiful harmony in some of the Italian inlays, and he was at one with those who condemned perspective work in inlaying.

Mr. LEWIS DAY said he should like to say a word more in defence of Mr. Webb's work, because he did not think that he had been quite fairly judged by Mr. Spiers and Mr. Aumonier. There were two kinds of effect to be obtained in inlay. You could get colour which was very beautiful, but you might also go for line, and in the specimens exhibited Mr. Webb had gone more for line, and it was beside the question to complain that he had not got colour. It was not right to compare this work with that done for church decoration, which was necessarily on a much broader scale. No doubt if Mr. Webb had had an opportunity of decorating the choir of a church he would have done it much in the style Mr. Spiers suggested, but these specimens were done with a view to being placed in a modern drawing-room. They all knew what a modern drawing-room was. It would be a mistake to decorate a modern drawing-room with bold effective work out of scale with all the other contents of the room. Mr. Webb's inlay was beautiful work, admirably suited to its purpose.

Mr. C. BESSANT said he knew something about the practical details of inlay work, and had great sympathy with it, as much as with wood carving, although it stood on quite a different footing and was applicable to different purposes. Many surfaces had to be plain, and in such cases inlay work would come in, though it was now rather neglected. If Mr. Webb did not do such work as had been shown he did not know who could do it, and it had a value in that respect. He looked upon it more as a piece of jewellery, a thing to be taken up and examined closely. If you wanted to have a broad effect you would use larger masses and not introduce colour; but even style had its value, and anyone who knew the difficulty of producing that kind of work must admire it. Whenever he explained to anyone how marquetry work was done, they always went away with a far better appreciation of its value than they had before. It was an art much neglected by architects, principally because they did not understand the materials used, and were rather afraid of it. Some of the best work was that treated in a very broad way with simple woods, such as box, in combination with dark woods. In the case of ivory, the inlay was cut out first before the ground work; in broader treatment you can put the two woods together and saw them through, and get all sorts of effects with the aid of shading by means of warm sand. In much of the old work the wood of the ground was cut right away, and as they had no glue to fasten the inlaid pieces they were fixed with small pins.

Mr. HAIGH said he had an old piece of work in which there was a good deal of green colour. He should like to know what wood that was.

Mr. BESSANT said it must be dyed; he could not say what dye was used.

Mr. A. PAYNE said they were much indebted to Mr. Webb for bringing forward this subject. In this country there was very little inlay work in the churches and cathedrals; but on the continent there was a great deal of it, especially in Italy. There was some charming work in the pulpit of a church at Sorrento and at Florence, the whole cathedral was one mass of inlay work. There was a good deal of inlay work in marble in some of the churches; for instance in the church of the Jesuits at Naples, where the columns, the walls, and the floor were inlaid; in fact it was rather overdone. Even with regard to wood inlay, there was comparatively little old work in this country; there was a little in Westminster Abbey, by Italian artists.

Mr. NEWMAN desired to add a word in defence of Mr. Webb. They came there to listen to his paper, not to criticize these particular works, which he took it were simply sent as specimens of the kind of work which was most difficult of accomplishment; the inlaying of wood with ivory.

The CHAIRMAN said he should like to add his testimony to the beauty embodied in the panels submitted by Mr. Webb, but it was clear that they were sent rather as *tours de force* than as examples of the author's mode of treatment for panels on a larger scale. He did not know any artist who had a more refined feeling for his work, and he was sure he would appreciate Mr. Aumonier's remarks as to the treatment of larger surfaces, and that he would give these a different treatment altogether. It always seemed to him that the Norfolk churches with their large panels of stone, filled in with cut flint, were the noblest examples of *pietra dura* work the world possessed. The Italians in their marble work had degenerated into little ornaments, birds, and fruit—mere playthings, but that flint work in Norfolk was on a nobler scale, and showed great breadth and contrast of form and proportion. Again, the Sviza room at South Kensington had some very interesting pieces of holly inlaid into panels of oak which was purely English, and provincial; they were somewhat rough, but exceedingly well done and in good scale. Another side of the subject which had not been touched was the great use of the art in South Germany and Switzerland, good effects being produced by the juxtaposition of various woods. It was inlaid, but inlaid solid, not veneer, but in some cases quite thick. A museum had been formed in Zurich within the last ten years, in which could be seen complete rooms, not only from Switzerland, but from Italy—one especially from Lugano, which was a beautiful example, in which the cornice and panels in the ceiling were inlaid. In Salzburg, Munich, and Berlin there were also beautiful specimens of South German inlaid woodwork. The architect who had designed the wall had given it rather too much projection in some members, and this had been redeemed by the treatment of the panels, and a charming effect had been produced by the inlaying of Hungarian ash with walnut and oak. At Ulm, again, he could recall a charming little house, now the museum of the town, in which the doors, architraves, cornices, and ceiling had this method of decoration carried almost to excess. In that museum, also, there was some of the most beautiful inlaying in colour on the backs of fiddles and other musical instruments, which were made in that district in the 17th and 18th centuries. The colours of some of those groups of conventionalised floral forms surpassed anything he had seen. This kind of work seemed to have been peculiar to southern Germany, especially Württemberg and Bavaria, and also the southern shore of Lake Constance. Inlaying was certainly worthy of more attention, and might be more used as a means of producing a good effect, where the architect and designer could meet on common ground without any rivalry. He concluded by moving a hearty vote of thanks to Mr. Webb, which was carried unanimously.

EIGHTEENTH ORDINARY
MEETING.

Wednesday, April 19, 1899; W. BOYD DAWKINS, F.R.S., in the chair.

The following candidate was proposed for election as a member of the Society:—

Lowe, C. W., Summerfield-house, Reddish, Stockport.

The following candidates were balloted for and duly elected members of the Society:—

Ash, Thomas Henry, Avonmore, Dudley-park-road, Acocks-green.

Barrett, C. Foster, Sheepcote-road, Harrow.

Batho, William John, Finchley and Hornsey-lane, N.

Benjamin, Henry Neville, 34, Devonshire-place, W., and 16, Leadenhall-street, E.C.

Bentley, Horatio Haliburton, 5, The Campsbourne, Hornsey, N.

Cochrane, J. R., J.P., Calder-glen, Blantyre, N.B.

Culbard, Arthur Dingwall Fordyce, A 24, Exchange, Liverpool.

Curven, Charles, 39, Victoria-street, S.W.

Edwards, E. Montague, 162, Romford-road, Stratford, E.

Good, Montagu, Bonsor Gold Mining Company, Selukwe, Rhodesia.

Longmore, William Alexander, 13, Prospect-hill, Walthamstow, Essex.

Lyttelton-Annesley, Lieut.-General Arthur Lyttelton, Templemere, Weybridge, Surrey.

Mackenzie, Alexander Marshall, 1, Bon Accord-street, Aberdeen.

Merry, Alfred, 4, Orient-terrace, Manor-road, Liscard, Cheshire.

Meyer, Carl, 35, Hill-street, Mayfair, W.

Pollock, Mrs., 40, Thurloe-square, S.W.

Runge, Adolphus, 4, East India-avenue, E.C.

Williams, Charles Thomas, Madras, India.

Wyllie, Major John Alfred, Rangoon, Burma.

The paper read was—

OUR COAL SUPPLIES.

By T. FORSTER BROWN.

The writer's apology for bringing this subject before the Society of Arts, is his desire to enlist the assistance of its members in inducing politicians and the public generally to consider and deal with the material and important problems which underlie the coal question, with the primary object of providing, if practicable, a remedy for, or counterpoise to the effect of, the future increasing cost of our supplies of fuel.

This future increased cost of coal, reacting upon the whole of our manufacturing industries, will undoubtedly land the nation in serious financial and political difficulties if remedial measures are not adopted, and these measures, to be of value, should be inaugurated during the period when the possession of good and cheap fuel enables the nation to maintain its commercial prosperity.

I will not attempt to dwell upon the origin and nature of coal, but proceed at once to the main problems I desire to direct attention to, and, shortly stated, they are:—

1. That whilst we have in Great Britain large unworked coal resources, sufficient probably to maintain a rate of working exceeding our present annual output for 300 years, or thereabouts, we are now rapidly exhausting the cream and cheapest of these resources; and in 50 years or thereabouts the greater part of the most valuable of our coal supplies will have been exhausted, except only such as can be worked at a greatly increased cost, which cost after half a century will rapidly increase.

2. That the United States of America possess far more extensive coal-fields than those of Great Britain, and that country already produces coal at a somewhat cheaper cost than we do, and so far as physical conditions affect the cost, will continue to produce cheaply for a far longer period than we can. With the exhaustion, therefore, of the cream of our coal-fields, and when we shall have nothing left but our more costly coal to work, the American competition will become of far more serious import to this country in all our commercial relations than it is likely to be in the immediate future.

3. The large coal-fields of Russia and China, when further developed, will also become serious additional factors in competition with us in the future.

Upon the first question of the coal supplies of Great Britain, I cannot do better than follow Professor Hull's (than whom I know no better authority) careful estimate of the approximate quantity of workable coal which will remain unworked at the end of the present century down to a depth of 4,000 feet below the surface, which is the probable utmost limit of depth at which it will be practicable to work coal. The resources exist in six large coal-fields, and a small quantity in Ireland, plus some small addition due to an extension of the coal measures between Dover and Bath.

These coal-fields and their estimated resources in seams of two feet and upwards in

thickness, down to a depth of 4,000 feet, as given by Professor Hull are as follows:—

(1.) The Midlands, extending into the counties of York, Derby, Nottingham, Stafford, Leicester, and Warwick. From this district, house, manufacturing, and steam coals are chiefly produced. Estimated resources, 35,000,000,000 tons.

(2.) The Great Northern, extending over portions of the counties of Northumberland, Durham, and Cumberland, chiefly the two first named counties. House and gas coals of the best quality, and steam and manufacturing coals are produced. Estimated resources 6,000,000,000 tons.

(3.) The North-Western, comprising Lancashire, East Cheshire, &c. House, gas and manufacturing coals. Estimated resources 11,000,000,000 tons.

(4.) Western group, comprising Bristol, Somerset, and Forest of Dean. House and second class steam coals. Estimated resources 2,000,000,000 tons.

(5.) The Welsh, comprising South Wales, including Monmouthshire, Denbigh and Flint. Steam, house, gas and manufacturing coals. Estimated resources 20,000,000,000 tons.

(6.) The Scotch, comprising the series of coal basins which extend across Scotland from Ardrossan to the Firth of Forth. Gas, steam, manufacturing, smelting and smith's coals. Estimated resources 8,000,000,000 tons.

(7.) The Irish coal-fields are estimated to contain of visible and concealed coal to the extent of some 155,000,000 tons. Making the total available coal resources in the year 1900 about 82,000,000,000 tons.

The conditions which regulate the value of the coal resources of all coal-fields are many and various: the thickness of the seams, their depth below the surface, the friability or otherwise of the roofs and floors of the seams, the inclination of the seams of coal, the dry or watery nature of the strata associated with the coal-beds; and the coal itself, its friability, the proportion it contains of carbon and hydrogen, and other volatile matter, and its comparative freedom from indestructible ash and sulphur.

It follows that whilst one coal-field, or part of a coal-field, may be extremely valuable owing to the measures lying nearly horizontal and at no great depth below the surface, the great thickness of certain seams, their high quality, and the general favourable conditions for working and so forth, another coal-field, or another portion of the same coal-field, may be of little value owing to the seams existing at

great depths, involving heavy pumping, being thin, lying at steep gradients, containing too much or too little volatile matter, or too much dirt and refuse in the form of ash and sulphur, making it impossible to work such inferior seams of coal in competition with the best coals.

More clearly defined, the most valuable part of any existing coal-field, in this or other countries, comprises seams of upwards of three feet in thickness of coal, containing from 12 to 30 per cent. of volatile matter, and in the case of certain anthracite down to 6 per cent., and leaving a residuum after burning of from 2 to 5 per cent. of ash, and from 15 to 1 per cent. of sulphur, which seams are deposited upon an easy inclination and with good roofs and floors. Whilst the less valuable seams of coal-fields contain coal-seams from two feet and upwards in thickness, containing from 5 to 12 per cent. of volatile matter, and again from 30 to 40 per cent. of volatile matter, also thick seams of best quality existing at great depths, steep inclinations, and so on, so that practically whilst certain coal-fields of the world produce coal of exceptional quality, such as the steam coal of South Wales, the gas and bituminous coals of Durham and the Midlands, the furnace coal of Scotland, the cannel coal of Lancashire, the anthracite and semi-anthracite coals of Pennsylvania and the Pittsburg region of the United States, and the coal of the Westport coal-field of New Zealand, which last named is a deposit of Cretaceous-Tertiary age, nearly every coal-field contains a considerable proportion of comparatively inferior deposits, and many coal-fields, more particularly those which are of a more modern geological age than the Carboniferous period, do not contain any of the most valuable coal deposits. Therefore, in taking the measure of the extent and resources of our coal supplies, it becomes of importance that we should have all the circumstances in our minds before attempting to generalise as to the real value and extent of our coal resources, what proportions are good and cheaply worked, and what proportions are of less value, and, under existing conditions not capable of maintaining such a supply of cheap and high-class fuel as will enable our industries and manufactures to compete successfully with the products of countries which possess better fuels which are worked at a cheaper cost.

Taking all the circumstances into consideration, the author of this paper estimates that of the best and cheapest of the coal supplies of

Great Britain there originally existed about 20,000,000,000 tons, existing at a less depth than 2,000 feet below the surface, and that there may be probably still remaining at the end of 1899 about 15,000,000,000 tons of this quantity, the bulk of which he estimates will be exhausted by the middle of the next century, leaving about 67,000,000,000 tons of coal still available, sufficient to supply 250,000,000 tons a year output for upwards of 250 years, but comprising coal either of inferior quality or best coal obtainable at a greater cost per ton than at present prevails owing to physical disadvantages by reason of depth and so forth.

The present depths at which our coal mining operations are carried on are comparatively shallow. There are some few collieries working at depths between 2,000 to 2,500 feet, but the average depth below the surface from which our existing coal supplies are obtained will not exceed probably from 750 to 850 feet; this average depth will increase gradually, and it is apparent that when the average depth exceeds 1,000 feet, and still more when the average exceeds 2,000 feet and so on, the causes which enhance the cost of working due to extra depth will come more and more into operation.

Up to the present, the altered conditions due to higher temperatures, and increased cost of working due to depth and temperature, have naturally not made themselves apparent. Four thousand feet has generally been considered the ultimate limit in depth for all coal-working. It is doubtful even if this limit can be attained, but if it is, it will only be at a very high cost of working, probably more than double the cost of working which now prevails, owing to the reduction in the useful effect of labour in high temperatures, and the large consumption of power in raising from great depths.

Probably it will take 50 years before the general average depth of working the annual coal supply of this country exceeds 1,500 feet, but it follows that as the average exceeds 1,500 feet, a constant but steady increase in cost of working must set in.

The cost of working coal in this country has for many years past been an increasing one, irrespective of physical causes, and at the present time there is no indication that this gradual increase of cost will not continue to operate. The causes are chiefly the increased cost of labour, the extra and increasing burden of rates and taxes, and the larger colliery staffs and improvements necessary to meet the

various requirements of the Coal Mines Regulations and Workmen's Compensation Acts.

But so far as cost is affected by natural causes, depth, thickness of seam, and quality, I think it will be a reasonable supposition that a moderate cost will prevail for another fifty years, at the end of which period physical causes will begin to operate which will have the effect of steadily increasing the cost until it reaches such a figure as to render profitable mining operations impossible, and this limit is believed to be about 4,000 feet below the surface.

It may be argued that with our increasing cost, means will be provided to reduce that cost with improved mechanical appliances and so forth. This alternative, however, will not bear investigation, for, as time goes on, although undoubtedly improvements will take place in mechanical appliances, in the application of labour for "getting" thin seams, in hauling, and in the manipulation of the coal when it arrives at the surface, but these improvements will equally apply to the operations of our competitors in other countries, and will still leave unsolved the comparative increase of cost due to great depth and high temperature, and increased cost in the working of thin seams in competition with the working of thick seams, and to a certain proportion of coal having to be worked of inferior quality and of less evaporative power.

At present, the greater part of our coal output is being worked from collieries possessing the thicker and more valuable seams lying at comparatively shallow depths below the surface; and we shall certainly, within the next 50 years, see an appreciable diminution of output owing to approaching exhaustion of these collieries, and there remains, at present, comparatively few unlet mineral tracts in this country, except where the coal lies at a great depth.

Of course, the duration of what at present remains of the cheaper and best coal seams depends upon the rate of output, but the period of exhaustion must sooner or later arise.

Summarising our coal resources, we have—in seams of 2 feet and upwards in thickness, within a depth of 4,000 feet below the surface—an estimated available quantity of coal (visible and concealed), including the Irish coal-fields, of 82,000,000,000 tons.

Now it may be well to inquire how far is this total of 82,000,000,000 tons, which is sufficient, at our existing rate of output, to supply the

requirements of Great Britain for at least 300 years, available at a reasonable cost?

To begin with, from the commencement of the present century, and previously, coal has been worked, and at an increasingly rapid rate during the last 25 years, from the thickest seams of the best quality existing near the outcrop and down to a moderate depth below the surface, and the quantity already worked exceeds 5,000,000,000 tons. The good coal near the outcrops has been already practically exhausted and deep pits in later years have been necessary to win some of the best seams.

Anyone who is practically acquainted with coal mining is aware that with this increasing depth there is a distinct increase in the cost of working, and if all our coal at the present day was produced from a depth of 2,000 feet it would be much more costly than is our average present cost of working.

Once a depth of 2,000 feet or thereabouts is reached the effects of the increase in temperature and pressure due to depth begin to operate, in addition to the cost of the increased power required, and of course increased depth means greater capital outlay, and the interest upon this increase of capital also becomes a fresh charge upon the mineral produced.

Fifty years ago the average depth from which our coal supply was obtained was probably less than 300 feet below the surface. To-day the average depth from which the whole of our annual supply is obtained may be taken to be about 800 feet, and 50 years hence the average may have increased probably to 1,500 or 1,800 feet, the larger annual output rendering the process of exhaustion, as regards depth, more rapid in the future than it has been in the past.

The increasing cost due to the greater depths of winnings, so far as it is merely a question of more expenditure of power, has been and will be met partly by improved mechanical appliances as previously mentioned, increased outputs and so forth, but when the temperature becomes so high as to reduce the useful results of manual labour and horse-power, then we have a new element introduced which inevitably increases the cost.

The writer's experience in colliery operations, carried on at depths exceeding 2,000 feet, fully bears this out, and although it may be practicable to modify the conditions, even in regard to temperature, in some degree, a serious gradual increase of cost due to increased depth, &c., is inevitable. And already, notwithstanding the various improvements

which have been effected in mining operations during the last half a century, the average cost of raising coal to-day, irrespective of fluctuations in wages, is probably 15 per cent. above what it was 50 years ago.

The fact that within the last 25 years a great number of collieries have been opened upon large areas of coal-field, and that it will require 30 to 60 years to exhaust the resources of these modern collieries, indicate approximately the period when the cost will rapidly advance. It will only be upon the exhaustion of the bulk of the best coal available to already existing collieries, and the future output having to be maintained by recourse to deeper winnings that an important step in the direction of increased cost due to depth will begin to operate. Therefore, whatever remedial measures are adopted, they ought to be so arranged as to come into partial operation by the end of half a century, and be capable of adjustment so far as they can be utilised from decade to decade to counteract the effect of the increasing cost of working these remaining portions of our coal supplies.

It may be of interest here to state that a reasonable estimate of the horse-power produced by such portion of our annual output of coal as is utilised for industrial purposes is about 25,000,000 horses, and the approximate present cost at the points of consumption at between 25s. and 35s. per horse-power per annum; whilst if all our exports of coal and coal used for gas, and household purposes were included, it would represent 50,000,000 horse-power per annum, if it were practicable for man to perform the same labour, but it is not to the work of a population of 500,000,000 working people who would have to be supported.

I may refer, before approaching the question of the American coal-fields, to Mulhall's estimated areas of coal lands in various countries, which he gives as follows:—

	Sq. miles.
Great Britain	9,000
United States of America	194,000
Russia.....	27,000
China and Japan	200,000
Germany	3,600
Belgium and Spain	1,400
India	35,000
France.....	1,800

To which might be added enormous areas of lignite in various parts of the world. The coal-fields which have just been enumerated are chiefly of the Carboniferous period.

Our colonies of North America, Australia, New Zealand, and South Africa, are not given.

Assuming the coal acreage of America, China, and Russia, to contain a fair proportion of workable coal, it will be apparent how far in excess of our resources are those of these three countries, and that consequently how much larger is the extent of coal accessible in these countries, either without pumping, or at very shallow depth below the surface, and therefore at a cheap cost, compared with Great Britain.

2. With regard to the second head, that the United States possess more extensive coal-fields than Great Britain, and that their competition in the future will become serious in our foreign markets, including the markets of the United States.

America produces coal of all qualities, and the coal-fields extend over an enormous district of country provided with excellent railway accommodation; the rivers also afford unusual facilities for the internal cheap conveyance of the minerals. The great drawback of the American coal-fields, and our chief safeguard in regard to their competition with us in foreign markets, is the great distance at which the important American coal-fields lie from the Atlantic sea-board.

Nevertheless, America has made rapid strides in the direction of competition with this country—(1) By the cheap construction of the railways, and (2) by the exceptionally low rates per ton per mile charged for the carriage of minerals. These rates are something like one-fourth of the current rate per ton per mile charged for similar traffic in this country. At present, coal from the neighbourhood of Pittsburgh is delivered on the Atlantic sea-board at a lower rate per ton than coal of a similar quality is sold F.O.B. in this country, yet the distance from Pittsburgh to the sea-board is about 300 miles, I believe, and the cost of carriage of coal, I am advised, does not exceed one dollar per ton.

The American anthracite coal of great purity is widely and successfully used for commercial purposes, and the carbonaceous steam coals are of a high class quality, but so far as the writer is informed, are not so hard and do not bear carriage so well as the best Welsh steam coal. Notwithstanding, however, our low cost of working and cheap sea transit of late years, we are beginning to feel the pressure in our distant markets of the American competition. This competition will not become less severe probably in the immediate future, but if the

time arrives that British coal becomes more permanently costly F.O.B., the American competition will assume serious proportions.

3. Upon the third point of the competition of the Russian and Chinese coal-fields.

Russia possesses coal-fields of at least three times the area of those of Great Britain, and is now beginning to develop her coal resources in the South near the Black Sea. The present supplies are applied chiefly to home consumption for household and manufacturing purposes. The Russian coal is of various qualities, and ranges from anthracite to highly bituminous. It is produced at the present day in some districts in the writer's knowledge at a lower cost per ton than is the average cost of working in this country.

The distance of the Russian coal-fields from her sea-boards is greater than in Great Britain, and we have thus, as in the case of America, more or less of a safeguard, so far as competition with us in foreign markets is concerned, but the much greater coal-fields of China are now on the point of being more or less extensively developed. The extent is variously estimated, but it is probable that the Chinese coal-fields extend over a surface area equal in area to the American coal-fields, and there are reasons for believing that in the neighbourhood of the Gulf of Pe-chi-l collieries will come into working operations within a short period. This part of the Chinese field is believed to contain coals of good quality for navigation and manufacturing purposes, and is comparatively near the sea-board. The large coal-fields of Central China may not be developed so rapidly, but it may be noted that although distant from the sea board, yet the facilities for transit afforded by the large navigable rivers and cheap labour reduce the effect of this distance immensely, and the carriage from these inland coal-fields will probably represent a moderate cost. Besides, for internal consumption, provided the coal is good and worked cheaply, the distance to the sea-board is not so important.

The cheap labour available in China, and the shallow depths from which their coal will be worked, indicate that the Chinese coal will be delivered at the sea-board at such a low cost as will enable that country to compete with all other countries for the trade of the Eastern hemisphere. We have therefore, undoubtedly to anticipate very keen competition in the future, so far as our markets in that region are concerned, for many descriptions of manufactured goods and for coal.

the mercantile marine which frequent the Eastern seas.

The conditions prevailing in these principal foreign coal-fields are, therefore, in the direction of cheapening the production of coal; whilst in this country the tendency of the conditions is to increase the cost of working coal, and unless we can ultimately do something material to check this increase of cost, a time will arrive—the author thinks in half a century at the latest—when as a nation we shall have to face the probability of our manufacturing position being rapidly effaced in consequence of the dearness in cost of the fuel we have to employ in our various manufacturing processes, and in the supplying of our mercantile marine as compared with the cheapness of the coal used by our competitors.

Then, with regard to Germany and Belgium. These two countries are our chief manufacturing competitors in Europe. The German coal-fields are less in extent than our own, and the average qualities of their coals is possibly somewhat inferior compared with the best of our coals, yet Germany, by reducing the cost of carriage on her State railways to less than half the rate per ton per mile charged in this country, has been able to develop a large and increasing home and foreign coal trade from her principal coal-fields in Westphalia. As time goes on, however, difficulties will arise in Germany as well as in Belgium from increasing depths, and they will be of the same character as those we shall have to contend with in Great Britain. Germany and Belgium will, however, be probably in a worse position than we are, because they have already reduced their rates of carriage to a minimum, or hereabouts.

To Germany and Belgium the industrial competition of America and China will therefore be of the most serious import. Germany, however, is not as dependent on her coal for her maintenance and prosperity as we are on ours. The area of Germany is large, and her soil is more productive, and will feed a much larger population than the soil of Great Britain can support. Reviewing the whole question, this country is exceedingly well placed with regard to the distribution of her coal-fields, situated as they are generally near the sea-board, and possess coals of exceptional quality; so long, therefore, as our high-class fuels are producible at a moderate cost, we shall, provided we retain our maritime supremacy, in all probability remain in a flourishing commercial position, so far, at any rate, as

physical conditions affect the question of the cost of producing coal. In regard, however, to our internal means of communication, although a very comprehensive system of railways has been established for the accommodation of the enormous traffic of this country, the rates charged for transit as compared with those current in America, Germany and Belgium, especially for minerals, are exceptionally high, about four times the American rate per ton per mile, and twice the rates charged by Germany and Belgium. But notwithstanding this fact, by reason of our nearness to our home markets and to the sea-board, so long as our best coal remains unexhausted, at a moderate depth and cost, we shall probably be able to hold our position in the markets of the world with our manufactures.

But as the writer has suggested, in half a century from the present time conditions will become unfavourable for the production of cheap coal, and the problem he wishes to discuss is the nature of the remedial measures, if any, which it may be practicable to adopt to enable that half-century of probable prosperity being extended to two to three centuries.

If from the national point of view it was considered essential that the nation should possess all the turnpike roads in the country, how much more is it necessary that the nation should possess the railways, which are the far more important means of internal communication? Unfortunately, no provision was made for the State-building of the railways, although power was obtained in 1844 by means of which they can be purchased by the State, I believe, at any time. The railways have been constructed by private enterprise at an enormous cost, due to various causes; the annual net revenue, however, under existing conditions is something like £40,000,000 per annum, and in 30 to 40 years the net income will probably have increased to at least £50,000,000 per annum.

To this should be added the enormous loss by reason of the present system of management, the unsuitability of the rolling stock for economical working, and unnecessary competition involving the running of trains with inadequate loads, &c. Probably, the income of the railways of Great Britain, if they were in one hand, and the management organised on different lines, would represent an annual net revenue in 30 to 40 years time of £60,000,000.

Now, if this fund of £60,000,000 per annum or such part of it as becomes necessary were available to be drawn upon; that is to say, if

the railway rates for all classes of minerals, goods and passengers were reduced decade by decade to counteract the general effects of the increased cost of producing the minerals, we should be able to utilise the whole of our existing coal resources under practically as favourable conditions as we shall utilise the best and cheapest of our coal resources during the next fifty years.

FUTURE OF COAL.

It may be contended that at some period in the future a successful substitute for coal may be discovered, but we must bear in mind the extreme cheapness of coal and the possibility of so economising its consumption, that $2\frac{1}{2}$ lbs. of coal per hour will produce one horse-power on the average, equal if coal is valued at 7s. per ton to one horse-power for 10 hours per day for 1d. It does not, therefore, appear probable that a substitute of equal power is likely to be discovered at anything approaching such a cost, and what will happen as coal becomes dearer in this country, will be a gradual transference of the manufacturing operations which supply the world to countries where the cheapest coal is produced.

It further follows that so long as cheap coal can be worked in this country, the demand for it will continue to increase until at all events all the moderately deep coal areas available in Great Britain are occupied, and it may, it is suggested, be assumed that before the whole of those areas are occupied the output of coal, now slightly over 200,000,000 tons per annum, will be increased to 250,000,000 tons per annum.

And now as to the vexed question of our expensive means of internal communication in this country. It would appear that if during the next half-century the nation is spared international difficulties, such as a great war, we may expect to enjoy a most prosperous period in our manufacturing industries owing to the large supply of cheap and good coal. With markets in our widely-spread colonial empire, our position will remain unique, and if during that period something can be done to counteract fully, or even partially, the increasing cost of producing coal which will inevitably subsequently arrive, then the nation will be in a condition to maintain its existing commercial prosperity, so far as cheap coal is concerned, for centuries. But having regard to the long period during which this prosperity may be expected to prevail, and the economical conditions under which the nation

may exist, other favourable conditions may be created such as that of becoming the home of the finer industries, involving the employment of much labour and less fuel. This country may also become populous as a residential country, and, as it is the centre of a great empire, cheap coal supplies may in the far distant future become less of an urgent necessity.

The direction in which relief is to be found is the cheapening of our internal communications, and the reduction of our rates and taxes. Now the only mode of doing this appears to the author to be the repayment during the next half-century or thereabouts of the whole of the capital outlay of this country in railways, docks, sanitation, water, and other public workings.

It is obvious that the nation, in paying off the National Debt at a substantial rate, is providing in some degree for the relief of future generations, but whilst the repayment of this debt is of undoubted importance from the point of view of relief to our successors, and in providing a fund from which we can obtain loans for carrying on warfare, it may be observed that the permanent relief to the nation by paying off the whole of this debt will be about £25,000,000 per annum, an annual amount which has been swallowed up during the last few years in increased annual national expenditure. Assuming that by means of the repayment of the National Debt the annual expenditure to maintain our Army, Navy, and Civil Services, and Education, is reduced to under £100,000,000, how can even this enormous revenue be obtained if our commercial supremacy were to disappear owing to our country possessing cheap fuel?

Would it not be more prudent and far-seeing to apply the funds now devoted to repaying the capital of the National Debt to the acquisition for the State of our railways &c. From the revenue obtained, complete the repayment of the National Debt capital, during the considerable period, probably of a century after obtaining possession, when it would only be necessary to reduce the charges on our railways by a certain proportion only, still leaving a large revenue from the railways, plus the economies which would be secured in working them as one undertaking.

In this way the continued prosperity of the nation would be secured, as well as a fund be created, available for repayment of what may then remain of the National Debt capital.

Upon the assumption that the capital outlay upon railways and docks, and the local charge

for interest on loans for sanitation, water, &c., had ceased, rates and taxes would be reduced to a minimum, and ultimately, as the necessities of the commerce of the country required, the cost of travelling and the rates chargeable for goods, minerals, and live stock could be gradually from time to time lowered, until these charges are reduced to the bare working expenses.

This operation, if carried out, would have the effect of materially reducing the cost of living, food, and clothing, rent would be less costly, and labour would probably become much cheaper.

The whole of the indebtedness of this country for railways, docks, drainage, and water, and lighting may be estimated approximately at 1,500 millions of money (of these the first four mentioned are in private hands, the others are owned mainly by public bodies); if the interest upon this money were to cease, it would relieve the nation by at least £60,000,000 per annum, and this upon 250,000,000 tons of coal represents an amount which would more than counteract any increase in the cost of coal due to natural causes alone, until the practical exhaustion of our coal supplies.

If, however, this enormous capital is allowed to remain until the prosperous period of low cost of coal passes by, it would not be practicable to reimburse this capital, and the amount remaining unliquidated would become lost, and so cause widespread ruin to individual shareholders as well as to the nation.

What is suggested, therefore, as regards the railways is:—

1. That either the reversion of the railways should be purchased by the Government, taking effect at the end of say 50 years, and that afterwards the railways be worked under Government control, with such reductions in rates as the conditions of trade require, or

2. That the railway companies should be compelled by legislation to provide a sinking fund annually sufficient, at compound interest, to replace the whole of the capital which they have already created, or may create before the end of a period which the Legislature may fix after full inquiry. Part of the investigation would involve an inquiry as to how the amount of the sinking fund is to be obtained.

In the second event, at the end of the period, either the working of the railways should be taken over by Government or continued in private hands, subject to Governmental regulation, and absolute power to the State of reducing rates from time to time, and the surplus revenue, if

any, during the earlier period when the increased cost of coal would not be so heavy, beyond the working cost, could be apportioned between the railway companies and the Imperial Revenue as might be decided.

A similar proposal might apply to docks, and modified conditions to the trading investments of municipalities. The compulsory repayment within a given period of the capital invested in lighting, water and drainage, would afford facilities for reduction in rates and taxes in those municipalities in which the capital had been repaid.

Now, the fact is undoubted that the cost of working coal will gradually increase owing to natural causes alone, and that the increase will begin to affect the industrial power of the nation seriously in half a century or thereabouts.

It is also a fact that there will still exist at that time large coal resources equal to more than a couple of centuries on a consumption of 250,000,000 tons per annum, or 25 per cent. more than the present annual output.

Are we to lose by neglect the profitable use of this enormous annual wealth, or shall we in time take such measures as will enable us to continue to utilise it? That the emergency will arrive cannot be gainsaid; the remedy, if a remedy can be found, is open to argument and inquiry: but the present is the time to make the investigation, and not when the actual contingency is at our doors. It is no answer to urge that our successors can take care of themselves. They will not have created the capital or had the benefit of the use of the capital, but if left to them unliquidated, it will weigh as a millstone around their necks.

Finally, I may glance at the objections which have been raised to the adoption of the suggestion advocated by the writer, viz., of paying off the nation's indebtedness in railways, docks, waterworks and gasworks, sanitary and other capital outlays, during the period when the production of the cheapest and best of our coal resources secure to the nation a commercial prosperity which cannot be hoped for after the exhaustion of the best of our coal resources.

The chief of these objections are:—(1) That science, before the expiration of 50 years may discover some efficient substitute for coal; (2) that the State purchase of the railways will place too much patronage and power under Government control; (3) that the railways will not be efficiently managed under State control; and (4) that the altered conditions

under which the nations compete commercially 50 years hence may be so changed as to render the possession of coal-fields not necessarily of paramount value.

Objections 1 and 4 may be considered together. To refuse to face the position in the hope that something may happen within the 50 years is tantamount to hiding our heads in the sand, and waiting for something to turn up. If some discovery of science provided an effectual substitute for coal, however improbable, we should not in Great Britain have a monopoly of such substitute, but should have all the civilised nations competing with us. How infinitely stronger our national position for such competition would be if transport and inland communication by reason of the repayment of the capital value of our railways have been effected, was reduced by one half of what it is to-day, and our rates and taxes, by reason of the repayment of our municipal loans reduced to a minimum.

It would appear to the writer essential, whether we look at the question from the point of view of extending the period of the profitable working of our remaining coal resources, or from the point of view that at a certain period an efficient substitute for coal will be found, that the clearing off of the national liabilities, in means of communication, during the nation's prosperous period, would not only be the soundest of policies, but the only reasonable and prudent course to adopt. A prudent individual providing for his successors would undoubtedly adopt such a line of conduct, and if to an individual it is desirable, surely it is of paramount importance to a great nation to follow a prudent policy.

Then as to objection No. 2, that the State purchase of railways will place too much patronage and power in the hands of Government. I am aware and appreciate the serious objections to the course suggested from a political point of view; but the question whether we as a nation are to collapse financially in half a century, or continue to maintain our position for centuries, is altogether too serious to become the catspaw of any political party. If, however, the result sought of enabling the nation to reduce the cost of travelling and transit of goods and minerals by one half, when required after half a century, and a reduction in rates and taxes, can be equally well secured without the State purchase of the railways, then I should be content. The wit of our politicians surely can find some solution outside party politics of preventing the control

of so many voters being used for party or Government purposes.

Possibly one way out of the difficulty is that suggested, by compelling the railway companies to fund a portion of their income to repay their capital in from fifty to seventy years, the State being able to control absolutely permanent reductions of rates of carriage from the end of fifty years. This reduction would, as previously explained, be necessarily gradual, and only reach the minimum of the bare cost of working and management at a period considerably later than fifty years. If the course last-named were adopted, it would meet the third objection previously mentioned—that the railways will not be efficiently managed under State control.

I have now placed before you the problem of our coal supplies. The total supplies at the present and prospective rate of out-put will last probably three centuries, but the cheapest will only last half a century. That if we do not during that period of 50 years provide in some way to meet the gradually but steadily increasing cost of our coal, after 50 years, owing to natural causes, we shall be unable to compete successfully with America and the East, and it must follow that our commercial supremacy will disappear, whilst, it is suggested, if the capital value of our railways and other works were paid off in the 50 years and the cost of travelling and transit of minerals reduced by one-half, the increased cost of our coal, due to natural causes, would be practically neutralised, and the nation would be able to hold its own so long at all events as the coal resources of the country endured.

Is this not a question worth the serious present consideration of politicians and the nation although the actual emergency may be approximately half a century hence?

If the remedial measures suggested are inapplicable, or if other measures are preferable we ought to tackle them. The subject is worth investigation even if no practical remedy can be found; it would be only prudent to face the difficulty, with a full knowledge of what we may expect as the future prospects of our country.

DISCUSSION.

The CHAIRMAN said there was no doubt that the amount of coal in this country was limited and well ascertained, and it was equally well known that the

were other areas outside of England where there were large stores of coal, partly in America and in China, and he might add to those, another country which had not been alluded to, Australia. He could not say exactly how many square miles of coal there were there but he knew from his own observation that there were not less than 39,000 square miles of productive coal measures, containing seams more than 2 feet thick in New South Wales, and extending indefinitely northwards far into Queensland, and westward past the Blue Mountains region, into the centre of Australia. He did not accept the definition of an Englishman as being confined to dwellers in the small island which was called England; we were inheritors not merely of old England or of new England, but of that greater England, of which Australia formed so important a part. It was a remarkable thing that the English race had managed to get hold of the greater part of the more productive coal areas of the world. First of all taking America, not merely in the United States, but in the far west of the Canadian dominion, on the eastern side of the Rocky Mountains, there was a vast tract of available coal measures verging on the margin of these mountains into the most valuable anthracite seams which would be a great source of wealth in the future. And right away to the north, almost as far as the Arctic Sea, following the Mackenzie River, there was evidence of this great coal-field, which was part of the heritage of the English race. He might also mention Borneo and the great coal-field in South Africa as yet undefined. While therefore he felt that the time must come when the supremacy of this small island must yield to some other community in some other region, he felt that on all probability that community would still be English. It would belong to the English race. England was called England because the English came over, found it an admirable place to live in, conquered it, and took it. What our ancestors did in coming to this country, we their descendants were doing at the present time in other countries: they were planting a greater England almost all over the world. He did not, therefore, fear in the least that the power of the English race would diminish. He looked forward to its commercial supremacy as being assured, though he admitted that England could not continue to be the great centre of the production of coal for more than 50 or it might be 200 years hence. Still, we need not lose our commercial supremacy. If we did not get our coal in Great Britain, we could get it in various parts of the world. He had not made any allusion to China, but he could not help thinking that when this scramble for China was over, it would be found that the stupid Briton (as he was sometimes called) had got hold of the corner lots, just as he had done over and over again before. With regard to the proposed remedies, he should be much interested in hearing the discussion; but it seemed to him that the remedy of cheapening transport

was a very difficult one to apply. He did not think it would be possible to induce politicians to undertake the enormous responsibility of buying up the railways and all the municipal enterprises; and, on the other hand, he did not think the railways, except under compulsion, would reduce their rates. It would be impossible to do so under present circumstances, except at the cost of the shareholders, and therefore he saw enormous practical difficulties in that direction. Nevertheless, they owed their thanks to Mr. Brown for the admirable manner in which he had put this subject before them. Besides the question of the duration of the coal, there was the question whether there was any possibility of any other power, such as electricity, derived from water or some other source, to some extent replacing coal. The figure, based on the statement that a horse-power cost 1d. per day of ten hours, worked out to £3 13s. per annum; and it was a curious fact that the cost of an electrical horse-power ranged between £3 and £5. If you added the cost of the machinery by which the coal was converted into power, that would add considerably to the £3 13s., so that it would come to a figure probably greater than that of electrical horse-power generated by water.

Professor HULL, F.R.S., said there could be no question about the rapid exhaustion of the coal-fields. It was 1860 or thereabouts when he first undertook to make a calculation of the quantity of coal then existing in our coal-fields to a depth of 4,000 feet. At that time the output only amounted to about 60,000,000 or 65,000,000 tons per annum, and on that basis he came to the conclusion that our coal would last for 1,000 years. That was very satisfactory, and he and the rest of the community went comfortably to sleep about it, thinking there was plenty of time to deal with the matter later on. As time rolled on, however, the output of the collieries had rapidly increased, and now, as Mr. Forster Brown had said, our children or grandchildren might be brought face to face with a very important crisis in their commercial and manufacturing history—not the exhaustion of the coal, but the increase of its cost to such an extent that they would be handicapped with regard to manufactures compared with other countries. He did not see any possible escape from that position. In a longer or shorter period the cost of coal would be increased to such an extent that our mills and factories could not possibly be worked with the same economy as at present. There were only two ways in which the difficulty could be met. Either there must be a general decrease in wages, which no one would say was either desirable or practicable, or else manufactures must be reduced, and other countries would be able to compete in the production of cottons and other commodities, in which we at present held such an important position. He agreed with the Chairman in the wide view he took of this subject, that the centre of gravity of future manufactures and commerce must move either towards the west or

towards the south and east to Australia, or perhaps China. There were in China coal-fields of prodigious extent, as had been first shown by Baron von Richthofen and established by more recent surveys. If in the partition of China we got the lion's share and kept a sharp look out for those districts bordering the valleys of the great rivers where the coal-fields existed—recollecting that there were millions of inhabitants who would work for 3d. or 6d. a day, and do as much work as one got for 5s. or 6s. in this country—we might have manufactories established in China under British control which would vie with any in the world. It was said by some very sanguine people that when the coal became exhausted, or too expensive, some other motive power would be found; but they had been looking for it for a long time in vain. Some looked to electricity, but all the electricity generated at present in places like London or Manchester had to be provided by motive power derived from coal. Of course there was petroleum, but all the petroleum introduced into this country would be a mere fleabite compared with the coal supply. We had no Niagara in this country; if we had one in the North of England, we might set up a gigantic electric-power station, and supply all the factories in the centre of England; but there was nothing of the kind, and we could not even utilise the water supply from the hills without taking it away from the large towns which were already competing for it. But even if we lost a great deal of our manufactures, it did not follow that we should not remain the centre of commerce. Holland was a little kingdom which did not possess one ton of coal of its own, and yet not very long ago it was the greatest centre of commerce in the world.

Mr. ALEXANDER SIEMENS said the arguments brought forward in the paper were all based on the assumption that the manufactures of Great Britain depended in the main on cheap coal. At last year's meeting of the British Association, he read a paper on the cheap distribution of power, and put forward some figures which he could not now remember exactly; but he showed that in their works at Woolwich one quarter of the cost of power was due to coal, one quarter to labour, and one-half to fixed charges, interest, and depreciation. From that it could be seen at once that the cost of fuel was not so all-important as had been supposed. Of course, cheap fuel was an important factor, but it had not the overwhelming importance which Mr. Forster Brown sought to make out. He also referred to other countries, which he said had large coal-fields and cheap labour, and were therefore bound in future to cut out Great Britain altogether. They might do that if everything remained the same as at present, but it would not. When the coal-pits of Great Britain had to be sunk deeper, a great many more mechanical appliances would be used, and in spite of what Mr. Forster Brown, said he had full con-

fidence that by using mechanical means the cost of coal would not be increased to such a degree as he feared. At present in foreign countries, coal-cutting machinery was very much more employed than it was in Great Britain. One great factor in the cheapening of coal was already applied to foreign countries, and still Great Britain was able to undersell them, though using the primitive means of hand labour; and therefore British coal owners would wake up to the fact that by applying machinery, they could cheapen coal instead of increasing its cost, even if they had to fetch it from a greater depth. It was true also that in China at present people were content to work for 3d. or 6d. a day, but when they came more in contact with civilisation their wants would increase; that was the effect, and a very good effect too, of civilisation and they would not then work for 3d. or 6d. a day. Great Britain's coal-fields of 9,000 square miles had to serve for 40,000,000 people, the Chinese coal-fields were four times as large, but they had to provide for 400,000,000 people, or more; and when all these people woke up and wanted a good deal more than 6d. a day, they would want all their coal at home. He anticipated that the price of coal would go up everywhere, so that the advantages and disadvantages of the various nations would remain very much in the same proportion as at the present time, and he did not believe that in fifty years Great Britain would all of a sudden find herself incapable of manufacturing. The more civilisation spread, and the more communication was increased, the more equal all nations became, and their relative importance depended on their natural resources at their disposal. As Mr. Brown himself said, England, as regards coal, was placed extremely well; and, as Professor Hull remarked, was the same with regard to commerce. On the whole, therefore, he could not accept the gloomy picture which had been drawn of Great Britain in fifty years' time. Mechanical improvements were not so ineffective as had been represented, and Great Britain would still be able to keep the place she now occupied amongst the nations of the world.

Mr. A. O. GRANGER said Mr. Siemens's argument would be all right if the coal of other nations had been mined to the same extent as that of Great Britain, but what impressed him in travelling here was the deep coal mining was so prevalent, while in the United States, particularly in Ohio, Kentucky, Tennessee, and Alabama, where there was a coal field 1,000 miles in length, and of an average width of at least 50 miles, the average depth was practical above the water level, with veins of coal from 2 feet up to 6 feet or 8 feet in thickness. That offered an enormous future for cheap coal. They were accustomed to believe that commercial supremacy was closely connected with cheap coal. The southern parts of the United States would, he believed, be the centre of the coming empire, as it had not only cheap coal, but also cheap iron.

Mr. T. R. GAINSFORD said Professor Hull remarked that he did not know of any possible substitute for coal as a means of producing electricity in this country, but he would remind him that an important private Bill in Parliament this Session was one for utilising the water in the Highlands of Scotland for the generation of electricity, and it was not at all unlikely that that Bill would become law this year.

Professor HULL said his observation did not apply to Scotland.

Mr. FORSTER BROWN, in reply, said he did not mention Australia because it was an isolated continent, and, although it possessed large coal-fields, did not appear likely to be a serious competitor at present with England. It was suggested that instead of trying to make this country last a little longer, the centre of gravity should be removed somewhere else, but although the Anglo-Saxon race might hold the coal-fields of a distant country, it would not be quite the same as Great Britain. His idea was to suggest a way by which the home country, which they knew and loved, should be maintained for practically an indefinite period. That was why he put the position so strongly, and did not refer to the fact that the Anglo-Saxon race was likely, in America or elsewhere, to occupy the most valuable coal portions of the world. He wanted to see if there was any way by which Great Britain herself should still be maintained as the centre. With regard to a new source of power, no doubt if we could have a Niagara, or could utilise the falls of water in the Highlands, or anywhere else, we might get power; or we might get power from the waves; but his point was that having regard to the position of our coal-fields, we could not get power, broadly, to supply the commerce of the nation, except from cheap coal. Professor Hull suggested they might do without coal, and quoted the case of Holland; but when Holland was a great country, traffic on the seas was accomplished by means of sails; now it was by steam, and you must have cheap coal to insure maritime supremacy. He thought Mr. Siemens sailed round the question a good deal. All economy in the consumption of coal extended its use. Twenty-five, thirty, or forty years ago, a much larger proportion of coal was used in every kind of manufacture than is at present; but if you reduced the proportion to a minimum, and if your neighbour could supply that minimum at half the cost, other things being equal, your neighbour would take away your trade. Although, in certain industries, the proportion of coal used was small, the industries in this country were not confined to one or two things, and some of them, such as the production of pig-iron in blast furnaces, required a large consumption of fuel; it was not simply a question of horse-power. The proposal would enable the cost of labour and living to be reduced, thus reducing the cost of the part of manufacturing not applicable to fuel. It was suggested that there would be ways of getting over the difficulties of

deep working and so on. In a paper which he read at the British Association at Bristol, he had dealt with this part of the subject, and he did not think it wise to refer to it again; but whatever sort of machinery you used and however economical it might be, it would be less costly to obtain coal from a 6 ft. seam than from one of only 2 ft. With regard to temperature, he did not see how it was practicable to get over the natural increase of temperature due to the depth; it must increase the cost. The point of his paper was that it was possible by a little forbearance by buying the railways instead of paying off the National Debt, to extend the period of national prosperity by two to three hundred years. The other alternative seemed to assume there was nothing for it if his figures were correct than to see our prosperity come to an end in fifty or sixty years, or whatever the time might be. He did not think that was what Englishmen ought to do if, as he had pointed out, a far better course was practicable.

The CHAIRMAN then proposed a cordial vote of thanks to Mr. Forster Brown, which was carried unanimously.

Obituary.

C. WASHINGTON EVES, C.M.G.—Mr. Charles Washington Eves, who had been a member of the Society of Arts since 1887, died suddenly at his residence in Highbury New-park, on the 20th inst. He was born in 1838, and was educated in London, at St. Omer, and Bonn. He was long identified with the affairs of the West Indies. He acted as Hon. Commissioner for Jamaica at the Colonial and Indian Exhibition in 1886, and represented the colony at the Colonial Conference in 1887. He was chairman of the London Committee of the Jamaica Exhibition in 1891. He was a member of the Executive Council of Imperial Institute, and Hon. Colonel of the 1st Middlesex (Victoria and St. George's) Rifles. He read a paper on Jamaica and its forthcoming Exhibition before the Foreign and Colonial Section of the Society, on May 15th, 1890, and he took the chair at the meeting in December, 1896, when Mr. Frank Cundall read a paper on "Jamaica in the Past and Present."

General Notes.

ROMAN BUILDINGS.—The building trades special number of the *Illustrated Carpenter and Builder* (April 21st) contains an article on the "High Buildings of the Ancients," in which the discovery made by Professor Lanciani, that there were building laws in Rome before the Christian era, is alluded to.

There are frequent references by the Roman historians, orators, and poets, to the enormous height of the tenement buildings of Rome. In the reign of Augustus, a law was promulgated by the Senate which fixed the height of new structures at 60 feet on the street front, without making any allusion to the height in the rear, and in consequence these tenement buildings often rose several storeys higher in the rear than in the front. The number of storeys on the street front of some of these buildings were from ten to twelve, with fourteen or fifteen in the rear. The height of these Roman buildings was entirely irrespective of the width of the street.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

MAY 3.—“Ætheric Telegraphy.” By W. H. PREECE, C.B., F.R.S.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock:—

MAY 2.—Mr. Burton's paper on “Maiolica,” announced for this evening, is unavoidably postponed.

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

PROF. HENRY R. PROCTER, F.I.C., “Leather Manufacture.” Four Lectures.

LECTURE III.—MAY 1.

Physics of tanning—Theory of the pickling process—Mineral tannages—Tawing with alumina salts—Chrome tanning—Heinzerling process—Schultz or “two-bath” process—Basic or “one-bath” process—Iron tanning.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 1 ... SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Cantor Lectures.) Prof. Henry R. Procter, “Leather Manufacture.” (Lecture III.)

Royal Institution, Albemarle-street, W., 5 p.m. Annual General Meeting.

Engineers, in the Theatre of the United Service Institution, Whitehall, S.W., 7½ p.m. Mr. James D. Roots, “Petroleum Motor Vehicles.”

British Architects, 9, Conduit-street, W., 8 p.m. Annual General Meeting.

Victoria Institute, 8, Adelphi-terrace, W.C., 8 p.m. Prof. T. McK. Hughes, “Nationality.”

TUESDAY, MAY 2...Royal Institution, Albemarle-street W., 3 p.m. Prof. Silvanus P. Thompson, “Electric Eddy-Currents.” (Lecture I.)

Central Chamber of Agriculture (at the House of THE SOCIETY OF ARTS), 11 a.m.

Pathological, 20, Hanover-square, W., 8½ p.m.

Biblical Archaeology, 37, Great Russell-street, W.C., 8 p.m.

Zoological, 3, Hanover-square, W., 8½ p.m. 1. Dr. F. Ameghino, “Sur le Type primitif des Mollusques pléxodontes des Mammifères.” 2. Mr. W. E. de Winton, “Notes on Chinese Mammals, principally from the Western Province of Szechuen.” 3. Mr. Edgar A. Smith, “A Collection of Land-Shellfish from British Central Africa.”

WEDNESDAY, MAY 3...SOCIETY OF ARTS, John-street, W.C., 8 p.m. Mr. W. H. Preece, “Ætheric Telegraphy.”

United Service Institution, Whitehall, S.W., 3 p.m. Sir Richard Temple, “The Strategic Relation of Persia to British Interests.”

Archæological Association 32, Sackville-street, W., 4½ p.m. Annual Meeting.

Obstetrical, 20, Hanover-square, W., 8 p.m.

North-East Coast Institute of Engineers and Ship-builders, Westgate road, Newcastle-upon-Tyne, 7½ p.m. 1. Discussion on Mr. E. C. Chaston's paper, “The Manufacture of Shafting for Screw Steamers,” and Mr. F. Claws's paper, “The Increasing frequency of Failure of Propeller Shaft.” 2. W. E. Cowens, “Shop and General Establishment Charges in Engineering Works, and their Relation to Costs and Estimates.”

THURSDAY, MAY 4. Royal, Burlington-house, W., 4½ p.m.

Antiquaries, Burlington-house, W., 8½ p.m.

Linnean, Burlington-house, W., 8 p.m. 1. Mr. F. G. Parsons, “The Position of Anomalurus as indicated by its Myology.” 2. Miss Ethel S. Barton, “Nothcia anomala, Harv. et Bail.” 3. Mr. G. S. West, “Variation in the Desmidia.”

Chemical, Burlington-house, W., 8 p.m. 1. Messrs. H. B. Dixon and E. J. Russell, “The Combustion of Carbon Disulphide.” 2. Messrs. H. B. Dixon and J. D. Peterkin, “The Action of Nitric Oxide or Nitrogen Peroxide.” 3. Mr. H. B. Dixon, “The Mode of Burning of Carbon.” 4. Messrs. Henry J. Horstman Fenton and Henry Jackson, “Crystalline Glycollic Aldehyde.” 5. Messrs. Orm Masson and B. D. Steele, “The Blue Salt of Fehling's Solution and other Cupro-tartrates.” 6. Dr. S. B. Schryver, “The Preparation of Acid Phenolic Salts of Dibasic Acids.” 7. Mr. B. W. Allen, “The Maximum Pressure of Naphthalen Vapour.”

Royal Institution, Albemarle-street, W., 3 p.m. Mr. Lewis F. Day, “Embroidery.” (Lecture I.)

Electrical Engineers (at the House of THE SOCIETY OF ARTS), 8 p.m. Mr. P. V. McMahon, “Electric Locomotives in Practice and Tractive Resistance to Tunnels, with Notes on Electric Locomotive Design.”

Iron and Steel Institute, 25, Great George-street, S.W., 10½ a.m. Annual Meeting. 1. Presidential Address. 2. Reading of papers and discussions.

FRIDAY, MAY 5...Royal Institution, Albemarle-street, W., 3 p.m., Weekly Meeting, 9 p.m., Dr. W. J. Russell, “Pictures produced on Photographic Plates in the Dark.”

Iron and Steel Institute, 25, Great George-street, S.W., 10½ a.m. Annual Meeting. Paper and discussions continued.

Geologists' Association, University College, W.C., 8 p.m.

Junior Engineering, Westminster Palace-hotel, S.W., 8 p.m. Mr. W. H. Owston, “Gun Construction.”

Quekett Microscopical Club, 20, Hanover-square, W.C., 8 p.m.

SATURDAY, MAY 6...Royal Institution, Albemarle-street, W., 3 p.m. Mr. W. L. Brown, “To Iceland in Search of Health.” (Lecture I.)

Journal of the Society of Arts.

NO. 2,424. VOL. XLVII.

FRIDAY, MAY 5, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

CONVERSAZIONE.

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors, and the Lecture Room.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

CANTOR LECTURES.

On Monday evening, 1st instant, Professor HENRY R. PROCTER, F.I.C., delivered the third lecture of his course on "Leather Manufacture."

The lectures will be published in the *Journal* during the summer recess.

PRACTICAL EXAMINATIONS IN MUSIC.

The Practical Examinations in Vocal and Instrumental Music will be conducted by Mr. John Farmer, Balliol College, Oxford, and Director of the Harrow Music School, Examiner, and Mr. Ernest Walker, M.A., Mus.Doc., Oxon, and Mr. Burnham Horner, Assistant Examiners, at the House of the Society, and will commence on Monday, 26th June.

The last day for receiving applications is Saturday, 12th May.

Particulars can be obtained on application to the Secretary.

Proceedings of the Society.

NINETEENTH ORDINARY MEETING.

Wednesday, May 3, 1899; Sir JULAND DANVERS, K.C.S.I., in the chair.

The following candidates were proposed for election as members of the Society:—

Chatterjee, Sasi Bhusan, 8, Dixon's-lane, Calcutta.
Cunningham, Sir William John, K.C.S.I., East India United Service Club, 16, St. James's-square, S.W.

Johnston, J. Lawson, Kingswood, Sydenham-hill, S.E.

The following candidates were balloted for and duly elected members of the Society:—

Greene, Frank Arnold, 22, Martin's-lane, Cannon-street, E.C.

Hall, John Slocombe, 45, Chatsworth-road, Brondesbury, N.W.

Molloy, Harry J., care of Messrs. W. Watson and Co., 7, Waterloo-place, S.W.

Pakenham-Mahon, Captain Henry, D.L., 35, St. George's-road, Eccleston-square, S.W., and Strokestown, Ireland.

Wiseman, William Thomas, Cromwell-house, 160, Stockwell-park-road, S.W.

The paper read was—

ÆTHERIC TELEGRAPHY.

By W. H. PREECE, C.B., F.R.S.

On the 21st of February, 1894, I read a paper in this room on "Electric Signalling without Wires," in which I attempted to show how at that time "we were gradually by patient

plodding creeping along towards the period when I hope we shall be able to make real practical use of electro-magnetic disturbances." To-night I purpose to show you that we have attained that object. The experimental stage in wireless telegraphy had been passed in 1894 and we were then entering the commercial stage. I said in that paper: "The conditions are now so clear that given the localities between which it is desirable to communicate it is a mere matter of calculation to show what has to be done. It would be quite easy to speak between France and England across the Straits of Dover."

In March, 1895, the cable connecting the Island of Mull with the mainland was broken, and as some time might elapse before the repairing ship could reach the locality communication was set up with that island by my system of ætheric telegraphy. A gutta-percha covered copper wire, $1\frac{1}{2}$ miles long, was specially laid along the Argyllshire coast, and the ordinary iron wire connecting Craignure and Aros in Mull was used. The mean distance separating the two wires was about three miles. There was no difficulty in communicating. Public and Press messages were regularly transmitted until the cable was repaired. It created as much sensation at the time as Mr. Marconi's recent experiments from Dover to Boulogne have excited during the past week or two. Signalling through space without wires became a practical operation.

In 1896 a cable was laid for the War Department from Lavernock near Cardiff to the island of Flatholm in the Bristol channel. There are two important forts protecting the channel at these two points. The cable crossed a very much frequented route and an anchorage ground. It was speedily broken. The communication being very necessary, the cable was replaced early in 1898 by an ætheric telegraph, and since that time to the present day this communication has been maintained uninterruptedly, and is in daily use by the soldiers who work it.

I will show you the principle on which it is worked. It is due to the formation of electro-magnetic waves of induction. These waves, as they rise and fall, set up electro-magnetic disturbances in conductors in their neighbourhood, and if these conductors form part of a telephone circuit, musical sounds are produced in the telephone if the disturbances are rhythmical. Vibrations of about 400 per second give the most pleasing and effective note, and when the note is broken up into

dots and dashes, messages can be sent by the Morse alphabet.

You will perceive how simply the thing works, but you will also learn how rapidly the effects observed diminish as the distance increases when we use coils. The law regulating this distance is very simple. Indeed, in practice, and when the distance between the coils is considerable compared with the diameter of the coils, the effect diminishes as the cube of the distance. The distance to which communication is possible by overhead wires across a channel is limited by the length of the wire on each side, and by the delicacy of the receiving apparatus.

Attention is called at Lavernock and Flatholm by a very ingenious invention of Mr. Sydney Evershed. The vibratory currents are not used to produce sound, but they set up at the distant station vibratory movements in two loops of fine wire oscillating in a strong magnetic field at the low frequency of 16 per second in opposite phases. When these loops are properly timed, and the vibrations have sufficient amplitude, they make contact, complete a local circuit, and ring a trembler-bell.

Professor Oliver Lodge has devised another mode of calling attention. He proposes to produce loud sounds by making the coil of the telephone vibratory, instead of using an iron diaphragm, and transmitting these vibrations directly to a sound-board. The magnetic field in which the coil vibrates is produced by a powerful horse-shoe magnet. The Post Office is going to give this new call a practical trial. It is hoped that it will develop into a new receiver.

I am by no means satisfied that we have reached finality in this form of ætheric telegraphy. There is vast room for improvement. We can increase the energy emitted at the sending end, we can enlarge the primary circuit by using heavier copper and increasing the size of the coil. We can vary the frequency of the currents and also the character of the receiving apparatus. Indeed, there is a potentiality of research and invention in this field for those who have leisure and inclination. If it had any serious commercial value before it it would doubtless be exploited by enterprising manufacturers. Perhaps unfortunately, I did not patent it, and I have therefore no financial interest in it. The Post Office up to the present have used it practically only twice. It failed to act through sea-water, owing to the rapid absorption of the energy by the sea, and therefore it failed to be useful for light-

ships; but in the mean time a new method of doing the same thing in another way has been devised by Mr. Marconi, which has created a great sensation and to which I must now refer.

Instead of using electro-magnetic waves of low frequency—400 per second—as I do, he uses Hertzian waves of very high frequency, probably of as many millions per second. He employs an ordinary induction coil such as is used to illuminate vacuum tubes or to excite Röntgen rays. The primary circuit contains an accumulator of 8 cells and a Morse key which can direct through it currents of long and short duration so as to form the Morse alphabet, as in ordinary telegraphy, to send messages. The secondary circuit ends in a radiator composed of two metallic spheres, between which sparks pass. One sphere is connected to the earth and the other to a vertical wire, whose length varies with the square root of the distance through which it is desirable to communicate. This wire is suspended by a pole or mast. Each spark is composed of extremely rapid oscillations of electricity, setting up those electric waves which are known as Hertzian, though they ought to be called Maxwellian, for it was Maxwell who indicated their existence while Hertz experimentally detected their presence and showed us how to measure them. By this apparatus every depression of the key causes rays of electric waves to be emitted through the æther in every direction from the radiator as long as the key is held down. Thus those electric waves are transmitted through space exactly in the same way as light waves, and they follow precisely the same laws. Messages flashed by the heliograph from the Himalayas to the plains are signalled in the same way and by the same medium as Marconi's messages across the Straits of Dover. The first recorded message from Agamemnon to Clytemnestra, announcing the fall of Troy, was sent by the same agency. There is nothing wonderful in this. The wonder is that these electric waves should be detected at great distances through all weathers and seasons, during day and night, and in spite of fog, and snow, and rain.

They are detected by a very simple apparatus. It is called a coherer, and it forms a telegraphic relay. A small glass tube, about $1\frac{1}{2}$ inches long, has inserted in it two silver pole-pieces which tightly fit the tube, but which are separated from each other by a space of about the fiftieth of one inch. This space is filled by a mixture of fine nickel and silver filings

with just a trace of mercury. The pole-pieces have wires attached to them which enable the tube to form part of a circuit and which are sealed in the tube when the latter has been exhausted. In its normal condition this metallic powder is virtually an insulator. The particles very slightly touch each other—so slightly that no current passes. They lie higgledy-piggledy, anyhow, in disorder. But let them be placed in an electric field, let electric waves pass through them: they are instantly “polarised;” they are installed in marshal array; their mutual contact is increased; they are subjected to pressure; they “cohere,” as Professor Oliver Lodge expresses it; they become a conductor, and an electric current passes if the coherer forms part of the circuit of a local battery. They will continue to act as a conductor until they are “decohered” or restored to their normal insulating condition by mechanical shaking. Mr. Marconi causes a small hammer to strike the glass by the very current the coherer has caused to pass. If the waves have ceased, the tube is instantly decohered. If the waves continue there is no apparent decoherence. This current can at the same time emit either a sound or record signals on paper by ink which in each case can be read. One side of the coherer is connected to a vertical collecting conductor similar to the transmitting conductor, and the other side is connected to the earth. The coherer is an extremely reliable instrument—stable and certain in its action. I have one given to me by Mr. Marconi in 1897 that has never failed to act. I am using it to-night.

It will be seen that the apparatus is characterised by extreme simplicity. The vertical conductor is common to the transmitter and the receiver. At each terminal there must be both transmitting and receiving apparatus, but the effect is improved if the receiving wire be thin and the transmitting wire thick. When signalling from A to B the vertical conductor at A becomes a wing of the radiator, while that at B is a wing of the coherer. The reverse takes place when signalling from B to A. The coherer is protected from the influence of its own radiator by being encased in an iron shield.

The rays can be directed in any given direction by parabolic reflection, but this is effective for only short distances, for a long vertical conductor cannot be used with reflectors. For long distances, tuning or syntonising is the most probable effective mode of securing secrecy;

but Mr. Marconi is still in the experimental stage in this branch of the subject. Syntony is attained when the transmitted impulses of a vibration recur in the same period as the natural period of vibration of the receiver, and thus increase the amplitude of its vibration. When we sing any particular note into a piano the strings of the piano emit only the same note that the voice sounded.

The vertical conductor is an essential feature of Mr. Marconi's system. It determines the distance to which signals can be transmitted. A conductor 20 feet high will signal well to a distance of a mile, 40 feet to 4 miles, 60 feet to 9 miles, 100 feet to 25 miles, and 120 feet to 36 miles. The height of the conductors used in the Boulogne experiment is 150 feet; those used between Alum Bay, in the Isle of Wight, and Poole, a distance of 18 miles, 80 feet high. The law as determined by experiment is this, that the distance increases as the product of two vertical conductors of different heights. This of course is the above law of the square when the lengths of the two conductors are alike.

The effects are distinctly best when signalling across the clear space covering the sea. The sea, like a sheet of metal, reflects these waves, but what does the irregular surface of the earth do? Mr. Marconi has obtained very satisfactory signals between positions which have been screened from each other by hills. French officers on board the *Ibis* at Sangatte, near Calais, on Monday succeeded in speaking to Wimereux, 20 miles away, over Cape Grisnez, a lofty promontory. We do not know at present much about the absorbing influence of the earth upon electric waves. There is room for experiment here. Indeed, the whole subject bristles with new fields for research. It is a misfortune that our physicists have done so little in this direction. Many of them seem to think that there is more importance in discovering priority of invention than in making an invention itself.

Mr. Marconi has been very busy in experimenting between the Isle of Wight and Bournemouth, and with moving ships in the Solent. He maintained communication between the Queen at Osborne House and the Prince of Wales on board the Royal Yacht *Osborne*. The proceedings of the yachts in the Kingstown regatta of July last year were signalled from a following steamer, and regularly printed every evening in the *Daily Express* of Dublin. Lloyd's signalling station at Rathlin Island, in the north of

Ireland, was placed in communication with Ballycastle. The two places are $7\frac{1}{2}$ miles apart. On the 27th March communication was made through a distance of 30 miles between the South Foreland and Wimereux, near Boulogne. Communication has also been established and continuously maintained between the South Foreland, near Dover, and the East Goodwin Lightship, a distance of 12 miles. There was a collision on Friday last between a steamship and this lightship during a thick fog. The fact was immediately communicated to the shore. Fortunately the damage was slight, but, of course, the most was made of such a stroke of luck. Although I had watched and assisted Mr. Marconi in his experiments from his first introduction to me in 1896, and the Postmaster-General had taken the greatest interest in the system, it was thought that independent experiments should be made to confirm our opinion of the practicability of the system. They were made in September, 1897, near Dover. Mr. Marconi's results were confirmed. I reported on the practicability of the system, and the Wireless Telegraph Company, who had secured Mr. Marconi's services and his inventions, were informed that they could connect Sark with Guernsey and the Post Office would open Sark as a public office. They were also informed that the Board of Trade and the Post Office, with the consent of the Trinity House, would be glad if they would connect the South Sand Head Lightship with Dover. Neither of these extensions have yet been done. The company preferred to experiment elsewhere, as I have narrated, to prove what was not necessary to be proved that it was possible to signal across the Straits of Dover, and to show that great distances could be connected. The result is that for nearly two years after its practicability was affirmed, not one single independent commercial circuit exists. The operations of the Wireless Telegraph Company are mysterious and inscrutable.

Captain Jackson, R.N., in December, 1895, commenced at Plymouth working in the same direction, and he succeeded in getting Morse signals through space before he knew anything of Marconi or his system. His reports to the Admiralty, however, were confidential. Had they been published he would have anticipated Mr. Marconi.

When Mr. Marconi was showing the working at the South Foreland to the officials of the Post Office, he received a sharp shock. There was atmospheric electricity about, and Mr.

Marconi repeated Franklin's experience. Sharp sparks were elicited from this miniature lighting, and at the same time erratic signals were observable at Boulogne. The speaking to Boulogne was not interfered with. The officers on board H.M.S. *Vernon* at Portsmouth one day observed similar disturbances, and obtained distinctly the letters A R E. Was this due to Mr. Marconi's experiments at the South Foreland, or was it due to atmospheric electricity? I think the latter, for I have frequently read letters, especially R, on Morse telegraphs when lightning was about.

There can be no question of the commercial value of the system for lightships, isolated lighthouses, shipping generally, and for naval and military purposes, but for commercial uses, such as telegraph communication with France, the system is at present nowhere. A single cable to France could transmit 2,500 words a minute without any difficulty. A single Marconi circuit could not transmit more than 20 words a minute. It is not wanted in this direction. Its name has led to the popular illusion that the poles and wires which disfigure our house-tops will disappear, but there is no evidence at present that a single wire can be dispensed with. It may add to our systems at work. It cannot diminish the number of circuits at work. There may be many outlying islands that can be connected to the mainland, but this can be equally effective by my own electro-magnetic system. It must not be forgotten that this system of mine is in active practical use, and that its use can be largely extended. It is also open to all, and is not restricted by patent rights. It is, perhaps, unfortunately for me, not in the hands of an enterprising band of capitalists. If it were, it would not have been so soon forgotten. Wireless telegraphy is many years old. It is capable of great improvement, and if an electro-magnetic receiver can be devised as sensitive as the coherer it would work to equal distances, for the waves in each case extend precisely as far in the one case as in the other. Now we require parallel wires that extend to some distance on each side of a channel—a more sensitive magnetic receiver would reduce this to very short lengths. Other minds are at work on the subject.

I have not sufficient leisure to devote the requisite time to develop Ætheric Telegraphy, either on my own plan or on that of Mr. Marconi, but it has a potentiality of public use that is far beyond the dreams of newspaper writers.

Mr. Marconi is to be very sincerely con-

gratulated on the success of his experiments. He has attracted the attention of the public to a very fascinating field of electrical development, and thereby has indirectly served the progress of scientific education.

DISCUSSION.

Mr. A. G. LOW asked if a similar system of telegraphy was not tried, some years ago, by a gentleman from Dundee.

Mr. PREECE said there was a Mr. Lindsay, of Dundee, who used the water of the river Tay to complete his circuit. He came to London in 1854 or 1855, and submitted his invention to the Electric Telegraph Company, and the trial experiments were left in his hands. He had the pleasure of experimenting with Mr. Lindsay's plan across a large tank specially constructed for the purpose. It was merely a repetition of a plan suggested by Mr. Vail and Mr. Morse, as far back as 1845. They then tried to communicate across the Susquehanna; but it was not wireless telegraphy, it was simply utilising the conductivity of water to complete the circuit.

Mr. PRAED inquired how, in the Marconi system, the long wires made the messages more distinct. He could understand the use of long wires in the magnetic circuit, but he did not understand the use of the perpendicular conductors, as in that case it was not a closed circuit.

Mr. PREECE said in the electro-magnetic system, the wire was horizontal, and the electro-magnetic lines of force were rings round the conductor, the wave front being horizontal and passing into space in a horizontal direction. The receiver must, therefore, be horizontal also, in order that it might be cut by as many lines of force as possible. In the other case the lines of force were electro-static, and at right angles to the lines of electro-magnetic force and to the conductor. Therefore, in order to secure the greatest number of lines, the transmitting wire must be perpendicular, and the receiver also. The electro-magnetic system dealt with currents, in which case there must be a closed circuit, but with the Hertzian waves there was no circuit; they were propagated in all directions perpendicular to the wire.

Mr. H. FENTUM PHILLIPS asked what current was used. He understood that Mr. Marconi used accumulators, but that Professor Oliver Lodge had used dry cells. Would dry or Leclanché cells be equally efficient in places where accumulators could not be obtained?

Mr. PREECE said it was a matter of indifference. You required a certain current through the primary wire, which on the present occasion was obtained from eight secondary cells. In the practical line established between Lavernock and Flatholm, dry cells were used. At the South Foreland, Mr. Marconi used 48 dry cells, joined up in four parallel sets of 12 each.

Mr. COLE asked if any figures could be given as to the length of wire required for a given distance.

Mr. PREECE said the law seemed to be that the best effect was produced when the length of line on each side was equal to the distance across the Channel in the electro-magnetic system. The law of distance was given mathematically in the proceedings of the Institution of Electrical Engineers, when papers by Professor Lodge, Mr. Evershed, and himself were read, but he did not remember the exact figures.

Lieut.-Colonel ALLAN CUNNINGHAM asked what was the maximum distance to which each system had been worked, and the rate of transmission in each. Also if the reflectors used for the Hertzian waves were of metal and polished; and as they were said to be reflected from the surface of the sea, whether this had been more marked, as one would expect in calm weather.

Mr. PREECE said he would take the last question first. He was not aware that any observations had been made in that direction, but it was an interesting point, and they should certainly be made. The reflectors used were of copper, nickel-plated, and polished; they must be metallic. With regard to a comparison of the two systems, he did not wish to raise that question at all. The Marconi system had been wonderfully successful for much greater distances than had been expected. The distance at Lavernock was about $3\frac{1}{3}$ miles, but he did not think there would be any difficulty in going 30 miles if you had a proper length of wire. The great advantage of the Marconi system was that you could cross the distance without so much wire on each side. For lighthouses and lightships the only practical system was the Marconi.

Mr. CHARLES BRIGHT said there could be no doubt that the Wireless Telegraph Company would be doing more useful work if it applied itself to establishing communication with lightships and light-houses, which was the principal practical direction in which ætheric telegraphy could be applied. What they were doing across the Channel was very interesting to newspaper readers, but seeing that the Post-office and the Board of Trade had invited them to establish communication with lightships, it was a great pity they did not set about it. He believed we were a long way behind Denmark, for instance, in

the matter of coast telegraphic communication, and, at any rate, more communication would be very useful, and it was very difficult to establish cable connections with such cases.

Mr. E. TREMLETT CARTER asked whether, in the experiments conducted near Cape Grisnez, Mr. Preece considered that the waves passed over the hill and down again, or whether they went straight through it. He could not see why they should be deflected upwards and then down again on the other side; and he was rather inclined to believe that they travelled in straight lines. A conclusive test of this question might be made by putting a transmitting device in a very deep mine, and having the receiving apparatus on the surface, so that the waves would have to pass through a large mass of rocky matter. The point was of some importance with reference to the question of long distance signalling. If they had to signal from London to New York the waves must either follow the curvature of the earth, or must go in straight lines at a tangent to the surface, when they would miss New York altogether, or they must go through a considerable chord of the earth's map, where they might be partially absorbed.

Mr. GAVEY said he had had the honour of being closely associated with Mr. Preece in many of these experiments, but he could add very little to what he had said. One incident, however, he might mention which had not been referred to. They were carrying out a series of electro-magnetic experiments across Loch Ness, and it occurred to him, after having signalled by the Morse alphabet, to try and speak through the telephone. They accordingly connected telephones with the two wires and spoke into them, and the voices were heard on the other side of the lake just as clearly as if they had been connected by wires, and not only the voices, but laughter, and other sounds in the neighbourhood of the telephone.

Mr. PREECE, in reply to a further question, said he believed the vacuum in the coherer was brought down to 4 m.m. He did not think any attempt was made to vary the degree of vacuum according to the distance, but he could not speak with authority on that point.

Mr. LEON GASTER expressed the satisfaction it had given him to hear Mr. Preece's explanation, and his belief that the system he had put in practice could be much improved. He should like to know what amount of power was required to work the two systems, and to what extent the system of reflectors could be utilised to send the waves forward in straight lines.

Mr. BRABY asked what was the difference in the effect produced by using four balls instead of two.

Mr. SHOOLBRED asked what exact result was produced by increasing the height of the wire.

Mr. BOULT asked how the vertical wire was attached to the apparatus.

Mr. PREECE said it was attached to the cohcrer at one end, the other end was connected to earth.

The CHAIRMAN then proposed a vote of thanks to Mr. Preece. The subject was one full of marvel and mystery, but he had explained it as clearly as possible, and had been able to do so all the better from having personally worked at it for so many years.

The vote of thanks having been carried unanimously,

Mr. PREECE, in reply, said Mr. Bright had made a somewhat invidious comparison between the coast communication in this country and in Denmark; and he did not think Mr. Bright could have been in that country. He had, and he went there as a member of the Royal Commission which dealt with electric communication with lighthouses and lightships, to see what was done there. They found it was very little—practically almost nothing. He never could understand how people who took an interest in this question could write to newspapers about it, without taking the slightest trouble to ascertain what was done in this country. They jumped to the conclusion that all Government officials were little better than fools, and that the Government itself did not regard the interests of the public, and that nothing was done to meet the wishes of the community. There was scarcely a single lighthouse or lifeboat station round the whole of our coast which was not in direct communication with the postal telegraph system. Thousands of the lifeboat stations were fitted with telephones, and were practically open night and day. A ship could not be wrecked or damaged without immediate information being sent to the place where the lifeboat was kept. There was only one case where that was not done, and that was in connection with the lightships; but the Government were now spending some thousands a year in maintaining electric connection with light-ships, and it was because there was such a difficulty in doing this by cable that they were paying so much attention to ætheric telegraphy. He had had a perfectly free hand to experiment, and had never been stinted in his expenditure for this purpose. He could not answer Mr. Carter's question with regard to the signalling over the hill at Grisnez, as he had not experimented sufficiently, but his theory was that the lines of force were curvilinear and went over the hill. They knew by experiment that the earth had a serious absorbing effect on the waves, as they could communicate much farther across sea than across the land—nearly twice as far. He hoped now that Mr. Marconi had stations at the Isle of Wight, at Poole, and at the South Foreland, he would be able to experiment in that direction. With regard to the power required for the two systems, it was identically the same. They dealt with two series of lines of force,

electro-magnetic and electro-static, but it was a well-known principle in the theory of electricity that the amount of energy consumed in those two series of forces was the same. He could not answer the question about the use of four balls instead of two; he could only say that Mr. Marconi had found that for long distances, two balls acted as well as Professor Righi's oil, though, he believed, he retained the four in his experiments with reflectors. He could not answer Mr. Shoolbred's question satisfactorily; he could only say that the length was determined by the number of lines of electro-static force you wanted to catch at the receiving end. Whether you used electro-magnet force, or electro-static, it was simply a question of the number of lines of force you could drag into your net.

Miscellaneous.

FLEXIBLE FILMS FOR SPECTROSCOPIC PHOTOGRAPHY.

Sir Norman Lockyer has lately been experimenting, and very successfully, with flexible film, with the idea of adapting it to spectroscopic photography. The large concave Rowland grating which he is now using for his solar spectroscopic photographs has 20,000 lines to the inch ruled on its surface, and is of 21½ feet radius, giving a spectrum of 30 inches long. The focal plane of this grating is of necessity considerably curved, in fact the plane of accurate definition at the edges of the field is about half an inch in front of the similar plane at the centre. It is, therefore, impossible to get a sharp photograph of the whole spectrum on a glass plate, in fact not more than 18 to 20 inches of the spectrum can be brought into focus on the same plane. This difficulty is, of course, got over by the use of a flexible film, which can be bent to the curvature of the field.

A print of one of Sir Norman's photographs, taken with this Rowland concave grating, showing the arc spectrum of iron with a comparison spectrum of the sun from wave length 3,600 to 5,200, is 30 inches long, and must be the longest solar spectrum photographed at a single operation. Sir Norman Lockyer also hopes that by using films, instead of glass plates, at the next solar eclipse, he will be able to obtain an increased number of photographs, owing to the rapidity with which the film can be shifted in the short space of time available for photographic operations. At the last eclipse the photographic work was concentrated on obtaining a series of photographs of the chromosphere both about the time of beginning and end of totality. By careful drill Mr. Fowler and Dr. W. J. S. Lockyer were both able to secure ten photographs at each of these important periods, the time occupied in making each series of ten exposures being 12 seconds. An apparatus for carrying films is also being designed which can be adapted to the spectroscopic cameras at present in use in the laboratory and observatory,

GOLD PRODUCTION IN THE PHILIPPINE ISLANDS.

Gold is found in a vast number of localities in the Archipelago from Northern Luzon to Central Mindanao. In most cases, according to a recent United States report, the gold is detrital, and found in existing water-courses or in stream deposits now deserted by the current. These last are called *alluviones* by the Spaniards. It is said that in Mindanao some of the gravels are in an elevated position and adapted to hydraulic mining. There are no data at hand which intimate decisively the value of any of the placers. They are washed by natives largely with cocoanut shells for pans. In the province of Abra, at the northern end of Luzon, there are placers, and the gravel of the river Abra is auriferous. In Lapanto there are gold quartz veins as well as gravels. Gold is obtained in this province close to the copper mines. In Benguet the gravels of the river Agno carry gold. There is also gold in the province of Bontoc and in Nueva Ecija. The most important of the auriferous provinces is Camarines Norte. Here the townships of Mambulao, Paracale, and Labo are especially well known as gold-producing localities. Mr. Drasche, a well-known German geologist, says that there were 700 natives at work on the rich quartz veins of this place at the time of his visit, about 25 years since. At Paracale there are parallel quartz veins in granite, one of which is 20 feet in width, and contains a chute in which the ore is said to assay 38 ounces of gold per ton. It may be taken that this assay hardly represented an average sample. Besides the localities mentioned, many others of this province have been worked by the natives. The islands of Mindoro, Catanduanes, Sibuyan, Samar, Panay, Zebu, and Bohol are reputed to contain gold, but no exact data are available. At the south end of the small island of Panaon, which is just to the south of Leyte, there are gold quartz veins, one of which has been worked to some extent. It is 6 feet in thickness, and has yielded from 25s. to 29s. per ton. In the island of Mindanao there are two known gold-bearing districts. One of these is in the province of Surigao, where placer and other townships show gravels and veins. The second district is in the province of Misamis. Near the settlement of Imponan and on the Gulf of Macajalar, there are said to be many square kilometres of gravel carrying large quantities of gold, with which is associated platinum. The product of this district was estimated some years since at 150 ounces per month, all extracted by natives, chiefly with cocoanut dishes.

USES OF GLASS.

Early in October of last year, a paving company, of Lyons, began laying in the Rue de la Republique in that city a piece of pavement of ceramo-crystal, ceramic stone, or devitrified glass. The United States Consul in Lyons, in his last report, calls

attention to this circumstance, and says that during the months of November and December, 1898, and in January of this year, this pavement has been driven over during all hours of the day and night. It has stood as hard usage as any pavement could be subjected to during that time, and is still in an admirable state of preservation. The glass or ceramic stone pavement is laid in the form of blocks, eight inches square, each block containing sixteen parts in the form of squares. These blocks are so closely fitted together that water cannot pass between them, and the whole pavement looks like one huge chess board. Like all thoroughfares in France, the road bed slopes gently to the curb on each side. Consul Covert gives an interesting account of a visit he paid to the Ceramo Crystal Manufacturing Company's works at the suburban village of Demi-Lune, about six miles from Lyons. The factories cover nearly 8,000 square yards of ground. At the time of his visit the work was stopped while additions were being made to the buildings in the shape of second storeys. In the yards were many tons of broken bottles, which the superintendent of the works stated was their "raw material." On the four sides of a large brick chimney were specimens of ceramo-crystal for buildings and interior decoration, some of the pieces as smooth as highly-polished marble, others being rough, like cut stone, and still others having a surface like common brick. The advantages attributed to this ceramo-crystal by the manufacturers are:—As a pavement, it has greater resistance than stone; it is a poor conductor of cold, and ice will not form upon it readily; dirt will not accumulate upon it as easily as upon stone, and it will not retain microbes; it is more durable than stone, and just as cheap. The Central Architectural Society of France made a report recently on this ceramic stone, of which the following is a brief synopsis:—An officer of the society reported that he had examined a square suitable as a pavement or floor for a stable, a courtyard, or factory; a block imitating polished marble; a block imitating mosaic; and a panel with moulding and ornamentation. He said—"From the various forms in which this material is presented, its use can readily be determined for both practical and decorative purposes. On careful examination, it is found that the Garchey ceramic stone is nothing but glass brought to a special molecular condition. In a certain sense, it constitutes a new substance, which resembles flagstone, granite, or marble. The manufacturer states that with this material he can copy any model that is presented. This new product is obtained from broken glass, heated to a temperature of 1,250°, and compressed in matrices by hydraulic force. The physical transformation of glass is due to devitrification under the Garchey process. The phenomenon of devitrification produces a sort of dissolution, more apparent than real; for, upon chemical analysis, the devitrified glass preserves the identical composition of natural glass. It may be said, then, that devitrified glass possesses all the intrinsic qualities (physical and

chemical) of glass except the transparency, while taking on an entirely different aspect. Furthermore, glass treated under this new method is made to resist crushing, frost, and heavy shocks, and to stand rough wear." This subject is being discussed in the French Press, and is receiving general consideration. An elaborate and exhaustive article in the "Revue des Deux Mondes," for November last, treated the question under the heading of "A Glass House," the writer asserting that a large house, constructed entirely of glass, would be an attractive feature of the Exhibition of 1900. He said that glass could be used for tubes, pipes, vats, tiles, chimneys for factories, and for buildings. Double glass walls in a house would admit of the circulation between them of cold or warm air, thus regulating the temperature. "As to the resistance of such a structure, it would certainly be equal to that of the most solid houses of the day, and it is lighter and less expensive than brick." The glass house or palace which it has been decided to build in the grounds of the Exhibition in 1900 parts of which are now being constructed, is thus described by the writer last quoted:—"The principal façade, in the form of an immense portico, its roof surmounted with spires, and with a winged statue representing light, will be supported by heavy columns. The ground floor, reached by a double flight of stairs, will be used as a great exhibition room. To the right and left will be large glass basins, overhung by grottoes of glass. In the interior of the hall will be five large openings, in which will be represented the five divisions of the globe."

THE SILESIAN CARPET INDUSTRY.

The manufacture of carpets is rapidly becoming an important industry in Silesia, and has its centre at the town of Schmiedeberg. The carpet is an imitation of the Smyrna article, and ranges in price from 12 to 25 marks (12 to 25 shillings) per square metre (10·76 square feet). The process of manufacturing is as follows:—The threads are twisted from German and foreign wool; various wools are used to find the right combination of strength and smoothness. Artificial wool is added to the inferior kinds, and the cheapest qualities are made entirely from the latter material. The wool, of which the thread is to be made, is first placed upon a machine called the "wolf" or "devil," by which it is torn to small pieces. It now proceeds to another machine called the "krempe" or "carding bench," which further completes the work of tearing. At the lower end of this carding bench a kind of drum is located, around which the thick smooth wool finally gathers, to be afterwards taken to the weaving room. Here the wool is twisted by a machine into a two, three, or four-ply thread, according to requirement. This thread is now taken to the dyeing room, where it undergoes a good washing to clean it from all

dirty and oily substances. Only real Oriental colours are used in this process. The coloured threads are then cut into small lengths of about 3 centimetres (1·18 inches), each to form the material for single loops. These loops are now sorted by colour into small wooden boxes, and these are handed over to a female labourer called *knüpferin*. The production of the carpet now commences. The United States Consul at Breslau says that the looms in use consist of two side parts connected by iron or wooden bars. The broader the looms the broader these bars and consequently the carpets they produce. The looms have two fronts so that work may be carried on on both sides at the same time. The smallest looms measure 1 metre (39·37 inches), the largest up to 15 metres (49·2 feet). The number of the working women depends upon the size of the carpet to be made. A space of three-fourths of a metre (29·5 inches) is allotted to each of them. Clever and intelligent workers, however, frequently undertake to manage double space. All the girls sit in one row or line and work simultaneously. The top of the loom contains the chain thread of linen or jute, while at the bottom the receptacle—viz., a drum for rolling up the finished article—is to be found. The chain threads are fixed midway between top and bottom of the loom, and serve for binding or for the construction of the carpet. They are passed through the shuttle and afterwards twisted round an iron bar. After this the chain is tightened and a seam made upon which the first row of loops is fixed. As soon as a row of loops has been finished across the whole width, a thick end thread of jute is passed across twice. After each passing, the chain threads are allowed to cross each other, so that they form a firm weave. Another row of loops is then tied, and the edge formed, and so on. The working girls are seated on low wooden stools, having at the height of their head the pattern of the carpet before them which they have to copy. Each has at her side the above-mentioned wooden boxes, containing loops of various colours. The patterns are printed or drawn on paper, and show small squares, each of which indicates a loop, and the colours on the paper correspond with those of the required loops. The girl starts with the first square at the left-hand side at the bottom row, and continues tying to the right so far as her space allows it. As soon as a row of loops has been finished the edge is made in the usual way, and this process is carried on until the whole pattern has been completed. At the finish a seam is added, and the carpet cut off and taken from the drum. The loose wool and the dirt are removed, and the carpet well beaten on the back to loosen the weaving, which has become hard during the process of manufacture. Next, the shearing-machine clips the top five or six times, until a smooth plush-like surface is produced, whereupon the seams are removed and false loops replaced by others, and the carpet is ready for use. The work is entirely done by piece, and a clever, industrious girl naturally earns more than one less capable. The

average wage for a girl amounts to 1.50 marks (rs. 6d.) a day, but the best workers earn as much as 3 marks (3s.). There are about 450 hands employed at Schmiedeburg, and 4,262 carpets, of various colours and size, are turned out per annum. Consul Erdman says that the carpets are such a good imitation of Smyrna goods, that it really takes an expert to distinguish them from the genuine. They are also a good deal cheaper than the Smyrna carpets, and there is naturally a large market for them throughout Germany. They are exported to Austria, Italy, Scandinavia, and Belgium.

TEXTILE INDUSTRY OF JAPAN.

The manufacture of textiles in Japan is not confined to certain localities, but extends by means of hand looms all over the country. The spinning-wheel was formerly in general use, but during the last 20 years it has been almost wholly displaced by spinning mills using machinery. More than 1,000,000 spindles are now thus operated, 47 mills in Japan producing last year an estimated yield of 650,000 bales of yarn of 400 lbs. each. The United States Consul at Hiogo says that more than 200,000 bales will probably be shipped to China during the current year, and the home demand for counts averaging No. 18 will be nearly supplied by the remaining 450,000 bales. Only one of the spinning mills in Japan has imported the machinery necessary for spinning the higher counts above No. 30. The Nippon mill of Osaka has done this, but so far, according to the Consul, has not made a success of it. Higher counts are steadily imported from England, and in greatly increasing quantities, to meet the home demand. When mill hands with greater skill are to be procured in Japan the spinning of the higher counts will increase more rapidly, in order to supply the home market and the demands from China and Korea. Many of the large class of persons formerly employed in spinning by hand are now engaged in weaving textiles on hand looms. It has recently been computed that more than 600,000 hand looms are in use in Japan, and it is stated that they employ 890,000 women and 50,000 men. As these hand looms are generally operated in private houses, giving a home character to the work, it can readily be seen why such slow progress is being made in the introduction of power-weaving machinery. The hand looms now in use are called *battan*, and are an improvement on those formerly used. They cost but about 5 yen (about 10s. 6d.) each, and take up little room in a house, while a power machine would require a separate building, and with the necessary power would cost say nearly 500 yen (about £50). The hand loom will produce about half as much as a power loom, but one person could attend to perhaps four or five of the latter at a time, and thus be able to turn out, say eight or ten times the product with a power loom as with a hand loom. The convenience, however, of having the hand loom in the

house, and the difference in its cost, will perhaps be sufficient to delay the introduction of power looms to any great extent for some time to come. The hand looms are hand-made, and are principally used in supplying some 1,000,000 pieces of goods, say 14 inches in width and from 12 to 25 yards in length, for the home market and for export to China and Korea. The Japanese manufacturers are very conservative in their business methods, and manufacture large quantities of goods only on order. The largest silk factory in Japan using power looms is the Kyoto Orimono Kaisha of Kyoto. It imported these machines from France. Silk in its various forms, from the raw material to the finished product, is mainly exported from Yokohama. The industry dates back to an early period, and is to-day in an advanced condition. The exports of manufactured silks from Japan in 1897 amounted in value to about £1,364,000. The manufacture of woollen goods is a new industry in Japan and a small one, as only about 13 per cent. of the woollen tissues used in Japan are made in the country. The raw material is all imported from China, Australia, and London. The four woollen factories of the country are located in Osaka and Tokyo. One is owned and worked by the Imperial Government, and manufactures supplies for the army and navy. Some of the better grades of cotton and woollen yarns are made there, but they are mostly imported. A large proportion of the woollen cloths used are made on hand looms. The first knitting machinery used in Japan was brought from England; some has since come from other countries, and the Japanese have copied all. The machines are of hand power and worked in private houses, from one to five being found in a house. The knitting business is not scattered through the country like weaving, but is concentrated in manufacturing centres, a great deal being done in Osaka. Large quantities of cheap underwear are made in Japan, all from cotton yarn spun in the country. Cotton and woollen yarns used in making the better grades are imported. Not much woollen underwear is used, the demand being confined to the better classes of the Japanese people, who also wear light-weight all-wool with open meshes in summer. This light-weight referred to has been made for some time in Japan for the Indian market. The Japanese children have lately begun wearing mixed knitted singlets in the central part of Japan. Nearly all the spinning machinery used in Japan still comes from England. The first spinning machine ever used in the country were sent from England. French and German makers have supplied a considerable quantity of the silk and woollen weaving machinery.

VITICULTURE IN SPAIN.

In the district of Cadiz, including Jerez, Port St Mary, Chiclana, &c., the vineyards gave in 1898 a worse crop as regards quantity than ever, though the

quality of the grape juice or *mosto* appears to have been more satisfactory than had been anticipated. The decrease in the crop is, according to Consul Vecqueray, due to the continued ravages made by the phylloxera, which now seems to have attacked the vineyards on sandy soil, which have up to recently been more or less free from the disease—those on the *albariza* or white clay soil, having principally been affected hitherto. As examples of the evil results due to the phylloxera, it may be mentioned that one vineyard which formerly produced up to 250 butts of 500 litres (500 litres = 880 Imperial gallons), only gave in 1898 about 70 butts; another gave only 15 butts as against 120 butts in the previous year, and a third which produced 138 butts in 1896 and 115 butts in 1897, gave in 1898 no more than 34 butts. Naturally the vineyard proprietors lose very heavily from this reduction in the produce of their vines, but they feel the loss all the more because they have to pay the same heavy duty as formerly on their plantations. In the course of the past year a Commission of vineyard proprietors went to Madrid to beg the Minister to either take this duty off altogether, or at any rate to limit it to the output of the vineyard. It is not yet known how far this Commission obtained its object. In order to resist the phylloxera plague, many vineyard proprietors have now adopted the plan of grafting the principal stems of their vines into stocks of the American vine. A few proprietors had already made this attempt in previous years, and during the past year reaped a satisfactory result, inasmuch as they found that not only the character of the Spanish wine was unaltered by the process, but also the produce of the vines was greater. The process is a very expensive one, and some vineyard owners may not be able to afford to attempt it. Consul Vecqueray has been informed that it costs about 1,000 pesetas (£40) for each *aranzada* (about 1½ acres), including the purchase of the plants, and that some 200 *aranzadas* were so planted in 1898. There is a provincial house in the Jerez district which supplies American vines of different kinds, and has sold several thousands in the course of the last two years. A vineyard proprietor purchases a few of these vines and plants them on a small portion of his own vineyard. In the following year he is able to take shoots from these vines and replant them, again grafting into them the Spanish vines. Thus, year by year, he will extend the planting of the American vine to the whole of his vineyard, but three years are required before the American vine, into which the Spanish stem has been grafted, will produce, and this, of course, adds to the loss and expense incurred by the proprietor. No other remedy, however, seems to be effective, and to prevent the sherry trade becoming totally extinct, it will probably be adopted by all vineyard proprietors. The disease shows its capriciousness by attacking chiefly the vines that produce good sound wines, leaving those that produce common wines almost untouched; and in the Jerez district alone, out of 8,000 hectares

(19,700 acres) planted with vines, it can be calculated that no less than 5,000 hectares (12,300 acres) are affected. Still the connoisseur of sherry need have no fear that he will not be able to obtain the genuine old wine of Jerez for many years to come, as there are considerable stocks of good, useful wines still to draw upon in the various Bodegas.

General Notes.

ALGERIAN WINE PRODUCTION.—The figures relating to the production of wine in Algeria show the steadily increasing importance of the industry. A very large proportion of the total production is received in France, where it is used in combination with other wines to produce the article which the trade requires. The yield of 1898 is given as 5,221,700 hectolitres, or, in round figures, 115,000,000 gallons. The area of the vineyards reached a total of 123,950 hectares, or 306,000 acres. In 1880 the production was 12,000,000 gallons; in 1833, 70,000,000 gallons; and in 1897, 113,000,000 gallons.

ELECTRIC STREET RAILWAYS IN GERMANY.—Germany is at present making rapid strides in the construction of electric street railways, and in the smaller cities a number of such railways are either in progress of construction or are being planned. In Meissen, Weimar, and Eisleben the roads are being built. The following cities, according to Consul Harris, of Eisenstock, are planning the immediate construction of electric plants and electric street railroads:—Pforzheim, Trier, Ratisbon, Colmar, Jena, Kaiserslautern, and Worms. There are no doubt other cities that are preparing to do the same thing. The population of those above mentioned varies from 15,000 to 50,000.

COPPER IN BOLIVIA.—The Bolivian copper formations extend in an almost uninterrupted line from south to north, following the general direction of the eastern chain of the Andes. The only beds worked to-day are those of Corocoro, upon the high plateau of Titicaca. The distinctive feature of these beds is the abundance of native copper, in forms varying from microscopic grains to great masses weighing several tons; in wealth they rank second only to those of Lake Superior. The most primitive and imperfect methods of working these beds are employed. The scarcity of fuel does not permit fusion on a large scale of the various combinations of the metal. As a matter of fact there are only two furnaces at Corocoro. The ore is broken with hammers by women, passed through mills worked by hand or by hydraulic power, undergoes two washings in inclined trenches, and finally is dried either by the sun or by artificial heat. The ore produced is of a standard of not less than 70 per cent. The quantity extracted in 1897, as given by the four companies of Corocoro, was 2,912,566

kilogrammes (6,421,000 lbs.). The Bolivian Government taxes every Spanish quintal (101 lbs.) of ore about 4½d. The net cost of a Spanish quintal of copper at Corocoro is about 12s.

PRESERVATION OF RUBBER TREES IN THE CONGO FREE STATE.—The Government of the Congo Free State, with the object of preventing the threatened destruction of the indiarubber trees in that country has promulgated a decree by which it is provided that for every ton of rubber yielded annually, there shall be planted not less than 150 trees. A bureau of control of rubber forests is created, and is charged with the enforcement of the decree of 1892, which prohibits the gathering of rubber in any other mode than through incisions in the bark. Infractions of this new decree, which bears date of January 5th, 1899, are punishable by a fine up to 10,000 francs (£400) or imprisonment. Employers and directors of corporations are held personally responsible for the acts of their subordinates. Guide books for the cultivation of rubber are furnished by the District Commissioners on request, and agricultural inspectors will be placed temporarily at the service of private owners.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock :—

MAY 10.—“Fruit Growing in Kent.” By GEORGE BUNYARD. SIR GEORGE BIRDWOOD, K.C.I.E., C.S.I., will preside.

MAY 17.—“The Law of Trade Marks.” By J. E. EVANS-JACKSON.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock :—

MAY 11.—“Agrarian Conditions under British and Native Rule: A Comparison of the Revenue Systems of British India and Rajputana.” By MICHAEL FRANCIS O'DWYER, I.C.S., Settlement Commissioner, Alwar. Colonel GEORGE HERBERT TREVOR, C.S.I., will preside.

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal. The EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock :—

MAY 16.—“The Artistic Treatment of Picture Frames.” By I. HUNTER DONALDSON.

MAY 30.—“The Revival of Tradesmen's Signs.” By J. STARKIE GARDNER, F.G.S.

CANTOR LECTURES.

Monday evenings, at 8 o'clock :—

PROF. HENRY R. PROCTER, F.I.C., “Leather Manufacture.” Four Lectures.

LECTURE IV.—MAY 8.

Oil dressing—The chemistry of the process—Combinations of oil and mineral tanning—Vegetable tanning matters—Chemistry of the tannins—Practical methods—Combination of vegetable and mineral tanning—Currying—The chemistry of oils and fats used—Theory of the currying process.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 8... SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Cantor Lectures.) Prof. Henry R. Procter, “Leather Manufacture.” (Lecture IV.)

Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Medical, 11, Chandos-street, W., 8 p.m. Annual General Meeting.

TUESDAY, MAY 9... Royal Institution, Albemarle-street W., 3 p.m. Prof. Silvanus P. Thompson, “Electric Eddy-Currents.” (Lecture II.)

Medical and Chirurgical, 20, Hanover-square, 8½ p.m. Photographic, 12, Hanover-square, W., 8 p.m. Mr. E. Sanger Shepherd, “The Photography of Colour.”

Anthropological, 3, Hanover-square, W., 8½ p.m.

Colonial Inst., Whitehall-rooms, Whitehall-place, S.W., 8 p.m. Sir John Robinson, “The Colonies and the Century.”

Asiatic, 22, Albemarle-street, W., 3 p.m. Annual Meeting.

WEDNESDAY, MAY 10... SOCIETY OF ARTS, John-street, W.C., 8 p.m. Mr. George Bunyard, “Fruit Growing in Kent.”

Geological, Burlington-house, W., 8 p.m. Royal Literary Fund, 7, Adelphi-terrace, W.C., 3 p.m.

United Service Institution, Whitehall, S.W., 3 p.m. Mr. Pulney Biglow, “The Yankee Soldier as I saw him at Tampa and Manila during the late War.”

Royal Society of Literature, 20, Hanover-square, W., 8½ p.m.

THURSDAY, MAY 11... SOCIETY OF ARTS, John-street, Adelphi, W.C., 4½ p.m. (Indian Section.) Mr. Michael Francis O'Dwyer, “Agrarian Conditions under British and Native Rule: A Comparison of the Revenue Systems of British India and Rajputana.”

Society for the Encouragement of Fine Arts, 8 p.m. Conversazione at the Galleries of the Royal Institute of Painters in Water Colours, Piccadilly.

Royal Institution, Albemarle-street, W., 3 p.m. Mr. Lewis F. Day, “Embroidery.” (Lecture II.)

Mathematical, 22, Albemarle-street, W., 8 p.m.

FRIDAY, MAY 12... Royal Institution, Albemarle-street, W., 8 p.m., Weekly Meeting, 9 p.m. Professor Thomas Preston, “Magnetic Perturbations of the Spectral Lines.”

Astronomical, Burlington-house, W., 8 p.m. Philological, University College, W.C., 8 p.m. Annual Meeting.

Physical, Chemical Society's Rooms, Burlington-house, 5 p.m.

SATURDAY, MAY 13... Royal Institution, Albemarle-street, W., 3 p.m. Mr. W. L. Brown, “To Iceland in Search of Health.” (Lecture II.)

Journal of the Society of Arts.

No. 2,425. VOL. XLVII.

FRIDAY, MAY 12, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

CONVERSAZIONE.

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors, and the Lecture Room.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. These tickets will be shortly issued. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

CANTOR LECTURES.

On Monday evening, 8th instant, Professor HENRY R. PROCTER, F.I.C., delivered the fourth and last lecture of his course on "Leather Manufacture."

A vote of thanks was passed to the lecturer. The lectures will be published in the *Journal* during the summer recess.

Proceedings of the Society.

INDIAN SECTION.

Thursday, April 27, 1899; the LORD CHIEF JUSTICE OF ENGLAND, G.C.M.G., in the chair.

The paper read was--

JUDICIAL REFORM IN EGYPT.

By SIR JOHN SCOTT, K.C.M.G., D.C.L., Deputy Judge Advocate-General, and late Judicial Adviser to H.H. the Khedive.

"Inter arma silent leges" and the splendid military achievements of the Sudan have diverted the attention of the students of modern Egypt from the progress made in the administration of justice in the country. I am very glad, therefore, to have this opportunity of placing before the public a short account of what has been done, under English guidance, to ensure evenhanded justice between native and native on the banks of the Nile.

There are, as everyone is aware, various systems of justice in Egypt. The ordinary right of a State to impose upon all those who dwell within its limits the authority of its own laws, administered by its own Courts of Justice, does not yet prevail. Foreigners enjoy extra-territorial rights, and in criminal matters they are only amenable to their own Consulate and their own laws; whilst their civil disputes *inter se* or with a native are placed under the exclusive cognisance of the mixed tribunals. This privilege of extra-territoriality was created by the Capitulations which were granted in mediæval times, in order to induce foreigners to settle in the Ottoman dominions, and which are still in force. They had their justification, as far as Egypt was concerned, in the fact that until recently there was no such thing as native justice. But under the British *régime* there has gradually grown up a national system of justice which will soon enable the Egyptian authorities to say to Europe, "We can now give you justice in our own Courts, we ask that all who dwell in our country shall be amenable to the ordinary municipal tribunals and

law." This is not a change that can be made by a stroke of the pen. The consent of the European Powers would be necessary, as, even if the mixed tribunals were abandoned, they could claim to re-establish Consular Courts. Naturally such a right would not be abandoned save on the strongest guarantee that sound justice would be administered by the Egyptian Courts. Yet, speaking as a man who honestly cares for the country, and who, by long residence and constant desire to bring forward the Egyptian, might almost claim *droit de cité* as an Egyptian, I am absolutely convinced the native tribunals of Egypt must eventually be the only tribunals in the country.

It is of the progress of these native tribunals that I wish to speak to-night. I was specially charged, as legal adviser to the Khedive for eight years (1890-98), with their development, whilst as an Appeal Judge in the mixed tribunals from 1876 to 1882, I had considerable experience of the time when Egypt possessed no native Courts worthy of the name. In my account I may have to mention myself more than I like, but I wish to say at the outset that I never initiated any important reform in judicial organisation without having first explained and discussed it with the Khedive, the Minister of Justice, and the leading members of the Legislative Council, and without this co-operation I could not have succeeded. You may make a canal or a railway without the consent of a people, but you cannot make a system of justice.

But Egypt has many masters, and I have not yet mentioned the one on whom I most relied and who always did the best for the country. I mean Lord Cromer. As I said in my farewell speech to the Egyptian Judiciary:—"His lordship knows the country and its needs better than any other man in Egypt, and he waits patiently till the moment has come when the reform can be made, and once he is convinced your plan is not only sensible but opportune, you are sure of his support, and this support I always had."

One of the secrets of Lord Cromer's remarkable success as an administrator lies in his patience. Each of his great reforms has had to wait its turn. When rebellion was suppressed and order restored, finance came first. "Put money in thy purse" is an essential preliminary to all progress. As soon as a sound, financial system was established, he turned to the development of the sources of material wealth. He took public works in hand, and he never did a better stroke of business in all

his busy life than when he persuaded the financial authorities of Egypt to place a million sterling at the disposal of Sir Colin Scott-Moncrieff for the barrage and general irrigation. It resulted in a glorious success. But meanwhile Lord Cromer let justice and education wait outside the door; he had invited Sir Benson Maxwell at one time and Sir Raymond West at another to devise a plan of judicial organisation, and encouraged Nubar Pacha to form native courts. But the time had not yet come for his interference. However, in 1890, he wrote in his Annual General Report on Egypt, "above all the judicial and police systems require to be put on a sound footing." His Lordship, having thus decided that the time had come for judicial reform, did me the honour of asking me to leave my judicial work in India for a year, and to spend that year in Egypt, with the view of there studying native justice as it then was, and making a report as to the best mode of its reform. I was lent to Egypt by the Indian Government, and spent a year in visiting the tribunals, assisting at the hearings, talking with the judges, examining their records, and generally studying the actual system in its working all over the country, from Assouan to Alexandria.

Then I made my report. It was, undoubtedly, a gloomy document. I had found codes, good enough in themselves, but a large number of the judges, whose duty it was to interpret and apply the codes, were quite unfit for the work, whilst the Executive did not enforce the decisions with any regularity. The Judiciary themselves were timid as regards the executive authorities, the police were corrupt, and the mass of the people entirely refused to give any information as to the cause or the author of any crime in their district. There were only seven tribunals altogether in the country, yet the great majority of the civil cases was so small in the amount in dispute, and the people were so poor, that the injured party could not afford to go any distance to obtain justice. There was no system whatever for the appointment of judges. A certain number were excellent magistrates, but many had been named arbitrarily by the Government, some by favour, some because they were unfit for the office they previously held. The tribunals had been apparently labelled "Rubbish may be shot here." The Bar was even worse than the Bench. There were a good many decent judges; there was hardly one capable advocate. I pointed out clearly all these defects, but I insisted that reform was wanted, not revolution. I have a

lawyer's dislike of radical remedies. They are very expensive, they disturb existing interests, and they upset the way of doing things to which the people have become accustomed. The native tribunals had been founded on the lines of the mixed tribunals, the French codes were the basis of their law, the people had to a certain extent got used to the French system, French was the foreign language then generally in use. As a judge of the mixed courts I had applied French law and procedure and had found they worked fairly well. With the exception of the Englishmen in the Court of Appeal and the English members of the Bar, there was hardly a person in the country who would have really welcomed at that time a complete change in favour of an English system of law. I, therefore, urged that better men were wanted, not new measures. As I said in one of my reports, *tant valent les juges tant valent les lois*. After much hot discussion my report was finally accepted as the basis of judicial reform, and I was persuaded to give up my Indian career for this new work in Egypt, not I confess without great hesitation, as two eminent Englishmen had preceded me without success.

Some cardinal changes were necessary as well as many [minor ones. We began with what was essential—"Festina lente" was always my motto. A certain number of the judges were totally unfit for their posts, and they could not be allowed to continue. There had been no regular system of judicial nominations, and many members of the bench reminded one of Figaro's saying, "They wanted an arithmetician, and so they chose a dancing master." For example, a doorkeeper of a recent Prime Minister had suddenly become a Judge of the Court of Appeal, and I could cite other equally flagrant cases. However, I consulted with the authorities of the Ministry of Justice, and the best men of the judicial staff, and gradually, after careful sifting, we were able to put on the retired list the most unfit, the Financial Department providing them with pension according to their years of service. But no judge was retired until we had found a better man to put in his place. By the end of my first year of office, thirty-three new judges, about 30 per cent. of the Judiciary, had been introduced in the place of the most incapable. We then made a strict rule that in the future a legal diploma was essential for judicial office. There was a school of law in Cairo, but it had been neglected to such an extent that it had not even a director. Fortunately a good many

young Egyptians had recently obtained legal degrees in France and Italy, so that we had a certain choice—a somewhat youthful choice no doubt—ready to hand. We at once set to work to regenerate the Egyptian school of law. We were luckily able to induce a professor of law from one of the Universities of France to accept the direction and he turned out a great success. No man in Egypt has done better by his pupils, no man is more loved and respected by them than M. Testoud. In two years' time we had a good staff of teachers, French, Italian, and Egyptian, and 100 pupils all being trained for the legal profession. The period of training was fixed at four years with annual examinations. As I was President of the Board of Examiners, I am in a position to say that the pupils worked excellently, though perhaps their enthusiasm was not so much from love of the study of law, as from the desire to secure Government employment. Their main defect was one common in the East. They trusted too much to memory and did not think out sufficiently the codes and general principles of law for themselves. No pupil was admitted without a certificate that he had passed the secondary examination in the Government schools, so that they were sufficiently grounded in general knowledge.

Having laid down the condition that a legal diploma was necessary for judicial service, we next established a system of gradual promotion of the judges. My object was to found a real judiciary in the country. The successful candidates who had passed all examinations entered the service from the Law School, in the lowest judicial class, at a salary of about £100 a year, and if they merited promotion they slowly climbed up the judicial ladder until they reached the Court of Appeal with a salary of about £800 a year, whilst Europeans, who had to change country and climate, received £1,000 a year. The principle of irremovability of judges was established for the Court of Appeal, whilst the judges of First Instance had an almost equally certain tenure, as they could only be dismissed on proof of grave misconduct, established by a judicial inquiry conducted by the Court of Appeal. Of course, a good many of the originally incapable ones still remained, but they were now in the minority, whilst the whole Judiciary was undoubtedly leavened with a better spirit, and we continued very gradually to eliminate the most unfit by the inducement of pension, or the offer of other administrative work. The salaries may not seem in England to be sufficient, but they

are as high as those paid in Continental countries for judicial work. For instance, in Paris, the First President of the Court of Cassation receives only £1,200 a year. The other Presidents receive £800, and ordinary members £720. Appeal Judges receive £440 a year, Judges of First Instance £320, and *Juges de Paix* £120. In the provinces the salaries are less than they are in Paris. The salaries given are amply sufficient in Egypt for all the necessary requirements of life, and although a good salary does not make an honest official, it greatly lessens the temptations to dishonesty. A good salary, coupled with the certainty of tenure as long as they did their work well, made the post of judge the most popular function in the whole Egyptian administration. Certainty of tenure on condition of good service was such a novelty.

The difficulty of finding good men for the post of judge, and the gradual increase in the number of cases set down for hearing, set us to consider how we could diminish the number of judges required for the present work, so as to set free some of them for new work.

As an Englishman, I entertained strongly the opinion that the one-judge system in First Instance was the best. It concentrates responsibility, whereas three or five judges sitting together so divides responsibility that often the majority of the Court takes little interest in the business, and in practice everything is too much done by one man, whose individual action is saved from criticism by the presence of his colleagues. Of course, I am only speaking of cases in First Instance, but I felt that if I could improve the character and capacity of the First Instance judges, and teach them to face the responsibility of sitting alone, the quality of the work done would be much improved, and a certain number of judges would be free for new work. In appeal, especially in appeal on points of law, I hardly need add the authority of a plurality of judges is necessary both to satisfy the public and to ensure a right decision. I met with great opposition at first when I proposed the one-judge system. Those were days when anything English was eyed with suspicion. The Egyptians themselves did not dislike the idea, as the Mohammedan Judge, the *Kadi*, always sits alone; but legal training in Egypt is based on French lines, and, save in the most trivial matters, a Frenchman holds the plurality of judges essential to the proper administration of justice. But I fortunately found that the *Fuge unique*

system had been adopted in Algeria in the form of a *Fuge sommaire avec compétence étendue*, and eventually, after much discussion and considerable delay, the Council of Ministers decided in my favour, and I carried a Bill which enabled a single judge to decide in First Instance all civil disputes where the value of the claim did not exceed £100, and all criminal cases where the maximum punishment that could be inflicted did not exceed two years' imprisonment. As an ancillary measure I carried a second Bill that established local Courts of Appeal of three judges, who heard, in Final Instance, all appeals from a single judge. And thus the Central Court of Appeal was left free to the due consideration of really important cases.

The introduction of the one-judge system at once placed at liberty a considerable number of judges. Up to that time there had only been in the country seven tribunals with a central Court of Appeal, which heard all appeals of every kind of importance. Petty appeals were now separated from important appeals, and we proceeded to distribute throughout the country, at centres most accessible to the people, single judges, who sat daily for the hearing of civil or criminal cases. The whole number of judges in the country was rather over a hundred; the number of the *Parquet*, which in English may be described as the Public Prosecutor's department, was somewhat over seventy. Very gradually—our progress being dependent on grants from the Treasury for the establishment of these new tribunals—we established 45 one-judge tribunals all over the country. We chose our judges partly from those whom the reform had set free and partly from the best men in the Public Prosecutor's department. As a further ancillary reform, I carried a measure which limited the right of appeal to cases where the amount in dispute was not less than £10. The result of these changes was that the peasant, desirous to recover a small debt, say of a hundred piastres, was no longer obliged to travel many miles and obtain the decision of three judges, which decision, even if favourable, was liable to an appeal to a court in Cairo composed of five judges. He can now go the town close by, an officer of the court on his statement draws his claim for him, it is served at once on his adversary, a day is fixed for the hearing, and as there are no arrears in any tribunal, he gets his decision on the appointed day. That decision can be executed by the summary court if

the sum awarded is under £10; if the sum awarded is over £10 there can be an appeal, but that appeal goes, not to Cairo, as of old, but to the nearest provincial capital. The execution of judgments, which used to be arbitrarily withheld, is now carried out by the administrative authorities as regularly as it is in England.

The introduction and great expansion of the one-judge system rendered necessary the establishment of some system of judicial superintendence. Justice as the sole basis of social relations was an absolute novelty, and the new judges, though full of zeal and good intentions, were without experience. It had been necessary to choose young men, because the older generation had been brought up under an arbitrary system. The older judges required, perhaps more than the young ones, constant supervision as regards both the amount and the quality of their work. But I came to the conclusion that whilst superintendence was essential, the *revision* of judicial work was to be deprecated and avoided. Yet the Egyptian public could hardly believe in the impartiality, and freedom from corruption, of a judge, especially if he sat alone, isolated from his colleagues and free from all control. I know it will be difficult to persuade an English audience that the superintendence of judicial work and the inspection of judges can possibly be good things. Still things that sound bad in theory are sometimes excellent in practice, and England, with its centuries of freedom and education, cannot be taken as a model for an ignorant country like Egypt, which had been oppressed by foreign masters for a period beyond the memory of man. At any rate, I had come from judicial work in India, and had myself taken part in a system of judicial superintendence that had produced admirable results. Only a couple of days before I left India, one of the best judges on the Bombay Bench, who had spent 30 years of his life in the Indian Civil Service, and present here to-day, assured me that the great success of the Judicial Department in India depended upon this superintendence of the subordinate judges. I bore this opinion in mind and determined to apply to Egypt the Indian plan, with such modifications as were necessary. I could not utilise the Supreme Court in Egypt. Its reputation was not sufficiently established to justify such an augmentation of its powers. Still less could I utilise the district judges. Yet I had to find men of such weight and authority for my committee

of superintendence that their names would obtain universal respect. The office of Judicial Inspector existed in other parts of Turkey, but it was only a cloak to abuse, because the inspector was as corrupt as the judge. I had to find my men amongst the Europeans in the country. I decided on a committee of three, composed of the Judicial Adviser as President (myself at that time, now my successor), with the Standing Counsel to Government, an Italian, Signor Moriondo, who had held high judicial office in his own country, and the *Procureur-Général*, a Belgian, Monsieur de Grelle, who had also held high judicial office in his own country, as members. I thus secured a committee with European judicial rank, which would ensure respect and confidence. I did not confer on this committee the power possessed by a High Court in India. In India, a High Court can not only send for proceedings and require explanations of any subordinate judge, and inspect the conduct of business in any subordinate court, but it has also a power to revise judgments and to alter sentences. I determined, as I have already said, to stop at superintendence. Consequently the Committee of Judicial Control in Egypt has no power to vary any judgment or sentence. The *decisions* are absolutely free from any control, but the committee, through its inspectors, at first three in number and now six, examines the *work* of every tribunal. The inspectors come from the upper ranks of the judicial body, half English, half native. They make reports to the committee once or twice a week. Their reports are examined and discussed by the committee, and whenever any fault is *made clear*, the fault is communicated to the judge concerned, or if the matter is very important, notice is given by general circular to all the tribunals. In spite of much adverse outside criticism the plan has been received with cordiality, and every assistance has been given to it by all the judges throughout the country. The tribunals dread the reproaches of the committee, and the absence of any note or circular for any considerable period is considered by the judges a matter of congratulation. The necessity for fault-finding has diminished, but, I am bound to add, the day is still far distant when this superintendence can be entirely withdrawn. I must also say that it was never extended to the Supreme Court of Appeal, although it included the provincial Appeal Courts, whose appellant power was much more limited. Everything possible was done to strengthen the prestige and independ-

ence of the Supreme Court of Appeal as the highest judicial authority in Egypt. Before I leave the subject of judicial superintendence I should like to add the opinion about it expressed by Lord Cromer and my successor, Mr. McIlwraith, in Lord Cromer's recent report on Egypt. Lord Cromer says :—

“I have on several recent occasions alluded to the Committee of Judicial Control which was instituted by Sir John Scott, and which constitutes one of the most valuable of recent reforms in the judicial administration of this country. I can now quote Mr. McIlwraith's testimony on this point. ‘The system,’ he says, ‘has been the subject of much hostile criticism in some quarters, but it is found to work well in practice and it has a marked educational influence on the native judiciary in stimulating their efforts generally, and preventing the recurrence of particular errors of law.’”

The establishment of a judicial system in a country which had not known independence or justice for many centuries could hardly be secured without the assistance of Europeans. Lord Dufferin, in his report on the future of Egypt, maintained that European aid in the administration of justice would be necessary in the proportion of one European to three natives. It was difficult to find the right men, at the rate of salary which Egypt could afford, and the advantage of Europeans all over the country, not knowing the people or their language, was very doubtful. We decided to concentrate European assistance in the Supreme Court of Appeal, and in the Courts of First Instance of Cairo and Alexandria. The Court of Appeal is now composed of 20 members, of whom 10 are European and 10 are Egyptian lawyers. Of the ten Europeans, nine are English; one is a Belgian, and it is understood that when he retires his successor will be English. There are two Europeans in the First Instance Tribunal at Cairo and one at Alexandria. The rest of the judges at the provincial capitals and at the 45 judicial centres are all Egyptian. The majority are Mohammedans, but a due proportion of Christians, whether Koptic or Syrian, also hold judicial office.

One great obstacle to the increase of business in the native tribunals was their expense; the fees exacted were exorbitant, and as most of the civil claims were of very small amount, the people were deterred from coming to court. Several experiments in the way of reduction were made, without much success, as a general diminution of costs was not favoured by the Treasury on account of the risk of loss of

revenue. But eventually the financial authorities withdrew their opposition, with a result most satisfactory to themselves as well as to the country, and consented to a very great diminution of legal fees; which resulted in such an increase of legal business that the aggregate receipts were more than they were before. It is satisfactory to be able to state that the receipts in 1891 were £78,000, with a very high tariff, and in 1899 they reached £115,000, with a very low tariff, whilst the number of civil cases heard rose from 16,800 in 1891 to 69,400 in 1898, of which 68,445 are cases decided by a single judge.

It is astonishing how rapidly a judicial *esprit de corps* has sprung up in the country. The Judiciary have now become an important body in the State, and are no longer neglected outsiders in the administration, who could be named and dismissed in a day, who received orders from the powers that be, and carried them out as if it was part of their duty. They are men of legal education possessing legal degrees. They have their proper place and rank in the Government service and at the State levées, and they wear judicial costume when in discharge of judicial functions. The Khedive, in his frequent journeys through the country, never fails to see the judges and tribunals. I must not take up time by many instances of judicial independence, but I will mention three. I remember three years ago one of the richest and most influential people in Lower Egypt was charged with forgery. He moved heaven and earth to save himself from punishment, and was absolutely astounded when the court below found him guilty, and the Court of Appeal confirmed the conviction. In the same year, the son of one of the wealthiest proprietors in Egypt had chosen to amuse himself by organising a band of brigands, who attacked outlying villages and robbed and killed as they used to do in the good old-fashioned times. He was just as much astonished as my friend the forger when he found himself doing a long period of penal servitude. Only last year, a Prince, cousin of the Khedive, great grandson of the founder of the Khedivial family, walked into the principal club of Cairo with a loaded revolver and fired upon and wounded another Prince of the Vice-regal family with whom he had a quarrel. He, too, like the forger and the brigand, is suffering in a convict prison the effect of the new reign of equal law.

There was, however, a time of transition, when all arbitrary action was suddenly abandoned

in favour of the impersonal action of law, and it seemed as if the country was not ready for the change. The older fashioned inhabitant shook his head and said it would not do. "They want the hand of a master and the courbash is better than your codes" said one of the older Pashas to me. There was no doubt a risk in the experiment. In the old days guilty men may have escaped, innocent men may have suffered, but order was maintained. The following story will tell how things used to be done. Two travellers went to see Kalioub, a town a few miles from Cairo. They called on the Mamour (Governor) and talked to him of his province. Whilst they were there a report came of a murder, and the police brought in four men as the accused. The Mamour sent the men to his Secretary to be examined. The Secretary returned in a quarter of an hour and said that from the confusion of their answers he was convinced of their guilt. The Mamour then said "Good, telegraph to Cairo and ask what shall be done." Answer came back "Since the guilt is evident let them be hanged." And they were hanged next day. Whole villages were uprooted and the inhabitants deported to the South because murderers were not produced. Nubar Pasha once said that a woman could walk from Alexandria to Assouan with her gold bangles on her arms, without the slightest risk of robbery. When the rule of law was declared, this security for a time disappeared. Bands of brigands were formed, and whole districts were considered unsafe. The police connived at crime; the peasants refused, from fear of revenge, to denounce any offender whether great or small. The desire of revenge was not satisfied by the punishment of the offender by the law. I was present myself at the trial of an old man who had killed his neighbour for removing the landmark which divided their property. "Why," asked the presiding Judge, "did you do this, when the law had already punished your neighbour?" "Because," the old man replied, "I was bound to have my own revenge."

But this transitional period—which was at its worst when I was appointed—has now yielded to the reign of law.

There is now not a single band of brigands left in the country and there are as few crimes in Egypt as there are in England in proportion to the population. Not very long ago I had an interview, in a convict prison, with the most noted of all the brigand chiefs, a man named Ahmed Selim. He ought to have been hanged, for he had killed a great many people,

but he had only been given penal servitude for life. He talked freely, and bitterly complained that the peasants had betrayed him to the police, which, he said, would never have happened in the old days. And he added: "There is no trade of robbery now, the peasants only rob and then go to work, and then they work, and then they go to rob. But the brigand who was only a brigand has gone."

I have already stated that the *Parquet*, composed of the *Procureur-Général* and his deputies, corresponds to the office of the Public Prosecutor in England, but at the outset of our reforms this description was not formerly quite accurate. The *Procureur-Général* was something between a counsel and a judge; he could even ask the court to acquit the prisoner, and really played the part of an extra judge, who was not only charged with the prosecution, but held the scales of justice in his hands. This system may work well enough in France or Italy, from whence it was borrowed, but it led to many acquittals in Egypt. A weak court, or a lazy court, really followed the lead of the *Procureur*, and did not take the trouble to examine the facts and decide for itself. After the usual amount of discussion, I obtained a change in the system, and the *Parquet* is now confined to the direction of the police in the investigation of crime, and to the development of the charges as prosecuting counsel when the case has reached the stage of final trial. In order to ensure the accomplishment of this reform an Englishman was appointed as *Procureur-Général*.

Another change was made in favour of the speedy and certain repression of crime. The French system of the *Juge d'Instruction* had been at first adopted in its fulness. Every crime, however unimportant, had to go through the stage of judicial investigation before the *Juge d'Instruction*. The case was prepared by the police and *Parquet*, but however complete it appeared, it had to be examined, and all the witnesses heard, by the *Juge d'Instruction*, who alone could send it to trial. This caused not only great delay, but was so inconvenient to witnesses, that those who could give evidence always maintained they knew nothing, and the crime went without punishment for want of proof. We determined that only cases of great importance, requiring very delicate management in their preparation, should go through the preliminary of the *Juge d'Instruction*. The decision as to what cases should still be presented to him was entrusted

to the *Parquet*. As a matter of fact the *Juge d'Instruction* is scarcely ever called upon; the cases are presented direct to the court, with the result of greater promptitude, increased ease of obtaining evidence, and a more certain punishment of crime.

Until five years ago it was almost impossible to apply capital punishment as the extreme penalty of the law in the case of crimes however atrocious. Capital punishment was admitted as one of the penalties to be applied under the criminal code, but whilst this provision was adopted from the French law, another provision was introduced by Mohammedan professors which rendered the power almost illusory.

Article 32 of the Egyptian Penal Code ran as follows:—"The death penalty can only be pronounced in the case of a confession, or if at least two witnesses give evidence that they saw the accused commit the crime."

This article led to two unfortunate results. The police from excess of zeal were either induced to extract confessions, true or false, by violence, or they suborned witnesses to swear falsely as to what they had seen. Under the new *régime* these methods were strictly forbidden, and consequently, as murderers do not as a rule commit the crime in the presence of others, or confess their own guilt, capital punishment was hardly ever inflicted, even in the most atrocious cases of brutal murder. It was proposed to suppress Article 32, and to prove the crime of murder, equally with other crimes, by the ordinary laws of evidence. But the discussion lasted over a year, and the Mohammedan authorities finally yielded on its being shown that the penal code, applied throughout the Ottoman Empire on the authority of the Sultan, did not contain this exceptional provision. I hardly need add that capital punishment is still very rarely used, but in a country new to justice, where order and security are still imperfect, terrible cases of brutality sometimes occur which call for the punishment of death.

I will not trouble my audience with a detailed account of all the smaller changes we effected. There are one or two, however, I should like to mention. False testimony was terribly prevalent in the Egyptian tribunals. As in India, a judge's greatest difficulty was to find the truth in a heap of lies. Prosecutions for perjury were long and intricate. Some speedier remedy was required. We decided to empower the judge to treat flagrant perjury *séance tenante* as a contempt of court punishable by a

very limited period of imprisonment. The power has been much used, and already the lying has considerably diminished.

Before 1891 there was not a single Tribunal of First Instance which possessed a law library. The judges had their codes, but that was all. Yet these codes were taken almost entirely from the legal system in use in France, and each French Code has been explained at length in excellent commentaries compiled by eminent French lawyers. We selected those commentaries on the French Codes which have the greatest authority in France, and sent a complete collection of them to every tribunal, great and small, throughout the country. I may add that all the judges read and talk French as well as Arabic. French and Arabic were the languages used on an equal footing in the School of Law. Last year, I am glad to say, the Educational Department was enabled to add English to the languages used in the teaching of law.

Another change of some importance was made. Until a few years ago, no authorised reports were published of the decisions of the native courts. Yet publicity at a certain stage of judicial institutions is not only a check on judicial carelessness, but acts also as a stimulant to the production of sound and well-considered judgments. An able lawyer, who was one of the editors of the reports of the mixed courts, undertook to publish monthly the reports of the decisions of the native courts, and the result has been excellent.

There was no useful labour in the prisons. We carried a Bill empowering the present authorities to improve such labour as was suitable to the prisoner, and now there are many prison industries which not only bring in money, but enable the man to earn an honest livelihood when he is set free. The measure was much opposed. I remember when I attended the Legislative Council to support it, one of the older fashioned rose and asked if a Pasha was sent to prison would he have to work? I replied that I trusted the Pashas would never commit crimes, but if they did and were condemned they would have to work like anybody else. The Bill was passed by a very narrow majority. It was followed by a second measure, which enables the authorities to utilise prisoners for public works outside the prisons.

The prisons were defective in another and even more serious way. There was no distinction made between first offenders and hardened criminals, young boys and old men:

all were herded together. Prisoners are now classified and segregated, and juvenile offenders are sent to an excellent reformatory, where they are taught a trade and to read and write. Until four years ago there was no record kept of old offenders. Previous convictions are now recorded and proved in Court, whilst the Anthropometric system is introduced in the prisons.

There is one more point. The native courts have not at present any jurisdiction in questions of personal status—questions of marriage, alimony, divorce, or succession—which are decided according to the *cheria* or sacred law by the Kadis, under the direction of the Grand Kadi. All students of the Koran know that the amount of jurisprudence to be found there is really small. Mr. Stanley Lane Poole tells us that chapters II, IV, and V contain all the law of the Koran, but even in those chapters ritual and ceremonial and morality are strangely mixed up with civil and criminal law. However, round the law of the Koran, there has grown up a quantity of juridical literature, Arabic and Turkish, which is now given authority, and the Kadi courts claim the exclusive right to administer it so far as it relates to personal status. These Kadi courts had become subject to such abuse that they were a crying scandal. The country was hardly prepared for their fusion in the native tribunals. We, therefore, proposed to impose upon them a simple system of procedure, that is of first-instance tribunals with an appeal court, and to give the winning party the right of execution of judgments concerning inheritance and succession. Our proposal was accepted. A system of inspection, analogous to that practised in the native courts, was also created, and the control of the property of orphan minors was placed in the hands of the native Court of Appeal. More important still was a proposal to fuse the Grand Kadi's Court of Appeal with the Mohammedan members of the native Court of Appeal. This proposal, which I left in the hands of Mr. McIlwraith, my able successor, was accepted, thanks to to his advocacy, but it has not yet become law on account of the opposition of the Legislative Council for the astounding reason that the reform is contrary to the Mohammedan religion. This stubborn resistance to reform may lead to the fusion of the religious with the ordinary tribunals. Such a fusion would be most welcome in the country.

It would be the forerunner of a still more important amalgamation. It was the ambition

of Nubar Pasha, it was my ambition, it was the ambition of every lover of Egypt, to steadily improve the Native Courts, until they could fairly claim to administer every form of justice to every class of suitor, and to every nationality. Lord Dufferin said in his famous report of 1883 on Egypt:—"It is the natural and legitimate ambition of the Egyptian Government eventually to supersede the international tribunals by its own tribunals." It will take time. They are not yet ready. But I hope you agree with me that they are on the way.

Now I have told my story, I trust without wearying my audience. I propose, my Lord, to conclude my lecture with the final words I spoke at the leave-taking with my friends in Egypt last May:—

"I came to Egypt first in 1872 as a perfect stranger. I was welcomed on all sides as a friend, and from that day to this I have received nothing but kindness from all who dwell in Egypt. It is a satisfaction for me to feel that I have done some little good in the country which has treated me so kindly, and which I love so well. Sir Edward Malet, in a farewell speech in 1883, declared his great wish for the country was 'Justice, Justice, Justice.' I am proud to think I have had a part in the realisation of this grand desire. I found in 1890 a set of native tribunals that were struggling for existence. I leave behind me a set of national tribunals which will, I trust, be the backbone of the country for all time."

DISCUSSION.

Sir RAYMOND WEST, K.C.I.E., said this subject was one of very high importance to an English audience, because the credit of our country was most deeply involved in the success or ill-success which attended the late measures in Egypt; and in the basis of every reform there must be that moral element which was involved in the administration and appreciation of justice. He had no claim to speak on this occasion, except that having had a little experience in Egypt himself, as the predecessor of Sir John Scott, in the kind of work which he had to some extent carried out with remarkable success, although there was still something to be done, he had an opportunity of seeing what the necessities of the country were, and the means at our disposal of meeting them. Nothing struck even a casual visitor to Egypt more than the necessity of continued pressure on the population of the weight of intelligence and high principle borrowed from Europe, and that ought to be infused, first, into the indigenous administrative body, and, secondly—and this was even more important,—through the whole judicial system. That struck him very much when he went to give some assistance in the organisation of the

courts in 1885 and 1886. One of the first points which he was led to dwell upon in his conversations with Nubar Pasha was the very low position held by the native tribunals, which they must continue to hold as long as there was by their side another set of tribunals manned practically by delegates from the European Powers, representing their intelligence, but also their jealousies, and in many instances nominated practically not so much to administer justice to people in Egypt as to maintain the dignity and the interests of the country that sent them. Over and over again he dwelt upon the necessity of getting rid of this system, and though Egypt itself could not get rid of it, they would, at any rate, pave the way for it by raising by degrees the status of the judges of the indigenous tribunals. One means he proposed was that there should be an interchange of *personnel* between the two; that wherever it was possible to give a member of the mixed tribunals promotion, by putting him into one of the indigenous tribunals, the opportunity should be taken of doing so, and, on the other hand, when a man had distinguished himself in the native tribunals, an opportunity should be taken, if possible, of putting him into the mixed tribunals, and he hoped in that way there would be a gradual elevation, not only of the intelligence, but of the dignity and self-respect of the members of the native tribunals. He hoped that supplement to the general scheme advocated by Sir John Scott would receive his support so far as it might be found necessary in the somewhat changed circumstances now existing. With regard to the *personnel* of the courts, he might mention one matter which came under his own observation. When, as *Procureur-Général*, he took a part in conferences of the chief Court of Appeal of Cairo, he found that one of his colleagues had graduated in the position of station master. This judge had been able to show civilities to certain official persons, and as no more suitable way of rewarding him could be found he was put into the chief Court of Appeal. The *personnel* being such as it was, the necessity of supervision would naturally occur to any man of Indian experience, because in India it had been found very often that personal supervision of the courts, and an occasional visit by the superior judge or officer, and turning up of the records and discovery of negligences and ignorances here and there, had a most beneficial effect on the subordinate judges. This was a point upon which he often dwelt in his conversations with Nubar Pasha, and he had touched upon it at some length in one of his reports. He confessed there was a point in the system of revision, which was now apparently established in Egypt, which seemed to him to present difficulties. The working of a court and the way in which a judge carried out his duties were connected at every point with the administration of the law, and it always appeared to him that the right system of superintendence was that adopted in India, namely, that the inspector who went round and

discovered negligence or errors in the work of the court should report to the chief judicial authority, not to a branch of the Executive. Now under the existing system in Egypt it seemed to him that this difficulty would be pretty sure to arise: that reports would be made by inspectors to the committee of inspection, and the committee would issue directions thereon or make remarks on the business as done by the judges in the local courts which might not agree, but might clash altogether with the views taken on some points by the High Court; and that would be a most awkward result. He thought it would be found necessary in Egypt, if there were a system of mixed inspection, that the results should be sent up to the chief court, and be dealt with there by a committee, by individual judges, or, in important cases, by the whole court. The incompetence of the judges was now to some extent corrected by exacting from candidates for judicial office a diploma. In his time he did not feel competent to go far in that direction; but he had headed a deputation from the Bar in Cairo to Nubar Pasha, asking him to accept a scheme of organisation of the Bar, and in connection with that it was proposed that a school of law should be established. It appeared to him, however, that even now the school of law was not founded altogether on a sound basis. It was a school headed by a French lawyer and teaching French law, but in Egypt there was a Mohammedan population, and this population would thus be subjected to French law to be administered under British supervision. Nine out of ten European members of the chief court were English, but it was impossible that this supervision by Englishmen and the predominance of English influence should be dispensed with. He, therefore, thought this school of law would want a considerable amount of revision and amendment before it could be considered satisfactory. A law school in Egypt ought to take into account the fact that the mass of the people were Mohammedans who could not regard with reverence any law not founded upon or deduced from the principles of the Koran. It was quite possible at the present day, when the great intellectual movement of the century had certainly reached the younger classes of educated Mohammedans, to found a school which would create a rejuvenescence of Mohammedan law, which it must be remembered was for many centuries considerably in advance of the Christian law which prevailed in Europe from the 7th to the 16th or 17th centuries. There had been such diffusion of practical views, as well as of moral ideas, amongst educated Mohammedans, that if the idea were taken up, and a Mohammedan school of law established on enlightened and liberal principles, he believed it would attain a brilliant success, and would be quite capable, under the hands of a man of genius, of proving that the Mohammedan law was readily adaptable to all the necessities of modern progress.

Mr. JOHN MACDONELL, C.B., LL.D., said he

could not speak with any particular knowledge of Egypt, but he was glad of the opportunity of paying a mark of respect to his esteemed friend, Sir John Scott, and of pointing out that the story he had told was a most remarkable one—a story of work crowded into eight years, which might have been spread with credit over nearly a century. They had heard a great deal of the marvellous military and engineering achievements in Egypt; but, if he were not mistaken, when recent events had receded into the distance and assumed their proper proportions, the narrative laid before them that day of judicial reforms would be as durable as that of any of those achievements to which he had referred. If this work had been accomplished, not in the reign of Victoria, but in some of the old dynasties, his esteemed friend would not perhaps have had a pyramid, but certainly an obelisk, or a monolith, or something enduring, would have been erected to him. This work was to him of all the greater interest, because it was part of a movement which was going on pretty nearly all over the world; wherever Western civilisation came into contact with barbarous, semi-civilised, or retrograde communities, there went on a struggle similar to that which had been described; the conflict of Western ideas of justice and Western modes of procedure with Eastern. Particularly was there a conflict between the Western notion of purity of justice when it came into contact with the crude notions which prevailed in other countries. At all these points, with few exceptions, foreigners were more conspicuous than Englishmen. In the great work going on in Japan, Frenchmen were conspicuous; in similar work in Siam Frenchmen were now conspicuous; but at all events, in Egypt where a work comparable to any of those accomplished elsewhere had been carried out, it was satisfactory to know that Sir John Scott had been the agent. One of the facts to his credit was, that whereas in all those countries, as a rule, the Frenchman, or the German, in charge of the work had taken care to apply his own ideas and the system to which he had been accustomed, Sir John Scott had the wisdom not to import blindly into Egypt English ideas, but had taken as the basis that which he found there and which was in many ways unsatisfactory—a French system of law and procedure—and had made the best of it. Possibly some hints might be derived from his work, which might be useful even in England. He noticed an observation to the effect that in its desire to accomplish certain reforms, the Treasury abated certain fees, and he wondered whether that had hitherto been characteristic of the Treasury of any country except that of Egypt. He would conclude by expressing as strongly as he could the sense of indebtedness they must all feel to Sir John Scott.

Mr. H. M. BIRDWOOD, C.S.I., LL.D., said that Sir John Scott, at the close of his most excellent paper, had, with characteristic modesty, expressed the hope that he had not wearied his audience. He

would venture to assure Sir John that, far from wearying that assembly, he had successfully sustained the interest of his narrative to the very end, and, by his sketch—which was all too brief—of the details of his work in Egypt, had but whetted the appetite of all present for further information regarding the important measures of reform which he had introduced during the past eight years. To Anglo-Indians (such as were some of those there present), who had been concerned in the administration of justice in territories still to a great extent under tutelage, his narrative was indeed of absorbing interest. He (Mr. Birdwood) well remembered the conversation which Sir John Scott had referred to in far too partial terms. It was on the eve of his departure from Bombay to Egypt; and as he (Mr. Birdwood) described to him some of the salient features of the judicial system which had been adopted in the rural districts subject to the jurisdiction of the Bombay High Court, he was greatly impressed by Sir John's eager determination to secure for the people of Egypt some of those advantages which had been secured for the people of Western India by the establishment in most districts of civil and criminal courts within easy distance from the homes of the people—if not exactly at their own doors, in every town and village, yet not very far from the principal centres of population—and by the due and regular administration of justice in those courts. Sir John Scott was weak from illness at the time, and his strength of purpose, in depressing circumstances, in a strange land—if any land could be strange to one of his name—was a clear manifestation of the *perferendum ingenium Scotorum*, by which he had never ceased to be inspired, even to the present day. He (Mr. Birdwood) would not attempt to describe in detail the peculiar merits of the Indian system. Still there were one or two matters to which he wished to refer, as they had a distinct bearing on the subject of Sir John's paper. And, first, he wished to bear his testimony to the vast improvement which had taken place in the *personnel* of the judicial administration during the past forty years. He would speak only of matters within his own knowledge. He could not indeed recall a time when the administration of justice in the Bombay Presidency was in so deplorable a condition as presented itself to Sir Raymond West and Sir John Scott in the early years of their Egyptian experience. Still, he remembered a time when it was far from satisfactory. But there had been a steady improvement everywhere, which had been the result of much careful consideration of the requirements of the people and of an earnest and continued effort to raise the qualifications and the whole tone of the judiciary. He was referring mainly to the large body of native judges of the subordinate courts, by whom the great mass of original litigation throughout the length and breadth of the country was dealt with in the first instance. No officer could now be appointed a subordinate judge unless he had either practised for five years as an advocate of a High Court in India

or a pleader of the High Court of Bombay or had passed a sufficiently severe examination to test his knowledge of law—either the examination qualifying for the degree of “LL.B.” in the Bombay University or an equivalent examination prescribed by the High Court—and had, in addition to such test, practised, in accordance with a recommendation first made by Sir R. West, for a certain period in the civil courts or held certain offices therein, so as to become thoroughly conversant with legal business. Salaries had also been provided by the Government on a liberal scale, so as to attract candidates possessing the requisite qualifications; and promotion to higher grades of salary or jurisdiction was regulated, not merely by seniority, but depended also on the efficient discharge of duty. The records of cases heard by the subordinate judges came under the notice of the superior courts, not only upon the hearing of appeals, but could also be inspected by the judges of these courts, not with a view to any judicial interference, but in the exercise of a power of superintendence, recognised by law, with a view to the correction of faulty procedure and the prevention of any practice injurious to litigants or witnesses, and the more certain attainment generally of the objects for which courts exist. To this last duty special importance had always been attached by the High Court; for not only are there many matters connected with the disposal of judicial business which cannot well be considered at the hearing of an appeal against a decree or order, or an application for the revision of a decree; but the sub-judges are often at distant stations, isolated from any wide intellectual or professional society, and they welcome the periodical visits of the district judge or an occasional visit by a High Court judge, as furnishing an opportunity for discussing a hundred and one difficulties encountered in the daily practice and procedure of the courts. And, lastly, the High Court had used every effort, and with remarkable success, to raise the qualifications of the members of the legal profession practising as pleaders on the appellate side of the High Court and in the district and subordinate courts. The results of such a system, so patiently and thoughtfully worked out, had been most encouraging. The subordinate judges are, as a rule, well educated men of high character, who command the confidence of the people, and in the ranks of the indigenous judiciary and of the pleaders the Government can confidently seek for qualified candidates whenever the occasion arises to appoint a native of India to a seat on the bench of the High Court. As a matter of fact, there had been a succession of Indian judges of the Bombay High Court who had filled the position with eminent distinction. Sir John Scott had adopted methods in Egypt not very dissimilar from those in force in the Bombay Presidency. Judicial salaries had been made sufficiently liberal to attract the best talent available to the courts of first instance. Trained judges had replaced the incompetent judges

of former days. The number of courts had been increased, so that people had no longer to travel long distances to obtain justice. The administration of justice had been made as speedy and as little burdensome to litigants as possible. Sir John Scott had, moreover, proceeded with caution, correcting palpable abuses, which had long been unchecked, and improving the available machinery as best he could. That was the surest way to carry the people with him. Reforms so effected were likely to last. One of the methods employed was an adaptation, though in a modified form, of the system of superintendence which had proved so useful in India. It was most satisfactory to Indian judges to hear of the great success which had so far attended Sir John Scott's efforts, and the only further comment he wished to offer was that nothing had been said as to the improvement of the local Bar in Egypt, but certainly that could not be a matter which had been lost sight of. And, after all, the reformed judicial administration in Egypt was still in the days of its early infancy. Patient continuance in the good work which had been begun would bring incalculable benefit to the people. Sir John Scott was to be heartily congratulated, not only for the admirable address to which they had just listened, but still more on the great work of which he had laid the foundations so well and truly.

The Right Hon. JAMES BRYCE, M.P., D.C.L., said he had enjoyed the friendship of Sir John Scott for more than thirty years, and he had also been in Egypt twelve years ago, shortly before Sir John commenced the operations which had been described, and which had conferred such inestimable benefits on Egypt. He remembered asking about the condition of the local judges and tribunals when he was in Egypt in 1887, and the account he received was perhaps even then a trifle better than would have been given in most parts of the East; but still it was to the effect that there were extremely few judges amongst the natives who could be trusted to give an honest decision, and that the measure of intelligence and knowledge was comparatively low. Any one who had travelled in the East knew it was a matter of course, except in those parts where, as in British India, a Western Government had come in, that the judge should be corrupt. Nothing else was expected from him. He would be regarded as stupidly neglecting his opportunities if he did not plunder suitors whenever the chance came. Therefore, the difficulties which a judicial reformer had to encounter in an oriental country were immeasurably greater than any one could realise from a knowledge only of Western Europe. The old habits of ages had to be broken down, and the very idea of judicial purity was so strange that it took some time to create the public opinion which was needed to support the efforts of the reformer. Egypt had had as melancholy an experience of foreign tyranny and misgovernment as any other part of the

East. Sir John Scott had said truly that justice was the first great need of such a society, and that no country had had greater ill luck than Egypt, because no country had had such uniformly detestable administration ever since the Mohammedan conquest in the seventh century of our era, with the solitary exception of the reign of the Sultan Saladin, during which time there was a vigorous and effective execution of the law, owing to the initiative of that great sovereign, which made his reign long remembered as a kind of golden age in Egypt. After those many centuries, at last the hand of the West had appeared, and a work had been done there of which they might be justly proud, and no one had borne a worthier part in the reform effected in Egypt by Great Britain than Sir John Scott. He could say, not indeed from direct personal knowledge, but from what he had heard from many well-informed people who had lived in Egypt during the time, that it would have been impossible to effect those reforms but for the unflinching tact, judgment, courtesy, moderation, and sympathy (as far as possible) with native ideas which Sir John Scott always showed. The improvement effected was enormous, yet he was afraid that even such work as Sir John Scott had done could not be considered to be so firmly rooted that if the protecting hand of Britain was withdrawn it would be certain to survive. He would not enter on the interesting question raised by Sir Raymond West, whether there might not be an independent revival of Mohammedan law, and a prospect of developing it into a system fit for a civilised country; but he should have thought that, although that might be interesting as a legal experiment, particularly to students of legal history, it might have its political dangers, and he should feel serious doubts as to its expediency.

The CHAIRMAN said he had now the honour of proposing a vote of thanks to Sir John Scott for his interesting address. He ought at an earlier stage to have called attention to a letter received from Lord Dufferin, who wrote expressing his great regret at not being able to attend on that occasion, and he added that "Sir John Scott has done a great work in Egypt, and we were most fortunate in securing his services for that country." Letters of a similarly appreciative kind had been received from the Lord Chancellor, Lord Rosebery, Lord Kimberley, Lord Roberts, and Sir Edward Grey. No one who had listened to the very simple and modestly told story of the work of Sir John Scott could have any doubts that these compliments were, in their highest and best sense, deserved. He confessed it had been a peculiar pleasure to him to have been able to preside there, because, like his friend Mr. Bryce, he was a friend of very old standing with Sir John Scott. He took, like all other members of the Northern Circuit—of which Sir John was one—an honest and just pride in the fact that one of its members had achieved for himself so distinguished a career, and

had accomplished such solid work for his country. He recollected Sir John Scott when he thought him a man not likely to live long on the face of the earth, for when he was his colleague on the Northern Circuit he was in the most indifferent health; but at the same time he was always genial, sympathetic, determined, and courteous, as he was now, but he confessed he did not look forward with much hope to a prolonged professional life for him. He could only say it was one of the highest testimonials he had come across to the efficacy of hard work in promoting health, and to the salubrity of the Indian and Egyptian climates. It was a very remarkable story, a great work accomplished in something like seven years, and one could not but reflect that Sir John Scott must have had certain advantages in that. For instance, he had not the slow and cumbrous legislative machine that we had to deal with in this country. He was able to get his Bills without blocking through the legislative body, and without much difficulty, and he had the advantage undoubtedly, which he had recognised in his paper, of the strong moral and political support of, amongst others, Lord Cromer during the whole period. The change had certainly been very great. Sir John Scott arrived in Egypt to find a judiciary weak, unlearned, and corrupt, and he had left a judiciary with every hope that in time it would cultivate and acquire a sense of responsibility and self-respect as high as was to be found in the judicial systems of the West. He found a Bar marked by the same failings and shortcomings, and he had improved all these things. He found also that ordinary security for life and property were wanting, that crime went unpunished, and under the new and better system crime was now visited by adequate punishment, and the per-centage of crime was not as great in proportion to the population as in many of the communities of the boasted Western civilisation. One thing, however, struck him (Lord Russell) during the address, and that was that the great factor in such improved conditions had been British influence in Egypt. No one could doubt that this empire had made great sacrifices to help Egypt, and yet it was certainly a significant and a regrettable circumstance that the English tongue was not an instrument of knowledge or used in the courts of the country. Why was it? Why was there no immediate hope that that language and the influence of English thought should speedily become more general than it was now? When Sir John Scott cast about for the material with which to create the new judiciary, he had to rely on students who had got their education and their legal degrees, some in Italy, and some in France, but none in England. He wanted to know why? Was it not largely due to the fact that here in London, in their system of legal education, they did not recognise the great responsibilities they owed, and did not in their legal teaching offer the advantages which they ought to offer to attract from

all the English-speaking communities on the face of the earth, and where English influences prevailed, attractions which would induce students, including even those of foreign birth, to come to our schools? It was a positive disgrace that at this moment they did not offer any assistance in the teaching of the law which they had to practise abroad to any of the students that might come either from the Colonial dependencies, our spheres of influence, or even from such a country as India. He was aware that in the Universities there were students prepared for the Civil Service in India, and important work in that direction was being done; in Cambridge very largely by the efforts of Sir Raymond West; but in London—the great heart and centre of things, the seat of government, where the pulse of power beat most strongly, and from which radiated over the world in greatest measure the influence of the people of these islands—there was no provision of this kind, not even the very slightest. He thought this was a matter which required to be looked into, and he hoped they would find very soon that in the school of law which had been founded by Sir John Scott they might have the English language, which had been recently introduced, largely used, and competent English professors spreading ideas of English law, and with that ideas of English policy, and, therefore, of English influence. In conclusion, he might say that in the vote of thanks to Sir John Scott they were not thanking him merely for the literary merit and charm of his address, but still more for the great work which it recorded.

Professor A. V. DICEY, in seconding the vote of thanks, said that, like the Lord Chief Justice, he could carry back his memory of Sir John Scott for a great many more years than he liked to think of. He should like to give expression to what they all felt, that the work Sir J. Scott had done in Egypt was greatly owing to his extraordinary powers of sympathy, which were well-known on his old circuit. That was one of those gifts which was not perhaps quite so prominent in the Anglo-Saxon as some other virtues, but it was a gift which qualified the possessor more than anything else for administration in the East. Whenever he saw a young man, and he saw a great many, going out to govern India, he always hoped, and, in many cases, found that they were not only capable men but that they were sympathetic—that they would not go out with anything like dislike or contempt for men of one colour or another. He had never known a man who had so many English virtues of the highest kind, combining them with such sympathy, such tender sympathy, with the cause of the Egyptians themselves; for, after all, every man felt that the moral justification of England's presence in Egypt was that Englishmen were there, and ought to be there, for the benefit of Egypt, and not merely for that of England. Sir John Scott had represented this feeling better than any other man who could have been sent to

administer justice to Egyptians; and it was for that reason he joined with the greatest cordiality in seconding this vote of thanks.

The vote of thanks having been carried unanimously,

Sir JOHN SCOTT briefly responded.

Lord SHAND then proposed a vote of thanks to his noble and learned friend, the Lord Chief Justice, for presiding. He said he came there quite ignorant and inexperienced with regard to Egyptian matters, but anxious to learn, and he had learnt a great deal. It was certainly amazing that in so short a space of time Sir John Scott had been able to bring about such a radical and complete reform, for which Egyptians ought to be exceedingly thankful to him. He had heard for the first time of the system of inspection of judges. He could only feel thankful that there was nothing of the kind in existence when he was a judge of First Instance. With regard to his noble friend in the chair, he had been much struck with the many sidedness of Lord Russell's character, which had been exhibited within a very short period. There seemed to be no matter of interest in which he was not prepared readily to take part. He had recently delivered an important address to the Chambers of Commerce with regard to a subject of great interest to the whole community, upon which he had introduced a Bill in the House of Lords. Again, only the other day, he was presiding at one of the most important of charitable institutions of this country, that which took up discharged prisoners, who were thrown on the world with nothing to look forward to but a recurrence of crime unless a kindly hand were extended to them. And again at Gray's Inn, within two or three-nights ago, they found him helping the students by describing the art of pleading, and himself taking part in the education which was so valuable, and again that evening they had heard him within ten minutes deliver a most brilliant address, for which they would all concur in thanking him most cordially.

The CHAIRMAN having acknowledged the compliment, the meeting adjourned.

The *Times* of May 5th contains the following letter:—

“SIR,—Last Thursday, at the lecture I delivered on ‘Judicial Reform in Egypt,’ which you were good enough to fully report, the Lord Chief Justice of England and other speakers, whilst full of praise of what had been done, somewhat demurred at the scanty teaching of the English language and the consequent scanty use of English law and English lawyers in Egypt.

“I had not the opportunity at the time to explain how matters exactly stood. But I am now in pos-

session of all the facts, and if you are able to give me hospitality, I think the public might like to hear them.

“French was the principal European language in Egypt at the time of the British occupation of the country. No violent change was attempted. There were more important things to be done. Order, security, and good finance had to be established. Moreover, at that time and up to quite recently the French opposed with the utmost vehemence every English reform. Careful choice had to be made of the reforms to be pressed. So the question of the English language was not raised. In 1890, when I went there, the pupils in Government schools who learnt French numbered 3,199, while those who learnt English only amounted to 1,747. ‘Linguistic free trade,’ to use an expression of Lord Cromer’s, was allowed, parents were free to choose French or English for their children, and, as French was in general use and there was at that time no certainty the English would stay in the country, they naturally chose the predominant language.

“A few of us who were perfervid Britons organised a little later on an ‘English Language Prize Fund,’ and some £300 a year was subscribed by the English in Egypt and distributed to the pupils of the various Government schools over the country who were most proficient in English. But this artificial stimulus had only a very short existence. There was no lack of British zeal and British money. But Riaz Pasha, an old-fashioned Turk, came to power and absolutely refused to allow our prizes to be distributed. Still less would he hear of our annual meeting and public distribution. His advent occurred after we had bought our prizes; they were all stuffed into a big cupboard in the Ministry of Public Instruction, and I should not be surprised if our watches, books, inkstands, &c., are still in that cupboard.

“Lord Cromer would not interfere, so our scheme collapsed. His Lordship, quite rightly, as it seems to me, thought the moment inopportune to take a step which would have irritated not only the retrograde Egyptian Prime Minister, but also the French colonial party, at a moment when larger disputes needed settlement.

“Linguistic free trade, however, has produced excellent results since then. The figures given by Lord Cromer in his last report speak for themselves. The per-centage of French-learning pupils as compared to English-learning pupils in 1889 was 74 to 26. In 1898 the per-centage was 33 French-learning pupils to 67 English-learning pupils.

“The people have realised that the English intend to stay in the country. They will choose the language that is most to their interest to learn, and I feel confident that English will now advance by giant strides. Moreover, Lord Cromer is no longer checked by French opposition at every turn. He has a free hand, and no man in the country is more keen than he is to spread our language throughout the country. It would be useless to declare English a judicial

language in the native courts until the judicial, or, at any rate, a majority of the judges, has acquired its use. But that must come very rapidly now that English teaching is firmly established not only in the Government schools, but in the School of Law itself, the nursery of both Bench and Bar.

“Yours obediently,

“J. SCOTT.

“1, Adam-street, Adelphi.”

TWENTIETH ORDINARY MEETING.

Wednesday, May 10, 1899; Major-General Sir OWEN TUDOR BURNE, G.C.I.E., K.C.S.I., in the chair.

The following candidates were proposed for election as members of the Society:—

Carter, William Leonard, 51, Aynhoe-road, Kensington, W.

Jennins, Henry Horwood, Crown Works, Leeds, and West-hill, Chapeltown, Leeds.

The following candidate was balloted for and duly elected a member of the Society:—

Lowe, C. W., Summerfield-house, Reddish, Stockport.

The CHAIRMAN, in introducing Mr. George Bunyard, explained with great regret that Sir George Birdwood, who was to have presided on this occasion, was prevented doing so by illness. Mr. Bunyard was the author of “Fruit Farming for Profit,” which was now a text-book on the subject, had been connected with fruit growing for 44 years, was Chairman of the Edinburgh Fruit Conference, was for three years Member of Council of the Royal Horticultural Society, and was now Vice-President of the Fruit Committee of that Society.

The paper read was—

FRUIT GROWING IN KENT.

BY GEORGE BUNYARD,

Vice-President of the Fruit Committee of the Royal Horticultural Society.

IN THE PAST.

The county of Kent has always held a high, in fact, the foremost position as a fruit-producing centre. So far back as 1826, Hasted, in his famous Kent history (vol. 6, page 291), quotes Lambard, who says, “In this parish of Teynham, with thirty others lying on each side of the great road from Rainham to Bleau Wood was in his time (1570) the cherry garden and apple orchard of England,” and such it un-

doubtedly continued till within memory. Teynham, he says, was "the parent parish from which other plantations issued; for Richard Hayns, fruiterer to King Henry VIII., having observed those fruit plants, which had been brought over by our Norman ancestors, had lost their native excellence by length of time; and that we were served from foreign parts with fruits on that account, which he saw no reason for, as neither soil nor climate here were unequal to the bringing of them to perfection; determined to try a plantation of them here, for which purpose, having obtained, in 1533, 105 acres of rich land, then called the Brennet, and having with great care, good choice, and no small labour, brought plants from beyond the seas; he furnished the ground with them in rows in the most beautiful order. The fruits consisted of the sweet cherry, from thence usually called Kentish cherry, the temperate pippin, hence, for the like reason, called the Kentish pippin, and the golden renate, which sort, especially the first and last, have long been propagated from these in great quantities throughout the southern parts of this kingdom; but the Kentish pippin is now hardly to be met with even in this county. Pliny in his "Natural History," Book XV., chap. 25, says:—"Cherries were not in Italy before L. Lucullus's victory over Mithridates, king of Pontus; after which (in the year of Rome 689) he first brought them out of Pontus thither to Italy, 120 years after which they were transported into Britain."

Hasted (vol. 12, p. 46) says, apricots were introduced by one Worl, a priest, in the time of Henry VIII., and the red and blue Perdrigon plums and artichokes in Cromwell's time, 1570.

Sittingbourne, where the cherry trees attain gigantic size, and provide the largest and finest fruits, is at the present time one of the best districts for this specially Kentish product. No doubt, Hayns also grew pears, for there is no district that I am aware of, which produces such clean and well-developed pears, as it possesses a cool, deep, rich alluvial soil, and on that account has been largely drawn on by the brickmakers.

Michael Drayton, in his "Poly-Olbion," says (1563-1631):—

"O, famous Kent! quoth he,
What country in this isle that can compare with thee,
Which hast within thyself as much as thou canst wish—
The conies, venison, thy sorts of fruit and fish;
And what comports with strength: thy hay, and corn, and
wood,
Nor anything thou wants that anywhere is good?"

The Kentish cherry is grown to this day, also a similar but larger one, the Flemish cherry, both commonly called "reds." They are the Montmorency cherries of France. The golden rennet is one of our finest dessert apples. The Kentish pippin may either be the "Kent Fillbasket," or "Colonel Vaughan," still largely cultivated in Kent.

Gerarde, in his Herbal, 1597, figures six sorts of apples, but the Kentish pippin is not named, though he says:—"The county of Kent has a great many sorts of apples."

The proximity of Kent to the Continent would further account for the best known kinds of fruits of early times being introduced first by the Romans, whose custom it was to carry with them such fruits as they esteemed in their own land. For instance, the Roman station of Reculver (Regulbium) is credited with a blue fig they are supposed to have introduced, which is by experts referred to the *Violette de Bordeaux* of our gardens, a fig familiar to visitors to the Riviera, which often makes its appearance in our London markets in October and November. Later on, the Norman monks would doubtless bring with them their best fruits to plant in their religious establishments, the remains of which still exist at Charing, Canterbury, Eltham, Rochester, and Northbourne, near Deal, where there is a well-situated walled monastic garden, which is reputed to have been the gift of Ethelbert and his Queen, Bertha, to St. Augustine. It may therefore fairly be stated that from very early times Kent has had the advantage of the best-known fruits, and, through the monks, those elements of cultural skill which (even more than a fruitful soil), tend to make the Kent fruit famous, and give the county the title of "the garden of England." Hasted states that there were vineyards at Barming and Tonbridge.

Passing from primitive ages to the time of the Hanoverian kings, we find that although some few orchards were planted, still there were other field crops, as cereals, potatoes, and roots, which realised high prices and made the fortunes of the farmers of those times; but speaking generally, orchards were neglected, and little or no cultivation was done; apples being mostly grown for cider and pears for perry, two beverages which, later on, were driven out of use by beer, so that we yet find here and there very ancient trees producing fruits the names of which are not even known by experts in our day. At the period before the railways were pushed into Kent (the South-Eastern Railway was made to Dover in Feb-

ruary, 1844, to Gravesend 1845, and the London, Chatham, and Dover, about 1858, tapped the Cray districts, now noted for strawberries), it was manifestly impossible to deliver fruit from Central Kent to the London markets in good condition, and growers could only look to local markets for the sale of their surplus or best fruit, while the inferior apples and pears went to the cider-press. In the district between Dartford and London fruit orchards were numerous, being within easy distance of London; and the North Kent districts largely supplied the metropolis, especially Erith, Bromley, Abbey Wood, and Lewisham. From close observation of old orchards we may conclude that fruit-planting as an industry was neglected for half a century, but was again followed up when railways afforded facilities for transit and new markets were opened in London. In the years between 1840 and 1860 large breadths of new orchards were laid down and the Kent cob nut began to be cultivated, while the new system of raising orchards on cultivated land, with gooseberries and currants beneath the standard trees, came into vogue. This system is called in Kent a plantation (among the rustics, a "platt") as distinct from orchards on grass, which latter were too often grazed by horses and cattle to the detriment of the trees. It is from the older orchards of this date that the markets are now flooded with the bulk of that inferior hard fruit which disgraces our shops, being badly grown, carelessly gathered, and marketed in a slovenly way, affording a powerful lever to those pessimistic writers whose cry of "Oh, fruit does not pay," which comes round as regularly as each Michaelmas term. It were well if these worn-out orchards were grubbed up and the trees used for firewood, although by careful pruning and surface-feeding, excellent examples may be produced, and the vast bulk pays. Still, from a commercial point of view, the placing on the market of quantities of rubbish depresses prices, and it were wiser to sell all such produce to the cider makers, or if of suitable kinds as Wellington or Goff, to the jam makers for pulp. On the other hand, such old trees, if healthy, might be head-grafted with some of our best modern kinds. The feature of the orchards of this period may be described as haphazard, combined with neglect as to feeding the trees. In many cases, cattle took from the grass orchards all the nutriment, and not being corn- or oil-cake fed themselves, added to the general poverty of the soil. One of our foremost

East Kent orchardists states that, until he introduced manure into his orchards, its use for this purpose was quite unknown. Noticing that some of his trees where cattle congregated grew better fruit than others near, he took the hint; and pears of choice sorts in his orchards were quite equal to the same kinds grown in gardens.

IN THE PRESENT.

Having glanced at the conditions that prevailed in the past, we arrive at the year 1869, when that period of agricultural depression set in, which has been a great factor in turning the minds of farmers and landowners to sources of revenue other than ordinary three or four course husbandry. The gardening press had for some time been dinning into the ears of the public that vast sums of money were leaving the country for the purchase of such hardy fruits as could be grown in Britain. The daily press caught the same spirit, whilst the agricultural papers took up the idea earnestly, but slowly. By degrees this idea became a fact, and those men who went in boldly for fruit-culture at that time have made fortunes; and many labouring men, who had plenty of hard work in them, began in a small way and extended on all sides as they accumulated capital. There was another factor which had to be reckoned with. The removal of the excise duties from hops and malt had so depressed prices that orchards were found to pay better on an average of years than hops or barley; and fruit trees were introduced in the hop gardens in order that when they reached a paying age the hops might be grubbed and the land laid to grass, as before the introduction of foreign mutton and beef, live stock was as yet a safe investment for farmers. For, in a grass orchard, as an old hand once remarked to me, "We get three crops: mutton, wool, and fruit." The growth of soft fruit for the making of jam and preserves, bottling, &c., which had hitherto been a local business, now became a vast industry, and thousands of acres of poor woodland and thin arable lands were adapted to the culture of strawberries and bush fruits in the Swanley and Cray districts of Kent. No small amount of their success in those parts is doubtless owing to the cheap manure which they procure from London, where the authorities very rightly decline to have it stored, and it is this fertilising agent more than the soil itself which has justly made the Swanley fruit a name all over the kingdom.

Fruit-culture then began to be taken up as a serious business, and every advantage of

Improved systems of culture was embraced. New kinds of fruits in each family were tested, and their suitability for market, when once known, caused them to be largely planted. The matter of pruning, which we take to be the crux of the Kent system, was carefully developed, and it was found that very much finer examples could be produced by severe pruning, while such fruit made the highest prices. Timely pruning, gathering of the crop at several pickings, with an extra top dressing of manure in summer, gave results never dreamed of before. Growers were not slow in following such evident sources of profit, while new and distant markets became available, as the Northern and Western Railway agents eagerly competed for this traffic; and so it came to pass that strawberries (which are one of the most perishable fruits) could be gathered at Swanley, and put on rail to reach Glasgow and Edinburgh the same day in good order.

My remarks in this division have hitherto referred more to soft fruits (currants, raspberries, cherries, and strawberries), but attention was at the same time given to plums and apples and the hardier kinds of pears, which soon proved themselves to pay handsomely for cultural care, while the introduction of the paradise stock for grafting apples upon, enabled growers to obtain crops from trees three or four years old in bush form. The fruit from such trees, by its proximity to the ground, and by the aid of reflected heat, possessed such beauty, size, and appearance, that even in years when a glut of fruit obtained, the apples from the paradise trees made a good paying price. In fact it pays a farmer to plant them on a 14 years' lease. Instead of the old tall orchard standard trees, plums planted as two year old trees, headed back low for half standards, became the rage, and gave a crop the fourth or fifth year, and by a combination of the plantation system with top fruit, very large returns were secured from a small acreage. A word as to the paradise stock. It is a surface rooting apple found in the central Asian mountains and was named *Malus Paradisica* from its being discovered near the supposed region of the Garden of Eden. This variety, though a weakling by itself, gives great vigour to the apple scions and buds placed upon it, and causes the trees to produce fruit (as before stated) much earlier than trees raised on the crab apple. Heavy crops are frequently obtained on two-year trees and have to be thinned out. All the sorts of paradise apples have this

effect except the narrow-leaved French variety, which has such a restrictive action on the scion that it fails to make a paying tree, and unfortunately this fact has in the past caused the apple trees on this stock to be condemned. Our best nurserymen are now well aware of this, and only use for stocks the broad-leaved varieties. In the Royal Horticultural Society trials at Chiswick, it was found that the paradise apple stocks that were not grafted gradually dwindled away, while those which had "taken," or been worked, formed handsome and fertile trees. It is by use of these paradise stocks that nurserymen are able to supply examples in many cases capable of bearing fruit the first season after transplanting, as this paradise stock produces such abundant surface roots that the trees do not suffer on removal.

There is yet another factor that has assisted the culture of fruit in the past thirty years, viz., the introduction of steam for the purpose of clearing and deeply cultivating the soil, in many cases quite equalling trenching. The good work done by the Royal Horticultural Society through its publications, conferences, and exhibitions, has conferred a great benefit on the public by the introduction of novelties and the awarding of medals and certificates to the most deserving kinds. The gardening press has done loyal service in giving information, and the lectures and practical demonstrations by the County Council lecturers have brought home to the people the advantage of culture, and the rational use of preventive mixtures for blights, insects, &c.

While not agreeing with the American system of spraying with poisonous compounds (as Paris green, and London purple) for orchards and plantations, having regard to their dangerous character, yet the use of winter dressing of lime, soot, and soft soap, and sprays for insects when they appear in spring or summer, is very desirable. Many of our best growers spray as often as four times a year, both as a preventive and a cure, but a free use of manure, clean cultivation, and care to search regularly for insect blights in order to cure such before they spread, will render drastic measures unnecessary.

It would be well in this place to give the *modus operandi* in forming orchards and plantations as now practised by the best Kent growers. If an orchard be desired on what is now grass land, say cherries, they are planted at 36 feet apart in rows; but in order to reap an earlier return, plums are placed between the

cherries at 18 feet apart, as these commence to bear the fourth or fifth year, whereas cherries are some eight or ten years before they pay to pick. In planting, the turf is removed or dug in, and holes about 3 feet over and 1½ feet deep, are made to receive the trees, which, after planting, are staked, and if cattle are allowed into the orchard they are protected (cradled) with chestnut pales, made square or triangular to keep the heads of the trees from the reach of the cattle. The plums are pruned back the first year, but the cherries are better not cut back until they have made a year's growth. Care is taken to keep grass from rooting in the 3 feet circle, as its presence and penetrating power would otherwise absorb all the moisture necessary for the young tree to establish itself. The orchard trees are summer and winter pruned, and shaped, or balanced for five or six years, until they are fitted to be grown on, with an occasional thinning of the main boughs, and the ties which attach the trees to the stakes are renewed also. In forming a plantation, a field or stretch of ground which has been previously prepared by a crop of potatoes, peas, or greens, is deeply stirred, and the standard or half-standard trees are placed in lines, say 15 feet apart, for plums, small-growing apples and pears, and 18 to 24 feet for the larger kinds. These being planted, give the pattern for the bush fruit, which will then be introduced in long lines at 6 feet apart, so that horse hoes can be used to keep the land clean, all the trees of a kind being planted in a block so that the fruit can be gathered at one time. I strongly recommend that all new orchards be raised in arable land, when for some years a handsome profit can be made from intermediate vegetable crops, wallflowers, &c., the cultivation of which is of great benefit to orchard trees. In the culture of strawberries it is usual to plant after some crop which has been highly manured. The plants are set in spring, or, if favourable, in autumn. An acre requires some 12,000 for a plant at 2 feet apart, 30 inches from row to row. An improved plan now obtains of planting on the square, as horse cultivation can then be used both ways, and thus hand labour is saved.

The Kent Cob Nut is very extensively grown in Kent, where the largest-sized nuts are produced; being a hardy subject, not particular as to soil, many steep banks and stony patches of land that will not grow better fruits are planted with trees at 12 to 15 feet apart, and for some years until the cobs require all the ground, vegetable crops

or bush fruits are grown between them, which being highly manured help the nuts to form trees. They begin to crop the third year; many old plantations are found with trees 100 years old, some 24 feet through, and not more than 6 feet high, as they are severely pruned to keep the trees in the form of an inverted umbrella with about 9 to 12 main branches, all coarse wood being pruned away, as it is from the young spray that the nuts are produced. The female blossom appears in February and the male catkins or polliniferous flowers are best left on (or at least a portion of them) until the blossom is set, say March, before the winter pruning is carried out. They are also pruned in August, taking out the strong "wands" which are used for packing, and the top surplus growth is then broken off. A good plantation will yield ½ ton to the acre, but we have had two or three good years (1896-7-8) when crops have reached to 2¼ tons. Prices vary from 25s. to 60s. per 100 lbs. Standard apples and plums are often planted over them, and this gives a larger return per acre, but cobs are best alone, though they succeed fairly well under trees. Cob nuts will also flourish in good ground (soil), but that is usually reserved for choice fruits and too gross growth is not favourable to their cropping.

Birds.—I shall naturally be expected to give some opinion on this point. As far as birds are concerned, if all possible means are taken to destroy sparrows, and all bullfinches are trapped, the other birds' toll of fruit may be given them willingly for the general good they do in keeping down grubs and insects. I speak generally, as I am not unmindful of the attacks of starlings, blackbirds, and thrushes on our soft fruit crops. The cuckoo is one of the fruit-grower's best friends, as he alone will feed on the gooseberry caterpillar, while all the soft-billed migratory birds are insect feeders. I fear that in many places as much harm is done by the gun in causing canker, broken boughs, and twigs, as the birds themselves would do. It is to be regretted that such a handsome bird as the bullfinch must be destroyed, but he is a silly fellow and can be readily trapped alive, and there is a sale for good cock birds in all our large towns.

Insects.—To deal properly with the subject of injurious insects affecting fruit trees and bushes would require an evening by itself, and I can only here suggest that adequate manuring of the soil, burning all prunings and rubbish as soon as collected, combined with a winter washing of lime, soot, and soft soap on

the older trees, will to a great extent check insect ravages. Spring and summer spraying will be necessary for red spider on gooseberries, aphids in plums and damsons, and black aphid in cherries as soon as any insects are observed; they are readily seen, as the leaves curl on being attacked. Special formulas are given in most fruit books, but the safest remedy for spraying is soft soap and quassia. Where winter moth is prevalent, orchard trees must be grease-banded, care being taken to place a ring of grease proof paper on the stems before greasing.

IN THE FUTURE.

Without in any way venturing to prophecy we have seen enough of the success of the best fruit growers, to outline in some degree the probable course of commercial success in the future, for it is to the newly planted orchards, where the sorts are of the best for their special purposes, and where clean cultivation obtains, that we must look for our chief supplies in time to come. In America and Canada, they consider 15 years the average life of a paying orchard; the trees are then destroyed, and a fresh start made. In this country 25 to 30 years may be considered as the outside limit, and by that time the available nutriment in the soil may be considered to be exhausted by the standing trees.

It will, therefore, be well before that time expires to provide other orchards to replace the condemned patches. This may appear to many a drastic proposal, but the stimulating manures now given tend to strong sappy growth, therefore I think I have not overstated the case. Again the public is fast being educated to distinguish between good and inferior fruits and growers will find their future profit to lie in producing examples of the finest sorts.

At present, colour is the market factor in apples more than quality, red and yellow being chosen for dessert, and green or golden for kitchen sorts, and expert observers will notice that this excludes many of our best flavoured fruits, which being russety, or of a nondescript appearance, do not sell on the market boards, though where quality is asked for, they cannot long remain unknown. We may look also to improved methods of packing to secure higher prices. Instead of the half-sieve (four gallons) and the sieve baskets, choice fruits should be boxed and placed in punnets and suitable packages, so that on reaching their destination they need not be again handled

before reaching purchasers. Many advocate a non-returnable wooden box, such as is used for oranges. A start has been made with ripe gooseberries, white currants, and raspberries in punnets, and good prices result. The best strawberries are of course marketed in $\frac{1}{2}$ lb. and 1 lb. reputed punnets. I think also that the use of artificial manures suitable for special soils and crops must engage the attention of growers in the future. It is evident, from the use of kainit, soot, fish guano, basic slag, and rich portable manures, that the fertility of the land must be increased and retained, while with such manures, the crop of weeds which so often follows the use of stable manure may be avoided. There is another way in which growers should copy American producers, and that is by planting large bulks of one sort of either plums, apples, or pears, so that day by day buyers can make sure of a supply of the same article. The wisdom of this is seen in the fact that when a retailer gets an apple that suits his customers, and they have taken a fancy to it, the supply is often gone, and he buys another sort, which has to be tried before the public will take to it freely; whereas if a salesman were able to say "I shall have this sort for 14 days or so," the retailer could better gauge his wants and suit his customers. This also applies to plums, and in fact to all fruits. As I have before stated, all old and worn-out orchards should be destroyed, as I feel confident that, with the vast quantity of improved sorts which the nurserymen of the present time have distributed, there will be no paying market for inferior fruit. The fruit of the future, again, must be carefully gathered, evenly sorted, well stored, and honestly packed; those men whose character is known on the market can always make the best prices, and any sharp practices in the way of mixing sorts and topping-up always recoil on the sender.

In reference to the storage of fruit. I have here photographs of a fruit room, which has enabled apples in fine condition to be exhibited as late as the latter days of May. I do not pretend that such erections are necessary for market fruit growers, as in Kent we have ready-made rooms in the abundant hop oasts and stores of the county, and many contend that fruit marketed direct from the trees pays best; but the principle can be observed even in existing stores, which is—simply gather the fruit with care, only store perfect examples, keep the fruit in the dark, and never let the stores be too dry or allow the frost to enter. Cultivators must also test new

and improved varieties, and when found to suit their soil, embark in them largely. I am not hopeful of the progress of evaporated (dried) and crystalised fruit in this country, nor do I think that apple-rings are likely to pay the producer.

It must be remembered that the prunes of the Continent are really partially dried and prepared on the trees, in consequence of greater sunshine; and in drying experiments I have witnessed even our large plums come out of the ordeal—to use a common expression—all skin and bone.

Growers, too, must look further afield for outlets, and I feel that the system of sending such huge bulks to London markets, only to be ranshipped to other cities and towns, is doomed. Our largest growers pack their fruit, to suit distant markets, in baskets, barrels, or cases, as the particular market affects, and send it direct from their local stations instead of to London first, and thus make the best prices. It is obvious to all that here is neither time nor space in the large London markets to deal with the vast quantity that is sent there in busy seasons.

These remarks, however, are in no way intended to disparage London markets or London salesmen who do their very best for clients; but the course indicated will save those glutts of produce in the London market, and prevent lowest prices. London will always be well supplied, and can consume a vast quantity, but producers on either a large or small scale will find it pay best to send the best only for London sale. It is manifestly unfair to send the best only to distant markets, and the inferior to London, because the carriage is less, or it is a known fact that (as a rule) London buyers always give higher prices for picked fruit than provincial markets realise. There is a growing demand for fruit jellies, flavourings, temperance drinks, jams, preserved and bottled fruits, and further developments of these industries are to be looked for, not only in a trade sense, but in private families, as the process is now so simple with the new and improved automatic bottles. I have not touched on the culture of fruit under glass, because it is not within the scope of this paper. The most prosperous branch of this culture is no doubt the growth of peaches and nectarines. But we yet require more time to know what effect the maintenance and repair of the comparatively flimsy glass structures of the market growers may amount to, before we can consider the matter tested to an issue. Tomato

growing is really properly treated as a vegetable industry, though on the border land between a fruit and a vegetable.

It will be observed that I take an optimist forward view of this industry of fruit culture. Quite agreed. And I can go further, and say that no grower who has entered on the matter in a business way has ever failed to make a profit, naturally largest where most care is taken. Cases of failure are known, but they can be traced to a want of ordinary business acumen, and are often the result of following false leaders, or the development of a fad.

Fruit Sales by Auction.—These sales in Kent are looked forward to with great interest by buyers and sellers. Cherries are generally sold first, on the trees, and the competition is often very keen for choice lots. They have been known to make £80 per acre, but that is an exceptional price. Plums are often included. Bush fruits and strawberries are sometimes sold by auction where the grower prefers a certain price "cash down" to the chances of market sales. All these are called soft fruit sales, and later on pears and apples are also sold by auction as hard fruits. In these sales the buyers are either local men who make it a trade, or London salesmen who have made contracts to supply buyers. The buyers take all risks, the sellers getting ready-money and safe-guarding themselves by the customary rules as to damages. It is not advisable to sell fruit by auction from trees under ten years old, as naturally buyers' pickers are not so careful in gathering the fruit as the owners would be, and young trees are apt to be seriously damaged by heavy ladders being used. The growers pick young trees with step-ladders, which stand without the support of the tree itself.

The Kent System in other Counties.—My visits to various fruit centres have impressed on my mind the fact that we in Kent do not enjoy a monopoly of the best soils and situations, and it is certain that where the Kent systems of pruning and culture are faithfully carried out, there are thousands of acres of available land that could be profitably brought under fruit culture. This is demonstrated in many distant counties, where the orchards have been started with healthy young trees, the results astonishing the planters. I, as an expert, receive very fine fruit for naming from even Scotland and Ireland.

Social Aspect.—It will be conceded that the growth of fruit has had a marked effect on the health of the middle and lower classes,

and has also, I believe, helped the cause of temperance. This is due honour to sanitary engineers and authorities, I claim that the health of the large towns and cities has been appreciably improved by the fact that good wholesome fruit can now be purchased at a cheap rate, a remark which covers oranges and foreign produce also. It is admitted that the extended culture of fruit has perceptibly raised the standard of living in Kent, as among the rural population, so much can be earned by the women, girls, and boys, combined with the higher wages paid as piece-work to the fruit men who live in the county, that the villagers are better fed and clothed than they used to be. At the same time fruit-growing prevents that depletion of villages which goes on in other places, while the general prosperity of the country is increased. This is also a national matter, because the best soldiers and sailors are found in recruits reared in the rural districts. It is well known that large numbers of fruit pickers spend the summer months in Kent, coming from London and other populous towns, who, we fear, do not always take much cash back with them, but doubtless their health is benefited by the open-air work.

Probable Profits.—Hitherto I have spoken of practical matters relating to culture and disposal of produce. Naturally some idea of the profits of this industry will be looked for, and I feel unable to give these with any approach to accuracy because the information at my disposal has been rendered to me confidentially; and to speak of some of the large returns made would be unfair without discounting these results by losses through bad years, caused by wet seasons, late spring frosts, summer blights, gales, &c. Therefore, to arrive at an estimate it is best to take three years' profits and average them, when the result will work out as follows:—

Cherry orchards on grass, per acre,	£20.
Apple " " "	£15.
Mixed " " "	£15.

These estimates are for established orchards in full bearing, and such would probably pay the rent if used as grazing land for sheep independent of the top fruit crop.

	Per Acre.
Mixed plantations with top and bottom fruit over four years old	£20
Gooseberries alone	£25
Raspberries " 	£20
Red Currants " 	£12
Black " " 	£15

It will be readily understood that much depends on the state and condition of the orchards, and it may be remarked that these average profits are frequently doubled and trebled, while absolute losses are comparatively rare.

The cost of establishing a grass orchard variously estimated at £15 to £20 per acre for the first year's outlay. If on arable land (as before stated) the outlay may be recouped by vegetable crops before the land is laid down to grass. The expense of establishing a mixed plantation is placed at £30 to £40 per acre. In the latter, an earlier crop amply repays for the extra initial expense. In estimating profits some experienced farmers consider seven year a better average, as they fear that a less term is too short; as profits are sadly discounted by such indirect causes as strikes, epidemics, cold seasons, and wet weather.

The Kent System of Tenure as Between Landlord and Tenant.—The rule about Mid Kent is for the landlord to pay for such permanent trees as the tenant elects to plant. Some landlords also further allow a sum for planting and staking. Having first arranged with the agent or steward, the tenant is bound to plant, protect, and keep in order all such permanent trees. But if the tenant makes a plantation, he furnishes all the bushes, canes and plants necessary at his own expense, and at the expiration of the tenancy he has no claim on the landlord for his outlay. This is a simple matter, and has worked well when the tenancy is 14 years or more; but if a tenant dies, or leaves before the expiration of his lease the bushes are valued to the incoming tenant a tenant right; or the landlord pays for them and gets the sum from the new tenant, or should he be unable to pay, an extra rent is charged to cover the landlord's outlay. The passing of the Market Gardeners' Act, 1895 placed tenants who have planted in the past on a firmer footing, as under it the outgoing tenant can claim compensation for his outlay (before 1895); which is assessed by valuation if tenant and landlord are unable to agree as to terms.

It frequently occurs that valuers' estimates differ widely, and a third man, as arbitrator has to be consulted. I think in all cases a proper understanding should be arrived at on entering into a tenancy, and from experience I believe nearly all landlords and agents are ready to meet the wishes of a tenant possessing capital and energy. In order, however to guard against an unfair advantage being

taken by an improving tenant, it is customary on many estates for the words "under no circumstances shall this tenancy be considered as a market garden" are inserted in most leases. In other cases where the tenant finds the trees and plants, it is not unusual for an agreement to be made whereby the tenant at the end of his term receives a capitalised sum equal to — years' purchase on the increased letting value of the holdings, as then determined by agreement or valuation. In my opinion the Act would have been improved if a definite number of years had been fixed under which compensation could be claimed, as bush fruits are practically useless after 10 to 15 years, plums begin to decline after 25 years, and apples after 60 years; but under a 14 years' lease a tenant should have reaped his profit on all outlay except perhaps on a cherry orchard. Undoubtedly the best plan is for the tenant to be a freeholder.

Foreign Competition.—The imports of fruit from the Continent, such as early cherries, gooseberries and plums, &c., are variously viewed by dealers. Some maintain that they prepare the public to anticipate our British produce, others that foreign fruits depress the values of home produce. I ventured to say in 1881 that the time would come when the improved qualities of our home fruits, and the larger quantity grown would make it impossible for foreign growers to see a profit. This has already come to pass in grapes, where home growers have ousted most of the imported grapes, and as the bulk of glass-grown vines gets larger year by year, we may look for still further decrease in the supply of foreign grapes in our markets. One Covent-garden salesman sold four tons of English grapes the week before Christmas, 1898. Apples from America, Canada, and New Zealand, although facilities are offered or transit in many cases, often fail to pay the growers, though carriers and salesmen may reap a rich harvest, and it is evident that growers will not continue to send here if unremunerated for their trouble. Again the same demand for these fruits in such expanding countries and colonies gets larger year by year, and these two factors combined may give hope and courage to the home grower. As regards Tasmanian fruit, it reaches us after our own stores are exhausted, and thus with supplies from the Cape of Good Hope and California does not compete, but merely lengthens the season for hard fruits. In soft fruits, the home growers have little to fear, as the superior quality of home grown cherries,

gooseberries, and currants will be always appreciated, and the strawberry is practically untouched by foreign exports.

We are often told by croakers, "Oh yes, but fruit-planting is only, after all, a fad, and is sure to be overdone." I reply to this by stating that the largest planters are those who have already great breadths of fruit themselves, and holding as they do up to 1,000 acres, must be very good judges of the trend of future trade. Probably owing to higher prices, the imports of apples and pears into Britain for 1898 show a large increase, apples being 231,324 bushels more than 1897, and pears 7,059 more than 1897, the totals being 642,278 bushels of apples, and pears 18,951. Plums, on the other hand, although a short crop in Great Britain, were 266 bushels less than 1897, the total of 338 bushels being quite insignificant. I believe there was a cold spring on the Continent, so that they had little to send in 1898, and doubtless better prices obtained in their own local markets. I may here reiterate that it has been the opinion of many of our largest growers that when our acreage of fruit was large enough to provide for the wants of our population, prices, though still remunerative to the British grower, would fall so low that the foreign grower would not be able to send his fruit over at a profit. This has apparently come to pass in plums and grapes. In pears, we shall always be to a great extent dependent on the Continent, as our acreage of first-class pears is small, and, moreover, the pear is not so hardy or such a regular bearer as the apple. For example, two rows of pyramidal trees in a local garden gave 100 bushels in a good year and not more than ten bushels a year for the following two years. In apples, we must always remember that a large proportion of the 650,000 bushels imported are Tasmanian and Nova Scotian, which come after our main crops are exhausted, and are mostly dessert kinds. The foreign apples do not, as a rule, suit the cook, as they become leathery in puddings and tarts, and do not mellow or melt as our British produce does, so that the later British kitchen apples always make good prices. Where suitable stores are at hand apples pay for keeping. There, however, appears to be an opening for first-class apples after Christmas for the best Pearmain russets, &c., which (as stated) the public yet require some further education to appreciate, as they are mostly dull in colour and do not appear to advantage against the brighter imported fruits though much superior in flavour.

While I, as a Kentish man, have travelled through England I have been struck by the vast expanse of country where hardly any fruit is grown. Bearing in mind the teeming populations of the large northern manufacturing centres, the collieries of Wales and the north of England, it is evident that there is and must be a growing output for all produce grown; being after all produced in a comparatively small area.

Cider.—As already stated in olden days cider was largely made in Kent, and most old farmhouses had a cider press, but beer has now almost entirely taken its place as a local beverage. Your Society has already had a paper from Mr. C. Radcliffe Cooke, M.P. for Hereford, and I need not further allude to the subject, except incidentally, to mention that during the past few years it has been taken up by a Society in the Swanley district of Kent, which commands a ready sale; but they import some of their fruit from Somersetshire and Herefordshire, although, on the other hand, many tons of fruit find their way from Brenchley and Paddock-wood orchards to the Norfolk cidermakers, who certainly turn out a beverage that is refreshing and agreeable to those who are not born in a cider country, and who do not know the crucial points of excellence. Cider-making undoubtedly helps the prices of Kentish apples, large bulks of good sorts, but not of a size quite up to market sale, being sold for cider, relieve the London markets. The Hereford makers, however, maintain that unless special "vintage" fruit is mixed with our Kent apples the cider will not keep, because of the absence of tannin.

In conclusion, I would state that naturally the time at my disposal will not allow me to go into further particulars, but there are many useful pamphlets printed on the culture of fruit for market, and further details can be found in them and be studied at the reader's leisure. There is also much suitable information in the descriptive catalogues published by nurserymen who make the growth of fruit trees a speciality. Attached is a list of what we in Kent consider the best market sorts as distinct from the more choice fruits which are cultivated in gardens.

To indicate the interest taken in fruit culture by cottagers and small holders of land, no less than 50,000 lists of fruits in leaflet form with hints for culture have been sold by the Royal Horticultural Society, and a new edition is now

issued and sold cheaply to county councils the clergy, &c.

TABLE OF WEIGHTS AND MEASURES FOR LONDON MARKETS.

Sieve, 8 gallons; half-sieve, 4 gallons; pecks, holding 12 lbs.; punnets, $\frac{1}{2}$ lb., 1 lb., and 4 lbs.

FRUIT IS MARKETED THUS:—

Apples—Kitchen and dessert in sieves, choice dessert in halves.

Pears—Choice in halves, common in sieves.

Plums—Damsons in halves, gages in pecks and halves. Plums in halves.

Cherries, gooseberries, and currants in halves, containing 24 lbs. nett.

Raspberries, without stalks, "slipped" or "plummed," in tubs 30 lbs. and 50 lbs. each.

Strawberries in gallons and pecks, choice in $\frac{1}{2}$ lb. and 1 lb. punnets.

Dessert gooseberries, ripe in 1 lb. punnets and gallons.

Choice pears in boxes of 2 doz.

Raspberries, with stalks, for dessert, 1 lb. punnets.

Cob-nuts in sieves of 50 lbs.

VEGETABLES.

Potatoes—New, in 1 cwt. bags, or sieves of gallons; old, in 1 cwt. bags (2 bushels), or at per ton.

Greens—Brussels sprouts in half-sieves.

Headed cabbages, 60 to a tally in pads and crates.

Cauliflower, 60 to a tally in pads and crates.

Collards, in bunches of 12, at per doz. bunches.

Onions—Per 1 cwt. bag.

Parsnips—Bunched or per ton.

Carrots—Bunched or per ton.

Turnips—Early, in bunches; late, in 1 cwt. bags.

Celery—Per doz. heads.

The markets for vegetables of all kinds vary from season to season, and the leading kinds only are quoted in the reports.

DISTANCES TO PLANT.

Orchard trees, standard apples, cherries, pears, or plums in orchards should be planted about 15 to 30 feet apart, and must be well staked and protected from rabbits and stock.

NUMBER OF MARKET TREES REQUIRED PER ACRE:—

1,210 at 6 ft. apart—Closely pruned pears on quince or apples on paradise, and for gooseberries and currants.

680 at 8 ft. apart—Apples on paradise (every other one to be moved in a few years).

435 at 10 ft. apart—Feathered apples or plums.

303 at 12 ft. apart—Permanent bush trees, pyramidal and nuts.

- 193 at 15 ft. apart—Standard plums, damsons, or red cherries.
- 134 at 18 ft. apart—Ditto.
- 108 at 20 ft. apart—Standard apples, pears, &c.
- 75 at 24 ft. apart—Ditto and cherries.
- 48 at 30 ft. apart—Cherries where pastured underneath.
- 40 at 36 ft. apart—Cherries or apples.
- 36 at 40 ft. apart—Cherries or strong pears.

In plantations where there is both a top and bottom crop the standards may be placed at greater distances, noting that the apples and pears give a heavier shade than plums.

Strawberries for market (about) at 1½ ft., 19,350; at 2 ft., 11,000 per acre.

LIST OF BEST PAYING MARKET FRUITS.

APPLES.

Those marked * are recommended for orchard standards, the rest as plantation bushes or pyramids on paradise stocks
 † These are suitable for either purpose.

Dessert Apples to sell direct from the tree.

†Mr. Gladstone	July-August
†Beauty of Bath.....	” ”
Yellow Ingestrie, or Summer Golden Pippin	September
†Devonshire Quarrenden	August
†Colonel Vaughan	Sept.-Oct.
Lady Sudely	Aug.-Sept.
†Worcester Pearmain	September

Dessert Apples which require to be stored for a time before Marketing.

†Duchess Favourite (or Duchess of Gloster)	Sept.-Oct.
†King of Pippins	Oct.-Jan.
†Cox's Orange Pippin	Nov.-Jan.
†Gascoyne's Scarlet Seedling	Nov.-Feb.
†Cox's Pomona	Oct.-Nov.
†Baumann's Winter Rennet.....	Dec.-Jan.
†Cockle's Pippin.....	Oct.-Nov.
†Allington Pippin	Nov.-Feb.
*Duke of Devonshire.....	March-May

Kitchen Apples which require storing before Marketing.

†Stone's, or Loddington	Aug.-Dec.
†Warner's King	November
†Lord Derby	Nov.-Dec.
*Queen Caroline (or Brown's Codlin)..	Oct.-Dec.
*Tower of Glamis	Oct.-Dec.
*Wellington	Nov.-Mar.
*Winter-Queening	Dec.-Feb.
†Bismarck	Oct.-Jan.

Coe's Golden Drop (late)	Sept.-Oct.

DAMSONS.

Bradley's King. Hereford Prune. Frogmore (large). Shropshire. Farleigh Prolific, or Crittenden.

The above damsons are in fruit in September and October. Useful to shelter plantations on the exposed portions.

CHERRIES.

For Orchard Standards. (It is useless to plant less than an acre as they do not pay to look after, scare birds, &c., on a less area.)

White and Amber Hearts.

Frogmore Early	Early
Elton Heart	Early
Kent Bigarreau	Medium
Napoleon Bigarreau	Late
Florence Bigarreau	Late
Emperor Francis	Late
Ludwig's Bigarreau	Early

Red Sorts.

Kentish—Medium. Flemish—Late. Morella—Late
These can be used as standards or bushes.

Black Hearts.

Old Black Heart	Earl
Black Eagle	Medium
Early Rivers	First Early
Cluster or Carrone	Late
Werder's Black	Early
Waterloo	Medium
Black Tartarian	Late

BUSH FRUITS.

Currants.—Black Naples, Baldwin's Black, Lee's Prolific (black), New Red Dutch, Raby Castle (red)

Raspberries.—Norwich Wonder, Bunyard's Super lative.

Gooseberries.—Lancashire Lad, Winham's Industry Red Warrington, Crown Bob, Keepsake, Rifleman

Strawberries.—Royal Sovereign (early), Eleanor (late), Sir J. Paxton, President, and Laxton's Monarch, for local sale where they succeed. British Queen, Latest of All, and Dr. Hogg.

DISCUSSION.

The CHAIRMAN said Mr. Bunyard's observations as to fruit growing in the past were of great value, showing how apparently careless some of our fruit growers had been in the years gone by, when its cultivation had not been of so much importance as in the present time of agricultural depression; a depression which had driven farmers and landowners to set more store on the cultivation of fruit, which was found in many places to pay better than hops or barley, as was the case at Swanley in Kent, where the fruit had evidently a name widely known and appreciated. Mr. Bunyard had very properly drawn attention to timely pruning, which, as he said, had given most successful results, and also to the introduction of steam for the purpose of clearing and deeply cultivating the soil, as well as to the good work done by the Royal Horticultural Society in encouraging an industry which was likely, year by year, to attain the great and profitable proportions predicted by the late Mr. Gladstone and other equally eminent men who had taken an interest in the matter. He regretted to hear what Mr. Bunyard said as to the sparrow, a bird he had hitherto deemed to be the happiest in the world, not being fit to eat, and therefore being a part of creation which nobody troubled about; and whatever might be said as to the country sparrow, he hoped the cheery town sparrow might at any rate be spared. Mr. Bunyard's observations as to the destruction, after a given time, of orchards and the planting of new ones were of great value—especially at a time when the fruit competition from our colonies was so keen and had a tendency to oust from our markets

uit grown from worn-out trees such as adorned many of our own orchards. There were thousands of trees in this country which might well be devoted to fruit-growing, at a profit, under proper direction and supervision. In fact, we might learn a lesson from the active little island of Ceylon, which, when coffee failed some years ago, changed the cultivation to pepper and tea with enormous benefit. As to cider, its manufacture was undergoing great improvement; and he trusted that the absolutely careless manner in which apple orchards and apples were treated in Devonshire and elsewhere might soon be a thing of the past, and that cider would soon reach such a standard of excellence as would render it more and more popular with all classes. They would all agree that papers by practical men, such as Mr. Bunyard, were of great use to the Society, and of considerable value due to the community at large—especially on a question such as fruit-growing, which, in his opinion, had a great future before it.

Mr. W. W. BERRY said it had given him great pleasure to listen to this paper, and he might say that on this subject Mr. Bunyard was a prophet, not without honour, even in his own country, and the tenant farmers and landlords of Kent would always be grateful to him for the pioneer work he had done, for the advice he had given, and for the indomitable perseverance with which he had carried out his experiments over many years. The question of selection and packing of fruit was all-important. If he had 100 bushels of apples from a tree, he would throw away 60 per cent. of the best, even if he had to row away the other 40 per cent., but that was not at all necessary. If you picked out the very best, say 30 per cent., and packed them carefully in boxes, and then took a further 40 or 50 per cent. and packed them carefully in baskets, the returns from those two sections would be greater than from the whole 100 bushels marketed in a careless way; there would be a saving in carriage, in packing, and in other ways, and you could still have 30 to 40 per cent. of sound fruit to deal with, which you could dispose of to the "smasher," as the jam maker or cider maker was termed, at a fairly remunerative price. The same thing would apply to every kind of fruit. Another improvement was the steam cultivation of the land, not only in clearing old woodlands, but even on some of the best land in Kent, where he would not think of planting fruit trees without first thoroughly ploughing and stirring the subsoil by steam. He recently broke up 14 acres, first ploughing it 9 to 12 inches deep by steam, and then following the burrows with a powerful wheel implement to break up the soil underneath, being careful not to bring the subsoil to the top, but thoroughly breaking it up from 21 to 24 inches deep. The whole cost was not more than £2 per acre, if you hired the implements, and that was quite saved the cost of planting. Artificial manure was another important point. Any farmer or fruit grower could now be supplied with exactly the manure his land or

crop required, and at a moderate price—either prepared bones, guano, or some of the phosphatic manures which had been referred to. One of the principal reasons for which he would recommend these things in preference to farm-yard manure, was the economy in application. Apart from the question of weeds, which was very serious, especially with manure from London, the expense of hauling 20 or 25 tons of farm-yard manure on to an acre of fruit land, getting it to the plantation, and then getting it out and in amongst the fruit bushes was enormous, whereas if you had a suitably-prepared manure, with the proper quantity of potash, phosphates, and ammonia, it would all go in a one-horse cart and be carried out and sown broadcast on the land for three or four shillings. On a large scale that saving alone would make a good living for the fruit grower. With regard to foreign competition, there had been complaints for 25 years, but he thought the time had come to admit that the British fruit grower was largely dependent on the foreign and colonial produce. In the old days a small quantity of fruit could be sold during the season; there was a shop here and there, and fruit was very dear, and when any unusually large quantity was sent to market there was no one to distribute it. The season then only lasted three or four months, but now we had choice fruit all the year round. There were hundreds of shops, stores, and barrows—fruit was constantly put before the public, who were thus educated to the consumption of it, and insisted on having it, and thus the fruit-grower was far better off than he would have been without the foreign supplies. Reference had been made to the advantage of fruit and hop growing in keeping labourers on the soil, which was a matter in which he took great interest. Things were looking up a little in every branch of agriculture, and they wanted more labourers than they did a few years ago, but they could not get them. They were often in great straits for men to do a little extra work which they knew would pay for doing. If you went away from the most prosperous districts, up into the hilly and barren parts, you would find only one in three, or one in six of the cottages occupied, but down where fruit and hops were grown, and near the towns, there was an enormous dearth of labour. Instead of getting the assistance they used to have from the hill country, when there was any extra work, they could not now find it. In the villages where fruit growing was carried on, there was work during the winter in pruning, manuring, digging, making new plantations, and so on, and he was paying £1,000 in wages now, where £100 was paid when he was young; and a house could not be got for love or money, though five miles away there were empty houses, because there was no work for the men to do. The fruit industry, therefore, was a grand thing, and it must be the same in many other counties. Fruit was becoming more and more popular every day; it had never been overdone yet, except in one year, 1886, when there

was the biggest all-round crop of fruit ever known, and at that time the system of distribution had not developed in proportion. There might be a crop now three times as big as that, and it would all go to market, and the public would get the benefit of it. Enormous quantities of hothouse grapes and tomatoes were now produced in this country. Mr. George Munro had given evidence before a Parliamentary Committee that in one year he had sold 700 tons of English-grown hothouse grapes, in addition to those from the Channel Islands, and more than 1,000 tons of tomatoes.

Mr. J. ASHBEЕ said it was perfectly true, as the last speaker had said, that it was much better to keep inferior fruit out of the market altogether, than to put it in with the better class. He had repeatedly seen the sale of good apples entirely spoiled because certain growers thought that they could get the better of the public by putting inferior ones in with them. There were two distinct classes of buyers: the man who bought the best and gave the best prices, and the man who bought the worst and only paid the lowest price. If you sent a mixed lot, the good man would not look at it, and consequently the lower-class buyer must have it, and he would only take it at his own price, and thus the grower often did not realise the cost of carriage, simply through carelessness and stupidity in packing his goods. Foreign competition in fruit was like foreign competition in everything else—cereals, hay, straw, eggs, butter, cheese, or poultry. Foreign fruit could not be kept out of the market, and it answered a very useful purpose. No doubt, it had stimulated the public taste for fruit; the more fruit people ate, the more they liked it. He had often wondered what our forefathers did for fruit; the people, generally, could have had hardly any. He could remember the time when the only thing you could get in winter was an orange. The colonies were making great strides in this direction. Cape Colony had recently come to the fore, and within a decade would be sending fruit here which would be a surprise to many people. But it would come in when the English fruit was over. English grapes were now just finished, and there would be a good opening for grapes from the Cape. They had a few this year, but nothing to what would be sent in a year or two. It was the same with apples, which were just beginning to arrive. Men had gone to the Cape from California, who were laying down hundreds of acres of land in fruit, and they would be sending thousands of packages before many years. But it would do no harm to English fruit, which was equal to anything in the world when well grown and properly sent to market.

Mr. GEORGE GORDON, V.M.H., said the course advocated by Mr. Berry of cultivating the land for fruit-growing by steam, was much better than what was described in the paper as the usual plan in Kent, namely, making holes, plant-

ing the trees, and keeping the surrounding space free from grass and weeds. It was much better to thoroughly pulverise the whole soil, so as to allow the free growth of the roots. A cultivated orchard was preferable to a grass orchard, though it might not be necessary to do more than horse-hoe it once or twice in season, so as to maintain a loose surface and prevent cracking. It was quite open to discussion whether even cherry orchards should not be dealt with in this way, with crops and bush fruit between the trees. For some years he had been watching a cherry orchard formed in this way. At first it was simply kept clear and after a year or two it seemed quite at a standstill. Then the whole ground was trenched by hand and the results were marvellous. The trees were planted eight years ago, and now they had heads from 12 to 15 feet in diameter, and a few days since they were literally one mass of flowers. The question of packing was very important. The Normandy growers sent over large quantities of plums packed in small boxes, holding from 6 to 12 lbs. The fruit came over in splendid condition, and the consumer could buy a box and take it home without any disturbance, and use the fruit as required. When plums were sent to market in sieves, they got shaken considerably on the journey; then when the retailer got them home, he turned them out on to the counter, shovelled them up into the scale, turned them out again into a paper-bag or basket, and by the time they reached the customer's house they had been so knocked about that unless used immediately they would be spoiled. He was sometimes told that the cost of boxes was prohibitive, but that could hardly be so, seeing that the Great Eastern Railway Company supplied boxes at from ½d. to 5d., the larger ones being big enough to hold 60 lbs. At any rate, the choicer kinds of fruit should be packed in this way. The renovation of old orchards was another point of importance, but this need not always be destroyed; he had seen orchards which seemed going to decay, by proper care brought into a highly fruitful condition. He knew a gentleman who had an orchard consisting chiefly of Blenheim oranges which were said to be quite worn out, but by opening out a space between the rows, trenching, and supplying with farmyard and artificial manure, the trees took a new lease of life, and were now vigorous and fruitful.

Mr. E. D. TILL thanked Sir Owen Burne for his remarks on Mr. Bunyard's reference to cider-making and he remembered that when Mr. Radcliffe-Coolidge read a paper on cider before the Society, the Chairman, Sir W. T. Thiselton-Dyer, was also sympathetic on the same subject. He would like to state his own experience. In 1895 there was an abnormal crop of apples in Kent, and he urged the Technical Education Committee of the Kent County Council to make experiments with a view to instructing Kentish people as to cider-making. They declined, but as a general crop is not too frequent, he urged two Scotchmen

farmers at Swanley, to get an expert from Hereford, erect a press, and as apples were plentiful they made 5,000 gallons that season. In a "glut" year liquid storage is the best way of saving a crop and relieving a glutted market of fruit. Something like 40,000 gallons have been made at Swanley since that experiment, and it is commercially successful. There is no difficulty in selling it. It contains a low per-centage of alcohol, $2\frac{1}{2}$ and 3 per cent., and although cider from Kent fruit is different in character from that of the West country, it is not deficient in fine quality and flavour. As to keeping properties, he had been lately drinking good cider, made in 1895-1896 from local fruit. In the Weald of Kent they have lost the true art of cider-making; they put sugar in it, which is a great mistake. The French were paying more and more attention to the manufacture of cider. Mr. Radcliffe Cooke had said he knew nothing for agriculturists which offered such an unlimited and profitable field as cider-making. Mr. Cooke's advocacy of cider, and specially in the interests of his own county, Hereford, had led to his being called the "great De-cider-atum." He would like to say that Mr. Bunyard had not referred to poultry keeping in orchards, but he thought it was a valuable and profitable adjunct, and he might mention that the production of poultry and eggs now was equal in value to the value of our wheat crop, and still admitted of immense extension.

Mr. D. LOUIS said the washing of fruit trees with poisonous materials had been practised for the last 50 years, and it was constantly done in France and elsewhere, as well as in England. He did not know of any recorded case in which any accident had arisen herefrom. In connection with artificial manures, he was pleased to hear Mr. Bery's remarks; he had been advocating it in Kent for some years, both because it was more efficient, and on account of the saving in carriage. But these things were adjuncts, not substitutes entirely for farmyard manure, and it was necessary that the right material should be applied at the right time and in the right way, otherwise it might be injurious. He lately had an interesting example of that on some thin soil in South Kent, just over the chalk. It had been dressed persistently with superphosphate, with very bad results; but when he saw the character of the vegetation he recognised that the soil was acid, and advised the use of basic phosphate. That was put down, and the result was an entire change in the appearance of the place.

Mr. BUNYARD, in reply, said he strongly recommended that all new orchards should be raised on arable land, except for cherries, for which he could not advise that course. It was true they did well under it, but if there came a severe frost—anything below 24° below freezing—the trees would be completely spoiled; and not only that, but where the ground was very well manured, the cherry trees ran away altogether. He was called in to advise at a place in Gloucestershire, where they had manured the trees highly, and they

made enormous growth, 6 feet in a year, but when they got a hard frost, the trees were completely spoiled. To farm a good cherry orchard, you must let it go on very slowly. With regard to renovation, if you had good sorts, by all means go in for it, but it was useless to take the trouble if the sort of fruit was not good enough to pay for it. With regard to spraying, he had to be very careful what he said. If he advised people to do this, it might be done carelessly, and very grave results might ensue. He knew of a case where a man washed his apple trees with London purple, and some of it fell on the gooseberries, resulting in a vast amount of illness. It was a good thing to use where people were sufficiently careful. A man once said to him, "I never tell people to do it, but I do it myself;" and that was sometimes his position.

The CHAIRMAN then proposed a vote of thanks to Mr. Bunyard, which was carried unanimously, and the meeting adjourned.

Miscellaneous.

THE SIBERIAN RAILWAY.

The *Economist*, of May 6, publishes a letter from its St. Petersburg correspondent giving some particulars respecting the above.

"On May 19, 1891, the present Emperor laid the foundation of the new railway in Vladivostok. The railway had to be built on account of the State, and its direction as at first fixed from Vladivostok covered a route of about 4,740 English miles. Later on, as is commonly known, the Russo-Chinese Bank made an agreement with the Chinese Government as to the construction of a railway through Manchuria. This railway has been called the 'Eastern Chinese Railway,' and will connect Vladivostok with the Great Siberian Railway, thus shortening the distance that was at first projected. As now projected, the system will embrace the following lines:—

	Length in English miles.
Western Siberian Railway	888
Central Siberian Railway	1,149
Transbaikal Railway	737
Eastern Chinese Railway, through Manchuria.....	1,000
Ussuri Railway to Vladivostock	141
Total rail	3,958

"The Central Siberian Railway leads to the Baikal lake, which will have to be crossed by trains in a special steamer received from England. The railway around the Baikal lake will be built later on.

"In addition to the above-named lines, there have been constructed in Siberia three branch lines, the aggregate length of which is about 700 miles.

“Since the opening of the traffic on the Western Siberian Railway and, later on, the Central Siberian, the number of passengers and the quantities of goods transported by these roads were as follows:—

Western Siberian Railway.

	Number of passengers.	Tons at 2,240 lbs. of goods carried.
1898 ..	350,000	483,870
1897 ..	236,000	341,774
1896 ..	160,000	169,355
1895	53,226

Central Siberian Railway.

	Number of passengers.	Tons at 2,240 lbs. of goods carried.
1898 ..	300,000	177,420
1897 ..	177,000	87,000
1896 ..	14,700	16,339
1895

“In four years from the opening of the traffic on the Western Siberian Railway the quantities of goods carried rose from 53,000 tons to 484,000 tons; the number of passengers has also increased considerably, and continues to rise. The Central Siberian road, also, which was not quite ready at the end of last year, shows a considerable expanse of traffic, and when the whole line to Irkutsk is in good working order there is little doubt that the traffic will increase in a great degree.

“The results of the working of the Siberian railways for the 11 months of each of the last two years were:—

	English miles. 1898.	English miles. 1897.
Length of worked sections of the Western and Central Siberian railways	1,425	888
Total receipts in 11 months ..	£ 665,151	£ 515,451
Receipts per mile	467	580

“The decrease in the mileage revenue can be explained by the fact that the Central Siberian Railway, until December 1, 1898, had only partly worked, the opening of it all the way from Obi to Irkutsk (1,149 miles) having taken place but lately.

“As it was expected that Siberia would export wheat, and in order to give a cheaper outlet to this produce, it was decided to connect the Ural Railway (Perm-Tiumen) with the Siberian in Tscheliabinsk, prolonging the Ural Railway from Perm to Kotlas, on the Dwina, thus creating a second route for the Siberian produce, *viâ* Archangel. Both roads are at present open for traffic.

“A third outlet for Siberian produce would be the Kara Sea. Some exports *viâ* the Obi and the Yenissei have been effected for the last few years, but as Siberia is also going to be put under a protection régime, it is hardly possible that ships should come in to ballast to the Obi and Yenissei, as the cheap Siberian products could not pay the high freights for

both ways. Although coal and salt are allowed to be imported free of duty, Siberia is herself rich in these articles, and does not want them (that is the reason why coal and salt have been allowed to be imported free of duty), salt being very abundant in many places in Siberia.

“Siberia is rich in minerals of all kinds, as also in gold; but until now all the production is carried on in the same way as it was some 100 years ago. It is to be hoped that the railway will bring new life into this business.

“Some parts of Siberia are very suitable for agricultural purposes, and now that they are connected with European Russia by rail, there is a wave of immigrants moving to Siberia.

“As it is clear at present to everyone that the traffic on the Siberian railways will be considerable, it has been decided by the Government to replace the 16·2 lb. rails by new ones weighing 21·6 lbs. to the foot. Whilst the first calculation was made for a traffic of three pairs of trains, now the railways are going to be adapted for the service of at least eight pairs of trains.

“The distance from Tscheliabinsk to St. Petersburg per rail is 1,724 English miles; to Riga, 1,925 English miles; to Libau, 2,037 English miles; to Koenigsberg, 2,087 English miles. If we add to these distances the length of the Siberian and Manchurian railways, say about 4,000 English miles, we find that the whole distance will be a very long one, and as the railway tariff from Vladivostok to one of the Baltic ports could hardly be taken at less than 8s. to 10s. per cwt. (of 112 lbs. English), the possibility of a transit traffic of Chinese or Japanese goods to Western Europe, or of English and German goods to Japan and China, is open to grave doubt, the sea freight from Chinese and Japanese ports to Europe being much lower. But whilst there is this doubt as to the possibility of a transit traffic of goods, it is thought that agriculture and mining in Siberia—and later on, industries—will develop very quickly, and give the railway plenty of work. Especially it would be so if Siberia could have Free-trade.”

CLOTH PRESSING BY ELECTRICITY.

At a recent meeting of the Industrial Society of Elbeuf, a report was made by M. Ch. Mouchel, on a new process invented by M. Chedville, which is known as the “electro-calidor” process, and consists of pressing cloth by means of boards heated by electricity. A special committee, appointed for the purpose, examined the manufacture and operation of the press boards. The result is declared to be most satisfactory, and the report, according to the United States Consul at Roubaix, is as follows:—The body of the press board is composed of asbestos past covered by a netting of German silver. This is again covered by paper pulp, which gives a pliable surface

without materially increasing the thickness of the press board, which measures from two to four millimetres (.071 to .157 inch). The first experiments were made by applying the electric current through holes pierced in the portion of the board projecting beyond the cloth. Experience, however, has led to the adoption of press boards with a trapezoid projection, of which the two obtuse angles are covered with copper. Spring clips provided with a metal connection and attached to a pliable conductor serve to transmit the electric current to the copper-covered corners of the boards, when the press is arranged for work. The electric press boards are used in the following manner. On a plate of sheet iron is placed a piece of cloth, between the folds of which are placed at equal distances three electric press boards; then there is another plate of sheet iron, another piece of cloth, and so on, until the press is full. An ordinary press holds eight pieces, the folds of the cloth being one metre (39.37 inches) wide. One of the largest firms of Elbeuf employ a system of hollow presses, and an iron track, sufficiently long to accommodate ten, communicates with each one of their hydraulic presses. Against the ceiling, and parallel with this track, are arranged two conductors, one positive and one negative. They are placed on either side, and a little beyond the line of the track. Large clips for transmitting the electric current are attached by pliable wires to these conductors. The hollow press is then placed between two of these clips, each of which communicates with a movable vertical distributor. The distributor is a simple grooved rod, the conductor being placed in the groove. Thirty pliable wires, each terminating in a spring clip, hang at an equal distance from this distributor. The clips are readily adjusted to the metal corners of the electric press boards, the positive on one side and the negative on the other. The current is thus established and the proper degree of heat generated, the time necessary varying from three-fourths of an hour to one hour and a half. The required current for a press board measuring one metre (39.37 inches) by 70 centimetres (27.5 inches) is 2 amperes under a pressure of 110 volts. A press of eight pieces, with twenty-four press boards, demands a current of 48 amperes to heat the press, and the amount of electric force expended in one hour and a half is as follows:— $48 \times 110 \times 1.5 = 7,920$ watts per hour. The mechanical force given a dynamo of 90 per cent. working capacity is 12.5 horse-power. The labour expended in one hour and a half is as follows:— $12.5 \times 1.5 = 18.75$ horse-power per hour. Supposing a consumption of 1.5 kilogrammes of coal per horse-power per hour, the quantity of coal necessary to heat a press may be estimated at about 30 kilogrammes (66 lbs.). Estimating coal at 25 francs (£1) per ton, the maximum cost of heating a press would then be about sevenpence. Comparison being made between the amount of coal required by the new system of pressing and the old—viz., direct heating in a special oven by means of sheet-iron

plates interspersed between the folds of the cloth—it is found that the old method is slightly dearer than the new, as the firm referred to above, who used the old system with as little waste as possible, and had thirty presses per day, state that they use at least a ton of coal a day for the heating of their plates, which involves an expenditure of 33 francs (26s. 4d.) for the presses used, or 1.10 francs (10½d.) per press. There is thus an economy of fuel; but the new system has other and more important points of superiority. The first is the perfection of the work. The heating of each press, and even of each piece, can be regulated mathematically, either by varying the number of press boards, or by increasing or diminishing the length of the heating. The cloth is heated slowly and without the inequalities resulting from the old system under which the two ends of each piece were almost in contact with plates heated to 500°. All manufacturers who have employed the new system speak of this point as a great advantage. A second advantage is the extreme cleanliness with which the pressing can be effected. The old style of plates heated in an oven often resulted in soiling the cloth, which is now entirely avoided. Another advantage is the economy in laborious handling necessitated by heating and transporting heavy cast-iron plates. The workshops can also be kept at a lower temperature, more favourable to the health of operators. The heat generated in the folds of the cloth is completely utilised by the new process, and a fraction less is lost by radiation than under the old system of heating by plates. If there is already an electric plant in the establishment (and few modern houses devoted to commerce or manufacture are without one) the expense is reduced. The boards are not costly, and with proper care will last several years. M. Mouchel thinks that the process above described is from all points of view a most important invention, and one which should be generally adopted.

Correspondence.

COAL SUPPLIES.

Professor EDWARD HULL, F.R.S., writes:—Mr. Forster Brown, in quoting so largely from my recent book (*Journal*, April 28, pp. 506-7) has forgotten to give the reference, which is scarcely fair to the book or its author. Perhaps you would therefore supply the defect in your next number. The title is "Our Coal Resources at the close of the Nineteenth Century" (E. and F. N. Spon, 125, Strand).

General Notes.

LIQUID HYDROGEN.—At the annual meeting of the members of the Royal Institution, held on

May 1st, Professor Dewar made a brief reference to the recent scientific work of the Royal Institution, and announced that having obtained liquid hydrogen in considerable quantity he had directly determined its temperature and other physical constants, finding its boiling point to be much lower than was previously supposed—namely, 20 degrees above the zero of absolute temperature, and attaining by exhaustion a temperature of only 15 degrees absolute. Pending the discovery in quantity of some yet lighter gas, there was no means in sight of bridging this gap and reaching the zero point. He also took occasion to warn the public against absurd exaggerations as to the properties of liquid air, which, originating in America, found their way into popular magazines in this country.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock:—

MAY 17.—“The Law of Trade Marks.” By J. E. EVANS-JACKSON.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal. The EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock:—

MAY 16.—“The Artistic Treatment of Picture Frames.” By I. HUNTER DONALDSON.

MAY 30.—“The Revival of Tradesmen's Signs.” By J. STARKIE GARDNER, F.G.S.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 15...Surveyors, Savoy-street, Strand, W.C., 8 p.m. Mr. R. M. D. Sanders, “Land Purchase in Ireland.”

British Architects, 9, Conduit-street, W., 8 p.m. Mr. H. H. Statham, “Nature and Architectural Ornament.”

Medical, 11, Chandos-street, W., 8 p.m. Annual Oration.

Victoria Institute, 8, Adelphi-terrace, W.C., 4½ p.m. Mr. A. T. Schofield, “The Physical and Mental Attributes of the Sexes.”

TUESDAY, MAY 16...SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Applied Art Section.) Mr. I. Hunter Donaldson, “The Artistic Treatment of Picture Frames.”

Royal Institution, Albemarle-street, W., 3 p.m. Professor W. J. Sollas, “Recent Advances in Geology.” (Lecture I.)

Statistical, in the Theatre of the United Service Institution, Whitehall, S.W., 5 p.m. Mr. T. E. Hayward, “Life Tables: their Construction and Practical Uses.”

Pathological, 20, Hanover-square, W., 8½ p.m. Annual Meeting.

Photographic, 12, Hanover-square, W., 8 p.m. (Photo-mechanical Meeting.) “Specimens of Work with Irregular-grained Screens,” &c.

Zoological, 3, Hanover-square, W., 8½ p.m. 1. Mr. E. M. Corner, “The Patella of the Divers, Grebes, and Cormorants.” 2. Mr. Stanley S. Flower, “Notes on a Second Collection of Reptiles made in the Malay Peninsula and Siam, from November, 1896, to September, 1898, with a list of the Species recorded from those Countries.” 3. Mr. G. A. Boulenger, “A Second Contribution to the Ichthyology of Lake Tanganyika.”

WEDNESDAY, MAY 17...SOCIETY OF ARTS, John-street, W.C., 8 p.m. Mr. J. E. Evans-Jackson, “The Law of Trade Marks.”

Meteorological, 70, Victoria-street, S.W., 4½ p.m. 1. Mr. H. N. Dixon, “The Mean Temperature of the Surface Waters of the Sea round the British Isles, and its relation to that of the Air.” 2. Major-General H. Schaw, “Some Phenomena connected with the Vertical Circulation of the Atmosphere.”

Microscopical, 20, Hanover-square, W., 7½ p.m. Exhibition of Pond Life.

Pharmaceutical, 17, Bloomsbury-square, W.C., 8 p.m. Annual Meeting.

United Service Institution, Whitehall, S.W., 3¼ p.m. Captain W. H. James, “Modern Weapons, and their Influence in Tactics and Organisation.”

Archæological Association 32, Sackville-street, W., 8 p.m.

Mining and Metallurgy, Geological Museum, Jermyn-street, S.W., 8 p.m. 1. Mr. A. R. Canning, “The Lucknow (N.S.W.) Goldfield.” 2. Mr. J. D. Kendall, “The Silver-Lead Deposits of the Slocan, British Columbia.” 3. Mr. S. O. Cowper-Coles, “Notes on the Electro-Deposition of Palladium.”

THURSDAY, MAY 18...Royal, Burlington-house, W., 4½ p.m. Antiquaries, Burlington-house, W., 8½ p.m.

Chemical, Burlington-house, W., 8 p.m. 1. Messrs. J. J. Dobbie and A. Lauder, “Corydaline” (Part VI.). 2. Messrs. C. F. Cross, E. J. Bevan, and T. Freidberg, “Oxidation of Furfural by Hydrogen Peroxide.”

Royal Institution, Albemarle-street, W., 3 p.m. Mr. Lewis F. Day, “Embroidery.” (Lecture III.)

Electrical Engineers (at the HOUSE OF THE SOCIETY OF ARTS), 8 p.m. Discussion on Mr. P. V. McMahon's paper, “Electric Locomotives in Practice, and Tractive Resistance in Tunnels, with Notes on Electric Locomotive Design.”

Historical, 28, Jermyn-street, S.W., 8½ p.m. Numismatic, 22, Albemarle-street, W., 7 p.m.

FRIDAY, MAY 19...Royal Institution, Albemarle-street, W., 8 p.m., Weekly Meeting, 9 p.m., Lord Bishop of Bristol, “Runic and Ogam Characters and Inscriptions in the British Isles.”

Quekett Microscopical Club, 20, Hanover-square, W.C., 8 p.m.

SATURDAY, MAY 20...Royal Institution, Albemarle-street, W., 3 p.m. Mr. E. F. Jacques, “The Music of India and the East, and Its Influence on the Music of Europe.” (Lecture I.)

Journal of the Society of Arts.

No. 2,426. Vol. XLVII.

FRIDAY, MAY 19, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.**CONVERSAZIONE.**

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors, and the Lecture Room.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. These tickets will be shortly issued. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

INDIAN SECTION.

Thursday, May 11, 1899; Colonel GEORGE HERBERT TREVOR, C.S.I., in the chair.

The paper read was "Agrarian Conditions under British and Native Rule: a comparison of the Revenue Systems of British India and Rajputana," by MICHAEL FRANCIS O'DWYER, I.C.S.

The paper and discussion will be printed in the next number of the *Journal*.

APPLIED ART SECTION.

Tuesday, May 16, 1899; Sir JAMES LINTON in the chair.

The paper read was "The Artistic Treatment of Picture Frames," by I. HUNTER DONALDSON.

The paper and discussion will be printed in the *Journal* on the 2nd June next.

Proceedings of the Society.**TWENTY-FIRST ORDINARY MEETING.**

Wednesday, May 17, 1899; JOSEPH G. GORDON, Member of the Council of the Society, in the chair.

The following candidates were balloted for and duly elected members of the Society:—Chatterjee, Sasi Bhusan, 8, Dixon's-lane, Calcutta. Cuningham, Sir William John, K.C.S.I., East India United Service Club, 16, St. James's-square, S.W.

Johnston, J. Lawson, Kingswood, Sydenham-hill, S.E.

The paper read was—

THE LAW OF TRADE MARKS.

By J. E. EVANS-JACKSON.

The subject of "Trade Marks" is not by any means a new one to this Society, and in bringing it once more before the notice of the members I do so with feelings of considerable diffidence, well knowing that the subject has been most ably and exhaustively treated on a number of previous occasions, notably by Sir Henry Trueman Wood, some 25 years ago, and by Mr. Edmund Johnson in 1881, and by other well-known authorities. At the same time, I cannot disguise from myself the fact that when these gentlemen dealt with the subject they did so under conditions differing very widely from those which prevail at the present time. The first-named gentleman read his

paper when the first Act was, so to speak, in the chrysalis state, and the latter after some five years' experience of its working. Since that date the subject, and also the commercial value of trade marks, have advanced to an enormous extent, and it is now felt by the great bulk of the manufacturers and merchants of this country—owners of trade marks—that some amendment of the existing law is absolutely necessary if the trade of the country is not to be curbed and weighed down by vexatious restrictions, which may possibly at one time have been advisable and salutary, but have now, by the expansion of trade methods and foreign competition, become irksome and dangerous.

It is for this reason that I have thought it advisable to bring the matter once more prominently before this society, in the hope that some assistance may be forthcoming to further the scheme for an amending Act, which, as a matter of fact, the London Chamber of Commerce, after very mature consideration, has decided to promote, and I do not think it would be outside the scope of this society's work were it to form a committee, to gather and put into form the views and requirements of the trading community on this subject.

I do not think that I am exaggerating when I say that for years past the practice which has prevailed at the Patent-office relating to word marks has been one in which confusion has predominated to an enormous extent, and this state of affairs has arisen from an apparent inability to arrive at anything like a consistent or logical definition of the sub-section of the Act as to what constitutes a "word trade mark."

The decisions in the law courts have been so conflicting that it would be somewhat surprising if the officials at the Patent-office had been able to adopt any consistent line or theory upon which to act when dealing with the applications before them. This fact does not, however, entirely or satisfactorily explain many of the decisions of the Comptroller-General, and I think you will agree with me that this is so when I say that it is within my own knowledge that when a few months ago an application was made to register the word "Jessamine" for soap—this application was refused on the ground that it was a geographical term. The attention of the learned Registrar was drawn to the fact that the Court of Appeal had recently decided that the word "Magnolia" was not a geographical term within the meaning of the Act, notwithstanding that there is a number of places

called "Magnolia." The Registrar, acting for the Comptroller, refused, however, to follow the ruling of the Court of Appeal, and refused the application for the word "Jessamine." Within a few weeks a similar application for the registration of the same word "Jessamine," was made by another firm for tobacco, and on this occasion the mark was accepted and registered. I do not profess to say whether or no the word is a word capable of registration under the provisions of the present Act, but I do submit that the Registrar was absolutely wrong in at least one of his decisions in dealing with this word. On the question as to whether such a word should be protected there ought to be no doubt, and the statute should be plain enough to make such a point quite clear.

Looking back we find that until 1875 there was no statute law regulating or providing for the special protection of trade marks, and up to that date trade mark owners had perforce to rely on the common law for any protection they might require against fraudulent infringements.

I think I may fairly say that for some 35 years, or thereabouts, before the passing of the first Act, the courts had recognised the right of property in, and exercised their authority to grant injunctions against the wrongful use of trade marks. The first leading case on this point is that of *Millington v. Fox*, in which Lord Cottenham decided that the defendant could be restrained, notwithstanding that the infringement might have been due to ignorance, fraud being entirely absent. This, so far as I am aware, is the first case in which actual vested property in a trade mark is recognised, and it is quite clear that since that date this right has never been disputed. Neither will it, I think, be disputed that it was from the establishment of this right and from the subsequent varying decisions in the courts there arose the imperative necessity for an enactment for the purpose of more clearly defining such rights, and for the establishment of a register, or record of ownership. This resulted in the Act of 1875, which provides, *inter alia*, that a trade mark must be registered for a particular class of goods, and that registration, as first proprietor, is *prima facie* evidence of the right to the exclusive use of such trade mark against all comers, and that undisturbed possession for five years is conclusive evidence of the right to a sole property in the said mark.

A trade mark is defined in the Act as follows :—

“For the purpose of this Act, a Trade Mark consists of one or more of the following essential particulars; that is to say—

“A name of an individual or firm printed, impressed, or woven in some particular and distinctive manner; or,

“A written signature or copy of a written signature of an individual or firm; or,

“A distinctive device, mark, heading, label, or ticket;

—and there may be added to any one or more of the said particulars any letters, words, or figures, or combination of letters, words, or figures; also,

“Any special and distinctive word or words or combination of figures or letters used as a trade mark before the passing of this Act may be registered as such under this Act.”

The Registry was opened on January 1st, 1876, under the able management of Mr. (now Sir) H. Reader Lack. The classification of merchandise under 50 heads at that time adopted still remains in force, notwithstanding that it has repeatedly been shown how necessary it is that, in many respects, this classification should be altered; for instance, a manufacturer dealing only in soap must register his mark in, at least, four different classes if he desire to have the sole use of such mark for soap.

The Act of 1875 was followed by an unimportant amending Act in 1877, but it was not until 1883 that any further legislation took place, although, as was speedily discovered, the Act of 1875 contained one great defect in that it did not provide for the registration or protection of word marks other than those which had been in actual use before the 13th of August, 1875. The greatest dissatisfaction resulted from this, and various tactics were adopted by applicants for the registration of new word marks. In many cases it was alleged, contrary to the fact, that the marks had been in use before the passing of the Act; in other cases trivial designs were added to the word and registration obtained for the word in conjunction with such designs which it was not intended to use. This unsatisfactory state of affairs existed until 1883, when a new definition of a trade mark was adopted, as will be seen from a perusal of Sec. 64 of the 1883 Act:—

1. “For the purposes of this Act, a trade mark must consist of or contain at least one of the following essential particulars:—(a) A name of an individual or firm printed, impressed, or woven in some particular and dis-

tinctive manner; or (b) a written signature or copy of a written signature of the individual or firm applying for registration thereof as a trade mark; or (3) a distinctive mark, brand, heading, label, ticket, or fancy word or words not in use.

2. “There may be added to any one or more of these particulars, any letters, words, or figures, or combination of letters, words, or figures, or of any of them.

3. “Provided that any special and distinctive word or words, letter, figure, or combination of letters or figures, or of letters and figures used as a trade mark before the thirteenth day of August, one thousand eight hundred and seventy-five, may be registered as a trade mark under this part of this Act.”

Thus, to the clamour from all quarters for some right to register and obtain protection for word marks, the Legislature made the concession that an applicant could register—“A fancy word not in common use.”

If the framers of this definition of a trade mark had with intent determined to use a word which must necessarily lead to litigation, they could not have adopted a better word for their purpose than “fancy.” What is a fancy word? There was nothing in the Act to indicate what was meant by the term, and nothing whatever to guide those who were interested in knowing. The word, according to the dictionary, has twenty meanings, but not one of these various meanings relates to words. I fancy a lawyer was at the bottom of that sub-section, and he must have fancied, and rightly too, that a fruitful crop of law suits would result, for such was the case. Many definitions of “a fancy word not in common use” were given, and one of the clearest is that of Lord Justice Lopes, who laid it down that the following conditions were necessary in order that a word should come within the meaning of the term.

“It must be obviously meaningless as applied to the article in question; it must be fanciful in its application to the article to which it is applied, in the sense of being so obviously and notoriously inappropriate as to be neither deceptive nor descriptive, nor calculated to suggest deception or description; and, further, it must have an innate and inherent character of fancifulness, which must not depend on evidence, and cannot be supported by evidence to show, that in fact it is neither deceptive nor descriptive, or calculated to be deceptive or descriptive.”

Amongst the words which the courts decided

did not comply with this condition, and consequently were not fancy words, are :—“John Bull,” for beer ; “Sanitas,” disinfectants ; “Hand Grenade,” fire extinguishers ; “Gem,” guns ; “Rokoko,” cotton goods ; “Compactum,” umbrellas ; “Carnival,” cigarettes ; “Melrose,” hair restorer ; “Tower,” tea ; “Emollio,” toilet cream ; whilst amongst those words which have been held to be fancy words, and capable of registration, are :—“Oomoo,” wine ; “Alpine,” embroidery, afterwards reversed ; “Bovril,” preparation of beef.

Take the last as an example. Does the word “Bovril” fall within Lord Justice Lopes’ definition of the term fancy word ? I cannot think it does, and when we remember that such words as “Invincible” for lawn mowers ; “Perfect,” furniture ; “Fir Tree Oil,” insecticides ; “Japanese,” blacklead ; “Walkinease,” boots ; “Standard,” oil wicks ; “National,” boots ; “Artisan,” stoves ; “Siveroid,” metallic alloy ; “Tip-top,” pipes ; “Domestic,” tea ; “The Vets,” horse powders ; “The Club,” matches ; “Universal,” kneading machines ; “Reliance,” soap ; “Perfection,” soap ; and hundreds of others of a similar nature were registered without protest at the Patent-office, it is clear that there was something wrong somewhere, for these marks certainly do not fall within the definition of Lord Justice Lopes. There are to-day numbers of word marks on the register that do not nearly comply with the precedent conditions as defined by the courts, and the owners of hundreds of such marks are undoubtedly living in a fool’s paradise, from which they may emerge with the inevitable notice of motion to rectify the register. The hardship which is entailed by this condition of things is apparent when we consider that a man may without any objection at the Patent Office register a trade mark, spend thousands of pounds on making it known far and wide, only to find that the courts will expunge the same from the register and deprive the owner of any rights he may have possessed or fancied he possessed.

The restrictions placed upon the registration of word marks by the cramped definition of a “fancy word” rendered it almost impossible to obtain word marks at all, or having obtained them, to be at all sure that the courts would regard them with any respect or allow them to remain on the register. This resulted in a renewed agitation for fresh legislation of a nature which would widen the definition of a

trade mark, so as to meet the well-known requirements of commerce.

In response to this agitation, Parliament, in the Act of 1888, substituted for “fancy word” or words not in common “use,” the following :—(d) “An invented word or invented words, or (e) a word or words having no reference to the character or quality of the goods and not being a geographical name.”

It is quite certain that the Legislature intended a much wider and more liberal construction to be placed on the provision of the Act of 1883 than the law courts thought advisable, and the very restrictive and almost prohibitive construction adopted by the courts had a disappointing and exasperating effect on the trading community which was thus hampered and absolutely injured in business. This feeling was to a great extent removed when the Act of 1888 came in force, and it was felt by those most interested that “the morning of our discontent” was gone, and this, no doubt, would have been so, and the trade mark owners of this country would have secured that which the Legislature most certainly intended them to have if the courts had adopted a more liberal and reasonable construction of the new terms. Instead of doing so, however, they followed the same course with reference to the provisions of the Act of 1888 as they had previously adopted towards the provisions of the Act of 1883, and placed the most restrictive and, at the same, inconsistent construction on the new terms. This caused, as was natural, a feeling of renewed irritation within the commercial community, while the then existing muddle has become a more bewildering maze of contradictions and absurdities, and the demand for a new Bill, such as that which is being promoted by the London Chamber of Commerce, will, I am sure, be regarded by all reasonable men as well founded and justified in the highest degree.

Having thus briefly dealt with the history of the subject up to this date, I will endeavour to deal with some of the points which I think call for attention.

In the first place, I think it would be to the advantage of all concerned if the Trade Marks-office were separated from the Patent-office, with the Registrar as sole responsible chief. This would not involve a removal from the present premises, but would enable applicants and their representatives to present their arguments at hearings to the head of the department, instead of, as is now the practice, to the second in command, viz., the Registrar,

who, when he is in doubt, terminates the hearing by saying that he will consult the Comptroller, and from the invariable result of such consultations it is reasonable to suppose that the views of the Registrar, rather than those of the applicant, are most prominently presented to the Comptroller.

Further, in an appeal from the decision of the Comptroller, which some few months ago was before the Court of Appeal, the Attorney-General repudiated the statement that the Comptroller had done such and such a thing, asserting that it was the Registrar who had done so, notwithstanding that all the documents bore at the foot the name of the Comptroller. That is, to say the least of it, unsatisfactory, and I submit that there is no occasion for a "buffer state" between the applicant and the head of the Trade Marks-office. For this reason, I suggest that the next Act should deal fully with the subject of trade marks alone, and should repeal all that portion of the Acts 1883-1888, dealing with trade marks, and I would point out that this necessary alteration would not involve one shilling additional cost.

The next point, and by far the most important one that I desire to submit, is the question of word marks. The commercial community of this country demands, and I think is justified in demanding, that a much wider range of words shall be available for registration, and obtain legal protection than the law as now defined allows, and that the section dealing with the subject shall be drafted so clearly and precisely that it will be out of the power of the courts to stifle the efforts of the promoters of such legislation. Word marks are at present refused on the ground that they are either descriptive of the goods—that they are geographical or pseudo-geographical terms—or that they are surnames. I see no reason, and I submit that there is absolutely no valid reason why a manufacturer should not be able to register any word, provided that it can be shown that such word has never been used by any other person for similar goods, and that it infringes no existing rights, and provided that it is not obviously descriptive of the goods themselves, although to some extent it may indicate somewhat of the character of the goods, or purpose for which such goods are to be used, for instance, "Pepsalia," "Somatose," "Vi-Cocoa," "Lactopeptine," all of which, more or less, indicate something of the nature of the goods to which they are

applied. The word "Vi-Cocoa" is now registered, but between the period of the first application and the actual registration some two or three years elapsed, during which period an enterprising German appropriated this name to himself, and registered it in Germany, to the damage of the English company, and I would here point out that one of the great hardships inflicted by the refusal to register words of this nature in this country is that the owner is unable to obtain protection in many foreign countries, where, as a condition precedent to registration, it is necessary to produce a certificate, showing that the mark is registered in the country of origin. Now, as a matter of fact, there are hundreds of marks in use here of great value, and to which the owners have the sole right to the exclusive use thereof under the common laws of the country, and any infringement of the same would instantly be repressed by the courts. Surely there can be no harm in registering such marks, and there is urgent reason to do so when it is remembered that the owner is cut off from protection abroad until he is registered here.

Then, as to the geographical objection, it is surely very absurd to say that a trader shall not use or be able to obtain protection for such words as "Sunflower," "Eureka," "Blackbird," "White Horse," "Elephant," "North Pole," and hundreds of similar words, because forsooth they are geographical names. It is true that the Court of Appeal has decided that the word "Magnolia" cannot be refused registration on the ground alone that it is geographical, but it is also true, as I said a short time ago, that the Registrar, acting for the Comptroller, refuses to be bound by, and to follow that dictum; hence I submit the necessity for some amendment.

Again (while, as a fact, the Act says nothing about surnames), words which, while having one obvious meaning to the general public, are rejected on the ground that they are surnames, and, consequently, not capable of registration. Under this head such words as "Swan," "Bull," "Partridge," "Badger," "Throstle," "Crow," and many others, are refused registration.

There surely can be no reason why a manufacturer, having adopted the device of a swan to denote his goods, should in registration be compelled to disclaim any right to the exclusive use of the words "Swan Brand," words by which the public know the goods in ques-

tion, and words which the public use in asking for such goods.

And, while speaking of names, I would for a moment draw attention to the fact that it is provided in the existing Acts that a trade mark may consist of:—

(a) “A name of an individual or firm printed, impressed, or woven in some particular and distinctive manner.”

Now it appears to me to be clear that this was intended by the Legislature to provide a means whereby a person or a firm might adopt his or their name as a trade mark, provided that it was represented in so unique a manner as to render it easily distinguishable by the ordinary public from any other name of a similar kind. But as a fact this provision is entirely disregarded, and is for all practical purposes a dead letter. Why it should be so is somewhat difficult to understand.

The next provision is:—(b) “A written signature or copy of a written signature of the individual or firm applying for registration thereof as a trade mark.”

This provision is in my opinion too restrictive and works harshly on a certain class of the trading community. It is well known that there are number of persons who succeed to businesses which have been carried on for years under some other name. These individuals continue to carry on the business under the name of their predecessor and adopt his signature, thus John Brown might succeed to a business which had been carried on under the name of Jones, Brown, and Co., and to change that title or signature would be detrimental, but this gentleman could not under this provision register the signature of Jones, Brown, and Co., because although it is the signature he uses in his business it is not his own signature as defined in the Act. Again, a limited liability company really has no signature, and I submit that it would only be equitable to provide in such a case that the seal of such company should be registerable.

Coming to the question of disclaimers as provided under Sub-section 2 of Section 64, I think it is important that any such disclaimer made under this provision should be limited so that the applicant does not thereby prejudice any common law rights which he may have in the subject matter to be disclaimed, and it ought to be clearly set forth in the Act that any such disclaimer is made simply for the purpose of the registration, and is operative only in so far as it limits the rights of the applicant under the registration itself.

I do not think that any objection can be taken to some such provision as this; and, as a matter of fact, the courts of Scotland have decided in a case recently before them that the applicant had not, by disclaiming the letters “C.B.” in connection with corsets, lost the common law rights which he had prior to the registration in question.

Another point which I think requires to be dealt with is the question of costs in an opposition. At present the only power which the Comptroller possesses in reference to costs is that he can award reasonable costs against an applicant who abandons his application after notice of opposition. He has no power to award costs against an opponent who abandons his opposition. This seems very unfair in view of the fact that if the applicant abandons his application he is liable to pay such costs the Comptroller may adjudge. There seems to be no valid reason why costs in an opposition should not go as in other cases, and follow the result in the ordinary course.

The next point to which I think it wise to draw attention is the absolute discretion vested in the Comptroller in dealing with the registration of trade marks. Under Sec. 62 it is provided that the Comptroller may, on application by or on behalf of any person claiming to be the proprietor of a trade mark, register such trade mark, but there is nothing whatever in the Act to compel him to do so, even with an application which complies with the law, and to which there is no objection. The discretion of the Comptroller should be considerably restricted, and provided that an application is in order, and complies with the conditions set forth in the Act, the discretion of the Comptroller to register should end, and the applicant should be entitled to registration without having to go to court, with the subsequent privilege of paying the Comptroller’s costs.

This discretion, at present, enables the Comptroller to adopt a different procedure with different applicants, and, as a matter of fact, certain trade marks which are now applied for in the cotton classes are refused registration, whereas marks exactly similar in all respects, and to which exactly the same objections may be raised, are accepted and registered in other classes. I submit that there ought to be an absolute uniformity in connection with all marks, and in connection with all classes of goods.

The last subject to which I desire to call your attention is the position adopted by the

English office with regard to the International Convention, for the Protection of Industrial Property, signed in Paris in 1883. When the 1883 Act was passed it was contemplated that the English Government would shortly accede to this Convention, and the 103rd Section of the Act pointed to some such action on the part of Her Majesty's Government.

Great Britain became party to the International Convention in 1884, since which date British subjects have been able to claim in all the other contracting States the benefits of this Treaty, but, curiously enough, for some reason which it is not possible to understand, the Convention, so far as relates to trade marks, has been ignored.

The subject of this Convention was first brought before the law courts on the refusal of the Comptroller to register the words, "Syrup of Figs," and an appeal was made from that decision, and tried by Mr. Justice Stirling, who, in giving judgment, used these words:—"Certainly, according to my construction of the Act, it does not afford the means of carrying out the article, and it will, no doubt, be for her Majesty's Government to consider—and, seeing the Attorney-General here, I have no doubt they will consider—what legislative steps ought to be taken to give effect to that article if necessary."

This very broad hint from one of her Majesty's Judges has also been ignored, and no steps have been taken to carry out this important provision of the Convention.

The matter subsequently came before Mr. Justice North in another appeal, in what is known as the "Carter's Little Liver Pill" case, when Mr. Justice North decided that the Convention entered into between Great Britain and the United States could not be enforced in the English Courts, and the Attorney-General—Sir Richard Webster—protested against either the Convention or the Protocol being read, using the following words:—"The Court can only receive their direction by statute, unless there is some right by common law principles, and except for the purpose of inducing your Lordship to take the view of the statute, which I most respectfully submit is not open to you to take, this Convention and Protocol ought not to be read." And further, "If there is any ground for complaint it is a matter for diplomatic interference and cannot be enforced in these courts."

The 4th paragraph of the final Protocol comprises the essence of the whole matter, and it is this which the Patent-office hesitates

to carry out, and which, to my mind, ought certainly to be carried out in the form in which it has been adopted in the Convention. The paragraph reads as follows:—

"Paragraph I. of Article VI. is to be understood as meaning that no trade mark shall be excluded from protection in any State of the Union, from the fact alone that it does not satisfy, in regards to the signs composing it, the conditions of the legislation of that State, provided that on this point it comply with the legislation of the country of origin, and that it had been properly registered in said country of origin. With this exception, which relates only to the form of the mark, and under reserve of the provisions of the other Articles of the Convention, the internal legislation of each State remains in force.

"To avoid misconception, it is agreed that the use of public armorial bearings and decorations may be considered as being contrary to public order in the sense of the last paragraph of Article VI."

It has been contended that if this provision were properly carried out it would enable applicants from those foreign States where the regulations as to trade marks are very lax to register in this country such words as "bitter" for beer, "black" for coal, and many other common descriptive words. As a matter of fact this is not so, because no applicant under the Convention would be entitled to register any trade mark in Great Britain which by registration would curtail any of the existing rights of British subjects.

The strongest argument employed against the adoption of this construction of the Convention is that it would be manifestly unfair to give foreigners any privileges with regard to registration which are denied to English trade mark owners, but I cannot see that there is anything very unfair in this when it is remembered that foreign countries adopt exactly the same course towards British subjects, and although some foreigner might register a mark in England which would be refused to an English applicant, similarly English firms in foreign countries can register, under the Convention, trade marks which would be refused to the inhabitants of those countries.

I further submit that if this argument has any basis at all, it is rather late in the day to bring it forward, and it ought certainly to have been discovered before the Convention was entered into. I have not yet heard a single argument adduced against the adoption of the provisions of the Convention, which

will, as a matter of fact, bear the light of day. The only objections are really matters of sentiment, and I think, as a matter of common honesty, the Government ought to take some steps to carry out the agreement into which they entered in this respect.

I think the reasons I have adduced are sufficiently reasonable to support the demand for an amendment of the existing law on trade marks; and an amendment of a character in accordance with the just and well-known desires of the whole trading community.

DISCUSSION.

Mr. HAYES FISHER congratulated Mr. Evans-Jackson on the manner in which he had treated his subject. The paper dealt mainly with word marks, which were the principal feature in modern registration. It was only within recent years that such marks had been allowed at all, the original idea being a design or "mark" of some kind. Objections to such words as "Black-bird," because it was geographical, or "Rainbow," because it was a surname, certainly seemed hyper-critical. With regard to the convention, he thought that England rather rushed into the matter with the idea of bringing about a millennium in the protection of industrial property. A universal trade mark would be a very good thing, and they would all like to see every one's property protected; but it was not such an easy matter. At the same time it was a pity that legislation should stop the initial efforts of a foreigner endeavouring to obtain protection here. Many of the points referred to were dealt with in the new Bill in a very thorough manner, and great credit was due to Mr. Evans-Jackson, who had given a great deal of time and labour to the committee which drafted the Bill. Many eminent counsel had also assisted, and it had been taken up by the London Chamber of Commerce and influential members of Parliament, so he believed it would do a great deal to distinguish between the goods of rival traders, and to diminish that constant litigation which was a curse to a commerce-loving nation.

Mr. F. P. M. SCHILLER said, however honest and comprehensive an Act of Parliament might be, he did not think the day had arrived when lawyers would not find some loophole by means of which a defence might be set up by those traders who were not as honest as could be wished. An almost inevitable blemish in trade mark law was that the Judge who tried the case had to consider not what he alone thought of the likeness between two marks, but what the ordinary purchaser of the article might be led to believe, and it was not easy to investigate the working of another person's mind. It

was easy enough for the ordinary person to tell whether the article offered him, whether Day and Martin's blacking, or some one's sugar, was what he wanted, or something else, but the difficulty was to gauge the amount of resemblance which would be necessary in the get-up of the so-called infringing article to deceive some one else. The Judge, who had no particular skill in the matter, had to judge what was in the mind of the retailer, and he did not see how that difficulty could be removed by legislation. One knew from reports of cases that, as had been said in one case, there was always the witness who proved the deception; the little girl who could not read or write, who was sent to fetch a particular article, and the dishonest trader deceived her. To a certain extent, the remark was meant to be satirical, but there was a certain amount of truth at the bottom of it, and perhaps some Judges did not spread their net wide enough. It might be difficult, in many cases, to properly gauge the likelihood of one article being mistaken for another, but, after all, the object of a trade mark was that the public might know where an article came from, and have the guarantee of quality which that secured. Formerly you had to prove that some one had actually been deceived, but now likelihood of deception was sufficient. A point which required careful consideration was the intention of the trader, because many people relied absolutely on what he told them, and he was convinced that an enormous number of frauds were committed which were never discovered. A purchaser who asked for a particular article was given another, and told by the shopman it was the same thing, and thus both he and the manufacturer were defrauded. He thought in such cases a heavy fine should be inflicted, such as was imposed under the Merchandise Marks Act. If a dishonest tradesman knew that if his offence were discovered he ran the risk of losing all the profit he had made by his unfair dealing, he would be much less inclined to go in for it. The great difficulty at present was to tell a client whether his proposed mark was an infringement of some one else's, and there the personal element of the tribunal was very important; one Judge would see a likeness where another did not. He did not think the disclaimer clause was very beneficial to trade interests. A man might produce a design which entirely distinguished his goods from anybody else's, and yet he might have to disclaim the bulk of the design. He might register a label for which he could claim no exclusive right, because there was no design on it which fell within the definition of the Act. He could only register the label as a whole, and he might have to disclaim the very portion which made it familiar to the public. It might be a label which offered a large reward for something, which was not uncommon. That printed matter would have to be disclaimed, though it was the very thing which caught the eye and enabled the article to be identified; in other cases it might be a name. He could not see the utility of the disclaimer

clause. Either a label or mark was distinctive, or it was not. If it was not it could not be on the register, and if it was it seemed unfair that it should be shorn of a portion of the device which went to make up its distinctiveness. He could not agree with Mr. Evans-Jackson as to the convention, that, if he might so put it, what was sauce for the goose was sauce for the gander; he must say that his sympathies were with the Attorney-General on that point. It was all very well to say, I offer you my house, and, therefore, I have a right to take yours; that seemed very fair; but if one house was in a slum in White-chapel, and the other in Grosvenor-square, it was not fair at all. The same principle applied to trade marks; it depended entirely on what were the requirements of the law affecting trade marks in the different countries. If in France or Germany you could register descriptive words referring to the quality of the goods, it was obvious that when the goods came over to England they would get an advantage which English goods did not enjoy, because our law was more stringent. Until some arrangement could be made by which trade mark law could be reduced to something like uniformity, the convention would only lead to injustice and friction in business.

Mr. J. F. ISELIN agreed with Mr. Evans-Jackson that a better definition was wanted for word marks, and it seemed to him that no reasonable definition existed, except possibly that in force in France and Belgium, by which any word which was in itself distinctive was regarded as a trade mark; but it was very doubtful whether that definition would ever be accepted by Parliament, or by the commercial community. He should be glad to hear the definition that Mr. Evans-Jackson proposed. Another point intimately connected with this was the question of the international Convention. There was no doubt that the present state of affairs was exceedingly unsatisfactory. So long as we were a party to the convention we were committing a breach of faith in not enforcing it; the British Government ought either to withdraw from the convention, or call an assembly of the other Powers, and endeavour to get it altered if it was objectionable. He believed one reason why the Convention was unsatisfactory, was on account of the diplomatic superposition, according to which all instruments of this character were drawn up in French, and thus terms of French law were used, which were ill adapted for use in England. The result was misunderstanding, such as had occurred in this case, and also in connection with the Berne convention and international copyright. The present state of things was intolerable, and if the Bill referred to only put an end to this very anomalous situation, it would be worth having.

Mr. S. BROMHEAD agreed with Mr. Evans-Jackson that a radical reform in the present law of trade marks was needed; and especially that a better definition should be given of what such marks might

consist of. He had often had applications refused for the most trivial reasons. On one occasion he applied to register a bird, and it was refused because there was already on the registry a mark, in one corner of which there was a bird on a tree. In another case the word "Boxa" was refused registration for cigars and cigarettes because there was a registered device of two boxers facing one another in a sparring match. It seemed to him there was an excess of caution about the present Registrar, who, in his intense anxiety not to interfere with the rights of those who were already on the register, unwittingly did serious injustice to those who came forward desirous of registering new ones. He thought it would be exceedingly dangerous to adopt Mr. Schiller's suggestion of fining heavily a tradesman who supplied one article for another. "Caveat emptor" was a good old maxim, and the buyer could always protect himself, and insist on having the article he wanted; it was his own fault if he did not. If he got an article not equal in quality to what he wanted, he had a right to complain, and he would naturally transfer his custom, and that was the natural penalty on the retailer. There were now an enormous number of manufacturers making similar articles, and the retail trader could not keep every brand in stock. He selected one or two of the best for his particular trade, which he could honestly recommend. If he did not keep Day and Martin's blacking, he would recommend something else as equally good; and if the purchaser took it and was satisfied, he did not think the tradesman should be treated as a criminal.

Mr. REGINALD BARKER said he had come across several anomalies in his practice of a similar nature to those which had been mentioned. The Registrar refused "Myrtle Grove" because there was a small town of that name in the United States, and to take a man's name, printed in the form of a monogram, as not being distinctive. The signature of an individual or a firm might be registered; but if the firm was turned into a limited company, and wanted to register the old signature, it was refused. Section 64 provided for the registration of an invented word, and of a word not having any reference to the quality or description of the article. Hitherto the Courts had read the two sections together, but recently it had been decided in the Solio case that a descriptive mark could be registered if it were an invented word. Since that the officials had been taking all sorts of invented words. Such as "Saltine," with a disclaimer of the word salt. These disclaimers were altogether objectionable and misleading; it would be much better to register the entire combination. Not every invented word, however, could be used, "Perfecta" being refused because it is Italian for perfect, and "Benaroid" because it suggested Benares. If a mark could not be registered here it could not be protected in foreign countries, which was a great hardship. With regard to classification, again, there seemed room for improvement; cigarettes were in one

class, cigarette papers in another, pipes in a third, and cigar lights in a fourth.

Mr. BROMHEAD wished to add a protest against all dictionary words being refused. He thought Indian or Greek, or obsolete words should be admitted; but they were frequently confronted with a dictionary of some outlandish tongue, and told that a word they wanted to use was found there.

Mr. F. G. UNDERHAY said there were two classes of trade marks, registered and unregistered, and it had been pointed out by Mr. Justice Stirling that the use of the words, "trade mark," was not an offence against the section of the Act which facilitated the use of the words, "registered mark," when there was no registration. The fact that there was a very efficient common law protection for unregistered marks, was a great mitigation of some of the evils pointed out in the paper. The remedy, however, was not quite so wide, the injunction granted was in a more limited form, and the owner had to prove his title. This involved great expense, and after having done it once, it had all to be gone over again in case of another infringer. If that hardship could be removed, the common law remedy would be almost as efficient as that conferred by the Act, and he did not see why the Judge should not be empowered to grant a certificate which would be available in future proceedings. There might then be a list of trade marks which had been established at law, though not registered, and if the rights thus established were not quite so extensive, they would be, in many cases, adequate. He thought also that all words used as marks should be taken in their natural meaning, and not refused because they had been applied to some obscure place somewhere or other, and were thus said to be geographical.

Mr. EVANS-JACKSON, in reply, said there was not much difference between Mr. Fisher and himself. He could not agree with Mr. Schiller that the tradesman should be criminally liable; it would be dangerous, as he would be at the mercy of his assistants if they sold an article which sometimes was not decided to be an infringement without some difficulty, even by a Judge. The onus ought not to be on the retailer, but on the manufacturer, or the man who put the weapon in the hands of the shopkeeper. With regard to the convention, if two men made an agreement to exchange houses they ought to fulfil it, wherever the houses were situated. When a bargain was made it should be adhered to; and his belief was that if individuals repudiated their contracts in the way the British Government had done the Attorney-General would order a prosecution. We had received the consideration, in so far as thousands of British manufacturers had obtained rights abroad, under the convention, which they would not have had unless those countries had believed that Great Britain would carry out her part of the treaty in an honest manner, as she

usually did. He should be glad to give Mr. Iseli the definition of a trade mark in the new Bill, though he was not altogether responsible for it, and should have framed it somewhat differently, but he gave way to more experienced and eminent men, on condition that the Bill should be referred to a Select Committee, so that experts and other persons interested might give evidence and suggest alterations. (He then read Clause 3 of the Bill.) It had been suggested by one gentleman that the officials were over-cautious, but, he thought, they were actuated by a feeling which was the growth of official life, that on their rested the business and trade of the country, that they knew how manufacturers ought to mark their goods, how merchants should put them on the market, and how the public should ask for them, and that manufacturers would not do as they wanted, they should do without trade marks at all. It was the desire of the schoolmaster to bring up a boy in the way he should go; but he thought the trading community were quite capable of getting on without schoolmaster of that class. With regard to the rule of *caveat emptor*, he did not think the whole responsibility should be put on the shoulders of the buyer. He did not regard an unregistered trade mark as of any value outside the ordinary get-up of a package. You could not take any proceedings on the mark only for passing off, as you could on an imitation of a wrapper. If it was only the benefit you got in the country, he should not register anything at all, because you got as much protection from the common law as it was for the purpose of enabling you to secure protection abroad. Every man naturally expected his trade to expand; and when he found orders coming in from different parts of the world he said, "The trade mark is getting valuable; I must register it." The Comptroller said he could not register it, but the Judge would stop any one else using it. That was what happened in the case of *Vi-Cocoa*; the Comptroller said it was descriptive, and then he appealed to the Board of Trade. Some little influence was brought to bear, and ultimately the mark was registered; but three years' delay had taken place, during which a German company took the name, and now had the sole right to it in Germany. If you had an absolute common law right, what objection could there be to registration; and if the Judge could give a certificate, why could not the Registrar? The convention would not allow the appropriation of the word "Bitter" for beer, if it clashed with any existing right; but if any one wanted to register *Black*, or *Nubian*, for coal, and no one had ever used it before, why should it not be done? It interfered with no one and we got something abroad in exchange.

The CHAIRMAN proposed a vote of thanks to Mr. Evans-Jackson for his paper, which had dealt in a valuable manner with a very important subject. It had also evoked a very useful discussion. The resolution was carried unanimously, and the proceeding terminated.

Miscellaneous.

COMMERCIAL EDUCATION IN ENGLAND.*

BY SIR HENRY TRUEMAN WOOD, M.A.

As I am addressing an audience composed mainly of others than my own countrymen, although it is an audience of educational experts, I may perhaps be permitted to preface what I have to say about commercial education in England, by a general sketch intended to indicate the points in which our English system of education—so far as we can be said to have any system—differs from that of our Continental neighbours. My remarks must be understood as referring only to England, not to the other parts of the United Kingdom.

It is only of comparatively late years that the Government has had anything to do with the education of the people. For some centuries back all English education was practically controlled by our two ancient universities—Oxford and Cambridge. They decided what subjects were to be taught, and how they were to be taught. The control they exercised over our English schools was an indirect one, but it was none the less effectual. The schools themselves were, like the universities, independent of Government, or, indeed, of any control. The principal of these are known as "public schools," though the term "public" has of late years also been applied to the public elementary schools. These are the early all developments of ancient foundations. Winchester, founded in the 14th century, and Westminster in the 16th, grew up under the shadows of great religious houses; Eton was established in the 15th century by the monarch, close to his own palace at Windsor; Harrow, which dates from the 16th century, is the most important example of the most numerous class of all, privately founded local schools—grammar schools as they were generally entitled—which have developed beyond their original founders' intention, and have eventually come to attract boys from all parts of the kingdom.

Of these schools there are, and have long been, a great number of different rank and varying importance. The most important of them have scholarships, which are held by the successful students at the Universities, some of them being associated with special colleges. The best boys from all of them went to the Universities, and the course of study which was most successful at the university was naturally the course of study which was preferred at the school. The *litera humaniores*, which were the main total of University education, included only Greek and Latin language and literature, Mathematics and Logic. Science—I have now in my mind the education of but a single generation back—was

ignored. The teaching of modern languages was perfunctory in the extreme; the same may be said of history and geography; while even English language and literature were almost entirely neglected.

Now an education modelled on these lines was not ill-suited for professional men—men who went from the University into law, the church, or medicine. But it was by no means suited, especially when cut short in its early stages, for boys whose future destination was the counting-house or the shop. I do not propose to discuss the vexed question of literary *versus* scientific education, but I should like to be allowed to put on record my own personal belief—that no finer instrument has been devised by the mind of man for mental training than the study of the classical languages; nothing better suited for education in the truest sense, that is the training of the mind to the acquisition of knowledge, and not the provision of information which may be useful in after life to the person who has acquired it in his youth. This, however, is not the question before us. We are not met to consider the training of scholars, but the sort of education best adapted to the requirements of the ordinary man of business, and given under the limitations inevitable in the conditions of the case, that is to say in a very limited period and during the early years of life—intended also not only to train the mind but to provide a means of earning a living. Commercial Education must in fact be a compromise between real education and business training. The more it inclines to the former the better.

With the growth of modern industry and commerce the necessity for a training better suited to the requirements of modern life became more and more evident, and the place was supplied, or partially supplied, by private adventure schools, which undertook to provide the essentials of a commercial education. Of late years also some important middle-class schools have been founded by institutions like the Boys' Public Day Schools Company, and the Girls' Public Day Schools Company, the teaching in which is of a modern if not of a commercial character. The growth also of science had its natural and obvious effect on educational methods. Scientific teaching was introduced at the Universities—it had been practically ignored at Oxford, and recognised at Cambridge only as a department of mathematics. The more important of our public schools introduced what was known as a "modern side," that is to say an alternative course which a boy might take, and in which science, modern languages, and mathematics took the place, to a greater or less extent, of the classical languages. Other schools modified their whole curriculum in a like direction; others again almost abandoned the ancient knowledge in favour of the modern. Such, in briefest and baldest summary, is the condition at which our system of secondary education has now arrived.

In the meantime, elementary education in England had been organised and systemised. At the beginning of the century elementary education was im-

* A paper read at the International Congress on Technical Education at Venice, May, 1899.

parted to the children of the peasants and agricultural labourers in village schools, most of which were sadly inefficient. In the towns there were various charitable institutions for educating the children of those who were unable to provide education for themselves, and there were also what were known as ragged and parochial schools, which were more or less of the same character as the elementary schools of to-day.

Early in the century, several important societies were established—they were mostly of a religious character—for the improvement of elementary education. By their assistance schools were founded throughout the country. These were maintained by voluntary effort, and so gained their name of voluntary schools, though they received aid from the Government, an annual grant being allotted for the purpose. This grant was first made in 1833. The expenditure of the subsidy was left to the two great educational societies—the National Society and the British and Foreign School Society, and the Government assumed no direct responsibility for the actual efficiency of the aided schools. In 1839, a Committee of the Privy Council was created to regulate the administration of Government grants for education, and this Committee still remains the governing body of our Education Department. The Elementary Education Act of 1870, with later Acts of 1876 and 1880, laid down the principle that sufficient elementary education should be provided for all children of school age, and established a system of School Boards, which Boards were to be and were formed in all districts where such sufficient provision for education did not exist. By a later Act of 1891, education was made gratuitous as well as compulsory. We have, therefore, now two great classes of elementary schools—School Board schools, in which education is free, and Voluntary schools, in which a fee may be charged. Both alike receive Government aid under certain conditions. As a rule, the Voluntary schools are connected with the Church of England or with one or other of the Nonconformist bodies. The Boards, which control the Board Schools, are elected bodies, and the teaching is undenominational.

(To be continued.)

General Notes.

RUSSIAN SCHOLARSHIP.—A Scholarship of at least £40 a year, tenable for two years, will be offered for competition among the members of Caius College, Cambridge, in their second, third, or fourth year of residence, for proficiency in the Russian language. Candidates must be British subjects of British descent who (1) have been educated at a public school in the United Kingdom, or (2) are sons of persons

holding appointments abroad in the British Public Service. They must be or have been candidates for a Tripos, and must have attained a creditable position in the Annual College Honours Examinations. The standard of examination for the Scholarship in Russian will be such as may reasonably be expected of candidates who have studied Russian for one year under the University Teacher of Russian. The scholar elected will be required from time to time to pass further tests in Russian. The Scholarship may in certain cases, at the discretion of the Governing Body, be held with another Foundation or an Exhibition.

MEETINGS OF THE SOCIETY.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock :—

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal. The EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., will preside.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock :—

MAY 30.—“The Revival of Tradesmen's Signs.” By J. STARKIE GARDNER, F.G.S.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, MAY 22... Royal Institution, Albemarle-street, W., 5 p.m. Adjourned General Meeting.

TUESDAY, MAY 23... Royal Institution, Albemarle-street, W., 3 p.m. Professor W. J. Sollas, “Recent Advances in Geology.” (Lecture II.)

Photographic, 12, Hanover-square, W., 8 p.m. Mr. Bishop, “Corea.”

WEDNESDAY, MAY 24... Linnean, Burlington-house, W., 3 p.m. Annual Meeting.

THURSDAY, MAY 25... Royal, Burlington-house, W., 3 p.m. Prof. L. C. Miall, “Water Weeds.” (Lecture I.)

FRIDAY, MAY 26... Royal Institution, Albemarle-street, W., 8 p.m., Weekly Meeting, 9 p.m., Sir William Conway, “Climbs and Explorations in the Andes.”

United Service Institution, Whitehall, S.W., 3 p.m. Mr. W. Marshall, “The Importance of Sea Power in the Growth of the Roman Empire, showing the lessons taught to ourselves.”

Physical, Chemical Society's Rooms, Burlington-house, 5 p.m. 1. Prof. S. Young and Mr. Rose-Innes, “The Thermal Properties of Normal Pentane” (Part II.). 2. Mr. C. G. Lamb, “The Distribution of Magnetic Induction in a Long Iron Bar.”

SATURDAY, MAY 27... Royal Institution, Albemarle-street, W., 3 p.m. Mr. E. F. Jacques, “The Music of India and the East, and Its Influence on the Music of Europe.” (Lecture II.)

Journal of the Society of Arts.

No. 2,427. VOL. XLVII.

FRIDAY, MAY 26, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.**CONVERSAZIONE.**

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman, and other members of the Council, will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors.

A selection of music will be performed by the String Band of the Royal Artillery in the Central Hall, and by the Red Hungarian Band in the Bird Gallery, commencing at 9 o'clock.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. These tickets will be issued shortly. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman, and must be signed by the member applying for it.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

The entrance to the Museum is in the Cromwell-road. Carriages must enter the grounds by the east gate and leave by the west gate. The cards must be given up on entering the Museum.

Visitors arriving or leaving by either of the Metropolitan Railways will be allowed the use of the District Company's Subway, which leads from the South Kensington Railway Station direct into the grounds of the Museum.

Fuller particulars as to the musical and other arrangements will be given in the Programmes which will be distributed on the evening.

Proceedings of the Society.**INDIAN SECTION.**

Thursday, May 11, 1899; Colonel GEORGE HERBERT TREVOR, C.S.I., in the chair.

The CHAIRMAN announced that as Mr. O'Dwyer was in India the paper would be read by the Secretary of the Section.

The paper read was—

AGRARIAN CONDITIONS UNDER BRITISH AND NATIVE RULE: A COMPARISON OF THE REVENUE SYSTEMS OF BRITISH INDIA AND RAJPUTANA.

By MICHAEL FRANCIS O'DWYER, I.C.S.

The heading of this paper opens out a subject too wide to be dealt with adequately without trespassing at great length on the patience of the Society, and too intricate to be treated fully without broader experience than mine. In practice, therefore, I shall confine my remarks to a comparison of a few of the most salient points in the revenue system of the Punjab, the province with which I am most familiar—and of the two Native States of Alwar and Bhartpur in Rajputana, in which I have been conducting the Land Revenue Settlement for the last two years. These two States, of which Alwar is ruled by a Rajput, and Bhartpur by a Jat chief, fringe the south-eastern frontier of the Punjab and the west of the North-West Provinces, marching with the British districts of Gurgaon, Muttra, and Agra. Up to the beginning of the present century their political and revenue history was practically the same as that of the adjoining British districts of the North-West Provinces and the South Punjab, which came under our rule on the capture of Delhi by Lord Lake in 1803. The village communities are modelled on the same pattern, the agriculturists are largely of the same race, and agriculture is carried on under similar conditions.

The contrasts and differences which a comparison of their revenue system with that of the Punjab or North-West Provinces may now reveal is, therefore, mainly due to the difference in the methods pursued during the last century by the native and British administrations. To trace the origin of these divergences historically would be an interesting but lengthy proceeding; to describe them as they now exist, and strike an observer who had come fresh from the British system of the Punjab, may not be altogether uninteresting.

Alwar and Bhartpur have each a population of about 750,000, or nearly equal to that of an average district of Northern India. This population lives mainly by agriculture, and each State levies, in round figures, about 21 lakhs of rupees a year as land revenue from the agriculturists, this being the chief source of income.

The prosperity of the State and of the agricultural classes is, therefore, bound up closely together, even more so than in British India, where the revenue from land does not amount to more than two-fifths of the annual income, and the well-being and contentment of the people as a whole are mainly dependent on the revenue system pursued.

In Alwar and Bhartpur, like the neighbouring British districts, the unit of the revenue system is the village community. In both States the land is generally in the hands of what may be provisionally called peasant proprietors, grouped according to ancestral descent or historical accident into such communities, each of which is treated by the State as a single entity with a corporate existence. The simplest way of comparing the British and native systems is to fix our attention on these communities, and to examine

(1). Their relative positions with reference to the State, and the relations of the different members to one another.

(2). The relationship of the proprietary body as a whole to the non-proprietary cultivators.

POSITION OF VILLAGE COMMUNITIES IN REFERENCE TO THE STATE.

As regards this fundamental question, the British and native systems start from the same standpoint, or rather the British Government inherited or adopted the theory of the native powers whom it superseded, viz., that the ultimate ownership of the land vests in the State, and that the State is consequently entitled to receive a share of the produce of the land from the persons

who occupy and cultivate it, or arrange for the cultivation. The principle is clearly embodied in Regulation XXXI. of 1803, perhaps the first authoritative legal enunciation on the subject:—"By the ancient law of the country, the ruling power is entitled to a certain proportion of the annual produce of every *bigha* of land." In the Punjab Land Revenue Act of 1871 this principle still finds clearer expression:—"The Government of India is by law entitled to a proportion of the produce of the land of the Punjab to be from time to time fixed by itself."

The most autocratic native ruler could not claim a wider discretion than this. It is in the working of the British and native systems that the divergence is to be seen. This may be considered in two aspects:—

1. The rights which the State has reserved to itself, and those which it has conferred or allowed to develop in the persons actually occupying the land.

2. The liabilities which it enforces in the case of the latter, in the form of land revenue and other claims.

As regards (1), the native system, while it recognised that immemorial custom entitled the occupiers of the soil to the right to hold it without disturbance, and transmit it to their descendants, provided they paid the State a share of the produce, whether fixed in kind or commuted into a cash payment, and whether varying with every harvest or fixed for a term of years, in practice it limited its demand only by the ability of the landholder to pay. No margin of profit was, therefore, left to the non-cultivating owner or occupier, as the State share absorbed all the rent which the latter could claim from the actual cultivator. The tendency of this system, which is, I believe, still traditional in most Native States, was to prevent or arrest the development of a body of proprietors as separate from the actual cultivators, existing on the margin of profit left between what they realised from their tenants and what they actually paid to the State.

The case often arose, and instances are still frequently met with, in which the State, instead of dealing with the village community direct, leased its rights to a farmer or lessee for a fixed sum, the latter having the right to realise direct from the village community, and to appropriate any margin of profit left over after paying the State demand. Such leases are, however, looked on as purely temporary, and give the lessee or farmer no right to oust existing occupiers as long as they maintain

the cultivation and pay their share of the produce. He may, however, settle cultivators to break up waste or take up abandoned land. The position of these lessees appears very analogous to that of the revenue farmers we found in Bengal, who were made into absolute proprietors of the estates which they farmed by the Permanent Settlement of 1793, but I have hardly come across a single instance in these two States in which the lessee was gradually translated into the position of proprietor. Such leases are generally given to individuals in cases where the village refuses to accept revenue liability imposed by the State, or when arrears accumulate against them, or if realisation of the demand by the State authorities becomes difficult, and the State disembarrasses itself of the burden and inconvenience of direct management in favour of a lessee, whose efforts to realise, aided by the stimulus of personal gain, are likely to be more successful. The result of thus making over the village to the tender mercies of a farmer is that the community, after a more or less brief experience of his methods, generally applies to have the lease set aside and offers to accept responsibility itself.

The broad fact, however, remains that in the ordinary Native State which has not come under the influence of the British system, the State demand absorbs all the profits of cultivation or the entire rental, and there is little or no room for the growth of proprietary as apart from cultivating rights. To quote the words of one of the clearest and deepest thinkers on the subject, from Thomason's "Directions to Settlement Officers" :—

"So long as the Sovereign was entitled to a portion of the produce of all land, and there was no fixed limit to that portion, practically the Sovereign was so far owner of the land as to be able to exclude all other persons from enjoying any portion of the net produce (*i.e.*, rent). The first step towards the creation of a private proprietary right in the land was to place such a limit on the demand of the Government as would leave to the proprietors a profit, which would constitute a valuable property."

This brings us to the second aspect of the question, *viz.*, the liabilities of the village communities or proprietary bodies to the State. It has already been shown that the British Government took its stand on the ancient usage entitling the State to a share in the produce of all land, and also claimed the right to fix that share itself from time to time. For convenience that share has been fixed in cash either in perpetuity as in the permanently

settled districts of Bengal and Madras, or temporarily, for a greater or less term of years, in the remaining territories, and it is the proportion of the produce which the State has from time to time fixed as its share, and the method by which the cash value of that share is assessed, that have so profoundly modified the pre-existing conditions in territories that have come under British rule.

In the districts permanently settled during the administration of Lord Cornwallis, 91 per cent. of the net rental or net produce was taken as the standard of the Government demand, and though the enormous expansion of cultivation and increase of prices within the last century have now made this assessment a feather-weight one, it was, according to our present notions, enormously high at the time, though it was a distinct advance on the old native system, which claimed to appropriate the entire rental.

This system could only be successfully worked as long as the State was content to receive its share in kind, or to appraise the value of the crops of each harvest, and to commute the estimate into a money payment at current rates; so that the demand of each year or harvest varied with the circumstances of the season, and the elasticity thereby secured was a security against the breakdown of the cultivators. Immediately a system of fixed cash assessments is introduced, an attempt to levy the full rental of an average year, in good years and bad alike, must inevitably result (at least in a tract open to great vicissitudes of season) in the collapse or impoverishment of the cultivator, and thus the State in its own interests—if it wishes to secure fixity of payment—must be prepared to forego such a margin of the average rental as will enable the cultivators to meet a bad year. It was, no doubt, partly for this reason, and partly from a desire to fix the landholding classes more permanently in the soil, by giving them a valuable interest in it, that the British Government has gradually reduced the standard of its demand.

Regulations IX. and X. of 1812 for the Bengal Presidency reduced the proportion to five-sixths, but this was only to operate in case of new assessments, the existing demand even where it exceeded that proportion being maintained, unless there were very strong reasons for reduction on other grounds. This continued to be the standard till 1844, when Thomason, in his "Directions to Settlement Officers" of the North-West Provinces, prescribed that the Government should not demand

more than two-thirds of what may be the net produce (*i.e.*, net rental) to the proprietor during the period of settlement. The increasing experience which was being acquired, with the extension of our rule over new territories, was now making it more and more apparent that a judicious limitation of the share demanded by the State was beneficial to the people by acting as a powerful incentive to industry, and thus, in the long run, was advantageous to the State as well. Accordingly, in 1855, we find the proportion still further reduced, and in the instructions for the settlement of the Saharanpur district, the principle was first enunciated that the State share should be limited to 50 per cent., or one-half of the average net assets. The regular settlements of the Punjab proper were based on this proportion, and as the traditional caution of settlement officers, especially when dealing with a tract where cash rents are not general, led them to make liberal allowance for the many varying and uncertain factors involved in ascertaining the money value of rents in kind, we find that the Punjab assessments are relatively much lighter than those of districts which were originally assessed under the earlier standards. My own experience of Punjab districts would lead me to estimate that the State share does not usually exceed from one-third to two-fifths of the net assets or rental; but this, of course, does not include extra cesses, for which another 10 per cent. might be added all round.

The fixing of one-half the net assets or net rental as the limit of the State demand, which has now become so familiar that some people write of it as if it were as old as the Vedas, and part of the immemorial usage of the country, dates back only a generation, and is limited to British India. It has never been adopted by native rulers, though in States where the assessment has been made by British officers or influenced by British ideas, something has been done of recent years to limit the State share. The Maharaja of one of the largest and most progressive States in Rajputana, when asked by me, in the course of conversation, what rights the zamindar possessed, and what share of the net produce the State claimed, seemed astonished that there could be any room for doubt on the point, and at once replied that all rights in the land belonged to him, and that the State share embraced the whole rental.

Of course, in practice the absence of reliable records, and collusion between the zamindars and the revenue officials, often enable the

former to evade payment of the full rental, or prevent this from being accurately ascertained. The State which I have referred to has never yet been surveyed, and possesses no reliable village maps or records. The village bodies are at present paying what was once and is still assumed to be the full letting value of the land. Reassessment operations have now been undertaken, and as the people there, as in many other parts of India, have a superstitious horror of their fields being profaned by a measuring chain, the procedure is something as follows. The reassessing officer, accompanied by his satellites and a number of expectant lessees or speculators, enters an estate. The people are asked what advance they are prepared to offer on the existing demand. If they demur, they are informed that their fields will be measured to ascertain the correct area of cultivation and of crops grown, while, at the same time, one of the accommodating speculators offers an advance of a certain sum on condition of being allowed to make his own terms with the cultivators. These frequently eliminate themselves from the dilemma of having their fields surveyed, or being ground under the heel of the revenue-farmer, by offering to pay as much if not more than the latter, and enter into an engagement accordingly for a term of years. If they refuse to agree, either the survey is carried out, and the future demand fixed on some definite data, or arrangements are made with the revenue-farmer, to whom the estate is temporarily made over, the cultivating rights of the zamindars being, of course, maintained as long as they pay the latter the rent he demands.

It follows, therefore, that the British system enables two classes to live by the land, *viz.*, the proprietor, who pays at the outside half of the rental or letting value of the land to the State, and the cultivator, who for his occupation of the land pays a cash rent or a share of the produce to the proprietor. Where the land is held by communities of peasant proprietors, as is generally the case in the Punjab and over a large part of the North-West Provinces, the cultivator merges in the proprietor, and thus the share of the total produce which the latter is able to retain after discharging his liabilities to the State is proportionably high. The difference between the net produce or the rental and the State demand represents a property of enormous value, which has only come into existence within the present century, and has increased in value, as the proportion claimed by the State

has been reduced, and as the growing facilities of communication and the opening out of new markets have enhanced the money value of agricultural produce, for the proverbial caution of assessing officers makes them slow to claim for Government at reassessment a full share in the enhancement due to rise of prices.

The most striking and important result of this policy has been to create in British districts an enormous demand for land among the non-agricultural classes and to inflate the credit of the landholders. Credit is based upon two things—the value of the property alienable, and the power to alienate. The growth of the former has been alluded to; the latter has been encouraged by our policy of free trade in land, and the general tendency of our legal system to recognise individual in preference to communal rights. Hence it has come to pass that no sooner had we granted to the landholding classes a valuable property than they began to alienate it by sale, mortgage, or gift. These alienations have largely been in favour of classes who heretofore had regarded, as they still regard in many native States, the possession of land as a burden not a privilege, and the class which has profited most by them are the village moneylenders, whose position enables them to take advantage of their *clientèle*, the village peasant proprietors, in seasons of scarcity or distress.

The economic distress—tending to grow into political discontent—which follows such widespread alienations, whereby the free peasant proprietor becomes the serf of the village moneylenders, has been forcing itself on the attention of the Government of India for the last generation, and among the legislative measures taken to cope with the evil may be instanced the Deccan Ryots' Relief Bill of 1875, the recent legislation prohibiting the alienation of the proprietor's home-farm in the Central Provinces, and the Bill recently passed into law, to amend the Indian Contract Act. The following extract from the speeches of the Legal Member of Council (the Honourable Mr. Chalmers) in charge of the Bill, will help to show the magnitude of the evil and the remedial measure proposed :—

“As honourable members are aware, the subject of agricultural indebtedness, and of moneylenders and their dealings with the poorer and more ignorant classes has long been engaging the attention of the Government. Opinions may differ—and may fairly differ—as to the nature of the remedies which we ought to adopt to meet an admitted evil, the magni-

tude of which differs considerably in different parts of India. We have been urged to put stern restrictions on the alienation of land, and to apply universally the provisions of the Deccan Agriculturists' Relief Act; but the conditions of tenure and of the land holding classes are so widely divergent in the different provinces of this great empire that legislation which would be suitable and beneficial in one province, would be unsuitable and prejudicial in another. We have been urged to extend to all classes the customs of *Damdupat*, according to which, interest on a loan can never exceed the principal; we have been urged to reenact the usury laws; and we have been urged to give the Courts a discretion in all cases over the amount of interest to be recovered in judicial proceedings. After careful consideration, we have rejected these suggestions. We propose now to enact the underlying principle and to propose that where the relations between the parties to a contract are such that one of the parties is in a position to dominate the other, and he uses his dominant position to impose unfair terms on the other, then the Court is to be empowered to open up the whole transaction, and either set it aside, or, if the parties cannot be restored to their original position, to see that right and justice is done. We have no wish to interfere with the freedom of contract where the parties to a contract are really fair, and contract with each other on a footing of equality. We recognise that, as Indian agricultural society is at present constituted, the moneylender is the capitalist, and an essential factor in it. We have no desire to eliminate or unduly harass the people who make loans to the agricultural and poorer classes. It is the abuses and excesses, and not the legitimate use, of the system which we wish to curb.”

This digression is, I fear, a lengthy one, but it illustrates the far-reaching effects of our revenue policy, and shows that the gift of a valuable property, with power to alienate it, has proved in many instances a double-edged sword; that the ignorant and poorer classes have frequently failed to profit permanently by it; and that to prevent the last state of these men being worse than the first, legislation has been necessary to secure the benefit of the concession to those for whom it was intended.

In the ordinary Native State no such problems arise. As the State demand absorbs all or nearly all of the profits of cultivation, the possession of land offers no inducement to tempt the outside capitalist or the moneylender. Hence, in the majority of Native States there is no market for land except among the cultivating classes, who may be anxious for its possession in order to extend their cultivation. The occupier alone can live by the land, and there is usually no place for the middleman, *i.e.*, the non-cultivating pro-

prietor or mortgagee, as what he realises in rent from the cultivator is paid in revenue to the State. Again, alienations of land to outsiders are generally regarded as contrary to custom, and are only allowed in the last resort if the relations of the alienor or other members of the village community are unwilling to take it up. Thus the two elements of credit are either wanting or are very weak. The value of the property alienable is inconsiderable, and the power to alienate is much restricted.

One result of this, and by no means an unwholesome one to my mind, is that the zamindar's borrowing powers are infinitely smaller than in British territory, and his indebtedness is proportionately less. He can, usually, only borrow from a moneylender on the security of his standing or coming crop. The moneylender, of course, if he trusts his client, will, and often does, advance him far more than this, but in making his advances he naturally has an eye to the possibilities of future realisation. From the land he can expect little, as sales of land in execution for decrees of debt are not allowed in the two States of which I have personal experience, and the land, even if sold, would fetch little. Mortgage of the debtors' holding, though it gives the lender a hold over the latter, and is, therefore, sometimes resorted to, gives him no return for his money, while accumulation of the debt at compound interest is barred by the general rule that the State Courts shall not decree interest exceeding the principal. The moneylender is, therefore, less frequent and less powerful in a Native State village than in British territory. In an ordinary village of the Central Punjab, assessed say at one-third of the net assets, the amount paid annually by the zamindars to the moneylenders as interest on debts, equals, if it does not exceed, the assessment paid to the State, the debt on which interest is charged being generally owing to compound interest, &c., out of all proportion to the original advances; so that the moneylender intercepts most of the surplus profits remitted in favour of the landholders by the British Government, which in a Native State would go into the State coffers.

Thus the high pitch of the assessment in Native States—oppressive though it may be in some instances—acts as a safeguard against indebtedness and expropriation. The fact, however, remains that the poorer zamindars, paying a high and fixed cash assessment, must borrow at times to tide over seasons of drought or scarcity. They do so borrow, but

not to the same reckless extent as their brethren in British territory, because they have not the same facilities, and they borrow less from the moneylenders than from the State—for agricultural improvements; and for their private necessities from the more prosperous members of their own class. To the latter, who are agriculturists themselves, they can give security by a temporary mortgage of part of their land, which would not attract the professional moneylender. Hence, while in British territory we find that moneylending to agriculturists is almost entirely in the hands of the non-agricultural shop-keeping class, in a Native State the agriculturists largely finance one another. The community is not as in British territory—where disintegrating influences have long been at work—joint only in name, but in fact as well. It is so from force of circumstances, having to hold together closely to keep its ground. The breakdown or desertion of any one shareholder reacts on the whole body, which has to assume liability for the weaker member. Hence the community will usually endeavour to keep a weak shareholder on his legs, and the most effectual way to do this is to keep him out of the moneylender's hands, by helping him themselves. In many British communities, the growth of individualism—so potent a force for development in some respects—has dealt a fatal blow to this co-operative spirit, and so far from a man giving a helping hand to his neighbour, he will give him a push downwards, hoping to profit by his fall.

In a Native State, therefore, the average zamindar, while he pays generally twice as much to the State as his neighbour in British territory would be paying for the same kind of land, is by that very fact prevented from rushing headlong into debt, and safeguarded in the possession of his paternal acres, while his neighbour, owing to the fatal facilities for credit, runs the risk of becoming hopelessly indebted to the professional moneylender, and is being more or less rapidly despoiled of his property by those who are in a position to take advantage of his ignorance and want of foresight.

A few examples will illustrate this argument more forcibly than any abstract reasoning. The two British *tahsils* of Nuh and Ferozpur, in the Gurgaon district, adjoin the Alwar *tahsils* of Kishangurh and Ramgurh on one side, the Bhartpur *tahsils* of Gopalgurh, Kama, and Pahari on another. The whole tract is inhabited by a homogeneous population of

Mohammedan peasant-proprietors—*Meos*—of the same race and habits. The agricultural conditions are practically the same, but the rate of assessment in Alwar is double, and in Bhartpur more than double of what it is in Gurgaon. All this tract was severely hit by the disastrous famine of 1877-78. To meet the scarcity, the British zamindars at once began mortgaging their lands to the moneylenders, and between 1st July, 1877, and 1st April, 1883, 13 per cent. of the cultivated area had been mortgaged in Ferozpur, and 8 per cent. in Nuh—mainly to outsiders. To such mortgages one might safely apply the maxim, "Once a mortgage always a mortgage," for it is the general experience of revenue officers that such mortgages by peasant-proprietors to moneylenders are rarely redeemed, except with the view of re-mortgaging for a larger sum to another mortgagee. In the Alwar and Bhartpur *tahsils*, on the other hand, where the distress was even more acute, and where the remedial measures taken by the State to alleviate it were infinitely less, not more than two per cent. of the cultivated area changed hands by mortgage within the same period. Nine-tenths of the mortgages were to brother zamindars, and many of these have since been redeemed. In 1883, 26 per cent. of the cultivated area in Ferozpur, and 20 per cent. in Nuh, was mortgaged, about two-thirds in each case being in the hands of moneylenders, while in 1898, the mortgaged areas in the adjoining Native States were only:—Kishangurh, 4·5 per cent., of which one-fifth was to moneylenders; Ramgurh, 9 per cent., one-fourth; Gopalgurh, 7 per cent., one-tenth; Pahari, 7 per cent., one-fourth; Kama, 5 per cent., one-fourth.

Of course, the fact that the zamindar is able to draw on his credit to tide over a bad year has many advantages, and probably at the time the distress of the Gurgaon zamindar was considerably alleviated by this resource. The matter has, however, another aspect. The British zamindar, with his extensive credit, bases his expenditure on the results of an ordinary year, and rather than reduce it in a bad one, has recourse to the money-lender, *i.e.*, lives not on his income but on his credit. In the recent Famine of 1896-97, in certain districts of the Punjab, though every facility was given to the people to earn a "living wage" by opening relief works at convenient centres, it was found that few of the zamindar class came on the works till they had exhausted their credit by borrowing all they

could on their land at usurious interest, and rather than dig and work they sold land for what would be half its value in a normal year. Their brethren in Native States, who had not the same resource, were, on the other hand, found flocking to relief works in British districts, and the close of the famine left them in *statu quo*, whereas many of the British zamindars had become more hopelessly involved in debt, or even parted with their land altogether.

If sales of agricultural land were taken into account, the results would be even more unfavourable for British districts. In the Native States under consideration, sales of land to outsiders are almost unknown, and sales to co-sharers are mainly limited to cases where a zamindar, having got into difficulties or possessing a larger area than he can work, makes over part of it to a co-sharer often for no consideration, beyond assuming responsibility for future revenue and past arrears. To the British zamindar, on the other hand, the enormous increase in the value of land offers a continual temptation to sell. The sale statistics for the Punjab, in the year 1894-95, show that on the average land sold for 54 times the annual land revenue taken by the State, and in 1895-96, I think, the purchase money represented nearly 70 times the land revenue of the land sold. In Alwar and Bhartpur it is only in very exceptional cases that land fetches five times the annual land revenue; in fact, when land is put up for sale for arrears of land revenue, there is often no purchaser to come forward in Bhartpur. In both States I have had to dispose of a considerable amount of agricultural land—the property of the State, or abandoned owing to the desertion or breakdown of the owners—and have usually found it advisable to make it over to zamindars, merely subject to payment of the land revenue, or with the addition of a small *nazrana* or fine on entry. In Bhartpur, though the standard of the State demand has now been reduced to two-thirds or three-fourths of the rental, I often met with great difficulty in getting the landholders to take up abandoned estates or shares in them, merely on condition of paying the revenue which is now being assessed. They have so long been accustomed to having had to pay the full profits of the land to the State—wrung from them often with great severity—that they are unwilling to accept responsibility for the future.

In these remarks I do not by any means wish to contend that the native system is the

better one, but merely to illustrate how deeply the development of our revenue system has affected the economic situation in British territory. The benefits and evils of that situation are entirely our own creation, and, as things are measured in the East, of quite recent growth. This I think not only justifies but compels us to take up promptly the task of redressing the evils which our system has indirectly brought about.

In one respect the position of an assessing officer is much easier in a Native State. Though he may have frequent complaints of over-assessment by the State he is not continually confronted, as in a British district, with the complaint that the people are being expropriated by the moneylenders, that the Government is carried on for the interests of the latter, and that they are able to work the whole legal and executive machinery for their own purposes. This too renders the work of assessment more difficult, for one would wish to deal lightly with an involved estate, and yet if one does it is the moneylender who reaps most of the benefit. This conflict of feeling often ends in the assessment being tempered to suit the position of the weakest, and thus involves a sacrifice of the just claims of the State. It is to meet this state of things that proposals have recently been formulated in the Punjab for differential assessments, by which land acquired by non-agriculturists would be assessed up to the full half assets standard, and land held by the agriculturist classes be treated more leniently.

In the two States I have mentioned a re-assessment of the revenue is now being carried out which aims at leaving to the landholders from one-third to one-fourth of the net assets, or rental, as their share of the profits. This at once enhances the value of their holdings, and makes them an object of desire to the moneylender and the capitalist. As it is the desire of the States that the agricultural classes for whom this liberality is intended should continue to enjoy it, they have anticipated possible evils by prohibiting the alienation of agricultural land to others than members of the same village community, or for special reasons to agriculturists of other villages. The rare cases in which it is necessary for the development of large areas of waste land to attract outside capitalists are met with by a special proviso allowing such alienation with the consent of the State.

The above remarks make it clear that though the British and native systems are

based on the same theory they differ enormously in the practical working and in the results. The so-called ownership of the landholding classes is a very limited and subordinate ownership in Native States, and the superior rights of the States, which in British India lie dormant and are only evoked when the landholder fails to discharge his comparatively lenient liabilities, are much more in evidence under a native ruler. This shows itself in innumerable ways, of which I will cite only a few of the most prominent.

In the case of waste land, the native theory recognises in the landholders only a right of user at the very most, and reserves to the State the right to allot it to outsiders for cultivation or grazing, or to enclose it for State purposes. The tendency of the British system, on the other hand, has been to divest itself, as far as possible, of all direct connection with the land, and to encourage the landholders to appropriate as much of the waste as they would undertake the ownership of, at a normal assessment. Thus it was only the hill-forests, for which no claimants were forthcoming, and the great expanses of virgin jungle, of which there was no actual occupier, and to which the adjoining communities preferred no claim, that were usually constituted State property.

Again, having once recognised the ownership of the landholder in the land, the British system makes that ownership complete and absolute, while the native system merely recognises the subordinate rights of the landholders as long as they do not clash with its own needs.

Thus, when the British Government takes up land for a road or railway, or other public purpose, it pays not only the full market value of the land, liberally assessed, but an addition of 20 per cent. in consideration of the forcible acquisition. The Native State, on the other hand, takes possession of the land without paying any compensation, and merely remits the assessment, in consideration of the fact that the landholder is no longer in occupation.

The British landholder may deal as he pleases with the trees growing on the land, and may kill any game that finds its way on to it; while in many native States the Raj claims either the most valuable trees, such as *shisham*, or all the trees growing on waste lands, and often in cultivated lands as well, and the landholder is prohibited from cutting them for agricultural purposes, even when injurious to his land. I have come across numerous cases in a well-governed State where every tree and

shrub, whether growing on cultivated or waste land, or even in the enclosures round houses, is claimed by the State, and where any attempt by the people to cut a few sticks for firewood, or for burning a corpse, from land in their own occupation, is severely punished.

In a Native State, too, the game laws are often worked with a severity worthy of William Rufus. We hear a good deal about the restrictions on firearms in British territory, and of the cruelty of refusing licences to enable the people to protect themselves and their fields from wild animals; but in the Native States I refer to only a few of the chief officials and of the leading nobles are allowed to possess firearms or to shoot game of any description. Recently, when inspecting his estate, I asked a Rajput notable, whose only amusement was opium eating, why he did not go in for sport. His explanation was, "My grandfather once shot a wild boar, and the Maharaja had his hand cut off. My father killed a deer, and was fined 500 rupees. Is it likely that I should run a similar risk?" A year ago, when returning from a tour in this same State, I met a policeman carrying a fine panther skin. In reply to my questions, he explained that the panther had a few nights before burst into the sheepfold of a neighbouring village. The owner of the sheep had rushed to their rescue, and, clasping the panther round the neck, had held him tightly till his friends, attracted by his shouts, came to his aid, and slew the panther with their cudgels. I remarked that the man must have been a very brave one, and deserved a reward. The policeman, with a smile, said, "This is his reward," and pointed to a figure in chains, who turned out to be no other than my hero. He had broken the State laws by killing a wild animal, and, all wounded as he was by the mauling, was being sent in for trial. Of course, under the circumstances, he would probably have been acquitted in the long run, but I was glad to be able to accelerate his release. The case illustrates the jealousy with which native rulers, if fond of sport themselves, as most of them are in Rajputana, protect game of all kinds. Our more liberal policy has cleared British districts of Northern India of all big game, and he who thirsts for happy hunting-grounds must now seek them under the ægis of native rule.

Another matter in which the Native State exerts its right of interference is as regards the internal administration of the village community. In British India the complaint is frequent that over-legislation, with its attendant

red-tapeism, and officious interference, is making our rule unpopular. In some respects, at least, our system is less inquisitorial than under native rulers. As regards the liability of the community to the State, having fixed this at the time of settlement for a term of twenty or thirty years for the estate as a whole, and the individual holdings that make it up, we leave the people to themselves, allow them, with the assistance of the *patwari* or village accountant, to regulate the distribution of the annual State demand on the lines laid down at settlement, and to make their own arrangements with their tenants, limiting our interference to cases in which complaint is made of fraud or over-realisation. The Native State system takes a much wider view of its position. The assessments are much more frequent. In one of the States I am dealing with there have been no less than nine separate reassessments within the last 42 years, involving not only an uncertainty fatal to steady development, but a continual harassment of the people by the revenue and assessing officials. The people are also encouraged to redistribute the revenue annually, according to fluctuations of cultivation, and though this gives more elasticity, it deadens individual energy, and opens the door to continual interference by the State officials, who often work the system for their own advantage. Again, even where the landholders are admitted to be proprietors or sub-proprietors, the State asserts a right to regulate their dealings with their tenants, and if they take from the latter a higher rent than the revenue they pay to the State, this is regarded as illegal, and the excess is confiscated by the State, not restored to the tenants. This system gives rise to vexatious complaints and drives the landholders to subterfuges, the most common of which is to record a nominal rent, agreeing with the State demand, and, in practice, to exact a larger one where this is possible. Hence it is infinitely more difficult to ascertain the real rents in a Native State, where the people fear that any profits that may be disclosed will be claimed in full by the State, than in British territory. Coming from a British district, where the landholders, conscious that they would be dealt with fairly, had met me frankly and candidly disclosed their rents and profits, it was rather a shock to find that in a more primitive, and, as I had hoped, a more unsophisticated society, I had to deal with a people whom the system had made adepts in the arts of subterfuge and concealment.

RELATION OF PROPRIETORS TO NON-PROPRIETORS.

I have left myself little time to discuss the second branch of the comparison—viz., the relation of the proprietary bodies to the non-proprietary cultivators. This will be more readily understood after what has been already said as to the superior rights and lesser liabilities of the proprietors under British rule. The large margin of the profit left to the landholders leaves room for the creation of a number of subordinate rights in land, besides that of the actual proprietor. Thus, intermediate between the latter and the tenant-at-will, cultivating from year to year at a full competition rent, we find the various classes of protected or occupancy tenants, who are not liable to ejection, except for non-payment of rent, and whose rent is usually fixed by the State, and cannot be enhanced beyond a certain limit, nor even up to that limit, without an order of Court. Such rights are generally acquired by persons who are not members of the proprietary body, but who have for generations resided in the village, and occupied the land continuously on payment of a prescriptive and non-competitive rent. The legal position of these tenants is very similar to that enjoyed by the Irish farmers under the present Land Acts; and though the position was originally regarded as of little value, and at the early settlements of Punjab districts, 40 years ago, the cultivators were often unwilling to accept the liabilities for the land revenue, which the possession of such rights entails, it is now eagerly coveted, as having a value little inferior to that of actual ownership of the land, and is one of the most fruitful sources of litigation between landlord and tenant.

In a Native State the powers of the proprietor are so restricted, and his liabilities so considerable, that hardly any room is left for the growth of such subordinate tenant rights. The most common phase is that while a certain body is recognised as the proprietors, and these are directly responsible to the State, still they and the non-proprietary cultivators contribute at the same rates to the payment of the State demand for the land which they cultivate. The only advantage which the proprietors possess is that, as in British territory, they have the disposal of the cultivation, the management of the waste or common land, and receive through their representatives, the village headmen, an allowance of from 3 to 5 per cent. from the State on the revenue, while they are also empowered to levy a cess for

village expenses, and to claim certain manorial dues, such as fees on marriage, &c., from non-owners.

Where the line of cleavage between owners and tenants is so indistinct, it will be readily understood that there is not much differentiation of classes among the latter. Thus the burning question of landlord and tenant in British India rarely arises in a Native State. The density of population is less, and the amount of waste land is generally so considerable, that the competition is more frequently among landlords for tenants than among tenants for the right to cultivate, and this, combined with the tradition that owners and tenants should all pay at the same rate, makes their position a fairly secure one. Claims by landlords to eject tenants, and claims by tenants to secure their position as against the landlord by obtaining rights of occupancy, are, therefore, comparatively rare. Even here, however, we can trace the influence of the British system with its tendency towards full competitive rents, and towards more sharply defining the positions of landlord and tenants or owner and cultivator. In those parts of Alwar and Bhartpur which adjoin British territory the owners are now following the example of their neighbours and beginning to claim enhancement of the customary rent, so as to secure for themselves part of the margin of profit—from one-third to one-fourth of the rental—left under the new assessment by the State, while the tenants, who were hitherto content with their undefined and customary status, have responded by coming forward with claims for occupancy rights. In the four northern *tahsils* of Bhartpur adjoining British territory, we have had to deal with about 10,000 such claims within the last two years. The movement has not yet spread to any extent among the more remote parts of the State, though the standard of assessment is the same, and in these the owners are far more willing to concede than the tenants are to accept the occupancy or protected status. They have as yet only dimly appreciated the advantages of such a position, while they still, with the memory of past over-assessment fresh in their minds, shrink from undertaking the responsibility for the land revenue which is incident to it.

Hitherto, I have dealt with some of the points of difference in the native and British systems, and the results they produce. The query will occur to many minds—which of the two conduces most to the happiness of the

people? This query presents perhaps too many varying aspects for any satisfactory attempt at generalisation, but all the same speculations of this kind have an attraction of their own, and, therefore, with every desire to avoid dogmatising, I think a few considerations may be ventured on the subject. If by happiness, we mean contentment with one's lot, I think, in many Native States, the scale would be found to weigh down in favour of the native system, while if we interpret happiness in the strictly utilitarian sense of material progress and prosperity, then the British system is undoubtedly and immeasurably superior. Which of the two ideals of happiness the native mind pursues, is a question not easy to solve, and the longer one resides in the East, and the closer one studies the people, the less ready is one to offer a solution.

Under the British system the State demand is lighter, there is more freedom, more scope for individual effort, a higher standard of comfort, and more security that he who sows shall reap; in fact, the system encourages enterprise and energy. On the other hand, though the assessments are lenient, they are more rigidly collected, the freedom allowed to individual effort often leads to the disintegration of the community, and enables a strong and unscrupulous member to aggrandise himself at the expense of the rest. The wider margin of profit left to the landholder attracts the moneylender and the speculator, who often intercept for themselves what the State foregoes in favour of the proprietary classes.

The high value of land, and the distinct and often conflicting interests therein—thereby created—conjoined with an elaborate and technical legal system, foster litigation, as well as indebtedness, and tend, unless checked by special legislation, to favour the expropriation of the weaker and more improvident landholders. Thus while material progress and rapid development are encouraged by the British system, they are accompanied by disintegration, inequality, and economic discontent. The native system tends to keep all members of the landholding classes on a common level. This not infrequently means stagnation, but this stagnation tends towards equality, and consequently to contentment.

The landholders of the Central and Western Punjab who have—partly by their own improvidence and partly through the effects of our legal system—been dispossessed of their hereditary lands, and now cultivate them as the tenants of the moneylender are, I believe, no

worse off, materially, than the majority of the landholders in a Native State. What chiefly galls them is the sense of inequality. They have been shorn of privileges which their brethren still retain, and they have to endure the spectacle of an outsider, often alien in race and religion, grown fat at their expense. With these "wounded soldiers" of the campaign of progress and individuality it is useless to argue that they are the authors of their own misfortunes, that they have themselves thrown away the benefits which our system has conferred upon them, that their position is no worse than it would be under native rule. The difficulty of making the Oriental mind accept logical conclusions has been for generations the despair of Indian administrators. All that it can grasp in the above phenomena is that the expropriation of the landholding classes has practically begun and proceeded apace under the British Raj; therefore, the British Raj is responsible for and must bear all the odium attendant upon the results of such expropriation. It does not stop to consider how enormously other portions of the community or other members of the same community have benefited by the same system. The views of the "submerged tenth" are apt to influence and colour those of the entire agricultural community. This, though its position has, on the whole, been immensely improved under British rule, realises that its progress has been much slower than that of the great non-agricultural middle-class, which has been in great measure the creation of British rule, and which has largely grown at the expense of the agriculturists. It does not at the same time realise clearly or fully that its position is immeasurably superior to what it would have been under native rule, and what it still is under similar communities in Native States. The position is a difficult one to explain, but the genius of a poet, possessed of an innate insight into the workings of the Oriental mind, has laid it bare in four lines:—

"By all ye will or whisper,
By all ye leave or do,
The silent sullen peoples
Shall weigh your God and you."

DISCUSSION.

The CHAIRMAN first read the following letter which had been received by the Secretary of the Section from Sir James Broadwood Lyall, G.C.I.E., K.C.S.I. :—

"I had fully intended to stay in town to-morrow, and hear my friend O'Dwyer's paper read, but I

regret to say that circumstances have occurred which make it necessary for me to leave town sooner than I expected. I am obliged to you for sending me the proof sheets. The paper seems to me a good, sound discussion of the comparison taken of the subject. It does not seem to me to be open to much discussion. The only remarks which suggested themselves to myself, after reading over the paper, were:

“(1.) That I believe the Panjab revenue assessments are nearer their standard of half net assets than Mr. O’Dwyer supposes. The methods by which the net assets or net rent are worked out by Panjab Settlement officers, give, I believe, an exaggerated estimate of the true net rent.

“(2.) I do not believe it would be possible for our collectors and their establishments to collect a revenue near as heavy as that collected in Native States from peasant proprietors. It would end by a break down, and the loss of their property by the peasants, as it always did in old days when the rates of our assessments were very heavy. A ruler of a Native State and his officials can do in this direction much that we cannot do.

“Mr. O’Dwyer does not in any way propose that we should follow the Native States, and raise the rate of our assessments, but there was in India a party which preached that doctrine, and which might take hold of what he says to use as an argument.”

He then proceeded to say that having had several years’ experience of Native States, first at Hyderabad and afterwards in Rajputana, he thought Mr. O’Dwyer’s summing-up of the merits of the two systems was a very fair one. If a person was content with his lot, and did not want to get on, or to raise his standard of comfort, but only to live as his forefathers had done, he might be rather happier in a Native State, but if he wanted to acquire rights and property he ought to be happier in a British district. There the education was better, which, perhaps, was not an unmixed good, but still it had been pushed on, and we could not go back upon it now, any more than we could in England, where he constantly heard that education was the reason why good servants were scarce. That was a point which did not apply to the Native States. It should also be remembered that Mr. O’Dwyer did not profess to do more than to speak as to two Native States, with which he was well acquainted, both of which adjoined the North-West Provinces, and had been for some time during minorities under the administration of British officers. He was not sure that other Native States in Rajputana would accept the statement that the ryots had no rights in the land. On this point he should like to quote what Colonel Tod said in a most valuable book, which was not so well known as it ought to be. The rajas, according to Colonel Tod, did not claim to possess the soil, but to have a rent, which they fixed themselves, because they gave protection. The soil, however, was supposed to belong to those who cultivated it. Colonel Tod said:—

“The ryot (cultivator) is the proprietor of the soil in Mewar. He compares his right thereon to the *a’khye d’hooba* (a grass which cannot be eradicated) which no vicissitudes can destroy. He calls the land his *baṭota*, the most emphatic, the most ancient, the most cherished, and the most significant phrase his language commands for patrimonial inheritance. He has nature and Menu in support of his claim, and can quote the text, alike compulsory on prince and peasant, ‘Cultivated land is the property of him who cut away the wood, or who cleared and tilled it,’ an ordinance binding on the whole Hindu race, and which no international wars or conquests could overturn. In accordance with this principle is the ancient adage not of Mewar only but all Rajputana, *Bhog ra dhanni Raj ho : bhom ra dhanni ma cho*—‘the Government is owner of the rent, but I am the master of the land.’” On another page Colonel Tod writes: “There are two methods of levying the revenues of the Crown on every description of corn, *kunkoot* and *bhattaic*; for on sugar-cane, poppy, oil, hemp, tobacco, cotton, indigo, and garden stuffs a money payment is fixed, varying from two to six rupees per beegah. The *kunkoot* is an agricultural assessment of the standing crop, by the united judgment of the officers of Government, the patel, the patwari or registrar, and the owner of the field. The accuracy with which an accustomed eye will determine the quantity of grain on a given surface is surprising, but should the owner deem the estimate overrated he can insist on *bhattaic* or division of the corn after it is threshed, the most ancient and only infallible mode by which the dues either of the Government or the husbandman can be ascertained. In the *bhattaic* system the share of the Government varies from one-third to two-fifths of the spring harvest, as wheat and barley; and sometimes even half, which is the invariable proportion of the autumnal crops. In either case, *kunkoot* or *bhattaic*, when the shares are appropriated, those of the Crown may be commuted to a money payment at the average rate of the market.”* He quoted those remarks because he thought that when Mr. O’Dwyer’s paper was printed, if it reached some of the Native States they might say the statement that there was no margin of profit for the cultivator did not quite apply to them. A person in England who knew nothing about India might be inclined to say, “Surely you can tell which of the two systems the natives value the most, because if they did not like the British system they would emigrate into the Native States, and if they did not like the native systems they would emigrate into the British districts.” That was a fallacy, and emigration statistics were of little value. Even in famines it was most extraordinary how the inhabitants of whole tracts of country would come into British districts, and when the panic was over they would go back to the place they came from, and scratch at the soil of their forefathers as they had done years ago; they

* Tod, “Annals of Mewar,” pp. 494, 502.

never seemed to want to leave their native land. Migration statistics, therefore, did not affect the argument. The majority of English officers must concur in what Mr. O'Dwyer said, that it was necessary for the Government to take some steps to redress the great evil, which had almost become a political danger, whereby, in the British districts, the cultivating class were being ousted from their paternal acres by the moneylenders. He doubted if the power given to the Courts to go behind the contract, which had been referred to in Mr. Chalmer's Bill, would suffice, and made some remarks describing the system whereby ignorant cultivators who depended on the Bunnahs for everything signed blindly in the books of the latter and executed bonds in which it was very difficult to determine what was principal and what was interest. The whole subject was a very difficult one which the Government had been considering for a long time, and he would be glad to see how the new change in the Contract Act worked, but he doubted very much whether it would be sufficient. No doubt many people had been struck by the brilliant pictures which Mr. G. W. Stevens had been giving in the *Daily Mail*, of his interesting experiences in India, and one short passage he had just read was worth quoting:—"The difference under our rule is not so much that justice is done, as that the law is enforced. The rich man benefits under this, for a raja's government would seldom let a rich man get out of a law suit with a full pocket; but the poor man suffers in the same proportion. In the old days the poor debtor was protected by the rapacity of judges and government. The usurer dared not go before the raja for leave to attach the peasant's stock and crops and land. 'Aha,' his Majesty would say, 'You must have been making money, my friend; we must look into this.' But in a British court the sacred contract must be upheld, and the ryot is ruined." Unless something was done more than had been done a great deal of discontent would remain in the British districts. As for Native States they differed greatly; in some people might be happier than the majority in British districts, though there was no comparison between the officers who administered justice in the Native States and in the British districts. Still, natives liked their own ways, they understood the native judge, and he understood them. He did not always limit himself to the evidence before him, as the British judge was obliged to do, and in that way a sort of rough-and-ready justice was sometimes done which the English Courts could not arrive at. Still the fact that the best governed States borrowed largely from British administration in all departments spoke volumes in favour of the principles we had long been trying to inculcate. The Chairman concluded by inviting remarks from other gentlemen present on the subject of Mr. O'Dwyer's able and interesting paper.

Mr. T. DURANT BEIGHTON said that Mr. O'Dwyer from the position he held—for his services at one time

had apparently been lent to a Native State, and at another time he served as a settlement officer in British India—had been able to make a most interesting comparison between the two systems. They had learnt that both in the British dominions and in the Native State, the Sovereign Power considered itself entitled to a certain proportion of the proceeds of every acre of land; but while the Native State had adopted the principle of rack-renting, and confessedly discouraged the formation of a zamindar class, or of any intermediate class between themselves and the actual rentpayers, the British Government had contented itself with a very much smaller share, and this had given rise to the creation of a large number of proprietary bodies intermediary between the Government and the actual cultivators of the soil. It naturally followed from the creation of these intermediary tenures that there were a large number of saleable interests involved, and the result was a fatal facility for parting with these interests to moneylenders; and this had further resulted in the expropriation of a large number of the smaller proprietors and tenants. In the Native States, at least those mentioned by Mr. O'Dwyer, matters were entirely different, and he thought Mr. O'Dwyer must have been conscious—or possibly unconscious—of a certain amount of humour when he drew so striking a contrast as to what happened in the respective districts. The Native States had certainly taken every precaution for preventing the squandering of the property of their people by taking very good care that they should have none to squander. They had done away altogether with the possibility of any money being borrowed by depriving their subjects of all security and of all credit. It was impossible for them to sell their birthright for a mess of pottage, because they had no birthright whatever to sell. That was the attitude of the two Native States of which Mr. O'Dwyer spoke. The Native State, therefore, was in the position of a beneficent mother, whereas the English Government, from this point of view, would appear to be acting somewhat in the manner of the bad fairy in the nursery tale, by giving gifts to her children which ultimately led to their ruin. It was only fair to say, however, that Mr. O'Dwyer had also dwelt thoroughly on the reverse side of this picture. They had heard of the advantages of British rule, the encouragement and progress of agriculture and commerce, and of this they were all conscious; but there was one advantage which had not been mentioned, namely, that the system of which they were speaking had resulted in the formation, at any rate in Bengal, of a large body of loyal, well-educated landowners, who played a very important part as intermediaries between the Government and the people in the furtherance of any measures of reform, social or political, and that, from the very nature of the case, could not be expected in the Native States. In the very interesting speech of Mr. Chalmers, in introducing his Bill to amend the Contract Act, which had been quoted, there was one pregnant sentence to the effect that, "where one of the parties is in a position

to dominate the other, and he uses his dominant position to impose unfair terms on the other, then the Court is to be empowered to open up the whole transaction," or modify it. He wished to state as emphatically as he could that the results of that enactment would depend entirely upon the interpretation the Courts chose to put upon it. He had had considerable experience as a judicial officer in India, and had found that the Courts had been apt to place too hard and fast an interpretation on the letter of these contracts. Over and over again cases would be found, on searching the records and reports of the High Courts, where the letter of a contract had been too stringently enforced—very often causing great injury and injustice to the debtor. Over and over again, the subordinate Courts had endeavoured to do justice between the parties, but they had been overruled by the High Courts, especially the High Court of Calcutta. There had been a great and increasing change in public opinion both here and in India with regard to the tyrannies connected with usury. A Select Committee of the House of Commons had been sitting in England, and he understood a Bill was before Parliament dealing with the matter. He wished the Legislature in India had seen their way to pass a hard and fast rule that the interest decreed by the Court should never be greater than the amount of principal borrowed. Without some such rule he feared that the letter of the law would continue to be too strictly enforced.

Sir JOHN JARDINE, K.C.I.E., said there were many facts stated in this lucid paper which could only have come from personal experience in the districts Mr. O'Dwyer had been settling, and his statement of the difficult question about the happiness of the people in different districts was admirably expressed. When Lord Lawrence was Viceroy he put the same question to a great many officers there, and the replies he got showed a good deal of knowledge and a great deal of variety of opinion. The Chairman had stated succinctly what most people would think about it, that the ryot in British territory, with his larger possessions, more valuable rights, and an opportunity of a better career, ought to be happier than his counterpart in a good many Native States; but whether he was so in fact was the important question which Lord Lawrence wished his officers to solve, and that was more difficult to answer. It was somewhat like the question discussed by poets, when they contrasted the adventurous and busy life of cities with the ease and quiet of the country, generally preferring a rural life; but when you went into the country you saw that the people living in those beautiful villages had grievances too. And any one who had been through the Native States, and had much to do with the people, would find that they too had grievances. Of course, it depended a great deal on the temperament of the particular people and their rulers. Some of these Native States had been in British hands for some time, and had accepted a modified form of the British

land revenue system. Sometimes you find a tyrannical prince, as was not uncommon in the old days, but in the south of India, where the Mohammedan doctrine that the State had absolute property in the land never much prevailed, the Hindu law was remembered by the Hindu princes and rajas, and they usually put a considerable restraint on the exaction of land revenue, although very often, in the course of time, new taxes got added on to it, and this made it ultimately an oppressive burden, which soon after the British invasion began to be redressed. He spoke of the Bombay Settlement, which was afterwards extended, under Lord Lawrence, to Berar and Mysore. That began in the time of Mountstuart Elphinstone, who wished to preserve the native system as much as possible, but he wrote that the British sentiment and the native sentiment on a great many points were absolutely opposed, and some of the things he wished to preserve would be regarded with disgust by British officers, whilst many things they thought first-rate would be looked upon by the natives with abhorrence. He foresaw that when the officers were appointed by seniority and not by selection it would be difficult to manage a system by British officers on native lines, and, therefore, a compromise had to be made. He began by reducing the rate—i.e., the half or third of the net profit on land; but even that was found to be too high, and it was decided to reduce it, fixing it according to the quality of the land, the neighbourhood of markets and so forth, and out of that arose the Bombay Revenue Survey, which brought in another benefit, of which the Native States had availed themselves—the mapping of village lands, putting down boundary marks, getting evidence about rights and so on, which pre-appointed evidence was useful for all time to come and saved a good deal of litigation. One result was that waste land came far more into cultivation and the Government gained in that way. As time went on the selling price advanced, though never in rural districts, up to 54 times the assessment. He thought it was generally between 12 and 20 times the annual rent. On the whole the cultivators were satisfied. Sir Bartle Frere, in 1865, brought in a measure which levelled up most of the tenures of the Presidency. There were a few valuable tenures, which were supposed to be so fixed that for a long time it was thought that after any length of time a son might come back and reclaim the land. What the Government did was to give the unprivileged ryot a hereditary and transferable title so that the son was not dependent upon the Government for his tenure from year to year, but had a right to keep it on if he chose to pay the assessment, which was not to be altered until the end of a long term, usually 30 years. Some of these leases had fallen in, and the Government had raised the rents generally without difficulty. He had been much struck with what he saw in the report of what may be called the settlement officers in Britain, that is the Commissioners who visited England, Wales, and Scotland, collecting evidence with regard to agri-

cultural depression. One object of Sir Bartle Frere was to prevent the farmers being evicted from the soil, and the Blue-books of the Agricultural Commission seemed to show the same evil here, and in many counties the farmers had shown a desire for fixity of tenure. It appeared that in Nithsdale out of 245 farms there were 172 new tenancies, the new people being often bankers, merchants, and business men, and this coincided with Mr. O'Dwyer's remarks about people not connected with the agricultural classes getting a footing in the Indian villages. He remembered, when First Assistant-Collector of Poona, noticing how curious the street of Ambegaon appeared, more like a village in Gujerat, and the ryots told him that the houses were the shops of the Gujerat moneylenders, who had become owners of nearly all the houses, while the original inhabitants were now slaving on the fields that once belonged to their fathers. That grievance was very much felt. Some years ago they were rather startled when a district judge in Bombay found in the report on which the survey was founded that it was the intention of the founders of the settlement to get rid of the poorer cultivators. Influenced as the statesmen of that time were by such authorities as Bentham and the political economists, they suggested that there was no disadvantage, but only an advantage in getting rid of farmers without capital, and getting capitalists in instead. It was really a change of opinion which had come over the official world in India between that time and this, as the evils grew greater, and that had led to a much more general feeling in favour of the extension of the equitable doctrine, so as to protect the farmers, as ignorant men, against the moneylenders, who were better educated. This influence was now strongly felt in legislation. First, it was applied to the great landowners, afterwards to the common ryots; and although there was much discussion about the theory and the result, he was inclined to think that the policy had justified itself. Not long before he left India he read a report on the Deccan Relief Act, 1875, by a district officer, who said that he noticed that the houses of the people were better, and they seemed to be living more happily. As regarded the judicial arrangements, he believed the system had worked well, and he wished those who attacked the High Courts would remember that it was not the Executive but the judges of the High Court of Bombay who had introduced English doctrines of equity with regard to mortgages so as to give the owner of land the right to redeem, and to protect him, as far as English equity could, against oppression on the part of his creditor.

Mr. ALEXANDER ROGERS said the main point to be considered was whether the ryots generally, including the zamindars, should be taxed to the utmost—that is, rack-rented—or not, and which was the most favourable system, taking into consideration the position of the people on one side, and of the Govern-

ment on the other. It was acknowledged, in the summing up of the paper, that the British system, which allowed a certain margin of profit to remain with the cultivators, had tended to the increase of prosperity, and the main point to be looked at was whether it did so or not. He had had a good deal of experience in revenue matters, but not in districts such as had been described in the paper. He had had to deal with *rayalwari* districts, and he maintained, from actual experience, that the Bombay Revenue Survey, as contrasted with the Madras system, had acted for the best. In Bombay a margin of profit was deliberately left to the cultivator in order to give the land a saleable value. The result was you could not find a scrap of land waste which was not taken up. In other districts, as in Madras, where that margin was not given, although the Madras people said it was, the result was that instead of there being no land to be got, there were over 6,000,000 acres of arable land waste. The revenue was collected in a great measure by evictions of the tenants, and when their land was put up for sale by auction to realise the Government revenue, 30 to 40 per cent. had actually to be bought in by the Government themselves. Mr. O'Dwyer acknowledged that the Bombay system encouraged enterprise and energy; on the other hand, though the assessments were more lenient, they were more rigidly collected. That was a matter of administration, and was entirely in the hands of the Government and Collectors; nominally the assessments were rigidly collected, but in reality they were not. The Collector of a district knew what the result of his operations would be, and he must be a born fool if he taxed the people so as to drive the land out of cultivation. The assessment was revised every thirty years, which afforded a test as to how it succeeded. At the time of revision careful statistics were collected to ascertain whether the condition of the people had improved or deteriorated. His experience was that there had been an increase of comfort in various ways. If tiled houses had been substituted for thatched houses, if the number of cattle had been increased, if the returns from the Courts showed that the value of land had increased, all these were signs whether the Bombay assessment system had answered. He could appeal to printed reports to show that it had afforded inestimable benefit, on the whole, to the cultivator in Bombay.

Mr. W. COLDSTREAM said Mr. O'Dwyer had presented a most accurate picture of the state of things which he had observed, as might have been expected, as he was an officer of exceptional ability, with a great talent for observation. It was quite true that the native system, which prevented the growth of market value in land, might (in a sense) be regarded as a real good in the present condition of things over a large part of the empire. There was no doubt the effect of the British system in the Punjab had resulted in some degree of injury owing to the ignorance

of the cultivators. Land had suddenly acquired a substantial marketable value, mortgages and sales were allowed, and supported by the Courts, and the zamindars forthwith began to taste the pleasures of the command of cash. They borrowed for marriages, for jewellery for their women, and mortgaged their land to its full value; the result was that many thousands of acres had passed for ever out of the hands of the original proprietors. The remedy, of course, was in the gradual education of the people and the progress of the country. When the landowner came to contract with the moneylender on an equal footing the evil would be remedied. They were now in a transition state, but he had no doubt that, in the course of a generation or two, things would settle down, and the maxims of prudence would prevail. The paper was a most practical and useful picture of the present condition of things and therefore of historical value. He thoroughly sympathised with the Chairman's allusion to Colonel Tod's book. It was a trustworthy description of the condition of Rajputana at the beginning of British rule; a valuable text-book and treasury of facts. Now-a-days the work of officials did not leave them time or energy to enter into these questions the way Colonel Tod did 80 years ago. As to the game laws in Native States for the protection of wild pigs, he had known of crops much damaged because the raja would not allow the zamindars to shoot the pigs, and much dissatisfaction resulting. In one native State the nilgae became very numerous, so that the zamindars' fields were periodically browsed down, and the nilgae, being considered a sort of cow, could not be slaughtered in accordance with the Hindu religion. However, after a time, a reference was made to Benares, and it was finally settled that it was not a cow, but a deer, and since then in that State the nilgae had almost ceased to exist.

SIR CHARLES CECIL STEVENS, K.C.S.I., said they had it on classical authority that a traveller with empty pockets would sing in the presence of the robber; but yet it had always seemed to him a little difficult to understand that a ryot who had neither property in his land, nor credit, could be happier for it. It would, at any rate, be scarcely safe to apply to the whole of India conclusions which were doubtless sound enough with regard to the portion of the country covered by Mr. O'Dwyer's remarks. He had had a good deal to do with these matters in Bengal, having been the member of the Board of Revenue who had had to deal with the enquiries preliminary to the law recently passed, and it was his duty to study the question of the prevention of the alienation of lands. After examining the facts, he came to the conclusion, in agreement with the great weight of opinion among the revenue officers, that the evils arising from the transfer of land in Bengal could be nothing compared to what they heard described by their brethren in the Punjab and other places. It seemed to him, therefore, that it was not necessary to pass a sweeping

law for that Province, and the recent legislation of the Indian Council contained the remedy which had struck him as being appropriate to the conditions of Bengal. Whether it would be sufficient for other Provinces, or whether something more drastic would be required he could not attempt to say; for he had been sufficiently long in India to appreciate the value of local experience and knowledge. So far as Bengal was concerned he could not accept the statements contained in the paper as entirely appropriate to either the British territories or the Native States. Their experience of the latter in Bengal was not very large: but, as Commissioner of the Chutia Nagpur division, he certainly thought the condition of the cultivators was happier than it seemed to be in those more important States of which mention had been made in the paper. There the zamindars were understood and were allowed to receive profits, and cultivators breaking up new land and labouring to make it productive, received much consideration; and the same thing was to be found in those parts which had comparatively recently come under British control. Nowadays, the moneylender in Bengal was acknowledged to have his uses. Very often he was not such a professional moneylender as those infesting other Provinces, but an inhabitant of the village, who operated in a very small way. It was to his interest to keep his ryots going, and he (the speaker) well remembered that during the scarcity or famine of 1882 to 1883, when he was the Collector of a district, the moneylenders were of the greatest possible service in helping to carry their ryots through their difficulties. An old friend of his, an indigo planter, who had lived among the people for many years, and had a very intimate knowledge of them, had told him that he found these moneylenders had a sentiment of *dharma* in the matter; they felt the ryots were dependent upon them, and it was their duty to assist them.

The CHAIRMAN then proposed a vote of thanks to Mr. O'Dwyer, which was carried unanimously.

Miscellaneous.

COMMERCIAL EDUCATION IN ENGLAND.*

BY SIR HENRY TRUEMAN WOOD, M.A.

(Continued from page 574.)

For scientific and technical education, we have yet other separate organisations. The higher scientific education, it is true, is to a very large extent under the dominion of the Universities, especially of the younger

* A paper read at the International Congress on Technical Education at Venice, May, 1899,

Institutions, such as the University of London, the Victoria University (Manchester), and the important provincial Schools and Colleges, mostly of recent origin and affiliated to the newer Universities. Elementary scientific instruction, however, like elementary education, is under Government control. As far back as 1836, Schools of Design were founded under the control of the Board of Trade. In 1852, a Department of Practical Art was established—soon after changed into the Department of Science and Art, which still continues as a separate Department of the Government, but is about to be combined with the Education Office into a general Department of Education. As at present constituted, the Department has under it the Royal School of Mines, the Normal Training College for Science Teachers, known as the Royal College of Science, and also the South Kensington Art Schools, known as the Royal College of Art. These are all in London. It also administers certain branches in other parts of the kingdom. The most important part of the work is, I think, its examinations. These were established for Science subjects in 1859. As early as 1853 experimental science schools were established in selected centres in the country, and a system of examination was introduced in 1859. Payments were made on each student passing an examination, and by this means a revenue was provided for these schools, and for numerous other similar schools which were established all over the country. Grants in aid of the schools were also made under certain conditions. This system, which is now being gradually superseded by payments on attendances, is open to criticism, and I believe this country has been allowed to retain a monopoly of the method of payment on results. Perhaps its apparently practical character recommends it to the English mind. It had at the outset many drawbacks. It encouraged cramming, and aided not a little the cult of the "great god Smatter." Teachers were induced to collect the greatest number of students they could gather together; and to teach them in such a way that they were enabled to pass a not very difficult examination, without acquiring any genuine knowledge of its subject. In a great number of cases all the students did was to acquire a smattering of some branch of science, which, perhaps fortunately for themselves, they very rapidly forgot. But, on the whole, the disadvantages of the system were more than counter-balanced by its successes. The ultimate result of the work of the Department has been to cover the country with a network of schools, some of which, aided by local effort, have attained the highest class, and to provide a means by which the poorest student of ability may obtain a scientific education, and the opportunity of starting on a scientific career. There are not wanting, among our more distinguished professors, some who began their training in one of the Department's classes. The Royal College of Science at South Kensington, intended for teachers, but available also for students who may never intend to become, or who have abandoned the idea of

becoming teachers, ranks with the best schools of science in the country. Its professors include many of the best known of our scientific men. And the result of the whole system is that an elementary school-boy entering a science class, and thence perhaps passing to one of the provincial colleges, may eventually enter the College at South Kensington, and obtain as good scientific teaching as the country can provide.

The demand for Technical Education came a little later. The discovery that the manufacturers of other countries were better instructed in the applications of science to industry than those of Great Britain led to the appointment, in 1881, of an important Royal Commission, which investigated the technical schools of Germany, France, Switzerland, and elsewhere, and embodied the results of their investigations in a very valuable Report. The Society of Arts established, in 1873, a series of technological examinations—examinations in certain selected branches of scientific industry—which were in some sort a supplement to the examinations in pure science held by the Government Department. There was, however, no payment on results for these examinations, which were purely of a voluntary character, and they attracted but a very small number of candidates. A few years later, however, the ancient companies of the City of London, survivals of the mediæval Guilds which regulated the trades and handicrafts of the City, and have retained considerable wealth, saw in the demand for technical education a means of employing their accumulated funds, and, by once more associating themselves with the trades with which they were nominally connected, of justifying an existence now become almost an anachronism. They, in 1879, took over the technological examinations of the Society of Arts, and by offering payments to teachers on a scale similar to those made by the Department, induced the formation of classes, and obtained a considerable number of candidates. These examinations, under their new administration, have flourished so well that for some years past they have been enabled to dispense with any payments, and yet they had last year as many as 13,000 candidates who entered for the examination. They also built and endowed at South Kensington, in close proximity to the Royal College of Science, an institution for the teaching of science as applied to industry, and besides this they established what may be termed trade schools, to act as feeders to their central institution. Thanks to the munificence of the Guilds, and the judgment with which their money has been expended, the state of technical education in England is now fairly satisfactory. The higher technical education is good, though not as good as at the better endowed schools on the Continent; while there are certainly more opportunities in England for the workman to obtain scientific knowledge in the basis of his craft, if he cares to do so, than in any other European country.

Next, as the demand had arisen in succession for scientific and for technical education, so now there

has been raised an outcry for commercial education. Our merchants in London, and the other great cities of industry, were struck by the fact that many young foreigners, principally Germans, have been willing to come over and accept lower wages than would be paid to much inferior English clerks. They did not at first quite realise the fact that many of these young men were the pick of their class, that they came to England, not because there was no room for them in their own country, but with the object of acquiring foreign experience, as well as a foreign language, that in the case of many of them pay was but a secondary consideration, and that as soon as they had acquired the necessary knowledge, they were quite ready, either to go back to their own country, or, if they remained in England, to set up as rivals of their employers. The advent, however, of this class of foreign clerks drew attention to the fact that they were far better educated for commercial purposes than young men of a similar class in our own country. This, and the fact that England is now feeling keenly the commercial rivalry of other nations in fields which she has so long regarded as her own peculiar property, led to a serious demand for improved commercial education. In this demand, probably those who made it did not very clearly realise themselves precisely what they wanted. They had impressed upon them the fact that the lads and young men who were entering their offices were, as a class, but poorly instructed, as compared with a like class in continental countries; they did not stop to inquire whether the deficiency was in quantity or quality, and they cried out for a reform in teaching methods, declaring that some new provision of commercial education was required, without saying—indeed, without knowing—what they meant by commercial education.

At the present time, as may be gathered from the preceding short summary of our English educational methods, the rank and file of our commercial classes are drawn from the general middle-class schools, or—as regards the lower grades—from the elementary schools; while our upper commercial classes—sons of men of business, or of professional men, whose education can be carried on later in life—receive the ordinary grammar or public school education of English lads—in some cases completed at the universities. The former class leave school at fourteen or earlier, with little knowledge of anything but reading, writing, and elementary arithmetic. They acquire by practice a knowledge of the business methods of their particular trade and industry, and as a rule turn out sufficiently capable servants. The more intelligent advance to higher positions. The rank and file carry on the routine tasks with which constant practice has made them familiar.

There is one question which cannot be neglected in the consideration of any department of English education—that is the question of athleticism. I do not think that persons of other nationalities realise to how great an extent our English schools are dominated by the love of sport and games. To a

large proportion of our *profanum vulgus* the two universities of Oxford and Cambridge are not primarily “seminaries of sound learning and religious education,” but two organisations which contend annually in a boat race. To the fashionable world of London our two greatest public schools—Eton and Harrow—are most in evidence when the boys come up to a well-known cricket-ground in London for their annual cricket match. At all our great public schools the heroes of the playing-fields form the dominant element in the school. It is said that no young master can hope for a situation in our upper class secondary schools unless he is an athlete as well as a scholar. He must have taken honours, not only in the schools, but on the river, or in the cricket-ground. The same influence extends through all our upper and middle-class schools, and affects our young men after they have left school. Our large business houses have their cricket clubs and their athletic clubs. The most recent polytechnics are not unmindful of the old Greek system of education, which comprised not only *μουσική* but *γυμναστική*, and they provide for physical as well as intellectual development. The champion in our amateur walking contests is at the present time a student in the London Regent-street Polytechnic.

As so much time and thought is devoted to the development of the body, it cannot be denied that the development of the mind, if it does not suffer, is likely to be delayed. I believe that on account of our devotion to athleticism, we are, to a large extent, regarded as barbarians by educational critics of other countries, and this feeling is not without its exponents among ourselves. I have myself no sympathy with such critics, for I believe that combined mental and physical training turns out a better product than mental training alone. But while I would ask educational authorities to remember that young folk have bodies to be trained as well as minds, I do not advise them to forget that they have minds as well as bodies. It must, I fear, be admitted that the cult of athleticism is carried to excess in our leading schools and our older universities. I would, however, point out what I do not think has hitherto been considered in this connection, that in most European countries every man is compelled to pass a certain portion of his life in the army, and that the drill and exercise to which he is subjected must, to a large extent, form the equivalent of our voluntary English sports and games. Compulsory military service, too, affects all classes alike, whereas in England the classes whose children fill the elementary schools have no such useful physical training, and are, I fear, beginning to show the want of it, now that they tend more and more to seek occupations not involving manual labour. I would also point out that there seems to be a tendency, at all events in France and in America, to encourage physical exercises in schools. In America, to my own knowledge, there has been a great change in this respect during the last few years. But, on the whole, it must be remembered in

comparing the educational condition of the young English clerk with his French or German colleague that the latter has probably devoted more time to his mental development, and is, besides, less apt to devote his attention to athletic amusements, instead of to the duties of his business. Such amusements too often form the real interest of his life, instead of its relaxation.

A few years ago it might, I think, be said with truth that there were no purely commercial schools or institutions in the kingdom. Some have lately been established—of these the most promising is the London School of Economics, in which instruction is given in matters bearing on the higher commercial education—economics, statistics, political science, commercial law, &c. There have, however, for a long time been evening schools at which those already engaged in business can continue their education. Although these classes do not owe their origin to the science school of the Department, it is, I think, owing to the development of these latter schools that there has been a similar development in classes for teaching subjects of a commercial character. The science schools, aided by the Government grant, added to their courses of instruction classes for the teaching of modern languages, book-keeping, shorthand, mathematics, and the like; while some of the older so-called mechanics' institutions, founded early in the century for the dissemination of popular knowledge and the improvement of the working-classes, were enabled, by the establishment of the science classes and the consequent money which they earned, to enlarge their operations, and to carry on more effectively than they hitherto had done their classes for teaching subjects other than those subsidised by the State. Further than this, day classes have been added. Thanks to private liberality, to the application of ancient endowments, and to the judicious application of the revenues provided by the State, there are now a great number of teaching centres where instruction is given in science, languages, art, and general and commercial education. In London, a number of such institutions have existed for some time past, and their number has recently been largely increased by the formation of several so-called polytechnics. The instruction is principally given in the evening, but most, if not all of them, carry on classes during the day also.

A few years ago, a great impulse was given to the development of these institutions by the fact that Government was able to assign to the County Councils (provincial authorities for local administration), certain funds to be employed for educational purposes. To assist the application of these funds, and to encourage their proper use, the Science and Art Department was also empowered to add to the list of science subjects, by teaching which its grants could be earned, many technical and commercial subjects, including in this latter category shorthand, book-keeping, &c., as well as foreign languages.

As far back as 1856 the Society of Arts esta-

lished examinations in general knowledge, conducted from a single centre simultaneously all over the kingdom, the object of these examinations being to encourage the formation of classes among the workmen's institutions then existing, and to afford the students of such institutions a means of testing their knowledge. It was on the model of these examinations that the examinations of the Science and Art Department were founded. The Society of Arts system has undergone various modifications, but for some years past the subjects with which they deal have been purely commercial. They include shorthand, book-keeping, type-writing, commercial geography, foreign languages (the examination in these is of a commercial, not of a literary character), &c. The students in the evening classes, accustomed to the periodical examinations of the Department, welcome those of the Society, and are encouraged by their teachers to enter for them, although there is no profit to be earned by their doing so. The fees are kept at the lowest possible amount, in fact, the examinations are now barely self-supporting, and, until the last few years, were conducted at a loss. During the present year, 10,500 candidates have been examined at 257 centres, situated in various parts of the United Kingdom. The examinations are in separate subjects, and a candidate can obtain a certificate for passing in a single subject. This method has its drawbacks, but it is found to suit the class which it is intended to assist. The attempt was made, some years ago, to substitute for the separate certificates a certificate in commercial knowledge, to obtain which it was necessary to pass in certain specified subjects, but the attempt proved unpopular, and the attempt was abandoned. A student prefers to come up for one year, perhaps, in French and in Book-keeping, and having a certificate in each of these, he will go in the succeeding year to German and Shorthand. A vast majority of these examined are of the commercial class—clerks, book-keepers, typists, shorthand writers, salesmen, and shop attendants, or young people preparing for such employment.

(To be continued.)

Correspondence.

PROTECTION OF INVENTIONS AND TRADE MARKS IN EX-SPANISH COLONIES.

According to advices just received from Washington, I learn that a circular has recently been issued by the United States War Department dealing with the above subject. The following particulars may interest your readers.

In territory subject to military government by the military forces of the United States, owners of patents, including design patents which have been issued or which may hereafter be issued, and owners of trade marks, prints, and labels duly registered in the United States Patent-office under the laws of the United States relating to the grant of patents and to the registration of trade marks, prints, and labels, shall receive the protection accorded them in the United States under the said laws; and an infringement of the rights secured by lawful issue of a patent or by registration of a trade mark, print, or label, shall subject the person or party guilty of such infringement to the liabilities created or imposed by the laws of the United States relating to such matters: provided that a certified copy of the patent or of the certificate of registration of the trade mark, print, or label shall be filed in the office of the Governor-General of the island wherein such protection is desired; and provided further, that the rights of property in patents and trade marks secured in the islands of Cuba, Porto Rico, the Philippines, and other ceded territory, to persons under the Spanish laws shall be respected in said territory, the same as if such laws were in full force and effect.

REGINALD W. BARKER.

56, Ludgate-hill, E.C.
May 18, 1899.

General Notes.

ROYAL INSTITUTION.—At a General Meeting of the Members of the Royal Institution, held on the 22nd inst., the following foreign scientific men were elected Honorary Members, in commemoration of the Centenary of the Royal Institution, which will be celebrated on the 5th, 6th, and 7th of June next:—Professor S. Arrhenius (Stockholm), Professor C. Barus (Brown University), Professor H. Becquerel (Paris), Professor G. L. Ciamician (Bologna), Professor N. Egorof (St. Petersburg), Professor A. P. N. Franchimont (Leiden), Professor A. E. Gautier (Paris), Professor H. G. Kayser (Bonn), Professor W. Körner (Milan), Mr. S. P. Langley (Washington), Professor G. L. Van der Mensbrugge (Ghent), Professor A. A. Michelson (Chicago), Professor H. Moissan (Paris), Professor R. Nasini (Padova), Professor W. Nernst (Göttingen), Professor W. Ostwald (Leipzig), Dr. E. Solvay (Brussels), Professor R. Thurston (Cornell), Professor E. Villari (Naples), Professor J. L. G. Violle (Paris), Dr. E. Ador (Geneva), Dr. L. Bleekrode (The Hague), Professor J. S. Ames (Johns Hopkins University), Professor G. F. Barker (Philadelphia), Dr. O. Liebreich (Berlin), Dr. W. L. Wilson (Washington).

MEETINGS OF THE SOCIETY.

APPLIED ART SECTION.

Tuesday evenings, at 8 o'clock:—

MAY 30.—“The Revival of Tradesmen's Signs.”
By J. STARKIE GARDNER, F.G.S.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

JUNE 1.—“The Port of Calcutta.” By Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal. The EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., will preside.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, MAY 29.—Surveyors, Great George-street, S.W., 3 p.m. Annual General Meeting.
Geographical, University of London, Burlington-gardens, W., 8½ p.m.
British Architects, 9, Conduit-street, W., 8 p.m.
Mr. T. J. Bailey, “Planning and Construction of Board Schools.”
- TUESDAY, MAY 30. SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. (Applied Art Section.)
Mr. J. Starkie Gardner, “The Revival of Tradesmen's Signs.”
Royal Institution, Albemarle-street, W., 3 p.m.
Professor W. J. Sollas, “Recent Advances in Geology.” (Lecture III.)
Central Chamber of Agriculture (at the HOUSE OF THE SOCIETY OF ARTS), 11 a.m.
United Service Institution, Whitehall, S.W., 3 p.m.
Major-General Sir W. F. Gatacre, “Hill Fighting and the best Mode of Training for the same.”
- THURSDAY, JUNE 1... SOCIETY OF ARTS, John-street, Adelphi, W.C., 4½ p.m. (Indian Section.)
Sir Charles Cecil Stevens, “The Port of Calcutta.”
Royal, Burlington-house, W., 4½ p.m.
Antiquaries, Burlington-house, W., 8½ p.m.
Linnean, Burlington-house, W., 8 p.m. 1. Mr. W. Botting Hemsley, “The High Level Plants of the Andes as illustrated by the Collections of Sir W. Martin Conway, Mr. Edward Whymper, and others.” 2. Sir John Lubbock, “Some Australasian Collembola.”
Chemical, Burlington-house, W., 8 p.m. 1. Mr. W. Popplewell Bloxham, “The Hydrosulphides, Sulphides, and Polysulphides of Potassium and Sodium.” 2. Dr. Sydney Young, “The Relative Efficiency of Various Forms of Still-head for Fractional Distillation.” 3. Dr. J. N. Collie and Mr. Thomas Tickle, “The Salts of Dimethylpyrone and the Tetravalence of Oxygen.”
Royal Institution, Albemarle-street, W., 8 p.m.
Prof. L. C. Miall, “Water Weeds.” (Lecture II.)
- FRIDAY, JUNE 2...Geologists' Association, University College, W.C., 8 p.m.
Philological, University College, W.C., 8 p.m.
Quckett Microscopical Club, 20, Hanover-square, W.C., 8 p.m.
- SATURDAY, JUNE 3...Royal Institution, Albemarle-street, W., 3 p.m. Mr. E. F. Jacques, “The Music of India and the East, and Its Influence on the Music of Europe.” (Lecture III.)

Journal of the Society of Arts.

No. 2,428. VOL. XLVII.

FRIDAY, JUNE 2, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****INDIAN SECTION.**

Thursday, June 1, 1899; the EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., in the chair.

The paper read was "The Port of Calcutta," by Sir CHARLES CECIL STEVENS, K.C.S.I., late Acting Lieutenant-Governor of Bengal.

The paper and discussion will be printed in a subsequent number of the *Journal*.

APPLIED ART SECTION.

Tuesday, May 30, 1899; Sir GEORGE BIRDWOOD, K.C.I.E., C.S.I., LL.D., M.D., in the chair.

The paper read was "The Revival of Tradesmen's Signs," by J. STARKIE GARDNER.

The paper and discussion will be printed in a subsequent number of the *Journal*.

CONVERSAZIONE.

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman, and other members of the Council, will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors.

A selection of music will be performed by the String Band of the Royal Artillery in the Central Hall, and by the Red Hungarian Band in the Bird Gallery, commencing at 9 o'clock.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. These tickets will be issued

shortly. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman, and must be signed by the member applying for it.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

The entrance to the Museum is in the Cromwell-road. Carriages must enter the grounds by the east gate and leave by the west gate. The cards must be given up on entering the Museum.

Visitors arriving or leaving by either of the Metropolitan Railways will be allowed the use of the District Company's Subway, which leads from the South Kensington Railway Station direct into the grounds of the Museum.

Fuller particulars as to the musical and other arrangements will be given in the Programmes which will be distributed on the evening.

Proceedings of the Society.**APPLIED ART SECTION.**

Tuesday, May 16, 1899; Sir JAMES LINTON in the chair.

The paper read was—

PICTURE FRAMES.

BY I. HUNTER DONALDSON.

We cannot to-night occupy much time in considering the origin or antiquity of picture frames, but may refer to some of the oldest known to us. The frescoes of Pompeii, still in parts perfect and beautiful, offer numerous examples of framing designed by the artists for the isolation of their subjects and the enhancement of their effect; these being the primary objects of all such framings.

At the British Museum Dr. Murray kindly pointed out their oldest frame, of about the 2nd or 3rd century of our era; it is of a hard wood like beech, of what we know as the "Oxford" pattern, with a marginal 1-inch flat, a groove to receive glass, and cord to suspend it by the corners. The panel had a portrait of encaustic, now nearly obliterated. I also saw an engraving of a Pompeian studio, in which a lady artist is sitting with a similar frame and portrait in it, near her. We then went to the finely preserved mummy from Hamara in the Fayoum, of a young woman once of much beauty, whose portrait on a 12 by 9 panel is at the head, with a framing of many folds of the cerecloth, which is ingeniously swathed so as to form a geometrical pattern all over the body. I am told that poor Egyptians who could not afford to have such portraits painted expressly for their lost ones, used to buy, from stocks of ready-made portraits, such as most nearly resembled the deceased, and when the swathing cloth decayed, such portraits were hung up as pictures. It was a custom of the Romans to have upon round, or shield-shaped wood, portraits called "imagines" of their celebrated dead, modelled in coloured wax, to carry these in the funeral processions, and afterwards to suspend them in the houses.

We know that the ancients painted in every style of art, excelling in all, and though Pliny says that "the greatest glory was obtained by easel pictures," he gives, as another reason for preferring them, the fact that paintings upon the actual walls cannot be saved in case of fire. We read that Cicero sent large sums of money to his friend Atticus, to buy pictures in Greece, for decorating his villa at Tusculum, and artists of distinction, like Polygnotus, must have been well aware of the importance and effect of suitable frames for their masterly works.

That no examples of beautiful ancient frames can now be found is not surprising, for we are told that the anti-pagan zeal of the early Christians led them to destroy everything they could which was pagan, however artistic; they used to put ropes round the marble necks of the almost divinely-beautiful Apollos and Venuses, drag them into the open, try them in public like criminals, find them (of course) guilty, and then pound to dust statues by men whose names we reverence to day. Thirteen hundred years later a religious zeal, not according to knowledge, led Cromwell's troopers to stable horses in Worcester Cathedral, whilst money was actually paid for the destruction

of stained glass which we should now consider priceless. We do, however, owe to the "Protector" the purchase of Raphael's cartoons for the nation. I mention this because it explains the reason why no frames have been handed down to us by which the subject can be illustrated.

There is not time to include in this paper frames made for predellas or altar pictures, those for the exquisite Venetian and other mirrors, or those designed for the sculptural works of such artists as Della Robbia, Donatello, and Sansovino, numerous and beautiful as they are; of these fine examples exist at South Kensington, in the Wallace collection, and elsewhere. Of the vast number of designs made to surround portraits engraved in the 16th, 17th, and 18th centuries, some prints, kindly lent by Mr. George Clulow, are hung here. And we are indebted to Mr. Hugh Stannus, always active in the interests of art, for the photographs which show framings in panels, walls and ceilings of the most celebrated Italian buildings.

Persons who will take the trouble to examine the frames used by the older English masters in oil and water colours, will notice the poverty of design and the want of taste of most of them. This was felt so much by the leading artists in the sixties, that they were led to make great improvements, and, *à propos* of the common-place expression, "What a beautiful frame," uttered sometimes by those incapable of judging the merits of a picture, two articles appeared with illustrations in *The Architect*, exactly thirty years ago. These were written by Mr. Phené Spiers, Master of the Architectural Schools of the Royal Academy, himself an accomplished artist. He said, "In a frame lies a not inconsiderable portion of the completeness of a picture, and there are fortunately a few painters, Mr. Leighton notably among them, who have long recognised the fact that their powers of imagination and composition ought not to terminate with their canvas." Mr. Spiers ably criticises the frames in the Exhibition of the Academy in 1869, and we shall have details of those frames on our screen, with his remarks for our information.

These were frames drawn with exceeding care by Mr. Phené Spiers, 30 years ago, and they were reproduced in *The Architect* with criticisms more lengthy than those I have referred to. For the benefit of those interested in frames I may say that some of the designs shown this evening will be reproduced in the

Journal of the Society of Arts, and I hope they will be found of use, for in the exhibition now coming on there are not many frames showing such artistic beauty as these, and very few equal to them in their general treatment. In the Academy there are many pictures with frames like No. 174, but the objection to the frame is this, that the large mould is close to the picture. The effect of that is to lessen the importance of the picture.

- 110. Mr. Poynter.—“The close juxtaposition of the pateræ suggests a running border; they should not have been emphasised at the corners.”
- 117. French.—None in the Exhibition giving more effect to the picture.
- 154. Mr. Alma Tadema.—A Belgian frame, somewhat similar, with burnish brought into the ornament, and not, as in the English, confined to the lines.
- 421. Mr. Alma Tadema.—Shows careful attention to style, the large Cavetto member making it rather less happy than 154.
- 81. Mr. Richmond.—Good, but not his design, too free use of the figures of devils.
- 174. Mr. Portal.—French, showing influence of Greek art more than any other frames, except those of Mr. Leighton.
- 432. Mr. Yeames.—Vigorous and bold, appropriate to the period of picture; improved by a deeper set-back and broader margin of plain.
- 99. Mr. Sandys.—One of the most original; the simple Gothic moulding and contour accord with style of picture, splayed surface at bottom giving solemnity to the subject.

This is mediæval in its treatment; the lower part is flat, all the mouldings terminate upon the flat, and for paintings representing ecclesiastical subjects such a frame would be particularly appropriate. You will find in South Kensington and other galleries altogether appropriate frames for religious subjects. In the Academy there is one flagrantly wrong.

- 272. Mr. Armytage.—Egyptian ornament, contour very good, accessories in keeping with subject.
- 795. Mr. Leighton.—Refined, showing knowledge of the best and most subtle forms of Greek art, the effect of painted ornament on the gilded surface of the frame very good, and might with advantage be more extensively employed.

The effect of painting upon the gold has been altogether disregarded in this country. If you go to Florence you will see a number of frames painted in a charming manner.

864. Mr. Leighton.—Well-studied, but less good, rather heavy, and tending to convexity in contour of mouldings

This is a very elaborate frame; it must have taken a great deal of time to design, but the general effect is not at all pleasing. The straight line is very injurious to a picture, there is no stereoscopic effect which a frame should give to the picture.

- 483. Albert Moore.—Simple and effective.
- 699. Albert Moore.—Sparkling and delightful.
- 485. Frank Walker.—Original, but section too straight.
- 730. Mr. Prinsep.—Based on Leighton's, but not Greek.
- 736. Mr. Graves.—Very good in design, and well modelled.

Fourteen years ago, Mr. W. R. Lethaby, in an able paper, drew attention to the poverty of design in frames then exhibited, with some remarks to which I shall refer later. Before this time much attention had been given by foreign artists to their frames, which were not unfrequently designed under the influence of the best Italian period, some examples of which will be shown. We are justified in expecting that since the year 1869 an advance should be seen in the designs of frames, especially by our principal artists, and some of the more recent ones will be displayed. We may soon hope that when the expression “What a beautiful frame” is heard, it may be found to proceed from a person whose cultivated taste and sense of beauty apply equally to the work of a true artist in his picture, and in the frame he has designed for it.

I do not think it can be claimed for the frames in this year's Academy that they show any advance in design upon those of thirty years ago; some of the largest are defective in architectural detail, and some have large, busy, obtrusive mouldings close to the pictures; there is a noticeable display of old frames, for which there is now great demand, and for the first time we see a number of gilt frames toned almost to the colour of wood; some of the most grandiose lack the refinement of those of '69, and although there is undoubtedly more variety than formerly, there appears to be less purity of taste. The true relation of a frame to a picture has probably never yet been the subject of a lecture to students, and the very alphabet of this phase of art is unknown to thousands of them.

I will refer to four frames. I assume my hearers have been to the New Gallery and seen the work of Mr. Holman Hunt, “The Miracle

ITALIAN FRAME, SIXTEENTH CENTURY.—South Kensington.

ITALIAN FRAME, SIXTEENTH CENTURY.—South Kensington.

of Sacred Fire," in the Church of the Sepulchre at Jerusalem. Mr. Holman Hunt has put fourteen figures in groups on the frame with a seven-branch candlestick in the centre, and he has modelled all these in gesso, the frame is gilt and it requires toning, but apart from that it is interesting. The curious thing is this, he has made a pediment and rested it, without any frieze, on two pilasters. He has ignored, in the most flagrant manner, the ordinary principles of architecture. In many frames at the Academy there are obvious departures from the recognised principles which govern such work. My friend Mr. Chapman, from Paris, sent me the *Journal des Débats*, in which a picture by M. Roll is mentioned. The subject of it is "Laying the First Stone of the Bridge of Alexander III. in Paris." Mr. Michel, the critic, says:—

"The frame is a great low relief of wood with unequally projecting allegorical figures; below is a Siren advancing from the prow of a barque, the oars of which seem to come from the forepart of the picture above, rays of light appear to drive the nocturnal owl into a corner; on the sides are Peace, Abundance, and the Arts. This frame is a work of much pride to the distinguished artist designer."

The frame which can perhaps take the first prize for eccentricity, at all events in the English galleries, is the frame designed by Mr. R. Machell, R.B.A., for a picture called "Parsifal." It must have been the subject of immense care and study by a highly intelligent man, and, no doubt, a true artist. I think you will agree, on looking carefully at it, that you would be sorry to live with it, and, secondly, that it is the most ambitious and least successful of frames this year. Incidents and characters of the subject are carved on the decorated frame, the centre being occupied by "Parsifal" raising the cup of the Holy Grail. In the picture of "Psyche's Bath" Lord Leighton has carried some details of the frame into his painting, but Mr. Machell has deliberately carried a large part of his subject into his frame; happily he is in this alone among English artists.

Not a little of the effect of picture-frames depends on their being hung in a suitable light; a side light in a too projecting frame may cast an injurious shadow. Not long ago I saw an exquisitely carved frame and an equally beautiful panel in low relief, placed between the two windows of a room; the work cost £1,200, and was practically lost for want of the side light which all such works should have. *A propos* of this, we may recall the

story of Douglas Jerrold and Albert Smith going to a picture gallery. On the stairs was a mirror, standing before which Albert Smith said, as he looked into the glass, "Ah! my boy, there's a picture!" "Yes," said Jerrold, "it wants hanging!" So, when we have a good picture in its proper frame, we must not forget that, as Jerrold said, it "wants hanging," and that carefully, in justice to the artist.

We must all have observed the great value of black in frames, especially in works of the Dutch and Spanish masters, sometimes with bands of tortoiseshell or fine lines of gold, with the varied and very characteristic wave mouldings which had their origin in Spain, and were adopted in Italy and Holland, the Dutch artists especially recognising the suitability of such framings for their paintings. Mr. Watts was among the first to observe this, but, curiously enough, the least happy use of black is perhaps in the large works of Mr. Watts at the Tate Gallery, where, at a little distance from them, broad bands of gold separate, instead of combining, the frames and pictures; this rarely occurs in the foreign examples. There are some good black and gold frames in our national galleries, and, as we know, in the mezzotints of Bartolozzi, Ward, and others. Black behind the glass, with gold lines and delicately-moulded gilt frames, gives great charm to the works of their time. The neglect of proper framing by early and very able masters in water colour is surprising, in view of the 17th and 18th century framing known by them, some of their finest works being injured by mean and meaningless surroundings. Men of acknowledged eminence, even in our own day, have not troubled themselves to consider the art of framing. It will, I think, be a matter of surprise that our noblest writer and critic, Mr. Ruskin, has not yet treated this subject in any of his beautiful works, and in many of those of authority upon painting which I have consulted, no reference to frames is made. I do not absolutely affirm that Ruskin never made such a reference, but I have spent a whole day in going through his works, and I could not find a single reference to picture frames, which is a remarkable thing. The most noticeable of English designers of frames is Grinling Gibbons, born in London in the latter half of the 17th century. He was recommended by Evelyn to Charles II., who commissioned him to execute the ornamental carving for the Chapel at Windsor; he also did the foliage and festoons of the Choir of St.

ITALIAN FRAME, SIXTEENTH CENTURY.—South Kensington.

FRAME OF "BATH OF PSYCHE" (LEIGHTON).—Tate Gallery.

Paul's, the baptismal fonts in St. James's, Piccadilly, and works at Petworth, Burleigh, and Chatsworth, Hampton Court, &c. His talent was wasted in carving pens and feathers that were mistaken for real ones, flowers which used to move on their stems by the air, &c. We shall all agree, probably, in thinking such work, however full of loving labour, unsuitable for picture frames, to which it has been applied; the modern English housemaid would soon reduce much of it to matches. On my last visit to Florence I found a fine example of Gibbons' carving in a public museum; and a very ambitious work in South Kensington Museum is his "Stoning of St. Stephen," probably copied from a painting. With some defects of perspective, it is not "the highest form of decorative design," in which Mr. Ruskin said, twenty years ago, "the English will never excel," but the rare sense of beauty in natural objects, the manipulative skill, and the tireless industry of Grinlin Gibbons will always secure a place for him in the annals of art as our most original frame maker.

As miniatures have always to be examined near to the eye, the effect of any mode of framing has not seriously to be considered; the oval form is obviously the best and most generally used, but the marked advance of this form of art has led to the adoption of square or oblong frames, generally in ormolu; these are not, however, quite within the scope of our paper. In nearly all the oval frames there is a gold moulding round the picture, and that flat moulding is burnished highly so that it is difficult to look at the picture without the glitter of the thing coming to the eye, and it impairs the work. Now, whatever our objection may be on patriotic grounds to things "made in Germany," it is only just to admit that we owe to that country the introduction of highly-finished frame mouldings in colour and gold, well suited for drawings, engravings, and the many and beautiful developments of photography; we have "bettered their instruction" with our framings in light and dark oak, walnut, and the shades of stained-green ash and oak which, with delicate gold lines, give such charm to these latter day works.

The Americans, too, have entered this field, and now Messrs. Graves and Co., of Pall Mall, have frames of their make decorated in the "Adam" and "Empire," and other styles, with ornaments laid in gesso, on stained-maple, walnut, oak, in tinted ivory, on neutral green, in bronze, on black, &c., of great

variety, and with harmonious effect. The style employed has perfect examples all around us, well-known to art lovers, but it has remained for our cousins to glean the field which was sown here and abroad a century ago, and the mezzotints, now so much sought, are charming in these surroundings. The "Autotype" Company have courteously sent some specimens of their less elaborate, but highly artistic, frames, and I cannot imagine any more suitable than these for the charming photographs with which they have made us so familiar.

[Having called attention to six frames which Mr. Donaldson said were admirably adapted for the works they surrounded, he drew attention to some frames lent by Messrs. Goupil and Co., which he said represented what gilt frames French taste preferred. English frames designed by the artists were of more refined character, and had more appropriateness in connection with the pictures. He next referred to some wood frames made in Florence, and drew particular attention to the extreme care taken to make the moulding intersect at the corners. After describing some slides, kindly lent by the authorities at South Kensington, Mr. Donaldson proceeded.]

The Florentine modern frames of carved wood, as you will see, have delicacy and beauty of detail; more elaborate and, necessarily, more expensive, they are of great technical merit, and are superior to any machine-made ones. Messrs. Goupil and Co., of Regent-street, have also lent gilt frames of marked character and high finish, with some others, specially suitable for works in oil. Messrs. Gillow and Co., of Oxford-street, have kindly lent a variety of interesting and artistic frames of Italian and English make.

Now, a serious impediment to the art of frame-making is the rule of our Royal Academy not to admit any other than gilt frames. I do not know in whose prejudice or interest such a regulation originated; but I am confident of the support of able artists in saying that it should be rescinded, and that in doing so an impulse would be given to the production of truly artistic frames in gesso and in carved and decorated woods, such as we see abroad, and enormous additional effect would be secured for paintings at every yearly exhibition. I earnestly hope that the enlightened President will soon distinguish his reign by effecting this much needed reform. The beautiful and allied arts of modelling in gesso, carving, inlaying, decorating, and enamelling, would be stimu-

FRAME OF "KING COPHETUA" (BURNE JONES).—Tate Gallery.

FRAME OF "MONTACUTE HOUSE."—South Kensington.

lated, and public encouragement be quickly given to such a progressive measure. I invite the opinion of the Chairman with regard to that.

The material objection, I believe, is want of space, but as Disraeli said, "a difficulty is a thing to be overcome," and by excluding works of a secondary character, the experiment might be made of giving one room to some of the measureless variety of artistic frames other than gilt ones. I am fortified in this hope by the fact that for the first time we see in the Academy this year some frames with the gold toned down to almost the colour of wood in pictures on the line. That is an enormous concession to the idea that frames might be improved and other than gilt. Oh! for another Alfred Stevens who would, with proper encouragement, and with his unequalled genius, have created a school of artist framers as fine as any known to the world. We are, as Mr. Lethaby wrote in 1885, still waiting for an inspired artist worker, who must be free and with pride in what he creates; he will be, as Stevens was, familiar with the glorious old Italian methods, and will, I trust, be able to overcome the narrow-souled economy of even a Minister of public works; then, indeed, it may be possible to read of an Academy picture some such notice as this:—

"The Florentine, Simoni Ceni, wrought the carving, and Gabriello Saracini gilded it, Spinello of Arezzo did the painting in 1385."

In lending these kakemonos and frames seen, Mr. Pheni Spiers says:—

"It has struck me that a few words on the framing or mounting of drawings in Japan might not be without some interest, seeing that, until within the last few years, their methods have been carried on for centuries uninfluenced by the customs or practice of other nations.

"The Japanese have two methods: the kakemono or hanging picture, suspended temporarily only in the house or temple, and otherwise kept rolled up and preserved in the godown—the fireproof store-room; and the framed drawing hung up in the temple or carried about in processions. In the latter case the frame consists of a simple convex moulding, the width of which varies from half an inch to 6 or 7 inches, according to the size of the picture, and this moulding is painted over with body colour with natural flowers (as in one of the examples shown), or with geometrical patterns, leaving the grain of the wood as a ground, or again with sprigs,

leaves, and flowers modelled in gesso (as in a recent example). Sometimes the frame is coated over with black or green lacquer, on which geometrical patterns or sprigs of plants are cut through to show the white wood. The more elaborate frames are richly decorated with *avanturine* lacquer, with geometrical patterns in gold lacquer, and the angles and sometimes the longer sides are strengthened and decorated with brass plaques incised with ornament. The drawing in these cases comes close up to the frame, with a border of black or red lines to isolate it from the frame.

"The kakemono, or hanging picture, is mounted and decorated in a conventional manner, which is apparently always rigidly adhered to, and which seems to have existed for centuries. The drawing is mounted on linen or paper, with a margin of from 2 to 4 inches on each side, and from 2 to 4 feet top and bottom, the lower border being about half the depth of the upper border. At the top and bottom of the drawing is a narrow strip of damask, the upper twice the width of the lower; on each side of the drawing the 3-inch margin is covered with damask or silk of a different colour, the depth of the border above (6 to 8 inches) being about twice that of the lower border. Beyond this, above and below, covering the remainder of the mount is a flowered silk or gold damask ground, with again double the depth at the top. A wood roll at the bottom, with ivory or polished ends, serving for rolling up the drawing; at the top is a semi-circular roll with rings to suspend the kakemono. From this upper roll hang two strings or tapes of the same material and colour as that of the upper mount, the original object of which is not clear, probably it is a revival of a custom of tying up the kakemono, but they are never missing. The damask or silks which form the borders are, as a rule, of much greater age than the drawing, and it is probable that the professional mounter, or perhaps the owner of the drawing supplies these materials, which are the remnants of ancient dresses either belonging to the family or acquired from actors. The latter, as may be seen from the Japanese colour prints, wear the most gorgeous dresses, and when done with, these would seem to be cut up and utilised, either for the purpose above stated, or as bags for precious pieces of lacquer, ancient tea-jars, or masks. In the two examples exhibited, one is a Buddhist kakemono, which was probably hung in a temple, the other has mounts of blue silk and

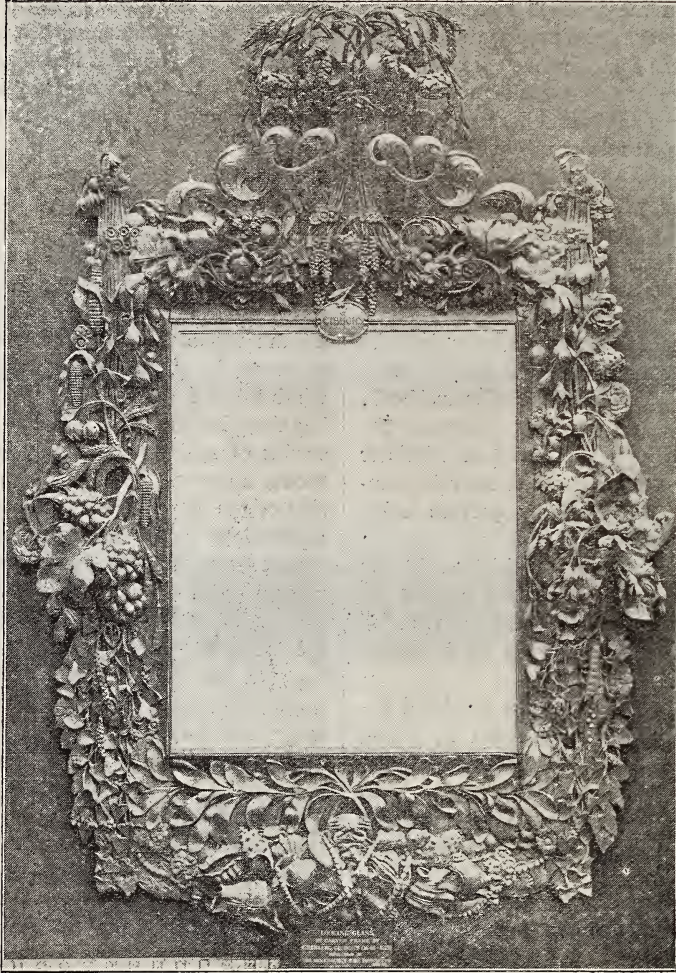

ancient damask which are really of much greater value than the drawing they frame, and of great beauty of colour."

A reference must now be made to "mounts," which are so extensively used; and of modern artists Sir Edward Burne Jones is the one who has given most attention to them. Some of his designs are marvels of elaboration, and those recently seen at the Burlington Fine Arts

1. Inch plain oak frame, natural colour, mount deep cream, for sketch on lighter cream ground.

2. Same frame, mount warm stone, for drawing on soft red ground.

3. Same frame, flat reeded, mount 4 inch stone, coloured with $\frac{1}{2}$ inch gold band near the deep bevel, $\frac{3}{4}$ inch band of deeper stone colour next to gold, with black fine lines ruled on the gold and to outline the band.

FRAME BY GRINLING GIBBONS.—South Kensington.

Club were striking evidences of his fertility and refined taste. Ruskin says, "All noble ornament is the expression of man's delight in God's work," and "genius" has been defined as "an infinite capacity for taking trouble;" these Burne Jones undoubtedly had. A short list of his frames, mounts, and grounds may be of use for future reference, and I therefore give the following examples :

4. Frame 1 inch reeded walnut, mount 4 inch grey-green, $\frac{1}{4}$ inch band of gold, 1 inch deeper grey-green, then another $\frac{1}{4}$ inch band of gold, lines of black on gold bands, for drawing in pencil on light cream colour.

5. A 2 inch reeded teak, coloured oak frame, $\frac{3}{4}$ inch gilt flat, for drawing on brown paper.

6. Same frame, flat of $2\frac{1}{2}$ inch light unvarnished oak, deep bevel, near which is a fine gold line, and

another $\frac{1}{4}$ inch wide, outlined black, for a richly-coloured sketch of King Cophetua.

7. One and a half-inch flat black-polished frame, with a groove in centre, for chalk drawing on brown paper, very narrow gold flat.

8. Inch reeded light oak frame, mount light brown, very thick, and bevel cut so as to show various layers of the paper, for drawing on cream colour.

9. One and a half-inch walnut frame, flat fluted, mount $\frac{1}{4}$ inch warm stone colour, with deep plain line indented near bevel, for drawing on brick-red paper.

10. Frame $1\frac{1}{2}$ inch flat, with 3 grooves, green-gold, mount cream colour, band of $\frac{1}{4}$ inch green-gold near bevel, for etching in silver and gold on deep grey ground.

11. One and a half-inch frame, black, slightly elliptic, with fine gold hollows on the edges, gilt narrow flat in some cases, and in others $\frac{1}{4}$ inch gold mounts, where the print or drawing is strong in colour.

12. One and a half-inch reed | walnut frame, $\frac{3}{4}$ inch mat flat, an oval inside of plain light oak, with fine gold hollow, forming sight, for portrait in black chalk on cream of light tone.

In conclusion, we may notice some changes in the last twenty years or so; a much more general employment of glass for oil paintings under suitable conditions of light, and for their protection in our climate; this has to be sometimes done, as in the Tate Gallery, by an added moulding, not improving to the frame. Another is the more general practice of framing water-colour works, as if they were in oil; this may properly be done when the colouring is of sufficient strength, and in all works there seems a tendency to employ broad bevells in place of the large gilt flats, and to allow the glass to cover them.

I submit for consideration some propositions arising from what has been said:—

1. That whilst the frame should be designed with reference to the picture; and may, in some cases, have details emblematic of the subject, it should not attract undue attention, or be eccentric; rustic subjects should not be put in highly enriched frames.

2. That the enriched mouldings of frames should diminish in importance as they approach the picture.

3. That works, not of much strength in water-colour, should have broader flats than those in oil, and not heavy gilt frames with much burnish.

4. That some pictures (like Lord Leighton's) are best without any burnish in the frames.

5. That landscape pictures, in most cases, are better in recessed than in projecting frames.

6. That the colour of a mount should not appear to blend with any part of the picture it surrounds.

7. That the gold in all frames should be toned to suit the pictures.

8. That some works have their best effect in carved wood, brown or black frames, with or without fine lines of gold added.

9. That strongly marked carved lines in frames, with corners and centres in high relief, are often injurious to the composition of line in the pictures.

DISCUSSION.

SIR GEORGE BIRDWOOD, K.C.I.E., C.S.I., said Mr. Hunter Donaldson had provided them with a most suggestive paper on a most captivating, but most strangely neglected department of applied art. It was a department of decoration so near and handy to them all, and yet so entirely unheeded and unexplored, that his only regret was that Mr. Hunter Donaldson had not dealt with it in a more systematic and more expository manner, surveying the full extent of our ignorance of it, and all the scattered sources from which we might derive information on it; that is to say, the sources through which we might trace the evolution, or, rather, in some instances, the devolution of the various existent types of picture frames, and receive the ennobling inspirations of artistic grace for the sustenance of the refinement and elevation of their traditional designs. The question of picture, as of sculpture,* frames, is indeed one of all but the very highest artistic importance; and painters and sculptors, truly reverent toward their art, ought to be more particular as to the framing, or other setting, of their divine handiwork, than even a writer about the binding and "forwarding" of his book. He had always taken the deepest interest in picture frames, and not only in relation to the pictures they enshrined—for the frame of a great picture should be regarded as its shrine (Latin, "scrinium") or ark, and should be designed in this devout regard—but also in relation to the position the enshrined picture has to permanently occupy; but he

* Frame is rather an awkward term to apply to a thing used merely to bind in, or enclose, any other thing, for in its primary sense it means the essential, and total fabric, body, structure, or form (as apart from the "materia prima") of things—as in these quotations:—"This goodly frame, the Earth"; "And spangled heavens, a shining frame"; "And whatever stirs this mortal frame." But every one now knows what is meant by the word frame as used in its secondary sense, in connection with pictures, and it is of happy augury in this connection that its ultimate meaning, in its Anglo-Saxon form of *fram*, is "excellent," "surpassing." In fact, frame is allied to the Latin *primus*, "first," and the Sanskrit *param*, "most excellent."

had never once given a thought to the historical genesis of the picture frame, until his attention had been drawn to the subject by the spontaneous and felicitous statement of his views and opinions on the artistic question of picture frames with which Mr. Hunter Donaldson had favoured and delighted them that evening. Of course the ultimate origin of picture frames is in the instinct—one of beauty as well as of utility—natural to finite reason, to define, that is, to fix bounds to, to frame-in, everything, even the infinite. Thus according to the Hecatæan geography, which is the geography of Homer and Hesiod, the whole habitable earth, the sun-rise lands [Asia, with Libya], and the sun-set lands [Europa: *cf.* Erebus, Hesperus, Hesperides], is framed-in by the circumfluent stream of outer Ocean; and in the Ptolemaic astronomy, which is the astronomy of all poetry and romance, the Seven Heavens of our planetary system are bound in by the Twelve circumambient Wardens of the Zodiac. Even the infinite comprehension and charity of the “Fides Catholica” has, from the 6th or 7th centuries of Human Salvation, been picturesquely defined by the peremptory terms of the circumscriptive creed of, as is said, “the holy prelate Athanasius.” In the Græco-Roman wall-painting of the 1st century A.D., formerly to be seen in the Casa d’Adonide at Pompeii, a pigmy is represented before an easel, painting a picture, and it is clear that he is painting in the frame as he paints the picture. This is what was done in the case of many of the wall-paintings of Pompeii; and what was, and is, done with many of the paintings in the Coptic churches of Egypt; and it is universally done by the native artists of India. The oldest actual example,* of an approximately determinable date, of this simple manner of framing in a picture, known to me, is the archaic Corinthian terra-cotta plaque in the Louvre, representing, in black figure painting, a potter at his wheel, before a heap of clay, turning the wheel with his left hand, and moulding a lump of the clay into a vase with his right, two finished vases hanging above him; the whole framed in with a heavy border of black. This is the proper framing for trivial pictures. In the Græco-Roman painting of the 1st century A.D., from the Casa del Ceruscio, Pompeii, now in the Naples museum, representing a female artist painting a Herm, a Cupid stands before her holding up a sketch of the statuette, stretched on a frame, which is obviously the original of the bald and arid so-called “Oxford frame.” This is the identical “*pictura in linteo*,” — “painting on canvas” — illustrated in

Rich’s *Dictionary of Roman and Greek Antiquities*, and Dr. Murray would appear to have shown Mr. Hunter Donaldson, in the British Museum, an actual frame of this description. It was evidently derived from the embroidering frame, and the weaving frame, of the ancient Egyptians, Greeks, and Romans; for, at least among the Greeks, pictures were painted with the embroiders’ needle long before they were painted with liquid colour and the brush. The only painted picture known to Homer is the “*pictura textilis*.”—“*acu picta*.” The frame of the classical lyre suggests an elegant modification of this otherwise wholly mechanical, unimaginative, and frigid form of frame. The earliest decorative frame known to me is Egyptian of the 14th century B.C., and it at once expresses in the most emphatic terms of art the subtle, sympathetic relations that must always subsist between a frame and the contents for which it is especially designed. In this case the frame and its contents are a specimen of massive jewelry, slightly more than 5 inches broad at the base, slightly less than 5 inches broad at the top, and just 4½ inches high. It is the sepulchral pectoral, now in the Boulak Museum, of Kha-em-nas, son of Rameses II., and it is wrought in lapis-lazuli and gold. What at once gives this splendid jewel its imposing dignity is that its frame is fashioned in the form of the *naos*, cella, or “holy of holies” of an Egyptian temple; or, as he would himself rather suggest, of the shrine within the “holy of holies.” We have another suggestion, of an analogous character, for artistic frames, in the terra-cotta amulets of the 1st or 2nd century B.C., stamped with figures of the Ephesian Artemis and the mystic inscriptions known as “Ephesia grammata.” One of these was found at Syracuse, and is to be seen in the museum there. The frame in this case is modelled after the actual *ædicula* (literally “little edifice”), canopy, tabernacle, shrine, or, in secular language, cabinet, of the goddess in the cella of the temple of the “Great Goddess of the Ephesians;” as that was modelled after the Greek frontispiece of the temple itself, with its pediment crowned with palmetted antifixes, and supported by pillars. In the sepulchral portrait of an Archigallus, or high priest, of Cybele, of the 3rd or 4th century B.C., now in the Capitoline Museum, at Rome, the frame is a plain moulding; from the high priest’s neck hangs an amulet of the *ædicula* type already described; and the sculpture is further interesting from the sort of shallow niche in which the head and shoulders of the figure are countersunk taking the form of the Buddhistic niche, which, in my belief, first suggested to the Greek artists, enslaved by the Arabian conquerors of Syria, the characteristic Saracenic arch. In the small portable shrines of Cybele, of the 3rd and 4th centuries B.C., found in hundreds throughout Asia Minor, and frequently in Greece, we have examples of admirable frames for memorial sculptures; the treatment of the plinth in these shrines especially satisfying the feeling for a strong support for the contained bust or statuette. The *ædicula* dedicated to Terra Mater, found in the

* On the ceilings of the temple of Amen-Ra, at Thebes, dating from the 14th century B.C., we repeatedly find representations of the vulture, the symbol of Maut, the consort of Amen, floating, on wide extended wings, in a clear, blue sky, bounded on either side, and on top, by a border of darker blue, studded with stars. But this three-sided border is probably a severely conventionalised form of Nuit, the goddess of the over-stretching Midnight Sky, and was evidently in no way intended as a true painted-in frame for these lacunarial tableaux, although it affords a beautiful suggestion of one.

Campo Verano, near Rome, and now in the Palazzo dei Conservatori, at Rome, is, in the artistic force of its severely simple construction, the noblest example extant of this type of sacro-sanct statuary. The representation of the *ædicula* of the Tauric Artemis on a wall-painting at Herculaneum, shows it to have been an arched canopy of the simplest open construction, resembling a garden wire-work arch, surmounted by a sort of archaic "fleur-de-lis," or semi-"thunder bolt." It would seem to have suggested the decoration of Lord Beaconsfield's statue on last Primrose Day, when the graceful canopy of arched palm branches was somewhat unhappily surmounted by a feebly-modelled coronet of primroses. In short, the *ædicula* in its endless permutations affords fruitful inspirations, not only for picture frames, but also for statue frames, whether tabernacular or mural shrines, or more familiar niches. So also does the cippus, or tombstone [*cf.* the Greek *stèle*, both going back to the phallic pillar, of which the most interesting Roman example was the urban Lar, the *Deus Rediculus*, also called Tutanus, who had his temple near the Porta Capena] of the Imperial Roman period; as may be judged from the cippi of the 1st century A.D., of Marius, Petilius, and Pintæus, found at Bonn, and now in the Bonn Museum. In the case of the cippus of Marius, in the corners left between the arch of the niche in which the deceased is represented on horseback, and the square head of the stone, are sculptured representations of the "dona militaria" (torques, &c.) conferred on him in life. This is a most happy way of relegating the honorific insignia of great men, which happen to be artistically unassimilable in their portraits, to the decoration of the picture frames. The cippus, of the 1st century A.D., of another eque, found in Rhenish Hesse, now in the museum of Mayence, and that of Q. Sertorius, found at Verona, and now in the Museo Lapidario there, and of Q. Statius, found at Athens, and now in the museum there, are examples of the simple and effective setting of memorial sculptures. On a cippus in the museum at Avignon only the insignia of office—the fasces and the curule chair—of the municipal magistrate commemorated are sculptured below his name. In a Romano-Gallic cippus in the Caen Museum, the tradesman commemorated is represented with a steelyard in his right hand, and the goods he is about to weigh in his left. In the Romano-Gallic cippus in the Sens Museum a blacksmith is represented standing in a niche (modelled from the arched doorway of a Christian church), beside his anvil, with a hammer in his right hand, and his fire-tongs hanging to the left of him. Another Romano-Gallic cippus of the Christian period presents the bust of an innkeeper, in a niche (similarly arched to the last), pouring wine from a flagon in his left hand into a tumbler in his right. There are many such Romano-Gallic cippi, and all are invaluable, not only as graphic illustrations of the arts, and crafts, and trades, of the period, but, more especially in the present connection, of the principles

which should determine the artistic treatment, of which the enframing is an integral part, of such subjects. There is a variety of the mural cippus, or it might equally well be said *ædicula*, called, I do not altogether understand why, *armarium*. This term is found first applied to a chest for arms, tools, tackle, &c., then to cases for books, cabinets, and cupboard of any kind, and to any room or place for holding tools, books, &c., and, finally, to the shrine-like cippi, or *ædiculæ*, containing family portraits, reproduced in wood, stone, or metal from the "imagines Majorum," or painted wax masks taken of the Roman nobility immediately after death. The practice of taking these post-mortem masks appears to have been almost universal in antiquity. It was followed by the Egyptians, Assyrians, Phœnicians, Carthaginians, and Italians, and it accounts for the lifelike character of their sepulchral portraiture, and particularly for the vivid individuality of the busts and portrait statues of the distinguished Romans which have come down to our time. There is in the Lateran a so-called *armarium*, of the Imperial Roman period, of a female member of the family of the Haterii. It was found with other funerary sculptures, all mural, of the family, on the Via Labicana, not far from Centocelle. The equipment,* [whence possibly the designation "*armarium*,"] or framing of the bust, presents a simple pediment, supported by a pilaster on either side, and by a rounded pillar a little in front of the pilaster to the right of the bust. The pillar on the opposite side is absent, and appears to have been broken away. On either side, at different levels, there is a bracket between the pilaster and the pillar, intended for a lamp to be lighted in honour of the revered dead. The pediment, within its architectural mouldings, is trailed with flowers on either side of the representation, apparently of a lighted lamp. The pilasters are scrolled with hearts-ease, while the remaining pillar is delicately imbricated. The bust rests on a narrow broken ledge of marble, and this "*armarium*" evidently wants its proper plinth: yet, as it stands, in the appropriateness, and the religious

* I use "equipment," to avoid the use of "frame," here usable only in the sense of the whole shape, form and structure—including the bust, or other sculptured subject—of this armarial type of mural monument. *Armarium*, among other things, means specifically a marine store; "*armare*" meaning [Charta Alfonsi reg: Aragon: 1288] to fit out, equip, a privateer; and in the case cited in the text the *armarium* is the complementary part, which, with the bust, fully equips, and gives form and shape to the memorial. [Equip, shape, and ship are the same word, and "ship-shape" a tautology.] *Armarium* is used also by Tertullian for the completed canopy of the Hebrew Scriptures. We have, on the other hand, *armariolum*, for the tabernacle in which the Corpus Christi was carefully kept under lock and key [Statua Ecclesie Leodiensis, 1237], and in Low Latin, *armariolus*, for the little chest in which certain of the utensils used in the Offices of the Christian Church were kept beside the High Altar: in these two instances *armarium* corresponding with the pagan *Sacrarium*, in which the *salinum patrum*, *patella*, and other sacred and mystic ancestral and prognostic symbols, were kept by the Romans.

sentiment, of its elegant and charming design, it is a perfect example of what the enshrining frame of a family portrait should be. The provision of the brackets for lamps at once fascinates the beholder, recalling the daily ceremonial commemorated in the hymn of Prudentius, "Ad incensum Lucernæ;" a beautiful and solemnising domestic rite which ought never to have been allowed to pass into disuse. But it is probably to the "consular diptychs," of the 4th and 5th centuries A.D., that we must look as the immediate precursors of the modern picture frame. The diptych and the triptych—"pictura in tabula"—had probably always existed; and Rich illustrates a triptych from a Pompeian mural painting, the exact location of which he does not give, as suspended, with a considerable forward slant, over a doorway. Under the Lower Empire, the custom prevailed of the consuls and other magistrates, on entering office, presenting their friends and patrons, as also the Christian bishops to whom they wished to be civil, with folding tablets of ivory, or wood, having their names, and their portraits, and their insignia of honour carved thereon. These were in fact their *cartes de visite*, and he (Sir George Birdwood) would fain see the fashion of them revived to the exclusion of the egregious photographic *cartes*. The edges of these consular diptychs are nearly always framed round, in low relief, with conventional decorations, identical in design with those of the frames of gilded "gesso," or of gilded and stamped paper, applied along the edges of the painted diptychs and triptychs, and other wood panel *ikons*, found at the present day among the Greeks, and Russians, and Copts, and Abyssinians. Labarte, in his *Handbook of the Arts of the Middle Ages*, in the chapter on "Painting and Calligraphy," at one time inseparable arts, gives three illustrations, which seem to me very suggestive of the gradual transformation of the panel *ikon*, and diptych and triptych, edging, or "selvage,"—if the word may be so used—into the modern picture frame. The originals of the illustrations are all in the National (formerly Imperial) Library, at Paris. The first, from a miniature of the 15th century, representing a female statue painter, has behind the statuette of the Virgin and Child a panel *ikon* of the Saviour's head, with a heavy, stamped, and obviously gilded, "selvage." The second, from a MS. also of the 15th century, representing a calligrapher at work, has at his feet a panel painting of the Crucifixion, the "selvage" of which is considerably raised above the surface of the paper. The inner edge of the "selvage" is obviously "bevelled" to the surface of the painting. The third, from another MS. of the 15th century, represents a female artist at an easel, painting a picture of the Virgin and Child already fixed in a round moulded frame, with, apparently, the ring for hanging the frame fastened to its top. The parallelism as regards "motives" and the details illustrating them, between the above 15th century miniature, and the Pompeian fresco of another

female artist painting a Hermes, described by the speaker at the commencement of his remarks, was remarkable and profoundly interesting. "Plus ça change plus c'est la même chose." Even more remarkable is the proof of the continuity of artistic methods and appliances, afforded by a painting in a 5th century MS. of the *Materia Medica* of Dioscorides at Vienna, representing an artist copying a mandrake plant, held up before him by the goddess Euresis, on a quarto sheet of vellum, fastened to the drawing board resting on the easel by six "drawing-pins." The speaker said he thought that in these few references, which might be indefinitely extended, he had sufficiently traced the true pedigree of all the traditional modern varieties of picture frames, and pointed out the direction in which to look for promptings for their improvement. The Italians of the Renaissance modelled their best picture frames from these ancient armaria, cippi, and ædicule, as is very clear from the actual examples, and the reproductions, of Italian renaissance frames in the South Kensington Museum; and it is equally clear that Sir Frederick Leighton and Sir Philip Burne-Jones were directly inspired by the later in designing their classical frames, which, in Sir Frederick Leighton's hands, always harmonise perfectly, with the pictures they contain. If he might generalise from the instances cited, he strongly advised the revival of the use of wood, or metal, or composition, self-edged panels for trivial paintings; while for family portraits, and great imaginative pictures, he would like to see the fullest development given to the picture frame as a shrine; and of course to the enframing by moulding, niche, canopy, or other equipment, of statuary. But the great point was that the artist should have the first and last word in the framing of his work; it should be part of his covenant alike with the patron and the dealer in frames, who both require to be taught that frames have to be made for pictures, and not pictures for frames—not since sculpture and paintings rose above their restricted status as the handmaids of architecture, and became independent fine arts. The frame and its picture are commutually inseparable, as the wine cup from the red wine in it, and as the setting of a jewel from its priceless gems. In the words of Schiller, Truth is independent of its vehicle, but Beauty is made perfect alone by its environment, literally—"the vessel makes the content":—"Bei dem Schönen allein macht das Gefäss den Gehalt." The speaker added that he would not enter into any consideration of the views and opinions expressed by Mr. Hunter Donaldson on the strictly æsthetic problems connected with picture frames. Mr. Hunter Donaldson was thoroughly qualified to address them on the subject, which was so fresh, in spite of being so familiar to them, that he knew of no writings of any kind on it, except the papers by Mr. Phené Spiers, mentioned by Mr. Hunter Donaldson, and some papers they had just heard of as having been written 18 years ago by their esteemed colleague on the Applied Arts Committee, Mr.

Hugh Stannus. Mr. Hunter Donaldson was for 25 years a partner in the firm of Gillows and Co., and for nearly 50 years he had been connected with the great international exhibitions held in this country and on the continent. He was, on the nomination of H.R.H. the Prince of Wales, appointed a Juror on Decoration for the Paris Exhibition of 1878, when he was made a "Chevalier" of the Legion of Honour. He was a member of the Lord Mayor's Committee for the Paris Exhibition of 1889, and decorated the British Section; and was promoted for these services to the rank of "Officier" of the Legion of Honour. He was also a Commissioner for the Melbourne Exhibition of 1888, and is a member of the Advisory Committee on Decoration of the British Royal Commission for the Paris Exhibition of 1900. He (the speaker) was under the deepest obligations to Mr. Hunter Donaldson, who was one of a group of very old and very valued personal friends, including the late Mr. Robert Phillips, the late Mr. Foster Graham, Mr. Vincent Robinson, Mr. George Lock, Mr. Lazenby Liberty, the late Mr. Juliano, the late Sir Henry Doulton, Sir Thomas Wardle, and others, to whom he owed all the little practical knowledge he possessed of the artistic industries of this country; and it gave him unfeigned pleasure to propose the vote of thanks to Mr. Hunter Donaldson, which he would ask the Chairman to put to the meeting at the close of their proceeding that evening.

Mr. HUGH STANNUS said such a paper as the one to which they had just listened, which gathered into a focus all that had been said or thought upon the subject, was one deserving of their best consideration, and as it was impossible at that late hour to properly discuss it, he could wish that another opportunity could be found for the full discussion it deserved. He had himself given a lecture upon this very subject eighteen years ago, and on looking over his notes he was struck with the similarity of idea in the two papers.

The CHAIRMAN said nothing had exercised the minds of artists more than the question of having appropriate frames for their pictures. The difficulty was not only that the style of the frame should be fitted to the picture, but that the particular details of the frame should be absolutely in accord with the picture. In the present day artists could not afford to go to a specialist on frames, they had to trust to the trade carver and gilder. He quite agreed with Mr. Stannus that the subject was one which might be discussed on a future occasion, or form the subject of another paper next session. In conclusion, he proposed a hearty vote of thanks to the reader of the paper.

The vote of thanks was carried unanimously, and the meeting adjourned.

Mr. PHILIP H. NEWMAN writes:—While the almost unique character of the paper makes it of great academical importance, it is to be regretted that its practical utility is lessened by the nature and conditions of things. Circumstances are inimical at the present time to the application, excepting in a limited degree, of many of those principles Mr. Donaldson and most of us recognise as lying at the root of the subject. On the one hand we are ruled and fettered by the picture exhibitions, which necessitate some approach to uniformity in framing, while on the other we are vexed by modern decorative schemes that almost exclude pictures as incongruous features, difficult at all events to harmonise with such schemes. Putting aside, however, these perhaps temporary difficulties, we have one constantly with us, *i.e.*, the preference almost universally shown for gold frames, although gold in many instances, and of any tone may be the worst possible surrounding for the work it is made to enclose. If we look into the pictures of de Hooghe, Metsu, or Terborch, we find quite impartially black or gold frames hanging on the walls of the painted interiors these artists present to us, and believing, as one must, to a considerable extent in the realism of their art it is fair to suppose that these painters pictured pretty generally what they saw; indeed, the cursory observer might suppose that the Dutchmen knew very little about the matter and cared less, so long as they decently furnished their walls, but on reflection one would incline, I think, to the opinion that the use of black as well as gold frames indicated an experience, if not instincts or scientific knowledge, that the effect of the low tones and deep rich shadows of their pictures was subserved and enhanced to a greater degree by a black frame than by a gilt one. It is for this reason that I attach more value than Mr. Donaldson apparently does to the tonality of a frame rather than to its conformation, although I quite agree with Sir George Birdwood that the pilaster or, as we might define it, portal type, is in its very nature the most suitable form in the majority of instances, and I would add especially so in figure subjects other than rustic or humble genre. All that Mr. Donaldson says in regard to disturbing elements of form is undoubtedly true, but I think it must be admitted that want of suitable tonality may be more disturbing still. In reference to the use of gilding, it has been the custom to regard it for some insufficiently explained reason as a non-disturbing element in decorative work, and axiomatically that gold will take care of itself; that this is not the case, however, is sufficiently obvious by a few experiments with picture frames; it will be found that the interplay of reflections, unless the gilding be toned to nullity always causes disturbance, and halation destructive of the colour values of a painting and their proper appreciation by the spectator. This is made distressingly manifest if one puts an old master into a new frame, but it is equally true of course, in degree, where a new work is concerned. Gilding has always a tendency to

enlarge, and amplify surface, and it is to ignorance of this effect that must be attributed in no little measure some notable failures and disastrous results in recent decorations. A building or room cut up by gold lines or mouldings is sensibly belittled, the mouldings being magnified out of all architectural proportion; on the other hand, gold used in masses, as in the lunettes of St. Mark's, at Venice—to take a single instance—adds apparent size and amplitude to the building. Our aim being to adorn and set off the picture with the frame and not to distinguish the frame by the picture, it behoves us then to be very careful of the tonality of our gold, if gold must be used, or else instead of enhancing the painting we shall, as is so often done, detract from it, by seriously affecting its values. In regard to the difference of framing in oil or water colour works, the latter have for many years so nearly approached the former in force and richness as to necessitate very little variation of treatment in framing. There are, of course, cases where the scheme of colour is very light as in landscape sketches, having skies with large areas of light clouds, &c.; in these instances white or light mounting gives an additional charm in the nature of a vignette. In reference to the framing of photographs, the most satisfactory results are obtained when the tones of the photograph are borne out by the prevailing colours of mount and frame: a dull green frame is possible with some cool grey photographs, especially when there is relief by dull gold. I regret that I cannot agree with the reader of the paper in several instances in his general admiration of the mounting of the photographs which were shown on the walls.

General Notes.

COAL IN KENT.—At the opening of the Fourth Annual Congress of the South-Eastern Union of Scientific Societies at Rochester, on the 26th May, Mr. W. Whitaker, F.R.S., President of the Geological Society, and President of the Union for the ensuing year, delivered his inaugural address, the subject of which was, "The Deep-Seated Geology of the Rochester District." Alluding to the borings that had been made for coal in Kent he suggested that that neighbourhood was one in which trials should be made. To get coal they had to go something like 2,000 ft. down, and they could be sure that the people who wanted the coal would not dig more holes than they could help. He felt that the discovery of a new coalfield was a very important thing. The prosperity and wealth of the nation depended very largely upon coal. Therefore, if it affected the pretty scenery around they must bear with that for the general good. He did not see why the effect on the scenery should be

so excessive as people generally thought. Coal, like chalk, might be worked all out, and when a colliery was exhausted the country would revert to its natural state. Of course, it was uncertain where those coal-fields were, and they could only make a guess at it. The only thing was to try and prove whether they existed there. That would be done some day, whether people liked it or not, because if there were valuable riches underground, they would be forced to look after them.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, JUNE 5.**—Farmers' Club, Salisbury-square Hotel Fleet-street, E.C., 4 p.m.
 Royal Institution, Albemarle-street, W., 5 p.m. Centenary Day Celebration.
 Engineers, in the Theatre of the United Service Institution, Whitehall, S.W., 7½ p.m. Mr. R. G. Allanson-Winn, "Foresore Protection, with special reference to the Case System of Groyning."
 Chemical Industry (London Section), Burlington-house, W., 8 p.m. 1. Dr. S. B. Schryver, "A New Method for the Analysis of Commercial Phenols." 2. Dr. S. Rideal, "A Demonstration of Printing by Electricity without the Aid of Rollers or Ink." 3. Dr. J. Lewkowsitch, "Notes on Cacao Butter."
 Geographical, University of London, Burlington-gardens, W., 3 p.m. Annual Meeting.
 Actuaries, Staples-inn Hall, Holborn, 5 p.m. Annual Meeting.
- TUESDAY, JUNE 6.**—Royal Institution, Albemarle-street, W., 3 p.m., Centenary Celebration. Commemoration Lecture by Professor Lord Rayleigh. H.R.H. The Prince of Wales, K.G., Vice-Patron, presiding. Evening Reception by the Lord Mayor to Members, Foreign Guests and Representative Men, at the Mansion-house.
 Biblical Archæology, 37, Great Russell-street, W.C., 8 p.m.
 Zoological, 3, Hanover-square, W., 8½ p.m.
- WEDNESDAY, JUNE 7.**—Royal Institution, Albemarle-street, W., 9 p.m., Centenary Celebration. Commemoration Lecture by Professor Dewar, F.R.S. His Grace the Duke of Northumberland, K.G., President, presiding.
 Geological, Burlington-house, W., 8 p.m.
 Civil Engineers, 25, Great George-street, S.W., 10¼ a.m. Engineering Conference. Opening Address by Mr. W. H. Preece (President).
 United Service Institution, Whitehall, S.W., 3½ p.m. Lieut.-Col. R. L. A. Pennington, "The Training of a Battalion of Infantry."
 Archæological Association, 32, Sackville-street, W., 8 p.m.
 Obstetrical, 20, Hanover-square, W., 8 p.m.
- THURSDAY, JUNE 8.**—Royal, Burlington-house, W., 4¼ p.m. Antiquaries, Burlington-house, W., 8½ p.m.
 Civil Engineers, 25, Great George-street, S.W., 10¼ a.m. Engineering Conference (continued).
 Mathematical, 22, Albemarle-street, W., 8 p.m.
- FRIDAY, JUNE 9.**—Civil Engineers, 25, Great George-street, S.W., 10¼ a.m. Engineering Conference (continued).
 Astronomical, Burlington-house, W., 8 p.m.
 Physical, Chemical Society's Rooms, Burlington-house, 5 p.m.
- SATURDAY, JUNE 10.**—Botanic, Inner Circle, Regent's-park, N.W., 3¼ p.m.

Journal of the Society of Arts.

No. 2,429. VOL. XLVII.

FRIDAY, JUNE 9, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

EXAMINATIONS, 1900.

The Society's examinations for the year 1900 will be held on March 26, 27, 28, and 29. The last day for receiving applications will be the 7th of March. This early intimation is given for the convenience of the Managers of Institutions who are preparing their own programmes for next year. The Society's Examination Programme will be issued about the usual date—the end of August.

CONVERSAZIONE.

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman, and other members of the Council, will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors.

A selection of music will be performed by the String Band of the Royal Artillery in the Central Hall, and by the Red Hungarian Band in the Bird Gallery, commencing at 9 o'clock.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. These tickets have now been issued. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman, and must be signed by the member applying for it.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

The entrance to the Museum is in the Cromwell-road. Carriages must enter the grounds by the east gate and leave by the west gate. The cards must be given up on entering the Museum.

Visitors arriving or leaving by either of the Metropolitan Railways will be allowed the use of the District Company's Subway, which leads from the South Kensington Railway Station direct into the grounds of the Museum.

Fuller particulars as to the musical and other arrangements will be given in the Programmes which will be distributed on the evening.

Proceedings of the Society.

APPLIED ART SECTION.

Tuesday, May 30, 1899; Sir GEORGE BIRD-WOOD, K.C.I.E., C.S.I., LL.D., M.D., in the chair.

The CHAIRMAN said Mr. Starkie Gardner needed no formal introduction to a meeting of the Society of Arts. He was known to everyone familiar with the history of the remarkable revival, in the current generation, of the artistic industries of the United Kingdom, his name being identified with the resuscitation, during the past fifteen or twenty years, of the once famous English art of decorative iron work, both founded [*i.e.*, "poured" out] or cast, and forged [*i.e.*, "fabrica-ted,"—fabre-fact-ed] or hammered [*i.e.*, "smilt(h)en"]. We would appear to have had a reputation for the artistic treatment of iron, even before the spacious times of our great Tudor sovereigns, Shakespeare, with perfect historical propriety, making, in III. Henry VI., II., 2, the Duke of York taunt Queen Margaret with being:—

"Iron of Naples, hid with English gold."

To the Society of Arts, in particular, Mr. Starkie Gardner was intimately known, both as an active member of our Applied Art Section, and as a most highly esteemed lecturer. The first paper he read before us was in 1887, on "Wrought Iron Work." It was subsequently expanded into the South Kensington Museum *Handbook on Ironwork*, of which (owing to

one of these preposterous mysteries of clerical procedure that are never to be understood by the laity), it is to be deeply regretted, only the first two parts have as yet been published. Mr. Starkie Gardner's second paper here was in 1888, on "Monumental Brasses;" his third, in 1891, on "Enamels and Enamelling;" and his fourth, in 1894, on "Pewter." They are all papers of unusual interest and merit, and with the paper to be read that evening, they cover nearly the whole ground of Mr. Starkie Gardner's enlarged practical experience as a thoroughly trained and highly accomplished art worker in every department of decorative casting and smithing. In enriching our *Journal* with these five papers, Mr. Starkie Gardner has rendered an invaluable service to the Society of Arts, and laid us under lasting obligations to him, and he may be assured of our unfeigned gratitude, mixed though our gratitude might be, as for his own part he confessed it was, with something of the sense of yet further favours at his ever helpful hands. He hesitated to express his own admiration of Mr. Starkie Gardner's special work as a craftsman, for to do so might be taken to imply that he had some title to speak, among the experts present, on the subject—and he had none. Nevertheless, and as he was old enough to be Mr. Starkie Gardner's father, he would venture to indulge himself, and say frankly, that in all the range of contemporary decorative art, there was nothing more delightful to him than the characteristic productions of Mr. Starkie Gardner's melting-pots and stithies in Lambeth. From the beginning Mr. Starkie Gardner had led the revival, during the past fifteen years, of artistic smithing in lead, pewter, copper, bronze, and iron; the rapidly spreading popular appreciation of artistic iron work in particular is wholly due to his personal labours and influence; and he is now everywhere recognised as standing at the very head of the old English art he has recreated among us, and restored to its former place of pride and honour in this country. After basket making, weaving, and potting, smithing—earliest in copper, later in bronze, and, last of all, in iron—was the most ancient of arts, and it remains the master craft of all crafts, without which few of them would ever have reached their present excellency. The use of iron, in place of wooden, stone, copper, and bronze tools, was indeed a great factor in at once differentiating Greek from Egyptian sculpture, the latter continuing to be wrought with the traditional tools even after the introduction of iron into Egypt. The terms "faber" and "fabrica" were first applied among the Romans to the blacksmith and his workshop respectively, and "faber" continued to mean, *par excellence*, blacksmith, even after the application of the term was extended to any artisan, and "fabrica" to any workshop, and the blacksmith was specifically designated "faber ferarius." In all his fabrications there was the strong impress of his own individuality; the individuality not only of the born and laboriously trained artificer, but of one who had

received into his heart the elevating and refining inspirations of scientific and literary culture. Before Mr. Starkie Gardner became a worker in iron—"faber ferarius"—he had devoted himself to the study of natural history, more especially of botany, conchology, and geology; and he has contributed several papers to the transactions of the Royal Geological Society, and published a book on the fossil coniferæ. It is obvious to anyone who has seen typical examples of his iron work, that these studies have been of the utmost use to him, not only in draughting his designs, but in actually manipulating the details of them at the forge. But these studies have been of still greater advantage in fostering in him, above a thorough knowledge of his trade, the love of his art. It is true that a handicraft is made perfect only in the loving observance of its art—"servus arte fabrica peritus;" but in all the work that Mr. Starkie Gardner has produced during the past fifteen years, he has produced nothing that is not becoming to, and to the greater credit of, his art, and he has produced nothing for the sake of trade only. This is the highest praise that can be accorded to an industrial artist, and by general consent, it is the praise pre-eminently due to Mr. Starkie Gardner. He has lived for this praise; and as epigrammatically formulated—with another application—in the well-known, but never hackneyed, line from Seneca, it might well be inscribed over the entrance to his fabrica in Lambeth:—

"Id facere laus est quod decet, non quod licet."

The paper read was—

THE REVIVAL OF TRADESMEN'S SIGNS.

BY J. STARKIE GARDNER.

When, at the request of our Chairman, I undertook to read a paper on "Signs," I hoped that not much research would be necessary. I soon, however, became aware that to do justice to it would be almost like writing a history of England. I only now begin to understand why our Chairman selected it, and that I was perhaps somewhat rash in agreeing to undertake the preparation of such a paper. But that books on the subject have already been written by Larwood and Hotten, Philip Norman, and Hilton Price, I could hardly have dealt with signs at all this evening. To become really a pundit on this difficult and abstruse subject, some knowledge of heraldry, astrology, mythology, theology, archæology, zoology, history, biography, and geography, is needed. I scarcely possess more than a limited acquaintance with many of these branches of knowledge.

The necessity for displaying some sort of sign, if one wishes to barter goods, accom-

modation, or service, against money or kind, can hardly be disputed. In a new settlement the first care of the intending storekeeper is to scrawl his name and trade on a piece of wood and hang it out to attract the passers-by. In America this is called "setting up one's shingle." The necessities of the budding communities of to-day were no less felt in the past. In days when customers could not read, a representation of the commodity on sale

honoured customs of trade and hospitality rendered signs unnecessary, and there is no mention of them in the Bible, Josephus, or the Arabian Nights. Neither has anything indicating their use been met with in the excavated cities of Asia and Africa. It seems, in fact, that signs were an institution almost peculiar to Europe, for it is only within its limits that records of them appear — doubtfully in ancient Greece, but

FIG. 1.—DESIGN BY TIJOU, 1693.

would be more serviceable than an inscription. If opposition stores were competing, more telling representations of the same objects, more attractively rendered, would serve to distinguish one establishment from the other.

Such signs must have been in use from remote times. It is only when the wares themselves can be displayed to the passers-by in safety that signs can be dispensed with, as in open bazaars and markets. In the East, time-

with certainty in Rome. The most venerable is that of the Bush, denoting the tavern in Italy, which reached Roman Britain. Our ancient proverb, "Good wine needs no bush," commemorates this most venerable of signs, the symbol of the house in which jovial companions foregathered. The Cock, and the Chequers, are also Roman signs, which, no doubt, equally found their way here, and link our civilisation with that mighty Empire,

our indebtedness to which we are perhaps apt to underrate.

In the earliest times, when people in England were mostly illiterate, only very easily understood signs could be used, clearly denoting the nature of the establishment and the trades carried on. In days when people and things actually were what they seemed to be, and there were no shams, embattled walls really symbolised the power of the noble, and banner-shaped vanes and finials proclaimed his degree. The church, the monastery, the mill, the smithy, the shambles, the malt-house, were all easily recognised; the tavern or ale-house almost alone required some distinguishing sign. We consequently find that the earliest ordinances made it compulsory for these to display the Bush—the ivy bush—sacred to Bacchus; whilst other traders might display signs or not as they pleased. In the towns where more recondite trades were carried on, their kind was advertised by such articles as a wool-pack, tailors' shears, barbers' pole, oil-jar, or magnified boot or glove.

All signs of this nature are common or collective—that is, used in common by all engaged in the same trade. They are scarcely mentioned by old writers, but are seen in the earliest illustrations, something very like a "wine bush" appearing in the Bayeux tapestry. Among well-known examples of collective signs are the three golden balls of the goldsmiths, the three gold crowns of the drapers, the vintners' three tuns or bunch of grapes, the wheatsheaf of the brewers and bakers, the compasses of the masons and carpenters, and so on. Interesting as this branch of the subject might prove, it is not my intention to pursue it farther to-night.

Signs, distinguishing and peculiar to individual establishments, are the product of a later and more sophisticated stage of civilisation. They, perhaps, only came into use on the definite adoption of distinguishing badges by the nobility. The noble in residence in a city would, in feudal days, entertain his vassals and neighbours coming from his own part of the country; and, in his absence, hospitality would be dispensed by his seneschal or major-domo. Doubtless, as the feudal feeling relaxed, and guests became more casual and numerous, some payment might be looked for, if not by the nobleman, by his stewards. Similarly, in hospices and monasteries, entertainment could be had, but payment from the well-to-do would be expected, as it is in continental hospices at the present day. In very remote parts, where

travellers are rare, one is warmly welcomed, and no payment accepted; in more frequented routes, however, payment, though nominally optional, is expected; whilst along the regularly beaten tracks bills are made out and presented in the usual way. Under the latter circumstances, the business of entertaining well-to-do travellers becomes a source of considerable profit, and the nobleman's steward, equally with the rich merchant, would fix up some sign indicative of a readiness to receive paying guests. The citizen would distinguish his house by some fanciful device, like the trade marks of to-day; or by a rebus, such as that handed down as the Bolt-in-Tun. We know that the nobleman displayed a painting of his arms on his town house, a custom surviving to this day in the painted hatchment. No less a person than the poet Chaucer, summoned as a witness in the Scrope and Grosvenor dispute, as to the right to the Bend-or, deposed that in walking up Friday-street he saw a sign with these arms painted on, put there by a Knight of Chester whom he had not previously heard of. Amateur Bonifaces were distinguished from professional as "herbergists," and their houses only resorted to by people of substance. Such establishments were, beyond doubt, the origin of the *bonâ-fide* hostelry or hotel.

Individual signs, unlike the collective signs, are referred to by nearly all our older writers, such as Chaucer, Froissart, Shakespeare, Ben Jonson, Beaumont and Fletcher, and some of them are inwoven into our national history. Some still existing signs vie with, and even surpass, our oldest families in their venerable antiquity, dating back to the Plantagenets. The more ancient, if existing, would present a pictorial history of our manners, customs, sports, and pastimes for 500 years past, and more or less correct representations of all our popular heroes. Walpole, writing a century and a half ago, remarked:—

"I was yesterday out of town, and the very signs as I passed through the villages made me make very quaint reflections on the mortality of fame and popularity. I observed how the Duke of Cumberland's Head had succeeded almost universally to Admiral Vernon's, as his had left but few traces of the Duke of Ormond's. I pondered these things in my head, and said unto myself, 'Surely all glory is but as a sign.'"

The custom of not merely two, but hosts of a trade agreeing to cluster together, as in Goldsmiths'-row, Leather-lane, Ironmonger-lane,

* Walpole to Conway, April 16th, 1747.

Budge-row, rendered it difficult to find enough appropriate and specifically distinguishing names to provide for each establishment, a difficulty such as is encountered in christening our numerous men-of-war to-day. For such multitudes of distinctive signs the realms of history (natural, sacred, profane and fabulous), of husbandry, travel, humour, of gastronomy and astronomy, the *ménage*, religion, sport, and profanity, were ransacked. Everything upon, above, or beneath the earth was pressed into the service, from the Virgin Mary to His Satanic Majesty; from our sovereign lord the King to Dirty Dick; the Moon and the Cheshire Cheese. The Cockatrice, Phœnix, Salamander, Griffin—fearful wildfowl these—and the more popular of the patron saints, figured largely on the signboard; nor were the ever-welcome devotees of the Leather Bottel and Pewter Tankard unremembered.

Of such signs as the Sun, Star, Crescent, Dolphin, Flying Horse, Fortune, Elephant, Bear, Lion, Cock, Wheatsheaf, Ivy and Vine, and Chequers, it is impossible to guess the antiquity. Some belong to Pagan times. The Adam and Eve, Salutation, Angel, Virgin, Baptist's Head, Crosses and Cross Keys, Mitre, Nuns and Friars, must be Christian—signs like Neptune, Atlas, Hercules, Golden Fleece, smack of more freethinking times; while the Mother Redcap, Mother Shipton, Dick Whittington, Robin Hood, Guy of Warwick, the Black Prince, and the John of Gaunt, Falstaff and Palsgrave, speak for themselves.

Some of the many Kings and Queens Heads and Crowns may date back to mediæval times, The landlord of a Crown Inn was executed by Edward IV. for venturing upon the mild joke that he had made his son heir to the crown. The Tabard and the Bell in Southwark are mentioned by Chaucer in 1383, and the White Hart, hard by, was Jack Cade's headquarters, and has been immortalised by many pens, from that of Shakespeare to Charles Dickens. This, with the Antelope, Dragons, Red, White, and Black Lions, White and Blue Boars, Swan, Hawthorn, Feathers, and Rising Sun, were Plantagenet badges and extremely popular while the dynasty lasted. Henry V. was entertained at a Red Lion on his return from Agincourt in 1415. The White Hart in Bishopsgate bore till quite recently the date 1480 on its front. The Boar's Head in Eastcheap is mentioned in the time of Richard II., and was once London's principal tavern. It was in this house that Prince Hal and his

two brothers made such a riot that they merited the attention of the mediæval chucker-out and were taken before the magistrate. The Duke of Somerset, prophetically told to beware of castles, was killed by Richard Plantagenet in a Castle tavern. The Chequers on the Hoop was visited by Chaucer's "Canterbury Pilgrims," and a Chequers tavern stood in Lambeth in 1464.

The Tudor badges naturally supplied a fresh set of popular signs, of which the Rose was the favourite. Our saying "Under the rose" has not, however, an English origin. Perhaps some present have sat under the huge rose in the pleasant vaults of Bremen, where the town councillors were wont to meet to quench their thirst with draughts of Rhenish. The Bull and Mouth and Bull and Gate are believed to commemorate an event in the reign of Henry VIII., the taking of Boulogne. Bulls and Bears became extremely popular signs under Elizabeth, when baiting these animals was the favourite national amusement.

There must have been a great massacre of Popish signs upon the demise of Queen Mary, such as Cross Keys, Maidens, and Catherine Wheels. The Three Nuns, in Aldgate, mentioned by Ben Jonson, and the Pope's Head in Cornhill, which existed in 1464, and the Mitre, in Cheape, extant in 1475, are notable survivals, which still continue to flourish. These, like the Three Cranes in the Vintry, and the Mermaid Tavern in Bread-street, were once household words. It was in the latter that Raleigh established a literary club frequented by Shakespeare and the wits of the day. The only known letter to Shakespeare is dated from the Bull Tavern in Carter-lane. Of equal celebrity were the Rainbow and the Devil in Fleet-street, and Hell and Heaven, in Westminster, alluded to in Butler's "Hudibras." The Society of Antiquaries was incubated in the Young Devil Tavern, in Fleet-street, though the august society in whose rooms we are assembled, was evolved in the cooler atmosphere of a coffee-house hard by. Of the religious signs spared on the death of Mary, comparatively few survived the more drastic disestablishment under the Protector, Cromwell. An Act of Parliament even extinguished the Golden Cross, in the Strand, as savouring of superstition.

Of the signs introduced by such events as the Stuart Accession, the Commonwealth, and the Restoration, it would detain you too long to speak. Neither can we run through the catalogue of the hosts of admirals, generals,

litterateurs, and poets commemorated during the centuries of struggle, through which we have attained to our present state of wealth and

fantastic, or far-fetched signs must also be passed over. The sporting signs of the Horn, the Greyhound, the Gun, the Nag's Head, the

appear from our sign-boards, and the nation ceases to drink to their memories and think of their deeds. The innumerable whimsical,

and speak of the tastes of our ancestors even more than of our own. When destined to disappear before the march of progress, may

some at least survive, like those perpetuated in the names of streets and squares, as Half-moon-street, Hart-street, Red Lion-street and square, and Falcon-square.

Under Richard II. it had been made compulsory on inn-keepers to hang out signs, though other trades might do as they pleased. Within 20 years of his death, the great projection of the "ale stakes," as tavern signs were then called, impeded the highway, especially in Cheape, and injured the stability of the houses, and an Act was passed to limit them to not more than seven feet in length.

pations, without impediments, molestation, or interruption of his heirs or successors." His son, Charles II., however, took advantage of the Great Fire to abolish this privilege, and compelled all signs to be fixed to the face of the house. This fashion of fixing painted signs to house fronts, instead of hanging them out, has been maintained on the death of armigerous occupiers up to the present day. The carved stone and cast-iron signs let into the fronts of houses, chiefly date from the edict of Charles II. Soon afterwards, the hanging signs were again numerous, the difficulty of providing

FIG. 4.—EXISTING SIGN AT BRUGES, 16TH CENTURY.

Repressive and permissive measures seem to have alternated ever since. Sometimes the streets were graced with innumerable signs, hung out as banners are on gala days, their numbers defeating the object in view by obscuring each other. The efforts to outvie one's neighbours, caused the signs, at times, to become so serious a nuisance, that legislation had to be resorted to. Charles I. granted to the citizens of London on his accession, as a special boon, the right "to hang out signs and posts for the better finding out of their dwellings, shops, arts, or occu-

names introducing a dual nomenclature, when such combinations as the Cock and Bull, Cat and Fiddle, Goose and Gridiron, became the fashion. The necessity for signs relaxed when the streets were numbered. This commenced in 1708, it appears, with Prescott-street, Goodinan's Fields, for Hatton writes "instead of signs the houses here are distinguished by numbers, as the staircases of the Inns of Court or Chancery." Until then it was absolutely necessary to identify houses unprovided with signs or some distinguishing feature, as in the vicinity of some other house adequately

distinguished by some sign as "over against" the Load of Hay or Yorkshire Grey. Omnibuses, like their forerunners the stage coaches, still as far as possible choose public-house signs to mark their destinations and stopping places. The coffee-houses in the 17th century, entirely new and smart institutions, struck the greatest blow at the use of signs. Wishing it to be understood that they were not to be classed with the older tavern, they broke away from old customs and inaugurated the new mode of merely writing up the name of the owner as Dick's, Tom's, Wills', Sam's, Buttons', Peales', or more high sounding names as the Smyrna or Cyprus. The last repressive Act was passed in 1762, for taking down all overhanging signs under a penalty of £5 and 20s. per day, and this was so effectual that scarcely any remained by 1770, except a few over the book-stalls in Holywell-street, which are noticed by Mr. Wheatley, in his book on London, as existing down to 1849.

The mediæval form of projecting sign, as pictured by Larwood and Hotten in their excellent book, was a carving in wood fixed within a hoop. The hoop was a very venerable and ancient affair, handed down from Pagan times. The ivy garland in honour of Bacchus, the so-called "bush," and the universal tavern emblem, required a backbone, and this backbone remained after the ivy had been stripped from it. Some ancient illustrations show that the tavern "Bush" became elaborated into a series of intersecting hoops, garlanded over, and surmounted by a crown of evergreens, perhaps additionally decorated with ribbons on gala days. From simple and pure to rich and fantastic is the order of progress in matters decorative, with set-backs when revulsion of feeling sets in. The Jacks-in-the-Greens, nearly the last and now almost extinct survival of the old May-day revels, but which were quite common in my younger days, were merely tavern signs perambulating the streets. Jacks-in-the-ale-house, but the ale-house turned loose into the streets, attended by a motley crew of revellers. Sayings such as "As wise as an owl in an ivy bush" show that the words tavern and bush were synonymous. When the mere "bush" no longer sufficed the existing hoops were utilised to hold some badge distinguishing the house, specifically distinguishing badges being held to be *de rigueur*, garlanded and beribboned, it may be, on festival days. A George-in-the-Hoop is recorded as a tavern sign of the reign of Edward III., and others as Cocks or Hens

"in-the-Hoop" are mentioned in the time of Henry VI., and to these doubtless the singular phrase "Cock-a-hoop" is to be traced.

Belonging to a much later period is the more sophisticated fashion of hanging out actual pictures illustrative or descriptive of the name of the house. These were set in richly-worked frames, and often depended from very handsomely-carved or worked brackets or supports. There are vague traditions that pictures by such world-renowned masters as Holbein, Correggio, and Paul Potter, have suffered the indignity of having been thus hung out to attract the passer-by. It is absolutely certain that paintings by celebrated English academicians, such as Hogarth, Wilson, Harlow, Moreland, Old Chrome, David Cox, and others, have served this purpose. Some distinguished academicians as Cipriani, Charles Cotton, Samuel Wall, and John Baker, really commenced their careers as sign-painters; and, if we may draw conclusions from the price of £500 paid for a picture of Shakespeare for a sign in Little Russell-street, Drury-lane, the profession was perhaps not a bad stepping-stone to more enduring honours—especially as those called in to paint the sign sometimes stayed to paint the apartment as well. The paintings of a room in the Pope's Head, Cornhill, deserved the encomiums of the genial and observant Pepys; and those of the Rose, near Temple Bar, of the more critical Walpole. The great mart for the average pot-boiler sign kept in stock was Harp-alley, Shoe-lane, while a more *recherché* class could be commissioned from the coach-painter. In 1762 an exhibition was held by a self-styled Society of Sign Painters, to which Hogarth, who fully entered into the joke, was a contributor.

When picture signs were so popular and at times magnificent, the supports and frames which surrounded and suspended them were worthy of them. These were of carved wood or iron, or of both combined, gilded and painted, and sometimes so preposterously massive as to pull out the front of the house they adorned. A particularly ill-contrived construction caused a front to fall out in St. Bride's-lane, in 1718, killing, with others, the King's jeweller and two ladies. A sign of the Three Queen's in Clerkenwell, on the other hand, was so firmly built in, that when ordered to be removed, in 1764, it cost £200 to take down. Among the many large and elaborate

constructions London could boast of, those pre-eminent and reputed to be the largest, were the signs of the Castle in Fleet-street, and of the White Hart in Southwark. A Frenchman, by name Misson, visiting England in 1719, says that though signs were kept small in Paris by restraining influences from above, in London they jutted out so far as to touch each other, and to stretch right across the narrower streets to the opposite wall. Many, he remarks, with their painted and gilt iron supports, must have cost over 100 guineas. Another Frenchman travelling in England in 1765, saw nothing to chronicle on landing at Dover, except the enormous size of the public-house signs, and the ridiculous magnificence of the ornaments with which they were overcharged. Every sign formed a triumphal arch which crossed the streets. A picture of a particularly elaborate sign, that of the White Hart at Scole, in Norfolk, which cost, in 1655, £1,957, represents an immense arch with carved panels of deities and heraldry, crossing from the house and resting on a brick pier on the opposite side of the road.

As a practical worker in iron, it may naturally be expected that I should show more partiality for the iron brackets which supported the signs than for any other part of the structure. This is in truth the case. When and where iron was first used for the purpose I do not know, and therefore shall not pretend to say, but probably the use dates well back into the middle ages. Illustrations of iron sign brackets occur in the design books of the 17th and 18th centuries. That such a renowned architect and designer as Jacques Androuet Du Cerceau should have thought it worth while to devote a page of illustrations in his celebrated treatise on architecture to them, proves that so far back as the 16th century iron sign brackets were esteemed as vehicles for artistic treatment. The designs are in the taste of the day, simple and slightly inclining to the geometric, charmingly evolved by a refined ornamentist, but not by a practical iron worker. The illustrations were published in 1570 (see Fig. 6, p. 620). The author lived in a house with the sign of the hoop, and the surname, Du Cerceau, "of the Hoop," which afterwards became so famous, seems originally to have been a nickname, due to this circumstance. The introduction of the human figure implies that smithing of the highest order was available, and probably that of France in the Renaissance has never been surpassed. Next in point of date is the leaf from the treatise of a

practical mechanic—Mathurin Jousse (see Fig. 5), who dates from La Flèche, and wrote in 1625. This is the earliest treatise on smithing extant. The designs are crude and not particularly well drawn. It must be remembered that the French in the second half of the 17th century, far from encouraging extensive signs in their streets, restricted them by law to very modest dimensions. Probably, for this reason, none of the great designers in France, who published such sumptuously-illustrated books on iron work, have cared to give any illustrations of sign-brackets. It was otherwise in England, how-

FIG. 5.—DESIGNS BY MATHURIN JOUSSE, 1625.

ever, at this time, as we have seen, for magnificence in the matter of signs was the order of the day. Nothing more elaborate can well be imagined than the three designs for sign-brackets comprised in Tijou's book, published towards the close of the 17th century (see Fig. 1, p. 613). Tijou, it is known to most of you, was the designer and contractor for the iron work at Hampton Court Palace, St. Paul's Cathedral, Chatsworth, and other places. Any smith present will, however, at once perceive that these designs could never have actually been carried out, or even drawn by a practical man. They go far to prove, I may incidentally remark, that Tijou was not himself a crafts-

man or expert, but merely a designer, whose designs, moreover, required a very great deal of alteration at the hands of experts before they could have been handed out for execution by the smith. The old tradition that Huntingdon Shaw, of Nottingham, really executed the work may not be far wrong. His charming book of designs, published in 1693, has been reprinted by Messrs. Batsford. This by the way. Unfortunately, illustrations of English sign-brackets previous to the enactment of 1765, which condemned them to destruction,

comb (see Fig. 4, p. 617). Judging from the contemporary font-cranes, which it greatly resembles in its details, it must date from about 1500. There are a few others in the Low countries, preserved in museums, of almost equally early date—all, both sign and bracket, being solely of iron. In Germany a few of late Renaissance date may still exist, like the fine specimen illustrated, and now in the South Rensington Museum; but as in the Belgian, the vast majority are of the style of Louis XV., known as the Rococo. None appear to have

FIG. 6.—DESIGNS BY ANDROUET DU CERCEAU, 1570.

are extremely rare. Though Hogarth incidentally depicts a great many signs, only one is at all an elaborate piece of iron work.

Of actually existing iron sign brackets, there are none in England, speaking according to my limited knowledge, older than the Chippendale or Adams' periods—few, indeed, being more than a century old. To find older examples we must pass over to the Continent. The most ancient that I have met with is the remarkable bracket in the *Marché du Vendredi* at Bruges, from which still depends the model of a curry-

been designed for hanging pictures, but only to include signs made of beaten iron or copper. Those designed to receive a huge representation of a key, the sign of the locksmith in Germany, are the most elaborate, serving to illustrate practically the skill of the craftsman seeking custom as well as to decorate his abode. In France few sign brackets seem to have survived the Revolution, and in Italy and Spain there are practically none. No signs exist in England which can in any way compare with the series of illustrations of those in

the Brussels and other museums abroad. We are a law-abiding people, and allowed a clean sweep to be made of all our signs in the last century—scarcely an example remains dating farther back than 1762. With the sweeping law of that date all continuity and traditions of design were broken and never revived. The few that now exist are unlike the older ones, merely rudely embellished stays and supports to hold a board with the name of the house painted on it. They are frankly utilitarian. Now and then we chance upon a more pretentious example, elaborated by some local talent, but they are uniformly of flimsy workmanship and destitute of any principles of design. One of the best examples, is that at Mere, Wilts. There are others at the Bull, Bruton; the George, Thame; the Black Swan, Frome. They are all rather timidly executed in the earlier part of the century. Though so simple and late in date, village signs are often found in the travelling artist's sketch-book. They are certainly pleasing adjuncts to the village ale-house, and serve their purpose admirably.

It may be debateable whether hanging signs should be permitted in our London streets or not. If well designed and not too numerous, they add a certain picturesqueness—especially in certain situations. So long as they cause no practical inconvenience or danger to the public it would seem superogatory to prevent money being spent in the decoration of our not-over-beautiful thoroughfares, and to abrogate a privilege and custom that has, on and off, existed for several centuries. The omnipotent London County Council not having as yet definitely decreed that no more signs shall be erected in London, I am enabled to add a few modern examples to my series of pictures both of other people's and my own productions. The place of honour in this series must, I think, be accorded to the sign at the bottom of St. James-street, designed by Mr. De Wilde, once, I am pleased to think, on my own staff. It hangs high, but is very effective and well proportioned, and not inharmonious with the Norman Shaw building on which it is placed. An additional merit is that it is a pioneer, having been the first important sign put up in London during her present Majesty's reign.

Another very striking sign is to be seen at Heath's, the hatters, in Oxford-street, made by Messrs. Strode, from I believe the architect's design. Its merit is slightly lessened in

my eyes at all events, from the fact that it appears to some extent to have been inspired by the example just seen. Of signs made for public houses, those for the Rising Sun in Tottenham-court-road, and the Shades in Charing-cross are by my own firm, to the order of Messrs. Treadwell and Martin. Being my own offspring the less said about these the better. The most original and daring sign yet erected is undoubtedly that for the same architects, by my friend Mr. Shirley. It is quite alone and very quaint. The only fear I have about it is that if many signs with so great a projection were erected in our streets, the privilege of putting up any at all might soon be abrogated.

DISCUSSION.

The CHAIRMAN said it was, he thought, accepted by antiquarians that the shop sign of mediæval Europe was of Roman origin. The Romans would appear to have advertised by shop signs, and among them signs indicating one's trade or calling were used with far greater freedom than would be tolerated in Christian Europe, as those would realise who had seen the Pompeian sign, or the illustration of it in the catalogue of the *Museo Borbonico*, with the legend, "Hic habitat Felicitas." The sign of the Golden Ham is certainly of Roman origin, as a late Roman, or early Italian stone slab with five hams sculptured on it has been found in Italy, and is supposed to have been the sign of a penarius or "hamseller," afterwards used as his grave stone. The emblematical sculptures on the cippi of Roman and Romano-Gallic tradesmen were obviously in many cases derived from their shop signs. A marble relief found in this country, and now in the Blundell Hall, representing the manufacture of wine, is said by some to be a Romano-British wine merchant's sign. Others, with some reason, the speaker thought, regarded it as a sepulchral sculpture. He frequently saw in this country over the shops of hosiers a twelve-spoked wheel with a ram hanging from it. This was really an astrological sign, representing the circle of the Zodiac with Aries hanging from it, the hosiers' "Sign." Every trade has its zodiacal and planetary tutelaries, and they provide excellent motives for shop signs. In India and throughout the East generally, such symbolical signs exercise a great influence over the people. We all know the trade mark on the bottles of Bass's ale, a triangle with the apex upward, and coloured red. So represented, it is the symbol among the Hindus of Siva, and of fire, and of the most powerful generative energy, and its use on Bass's bottles has immensely helped to popularise their ale among the Hindus in India. It is said that the new Apollinaris Company paid

Messrs. Bass £10,000 for the use of this symbol as a trade mark on their bottles. But so far as the sale of Apollinaris in India went, they would have done better to adopt the symbol of Vishnu, and of water, the symbol also of reproductive power, the triangle with its base upward, and coloured blue. The Messrs. Allsopp's "red hand" is a good brand for Mahomedan countries, but it would be better were the fingers arranged in the formula of priestly benediction, another most potent symbol of creative energy among the Hindus. The crossed triangles, known to us as "the Shield of David,"* and "the Seal," and "Knot of Solomon" is the symbol among Hindus of Brahma, and supreme creative [combined generative and reproductive] power, and would make a good trade mark, or shop sign for use, in India. The *swastika*, both the red, or right to left revolving, and the blue, or from left to right revolving, representing the revolution of the sun in the upper and nether [region of the Cape and Australian colonies, or Patala—the classical Hades] worlds respectively, is a symbol equally revered throughout the East by Buddhist, Hindus, and Mahomedans. The pentacle, pentangle, pentalpha, known also as the "Pythagorean Foot," the "Druid's Foot," [Drudden Fuss] and "Fuga Demonorum," is a most powerful talisman among Mahomedans, and is revered also by the Hindus; and its use as a trade mark, or shop sign, would be highly advantageous among Mahomedan communities, particularly in popularising among them goods against which they are traditionally prejudiced, such as wines, spirits, &c., pigskin saddlery, &c. The Hindu "nava ratna," or "nine gems" jewel, a symbol of the "Seven Planets" (the waxing, full, and waning moon counting as three), suggests a most picturesque motive for an illuminated shop sign. But it was too late in the evening to go on in that way, and he would at once proceed to answer the question in the first paragraph of Mr. Starkie Gardner's paper—Why had he (the Chairman) asked him to prepare it? Whatever sinister motives he might have had in so doing, he had two perfectly righteous ones; one being that he well knew Mr. Starkie Gardner would provide them with a paper worthy of its subject; and the other, that being unable to provide himself with "a house and grounds" suited to his exacting tastes, he was selfishly, as well as, he hoped, altruistically, interested in the tasteful and picturesque decoration of our streets, to which end artistic shop-signs were a comparatively cheap, universally useful,

thoroughly national, and most effective means. Mr. Starkie Gardner had given them an excellent paper, full of far-brought learning, and, literally, "at-one's-door" suggestion, all stated in the most vivid and entertaining manner; and he felt perfectly certain that it would greatly tend to stimulate the growing demand among the higher class of London tradesmen, in every sort of business, for shop-signs of every variety and description. He did not understand Mr. Starkie Gardner's apparent objection to painted sign-boards. He seemed to think it derogatory to artists to paint sign-boards. But if the production of artistic shop-signs is to keep pace with the prospective demand for them, not only braziers and blacksmiths, but potters, and wood carvers, and painters, and even sculptors must all give a helping hand to the good and gracious work. Nothing was more detestable than vulgar advertisement, but advertisement was an absolute necessity of trade; it is an instinct of human nature, and it runs through all creation. The great thing, therefore, is to substitute for vulgar, and too often absolutely brutal advertisements, advertisements which are the best work of the best artists—whether of the "studio" or the "workshop"—of our day. Already our "public houses" are rendering great services in the gradual scenic improvement of the streets of London, and they should in every way be encouraged in this new departure. They are sure to profit by it. There is nothing more agreeable to a healthy man after a spell of any kind of hard work, mental or physical, than a draught of sound ale, and when he is invited to it by a homely, or quaint, or historic, or beautiful shop sign, the invitation is irresistible. There is nothing one more misses when abroad than the English country side inn, and on his return from India, having to settle in London, which was then a strange place to him, he was greatly delighted by finding in a shop in Westminster—in Bridge-street—given up to the sale of publications for the suppression of all sorts of vices, an admirable map of London, with every publichouse in this great city prominently marked on it in bright red. With its assistance, and taking parish by parish, it was wonderful to think of the number of London public-houses with which, in the course of twenty-eight short years, he had become personally acquainted. He had found them, for the most part, to be thoroughly respectable establishments, and the proprietors of all of them thoroughly honest tradesmen, judged, that is, by the goods they vended; for from Bayswater to White-chapel, and from Highgate to Brixton, he had never once been served with a glass of bad ale. But their signboards were, for the most part, a terrible eyesore; and instead of being a source of attraction, were a cause often of positive repulsion. All vulgar advertisements, advertisements which instead of being subordinated to, and emphasising, the architectural features of a shop, obliterated them; which were flaunted against the skies, or set up obtrusively in the midst of beautiful scenery, or which in any way showed a brutal disregard of other peoples' susceptibilities and common rights, were instinctively obnoxious to the public;

* Neither books, nor Eastern tradition—certainly not Indian—sufficiently satisfy me as to whether the descriptive phrases, "The Shield of David," "The Seal of Solomon," both refer to the crossed triangles, or both to the pentangle [not pentagon] or pentalpha; or whether one of the terms—I cannot decide which—refers to the crossed triangles, and the other to the pentangle. I believe the latter to be the "Seal of Solomon," and the former the "Shield of David," but cannot give chapter and verse for it. The decision of the Freemasons on this point, or on any point of Eastern symbolism, can never be convincing.

and were undoubtedly damaging to those who needlessly used them. He had no money of his own to spend, but he had spent immense sums of other peoples' money in advising them where to go for artistic objects; and he never recommended people who advertised vulgarly, for it was impossible to trust to the taste and judgment of such persons. On the other hand, a shop front, designed by a scholarly architect, with an artistic sign, whether it was a hatter's shop or a public house, was always the best of recommendations to the good things within. It was idle to run down advertisements simply because they were disfiguring and offensive; the proper remedy was to make them becoming and acceptable, as the publicans were so wisely doing; but this reform can never be adequately carried out without the co-operation of architects, sculptors, painters, and metallurgists. Mr. Starkie Gardner had led the way in the reform, and he should be all the better pleased if others than blacksmiths and braziers were found to follow him in the more enticing, and thoroughly popular method of shop embellishment, and street decoration, which had been his special contribution to the general Victorian Renaissance of art and artistic industry. He felt it a great honour to have presided on the occasion, and to be the channel through which the grateful thanks of the meeting were offered to Mr. Starkie Gardner.

Mr. JOHN LEIGHTON, F.S.A., said signs were at first intended for the ignorant who could not read, but the great thing now was to evolve something suitable for the well instructed. It was curious to notice how badly the rococo style went with metal, it being an agglomeration of disjointed elements thrown together, often very agreeable in effect, but at the same time it hardly seemed suitable for iron. It needed a lot of chiselling, and the great thing in iron work was to get smith's work, so as to utilize the metal as much as possible. The heraldic signs were very beautiful, and the sooner these who put up the royal arms substituted pierced ironwork for the present gaudily-coloured figures the better.

Mr. I. HUNTER DONALDSON said it was gratifying to find that signs were largely increasing in London, and they all knew how much they were indebted to Mr. Starkie Gardner, with his charming taste and thorough acquaintance with the best foreign examples, for the production of some of the most beautiful signs. He quite agreed with the Chairman that painting should be combined with iron work, and he could not conceive that Mr. Gardner would object to it, because the position which would under ordinary circumstances be occupied by writing could be filled up in the manner shown in Mr. Heath's sign. They were led to believe that some objection might be raised to signs if they became very numerous, and that they would interfere with each other, but he thought the

County Council might be safely trusted to see that they were arranged in such order and good taste as to present an agreeable effect, without that confusion which would result and must have resulted from the agglomerated arrangement which appeared to have obtained in former years. He had seen many of these signs in foreign countries, particularly in Germany, where they were more numerous than in any other country, possibly because beer was so largely consumed there; certainly they were extremely beautiful, and he had examined many of them in conjunction with Mr. Starkie Gardner. In going about London they must be conscious that almost every important street presented some evidence of the increasing taste of the English people for that art which had always been associated with the country and which ought to be highly prized. They had unfortunately a Government without an individual in it connected directly with the arts, and were therefore all the more indebted to gentlemen like Mr. Gardner who gave time, thought, and knowledge to the development of this taste. If we were to be redeemed from barbarity all such forms of art should be encouraged. The signs in all important streets gave evidence of improved taste in the people, and increasing enterprise on the part of shopkeepers.

Mr. W. G. TREWBY said he understood the reader of the paper to say that the Jack-in-the-Green was connected with the sign of a public house, but his belief was that it was a representation of a forest scene, with Maid Marian dancing, the green being intended to represent the place where the dance was performed.

The CHAIRMAN—The truth is, the May mummery of "Jack-in-the-Green," like most other remotely derived popular celebrations, had several origins. It was undoubtedly connected with the old public house sign of the "Ivy Bush"; and it had become connected with the legendary history of Robin Hood and Maid Marian. But, earlier than all these, "Jack-in-the-Green" came down from the most primitive pagan times, and the annual celebration of the revival of vegetation between the Spring Equinox and the Summer Solstice—Midsummer Day. It is analogous to the festival of "Green George," *i.e.*, "St. George-in-the-Green," held in Corinthia on St. George's Day, 23rd April; with the Maypole festivities once universally observed in this country on the 1st of May; with the Whitsuntide floral [Pinxterbloem] festivities of Holland; and with the St. John festivities held in Sweden on the eve of St. John's Day (24th June), when young fir trees are set up before every house, and arbours are constructed of fir branches, and the people sit out in them, eating and drinking, all the night through. The fullest information on the subject would be found in Fraser's *Golden Bough*, and enough for the "general reader" in Mrs. J. H. Philpot's *Sacred Tree*.

Mr. STARKIE GARDNER, in reply, thanked the Chairman for the way in which he had spoken of his efforts with regard to ironwork, which had now been continued for more than twenty years. He had tried to do his best, and certainly there had been a most marked revival of the trade. When he started there were very few smiths capable of doing any artistic work—you could number them on your fingers—but now there were a large number, and he was happy to know that no skilled smith need ever want a day's work. The demand was still far in excess of the supply, and it had been most gratifying to him to find that this revival had led to quite a display of talent amongst the working classes, such as had hardly been expected in England, though it was common in France and Germany. He must certainly disabuse the Chairman's mind of the idea that he was in any way disinclined to see painting associated with metal work. It was not that he did not wish it, but it was exceedingly difficult to find capable artists who would condescend to paint signs at all. There was a beautiful sign in Vigo-street, "The Rembrandt's Head," which he very much admired, and should be glad to come across the man who painted it.

The CHAIRMAN then moved a cordial vote of thanks to Mr. Starkie Gardner, which was carried unanimously, and the proceedings terminated.

Miscellaneous.

COMMERCIAL EDUCATION IN ENGLAND.*

BY SIR HENRY TRUEMAN WOOD, M.A.

(Concluded from page 593.)

Examinations on somewhat similar lines have also been recently established by the London Chamber of Commerce, which grants certificates to candidates who pass in certain specified subjects. The standard of these examinations is somewhat higher than that of the Society of Arts, and they are, I think, intended principally for pupils at, or leaving, school. The number of candidates for these examinations has up to the present not been very considerable, but the certificates, are, I understand, valued by employers as a test of the candidates' qualifications. Examinations, which are practically examinations in commercial knowledge, are also held by Institutions such as the Institute of Chartered Accountants and the Bankers' Institute—these, however, are of a strictly professional nature, and form the qualification for membership of the Institutes.

It will thus be seen that, though there are in London—and the conditions in the provincial cities are similar to those in the capital—scarcely any institutions providing specialised commercial education,

that city is by no means deficient in means for providing good primary and secondary education of a modern type. There exist a number of excellent schools where such education is provided at a moderate cost for boys up to the age of 14 or 16. There are also well-equipped evening classes or continuation schools where young people engaged in business during the day can continue their general education, and can also study subjects of a distinctly commercial character.

Whether such education is commercial education depends upon the meaning which is to be given to the term. Some people by commercial education mean a knowledge of business routine; others maintain that the only useful sort of training consists of a good grounding in general education, and that the knowledge of the business routine of any special trade must be acquired in the office devoted to that special trade. It has been remarked that the business man is not a genus by himself. Different training is required for the banker, the foreign merchant, the shipping agent, the railway official, and the insurance clerk; and of each of these, and of very many other classes, there are innumerable divisions—office boys, book-keepers, accountants, agents, travellers, managers, for each and all of whom a different preparation is necessary.

Again—the remark was made by Sir Bernhard Samuelson, the chairman of the 1881 Royal Commission on Technical Education—the methods of commerce are empirical. There is no pure science in trade. Here is the difference between technical and commercial instruction. Modern industry is based on science. Every branch of industry has its own associated branch or branches of science. These can be taught. What departments are there of science of which a knowledge is essential to the commercial employé? Of course, all—or any—knowledge may be useful to him, but that is only saying in other words that he wants a general, not a specialised, training.

The London County Council have recently rendered valuable service towards clearing up this question—the definition of commercial education—by the publication of a report on the subject by a sub-committee of the Technical Education Board of the Council. This committee took means to ascertain the opinion of a considerable number of typical employers of labour in London, and these opinions they have published, with a report of the conclusions which the committee themselves have drawn from the material they had collected. It is somewhat remarkable, considering the recent demand for commercial education on the part of employers, to find that the witnesses before the committee were practically unanimous in the opinion that for the lower grades of commercial employés special school training was undesirable. They all expressed their preference for a boy fresh from school, with the best elementary education, over the boy who would come a year or two later into the office, after having passed the

* A paper read at the International Congress on Technical Education at Venice, May, 1899,

additional time in acquiring a probably imperfect knowledge of so-called commercial matters, which possibly would have no application in their special house of business. An intelligent boy, they said, coming into the office at 14 would at 16 be far more valuable to them from the special knowledge he had acquired than a similar boy coming to the business at 16, with an imperfect equipment of so-called commercial education. It was urged that a few years later the boy who had had the more advanced instruction would then be the more useful of the two. This was admitted as possible, but, as a rule, the commercial experts seemed disinclined to allow even this much. They were, however, prepared to admit that boys, as a rule, left school much too early, and that it would be a great advantage if the school age could be extended for another year or two. But they were unanimously against early specialisation, and they one and all held to the point that, though it would undoubtedly be an advantage for boys to have another year or two's schooling, those years must be devoted to general education, not to instruction in commercial matters, or even to any attempt to acquire a knowledge of general business routine. It goes without saying that the education ought to be a modern one, and if classical languages were to be admitted, they were to have but a small part in it. Modern languages were important; book-keeping and shorthand should be included; and elementary mathematics were essential. All these subjects, too, should be taught with a view to their practical application—languages from a commercial, not a literary, standpoint, and all the other subjects in the same way. My own experience of the Society of Arts examinations leads me decidedly to the opinion that any attempt to teach special subjects at an early age is wasted, so far as they are taught with a view to their practical application. Even such a subject as book-keeping had better wait till, at all events, the end of the school age. Of the three or four thousand candidates who are annually examined in this subject—and these are certainly above the average of junior clerks—I do not think that much more than 10 per cent. would be found useful additions to the staff of the head accountant or book-keeper in a large firm. No doubt the preparatory training has been useful to all; but, at all events, in the case of the younger candidates, I am inclined to think that a further grounding in elementary mathematics would have been quite as practically useful, and would have proved a better mental training.

On the question of higher commercial education, opinion was very much divided. The system of carrying on sham commercial transactions at school, which is strongly advocated by many Continental authorities, and by some educational experts in England, met with scant support. It was considered that this was merely playing at business, and that the training so acquired would be of little use in practice. Some witnesses preferred for their higher posts, when

these were not recruited from the lower ranks, University men; others considered that the last year or two of educational life could be best spent in a foreign country acquiring a knowledge of its language and its business methods. On the whole, opinion was favourable to such institutions as the London School of Economics, previously mentioned, in which special teaching could be given to those who had made up their minds what line of business they were about to adopt, or were even already engaged in it.

Eventually the Committee decided to recommend (1) the establishment and encouragement of continuation schools for those who entered business offices at about the age of 14, that is to say boys trained in the elementary schools; (2) that departments should be established in many of the secondary London day schools for the preparation for commercial life of boys leaving school at 16, the education to be given being of a general character—modern languages, arithmetic, and commercial geography; (3) that there should be formed in at least one secondary London day school of the first grade a department for the preparation for business life of boys leaving school at 18 or 19, the teaching of which should qualify its pupils either to enter the higher ranks of commercial life, or to pursue an advanced course of study in some institution of higher commercial education; (4) that in the reorganisation of the London University, which is now under consideration, provision should be made for the establishment of a separate faculty of economic and commercial science, to which pupils of Class 3 could go.

On looking over what I have written, I find that it bears a great similarity to that ancient worthy Horrebow's celebrated chapter on "Snakes in Iceland," and that my remarks have been, in the main, a demonstration of the non-existence of any provision for commercial education in England. As regards higher specialised commercial education, this is certainly the case. There are no institutions with this object in England, or none at least which have passed beyond the experimental stage. But, as regards the provision of general education of a modern type, which is, at all events, an excellent preparation for commercial life, I think I have shown we are not lacking, and that our educational system is rapidly developing in the direction required. That it can so develop in any required direction is, I think, a special advantage of its free and unfettered condition. That our system is sadly unsystematic must be admitted, and this leaves it very open to criticism on the part of our more logically-minded continental friends. I know that our happy-go-lucky methods are abhorrent to accurate thinkers and persons of a logical turn of mind. I hardly dare to suggest that they have any merits, but I may perhaps point out that they have their practical advantages. The English method, like the system of natural philosophy elaborated by our great thinker, Darwin, depends upon and encourages the survival of the fittest. Ultimately good results are attained, though possibly after a wasteful expenditure of material, and a painful

result to many of the individual components of the material. As the demand for a different class of education—first in science, then in scientific technics, now in commercial technics—has arisen, that demand has been, or is being, more or less adequately supplied. I have myself no doubt that in a short time we shall develop a system of commercial education sufficient for our needs, and of practical value. It will be theoretically incomplete, it will not commend itself to the admiration of the philosophical expert, but it will, I believe and hope, turn out excellent practical results.

Correspondence.

LONG DISTANCE TRANSMISSION OF ELECTRICAL POWER.

In a paper of mine, published in the number of the *Journal of the Society of Arts*, dated November 25th, 1898, some tables are given for facilitating calculations connected with the transmission of electrical energy to a distance. In Table III., the column of current densities, with an inefficiency of 1·3, is wrong, and, as these tables may probably be copied, I desire to give the correct values of the current densities at the inefficiency 1·3 for the different distances and electric pressures, indicated by the reference letters A to K. These are as follows:—

A	1064	D	266	G	152

June 1st, 1899.

Obituary.

ARTHUR R. COWDROY.—Many members of the Society will regret to hear of the death of Arthur R. Cowdroy. He was for many years the library clerk of the Society, and in that capacity will have been well known to those members who make use of the library. His connection with the Society of Arts was a long one, dating from 1869, when he was engaged as an assistant to Mr. S. T. Davenport, at that time the financial officer of the Society. Very soon afterwards the library was placed in his care, and he has since that date been practically in sole charge of it. For some years past he was in failing health. He suffered from a nervous disorder, which developed into locomotor ataxy. He bore up against this with very great fortitude; but his illness lately assumed a more acute character, and after a short

period of suffering he died on Thursday, the 1st of June. He was the eldest son of the late Rev. J. Rathbone Cowdroy, of Liverpool.

General Notes.

RUSTCHUK INDUSTRIAL EXHIBITION, 1899.—An industrial exhibition, which is to be opened at Rustchuk on August 14th, has been organised by the Ministry of Commerce and Agriculture, under the patronage of Prince Ferdinand. It will comprise machines, motors, apparatus, tools, implements for every industry and handicraft, including agriculture. Applications for information should be addressed to the manager of the exhibition, Mr. Arthur Gobiet, Prague, Carolinenthal, Bohemia.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, JUNE 12...British Architects, 9, Conduit-street, W., 8 p.m.

TUESDAY, JUNE 13...Medical and Chirurgical, 20, Hanover-square, W., 8½ p.m.

Photographic, 12, Hanover-square, W., 8 p.m.
Prof. Vivian Lewes, "Acetylene."

Anthropological, 3, Hanover-square, W., 8½ p.m.
Asiatic, 22, Albemarle-street, W. 4 p.m.

WEDNESDAY, JUNE 14...Royal Literary Fund, 7, Adelphi-terrace, W.C., 3 p.m.

Royal Society of Literature, 20, Hanover-square, W., 1 p.m.

THURSDAY, JUNE 15...Royal, Burlington-house, W., 4½ p.m.
Antiquaries, Burlington-house, W., 8½ p.m.

Linnean, Burlington-house, W., 8 p.m. 1. Mr. R. T. Günther, "Contributions to the Natural History of Lake Urmi and its Neighbourhood."

2. Dr. A. B. Rendle, "A Systematic Revision of the Genus *Najas*." 3. Mr. Walter E. Collinge,

"The Anatomic and Systematic Position of some recent Additions to the British Museum Collection of Slugs." 4. Mr. J. E. Duerden, "The Edwardsia Stage of Lebrunia, and the formation of the Oesophagus and Gastro-cæcomic Cavity."

Electrical Engineers, Natural History Museum, South Kensington, W. Conversazione, 9 p.m.

Historical, 28, Jermyn-street, S.W., 8½ p.m.

Numismatic, 22, Albemarle-street, W., 7 p.m. Annual Meeting.

Chemical, Burlington-house, W., 8 p.m. 1. Mr. W. H. Sodeau, "The Decomposition of Chlorates, with special reference to the Evolution of Chlorine and Oxygen." 2. Dr. A. Harden, "The Action of Hydrogen Peroxide on Formaldehyde." 3. Messrs. A. Lapworth and E. M. Chapman, "Homocamphronic and Camphononic Acids." 4. Mr. A. Lafworth, "Action of Silver Compounds on A-Dibromocamphor." 5. Mr. A. G. Perkin, "The Colouring Matter of Cotton Flowers." 6. Messrs. H. A. Auden, W. H. Perkin, jun., and J. L. Rose, "Experiments on the Synthesis of Camphoric Acid." 7. Mr. W. T. Lawrence, "Methylisomylsuccinic Acid." (Part I.)

FRIDAY, JUNE 16...Quekett Microscopical Club, 20, Hanover-square, W.C., 8 p.m.

Journal of the Society of Arts.

No. 2,430. VOL. XLVII.

FRIDAY, JUNE 16, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****ANNUAL GENERAL MEETING.**

The Council hereby give notice that the One Hundred and Forty-fifth Annual General Meeting for the purpose of receiving the Council's Report and Treasurers' Statement of receipts, payments, and expenditure during the past year, and also for the election of officers and new members, will be held in accordance with the By-laws on Wednesday, 28th June, at 4 p.m.

(By order of the Council),

HENRY TRUEMAN WOOD,
Secretary.

CONVERSAZIONE.

The Society's *Conversazione* will take place at the Natural History Museum, Cromwell-road, S.W. (by permission of the Trustees of the British Museum), on Tuesday, 20th June. The reception by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman, and other members of the Council, will commence at 9 p.m.

The following portions of the Museum will be open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors.

A selection of music will be performed by the String Band of the Royal Artillery in the Central Hall, and by the Red Hungarian Band in the Bird Gallery, commencing at 9 o'clock.

Each member is entitled to a card for himself (which will not be transferable), and a card for a lady. In addition to this, a limited number of tickets will be sold to members of the Society, or to persons introduced by a member, at the price of 5s. each, if purchased before the date of the *Conversazione*. On that day the price will be raised to 7s. 6d.

These tickets will only be supplied to persons presenting members' vouchers (which can be obtained from the Secretary) or a letter of introduction from a member.

Members can purchase these additional tickets by personal application, or by letter addressed to the Secretary. In all cases of application by letter a remittance must be enclosed. Each ticket will admit one person, either lady or gentleman, and must be signed by the member applying for it.

Light refreshments (tea, coffee, ices, claret cup, &c.) will be supplied.

The entrance to the Museum is in the Cromwell-road. Carriages must enter the grounds by the east gate and leave by the west gate. The cards must be given up on entering the Museum.

Visitors arriving or leaving by either of the Metropolitan Railways will be allowed the use of the District Company's Subway, which leads from the South Kensington Railway Station direct into the grounds of the Museum.

Fuller particulars as to the musical and other arrangements will be given in the Programmes which will be distributed on the evening.

The cards of invitation have been issued to members.

Proceedings of the Society.**INDIAN SECTION.**

Thursday, June 1, 1899; the EARL OF ELGIN AND KINCARDINE, K.G., G.C.S.I., G.C.I.E., in the chair.

The CHAIRMAN, in opening the proceedings, said Sir Charles Stevens having filled the high office of Lieutenant-Governor of Bengal he could speak with great authority on the subject he had chosen. He had also sat in the Legislative Council of the Governor-General for several years, and the other members were accustomed to look to him for guidance in all matters appertaining to Calcutta. He would take this opportunity of saying that it always seemed to him that it was Sir Charles Stevens's great knowledge of the place and the people, coupled, of course, with his own sound judgment and fairness, that enabled him to deal so successfully with the time of disturbance which occurred while he was in office, and which, in less capable hands, might have had very serious results. He need not say much with regard to the interest attaching to the Port of Calcutta. Any one looking at it from a geographical point of view would be interested to know how it

came about that a port to which the only access was a tortuous channel where navigation was notoriously difficult and dangerous, should be unrivalled in the commerce of the eastern side of the Indian Peninsula. The student of history would also find much room for speculation as to how the small Bengal village of 200 years ago had now become the first city, politically and commercially, in the Empire of India. He must leave these matters to the reader of the paper; but from his own experience he might say that when he went to India, in 1894, there were many prophecies as to the future of Calcutta, some of them not very hopeful. Some were inclined to regard the Kidderpore docks as a white elephant, which would strangle the trade. It appeared to him then that the amount of coal shipped at those docks was extremely small, and he could not help thinking that it only required time for trade to develop in the same manner that dock accommodation had accomplished in other countries, under somewhat similar conditions. Any anticipations he had then formed had been more than realised by the result, for he believed trade in coal had been trebled since that time. He could not venture to say what the cause of that rapid increase had been. It had been suggested that it was contemporaneous with strikes in England, which could not be without their effect on commerce, even so far away. He had no doubt that there was every prospect of a great development of the coal trade in Calcutta in the immediate future, because the railway from the south which formed the last link of the East Coast Railway was now rapidly approaching completion. It was designed to open out fresh coal-fields, and all coal for export purposes must find its way to Calcutta. He could not forbear saying a word on one cause of anxiety for Calcutta, viz., that it was not now, as it was when he left India, free from plague; but even there there was cause for congratulation. Although the plague had come there it had never spread as it did in other places, and the confidence that now prevailed in the administration would encourage the people there in the belief that the Government would do all that it could to keep the plague in check, and with some reasonable hope of being successful. These points appealed to everybody, but those whose duty it had been to spend part of their lives in Calcutta, would feel a still greater interest in this subject. No one who had witnessed the scene on the Strand in Calcutta at sunset could carry away anything but a memory of beauty. There was there, no doubt, as there was elsewhere, the smoke nuisance, and he could not help thinking that the local authorities might be compelled to do something to mitigate it, and they had all the noises and inconveniences of a busy place. But still it was a scene where the bustling steamer of to-day was found side by side with the more graceful lines and tall spars of the sailing ship of the past; and he could not but think that many would have realised that this was a type of the manner in which the energy and enterprise of our

countrymen had found an outlet. That energy and enterprise which had done so much to create the Calcutta of the present, would do much to maintain its pre-eminence in the future.

The paper read was—

THE PORT OF CALCUTTA.

BY SIR CHARLES CECIL STEVENS, K.C.S.I.

When it was suggested to me that I should read a paper at one of the meetings of this Society my choice fell upon the subject of the Port of Calcutta; for, though I have not the advantage of being an expert in any of the several branches of the administration of the port, I had, as Chairman of the Commissioners for some five or six years, a strong interest in that administration; and, further, I reflected that, notwithstanding the superficiality of my own knowledge, I might serve the purpose of eliciting discussion by other members better informed and more capable of being useful to you than myself. Conscious, as I thought myself at the outset, of the complexity of my subject, I realise it more fully now that I am undertaking to deal with it, and I feel that I ought to ask you beforehand not to be surprised if I omit or treat inadequately topics to which time and consideration might well be given. I propose to sketch rapidly the circumstances which led to the establishment of the Port of Calcutta; next, to compare the trade of the present day with that of early times; I then will show you, shortly, the constitution of the authority which has to manage the affairs of the port, the remainder of my paper will attempt to explain, though partially, some of the difficulties connected with the river Hugli, and the suggestions which have been made for their evasion, mitigation or removal; and I will lay before you, as well as my limits of time and capacity may permit, two important schemes which are now under consideration.

I think that the popular notion of the origin of Calcutta is pretty accurately conveyed by the following lines from some verses called "A Tale of Two Cities" by the most popular poet of the day—Rudyard Kipling.

"Once, two hundred years ago, the trader came,
Meek and tame.
Where his timid foot first halted, there he stayed,
Till mere trade
Grew to empire, and he sent his armies forth
South and north,
Till the country from Peshawur to Ceylon
Was his own.
Thus the midday halt of Charnock—more's the pity!
Grew a city.

As the fungus sprouts chaotic from its bed,
So it spread.
Chance-directed, chance-erected, laid and built
On the silt."

Very different, and (I venture to think) not inferior for the purposes of a poet, is the true history of this great metropolis!

Though the Port of Calcutta is comparatively modern, its very name only having come into use scarcely two centuries ago, it is certain that from remote antiquity an important trade centre has existed in the lower part of the western mouth of the Ganges. Not only local products, but silks, raw and woven, from China found their way round by sea to the Malabar Coast, and probably further; and the oldest records of more modern times show that both in the eastern and western points where the great river met the sea there was very much activity, whether in the way of legitimate trade or of piracy, which preyed upon that trade but could not destroy it. This activity in both directions was considerably augmented by the Portuguese, who, in the early part of the 16th century, found their way to Chittagong on the east, and Sâtgação on the west—the former being named by them Porto Grande, or great harbour, and the latter (the precursor of Calcutta) Porto Piqueno, or little harbour—and enjoyed for more than 100 years the monopoly of the direct European trade, which the discovery of the sea route round the Cape of Good Hope had made possible.

Sâtgação, now represented by a few huts and the remains of a mosque (a relic of its later days under Mohammedan rule) was situated a few miles north-west from the town of Hugli, on the banks of the Saraswati, which, by tradition as well as probability, was once the chief western branch of the Hugli River. When the Portuguese came they were unwilling to expose their seagoing ships to the risks attendant on the navigation of the upper parts of the river, and anchored them in Garden Reach opposite a village named Betor, where huts were annually built for their accommodation, and destroyed after the despatch of the season's fleet. At this place the cargoes from Europe or the Spice Islands were discharged and sent up in country boats to Sâtgação; and the return goods (of far greater value) which had been collected at Sâtgação and the neighbouring marts, were brought here for shipment. The river at Sâtgação gradually silted up, and some of the native merchants began to desert it, and come lower down the river to meet the trade. Among others were

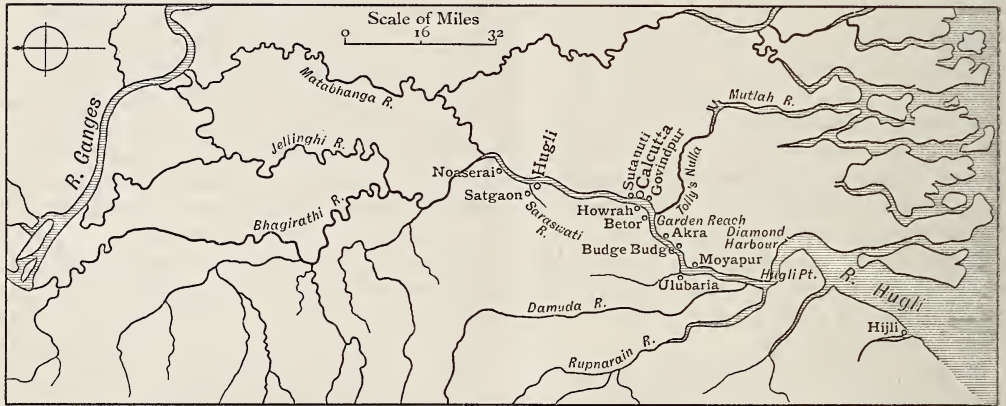

four families of Bysakhs and one of Setts, who cleared the jungles and founded the village of Govindpur on the left bank of the river Hugli, nearly opposite Betor, besides establishing a mart for cotton goods at a place which they called Sutanati, a little higher up. Sutanati was near where the Calcutta Mint and the Mayo Hospital now are, while the site of Govindpur is at present occupied by Fort William and Hastings. It may be pointed out as an advantage in the position of Govindpur that it was close to the trade route served by the branch of the Hugli which is now called Tolly's Nullah, but was at one time the main stream of the Ganges, and is to this day regarded by the Hindus as their holy river.

As Sâtgação became more and more incapacitated for commerce it was abandoned for Hugli, which enjoyed the advantage of being on a river still navigable. The Portuguese were permitted to settle there, and Betor disappeared from history, the site being utilised for the erection of the Tanna Fort, which, with another at Matiyabruj opposite, was built as a defence against the native and Portuguese pirates from Arracan and Chittagong, of whose misdirected energies a testimony remains to us in the "Rogues' River" and "Thieves' River," marked on the oldest English maps.

At length, in 1650, some servants of the East India Company were deputed from Bala-sore, where a station had been made 17 years before, to Hugli for the purpose of opening a trade. The way had been, in a measure, prepared for them by the misfortunes which had fallen upon the Portuguese on the spot through their own ill-behaviour, and by the diminished interest which was now taken in Portugal in Indian affairs. I need not enter into details of the history of our settlement at Hugli; it is sufficient to say that the bravery of our sailors, and the honesty and growing enterprise of the merchants, made them generally welcome; but they became a mark for the rapacity of the native administrators, especially those who were on the spot and could cause immediate annoyance. In the course of 30 years the position became unbearable; and whatever may have been the jealousies and quarrels of the East India Company's servants among themselves, they all agreed in the opinion that it was necessary for them no longer to remain defenceless, depending only on the forbearance of the native authorities, and that they must follow the example of the Dutch and Portuguese, and establish a fortified settlement—such indeed as the Company itself had already

acquired at Bombay and Madras. By no one was this opinion held more strongly than by Job Charnock, who had by this time come to Hugli after 20 years' service under the Company. He stood very high in the favour of his employers, and the eulogistic terms in which they always spoke of him—except when they did not agree with him—were in marked contrast with the singularly frank and uncomplimentary language which they were in the habit of using to, or concerning, their other servants. "A person" (they call him) "that has served us faithfully above 20 years, and hath never, as we understand, been a prowler for himself, beyond what was just and modest." There is no doubt that he was a man of ability and discernment, and that his long experience up country had enabled him to gauge accurately the influences which were working to disintegrate the

enormously superior force of Mogul troops; but by force and stratagem they held their ground for more than three months, and tired out the enemy. Terms were agreed upon; and a promise was given that the English should be permitted to go once more above the forts, and that the ratification of the agreement which Charnock had proposed at Sutanati should be obtained. These promises were not kept, and from Hijli the English went to Ulubaria. Here they remained for three months; but, finding this place unsuited for a settlement, they returned by consent of the natives to Sutanati, or Chuttanatty (as they called it); but Charnock informed the Captain-General of His Majesty's Land and Sea Forces in the North of India, of his firm resolution "not to settle noe trade" till the Sutanati articles should be confirmed, and some security

ESTUARY OF THE HUGLI.

Mogul Empire. The Court of Directors concurred as to the necessity for active measures, and a squadron was sent out to Bengal. A somewhat serious engagement ensued, in which, however, the English suffered but little loss; and the native governor of Hugli was only too glad to let them leave that place, when it suited their convenience to do so. Charnock took the forces to Sutanati, and halted there for some two months. In the meantime, the Nawab at Dacca renewed hostile measures; and Charnock, after taking the Tanna forts, and doing other mischief, abandoned that part of the country as too high up the river to be tenable. He then removed to Hijli, near the mouth of the estuary of the Hugli river, and took possession of that place with a small fort of very little strength. After a short time, the English were attacked and besieged by an

given against any demands that might arise afterwards on account of damages. He was indeed sensible that he had caused an amount of damage, which (to use his own word) was "irreparable" by him, and that "vast numbers of complaints" had been brought against the English to the Durbar. They stayed at Sutanati for over a year this time. Meanwhile, the Court of Directors, being dissatisfied with what had been done, sent out a powerful force, under a certain Captain Heath, with instructions to capture Chittagong. But the letters of the Court show that they had some misgiving owing to their want of knowledge, and that they were willing to accept any place which Charnock might already have settled and fortified; they say that since he "likes Sutanati so well," they were "content that he should build a factory there, but with as much frugality as

may be." Heath, however, against the advice of the Agent, and the majority of the Council, persisted in breaking up the settlement, and proceeding to Chittagong. The expedition proved a complete failure, and six months were spent in fruitless undertakings. At length the Emperor Aurangzeb, fearing that the English contemplated the withdrawal of their trade, and perhaps apprehensive of active mischief from them, caused them to be invited to return. Eventually, after further negotiations, they once more came back to Sutanati, and proceeded to erect, as necessity required, and as cheaply as possible, the humble buildings of mud and thatch which were indispensable for immediate occupation. A few years later, the fort, which had been desired so much and so long, was commenced at Calcutta—a village between Sutanati and Govindpur, where the Post-office now is—and, about the year 1700, the Settlement was for the first time called Calcutta. And long may it prosper as the capital of her Majesty in India!

It is with difficulty that I have restrained myself from entering much more minutely into the fascinating history of these early days. But for this I must refer you to the excellent book by Professor Wilson, of the Bengal Educational Service, on the "Early Annals of the English in Bengal." My obligations to this compilation are none the less, because I have myself studied nearly all his authorities, besides others (I think) which he has not mentioned. I have written so much as I have in the hope that I may assist him in correcting the very prevalent error that Charnock founded Calcutta (as it were) by accident, and that a few merchants, putting on an appearance of simple trade, insidiously by degrees made themselves masters of the country. It was by no such tactics—at any rate, in their dealings with the local chiefs—that our countrymen made their way. At the very beginning of operations in Cuttack, the boldness, not to say audacity and arrogance, of the merchant Cartwright impressed the Governor and obtained concessions for trade; and in all the history preliminary to the founding of Calcutta, I can find no indication of concealment of our national characteristics. The selection of the site itself was most deliberate, and was adhered to by Charnock with great tenacity. The soundness of his judgment has been amply confirmed.

It is impossible to form any very definite idea of the volume of trade either in ancient times or in our own earlier days. Cesare dei Federici, a Venetian merchant, who started on

his Eastern travels in 1565, and visited Sâtgáon, wrote in Italian a short account of his journeys. He describes how the Portuguese traders used to go about from market to market buying goods, and tells us that every year 30 or 35 vessels were laden with rice, cotton cloths of various kinds, great quantities of sugar, myrobalams, long pepper, butter (I suppose ghee), oil, and many other wares. And he tells us that in the harbour of Orissa (apparently the now silted-up harbour of Harishpur Garh), 25 or 30 ships, large and small, used to take in cargoes of rice, different cotton cloths, oil of "zezelin" (made of a kind of seed), butter, lac, long pepper, ginger, myrobalams, and cloths of "erba" or tussur silk. But we have no information as to quantities, values, or destinations.

The first English ship intended for Hugli was the *Lyoness*, despatched in 1650; but the agents at Madras would not permit her to attempt the navigation of the river to that place, and she was sent only as far as Balasore with a cargo of money and goods, valued at £7,336 17s. 5d. How much of this actually reached Hugli I am not aware. We learn from "Bruce's Annals" that, in 1668, the Bengal Stock was of the value of £34,000. But I have not been able to discover any means of estimating the value of the trade of other European nations or of the natives themselves.

We cannot afford time to attempt to trace with minuteness the gradual development of the trade of Calcutta, however interesting such a task might be. Though gradual, it was rapid. In 1682, the stock from Bengal was £230,000. In 1795-6 (a little more than a century from the foundation of the city), 170 ships, of a total burden of 57,696 tons, came to the port from places outside the territories of the three Presidencies, and 184 ships, with an aggregate tonnage of 67,785, went out to such places. In the same year the total value of the inward trade, including that from the coast, Manila, China, Penang, and New South Wales, was estimated at £1,563,200, and the outward at £3,778,704. There was a considerable fall in the next two years, doubtless the result of European politics. The opening of the trade in 1813 caused a great increase in the tonnage, so that in 1817-18, 428 ships, with an aggregate tonnage of 161,346, arrived from beyond Indian limits; but this increase was not maintained. Twenty-five years later, however, the average number of ships entered inward was 646, with a total tonnage of 262,251,

and the average value of the imports and exports taken together, including opium and treasure, for the years 1841-3, amounted to 14 crores and 59½ lakhs of rupees, or nearly three times the total of 1795.

I should have liked to be able to give you the figures of the shipping for the official year just past, but there has not been time enough to obtain them. In the year 1897-98, 1,102 seagoing steamers, with a gross tonnage of 3,311,415, and net 2,116,940, entered the port, and 1,097 such steamers, of 3,275,685 gross and 2,097,895 net tonnage, left it; besides these, 133 sailing ships, of 250,958 gross and 237,477 net tonnage visited Calcutta, and 126, of 232,586 gross and 219,808 net tonnage, went out. The gross tonnage entering the port was thus no less than 3,562,373, or more than 13 times as great as in the average of the years 1841-3. The average had increased from 330 tons (including only the foreign traders) in 1795, 377 in 1817, and 405 in 1841-3 to upwards of 3,000 for steamers and nearly 1,900 for sailing vessels. The average gross tonnage of steamers from European ports *via* the Suez Canal in 1897-8 was no less than 4,033. Thirty years ago more than three sailing vessels to one steamer entered the port; in 1897-8 there were more than eight steamers for one sailing ship. The influence of steam is as evident in the case of sailing ships as in that of steamers, since powerful tugs are now available and make it possible for much larger ships than formerly to use the river with safety. Since 1870 the average tonnage of sailing ships has nearly doubled, while that of steamers has increased by more than 237 per cent. I am not quite certain of the tonnage of the largest steamer which uses the port, but I think it exceeds 6,500. It is difficult, with these figures before us, to realise the hesitation in old days to bring ships of 400 or 500 tons up the river.

The kindness of my friend Mr. Baker, Collector of Customs (and now, I am glad to say, acting as Secretary to the Government of Bengal, and a member of the Provincial Legislative Council), has placed in my hands some statistics, as yet unpublished, of the trade of the year just passed. The total value of the imports from foreign countries alone, without counting the coasting trade, was no less than Rs. 29,65,21,828, and that of the exports Rs. 44,98,66,582; the total foreign trade thus amounted to nearly 75 crores of rupees, or, at the present rate of exchange, about 50 millions sterling. I have not the totals of the coasting trade. In 1897-8 above five-sixths of the total

trade was with foreign countries, and the remaining one-sixth with coast ports; but the latter trade was in that year somewhat abnormally swollen by the movements of grain in consequence of the famine, while foreign imports, in some respects, were injuriously affected by the inability of the poorer classes to pay for them.

In the past year cotton fabrics were by far the most important class of goods imported—a singular reversal of the old course of Indian commerce. Cotton goods account for nearly half the total. Sugar, too, instead of being, as it once was, a large item of export, was imported to the value of nearly 113 lakhs. The importations of salt, which in the old days was made in Bengal, but a considerable proportion of which now comes from Red Sea ports, were worth 52 lakhs. Machinery and railway plant together were of the estimated value of nearly 200 lakhs. The imports of gold amounted to 2½ crores of rupees.

On the export side, too, we see great changes from the course of the old commerce. Jute, raw and manufactured, is now by far the largest item, contributing over a quarter of the total. Even this is much below the ordinary proportion, as there was but a poor crop last year. In 1897-8 the value of raw jute exported was, as nearly as possible, one quarter greater. Next comes tea, which was valued at nearly 757 lakhs; hides and skins accounted for nearly 383 lakhs, and seeds (chiefly linseed) for 411 lakhs.

The exports of seeds were unusually heavy, as the trade was stimulated by failures in La Plata and Russia. The recovery of the trade in rice after the famine, and the high prices of wheat in Europe, caused the item of grain and pulse to rise to the aggregate value of over 522 lakhs of rupees. Of the old staples, opium (432 lakhs), indigo (187 lakhs), lac (86 lakhs), silk (53 lakhs), and saltpetre (34½ lakhs) are the chief that remain. But none of these appear to be in a very flourishing condition, though the attention now being paid to silk culture may have a good effect. The ancient export of very fine cotton cloths, which was once perhaps the most famous of all Indian products, is no longer prominent, if indeed it survives at all. Sugar is but a trivial item—but a small fraction of the value imported.

But a new industry, which has suddenly sprung up, and has grown with astonishing rapidity, is coal-mining. In 1896-7, the exports were 678,580 tons, foreign ports taking about a quarter of the quantity sent to coast

ports. In 1897-8, the total had increased to 1,136,606 tons (the coasts taking a rather larger proportion than before); and, in 1898-9, to a million and a quarter tons. The development of this trade is said to have been assisted by the restriction, in 1897-8, of the output of collieries in Japan, imposed in order to prevent inconvenience in the event of fuel being required for warlike purposes. The Straits Settlements, therefore, have had to indent on Bengal, and the trade is likely to be maintained. For the present, the limitation of the coal trade of Calcutta seems to arise from within the province rather than from without. It has hitherto been determined by the insufficient capacity of the railway to carry the immensely-increased output; but I understand that measures have been taken with the view of providing greater facilities. Raw cotton (68 lakhs of rupees) and twist and yarn (52 lakhs) are the most important of the remaining exports.

The Mohammedan rulers of Bengal appear to have been active in imposing taxes on trade, though the nominal rates were low. We read in Hedges' Diary, of 1682, of "the severall affronts, insolencies, and abuses, dayly put upon us by Boolchund, our Chief Customer," or Collector of Customs at Hugli. But I do not find any record of beneficial regulation, or of improvement of the harbour or river. After the foundation of Calcutta, the first work which has come to my notice is the building of a wharf in front of the fort in 1709-10. In the Bengal "Consultations" for that year, it is said, "we" (that is to say the Council) "find 'twill be a great security to the banks, and a strengthening thereto; 'tis therefore agreed we instantly sett about it, and make it with brick, and raise a breast-work to plant cannon there." A few years later, we find from the letters of the Court of 1727 that the river had been giving trouble, as it does to this day, by cutting the bank on the north side of Calcutta. The Court, while sanctioning protective works, complain that these ought to have been undertaken when the river was "first discovered to gullup away the ground." Not much work of this kind was done for a very long time. A writer, in 1853, says:—"Quays for the approach and use of shipping do not exist in Calcutta, neither are there any fixed landing stages, jetties, or floating piers; partly, perhaps, owing to the questionable nature of the riverside foundations, and the objections to attaching vessels to a quay-wall during the bore, and also from a general absence of energy and enterprise in the local

commercial interest." Moorings, lights, and surveys had, however, been provided, and were well managed by Government, though in a manner which is said to have been "devoid of all the self-improving energy which characterises the institutions of Great Britain."

One reason why the banks remained in a natural state was that "a general and indefinite idea was current that a comprehensive plan would some day be devised for securing greater advantages." Indeed there had been much talk of such improvements, and some were actually carried out; but though Government was far from unmindful of these things, its attention was distracted by too many cares to be fixed with sufficient steadiness on the affairs of the port. At length, in 1870, an Act was passed authorising the appointment of Commissioners for making improvements in the Port of Calcutta; they were created a corporation; and the powers and trusts created and declared by the Act were vested in them. Powers for executing certain classes of works were bestowed on them, and authority was given to Government to confer on them, with their consent, the office of Conservators of the Port, including its approaches. This office was made over to them by notification in 1881; and, with the exception of pilotage fees and hospital dues, all port dues and fees payable under the Ports Act were transferred to their disposal. Changes have been made in the law from time to time which I need not detail. Under the present constitution the Commission consists of a Chairman and Vice-Chairman, appointed by the Government, and 13 other Commissioners, of whom five are elected by the Chamber of Commerce, one by the Trades' Association, one by the Bengal National Chamber of Commerce, and one by the Calcutta Municipality; five are nominated by the Government.

The Government's power of nomination is so exercised as to represent the East Indian Railway and the Eastern Bengal Railway; one nominated commissioner is a merchant, and there are only two official members besides the chairman and vice-chairman. One of these is the Collector of Customs and the other the local head of the Indian Marine. The official functions of both these officers qualify them to render very useful service on the Board. All the remaining members directly represent trade and commerce. The chairman has hitherto been one of the members of the Board of Revenue, the highest executive officers under the Provincial

Government. Not he, however, but the vice-chairman, who is also chief engineer, is the chief executive authority by law, though in practice I used to be largely consulted. The constitution of the Port Commission is sometimes criticised; but I do not think that much practical evil has arisen from such defects as may exist. In the complicated conditions of modern trade it is not possible that every branch can have its representative: but in later times, both the President and Vice-President of the Chamber of Commerce have been Commissioners—greatly to the advantage of both the merchants and of the Port work. For these gentlemen, being at the head of the Chamber, with all its branches and 13 affiliated associations, are in a position to bring before the Commissioners the needs of any department which may not be directly represented. And I cannot mention the Chamber of Commerce without an acknowledgment of the immense service which this distinguished and very ably conducted society is performing in Bengal, not only by promoting and regulating trade, and carrying self-government still further than the Port Commissioners can do, but also by assisting the Administration of the Province with advice and support in affairs of importance.

The work of the Port Commissioners now comprises, with the exception of the pilot services and one or two other departments, the whole charge of the port, which extends for nearly 20 miles from the north of the city to Budge-Budge, at which latter place arrangements have been made for the import and storing of petroleum. They have also to provide for the lighting and survey of the approaches to the port. Their business is divided in the accounts into eight parts, viz.:—Jetties (including the tea warehouses, where tea is received, stored, examined, and, if necessary, re-packed, and the petroleum jetties and stores), inland vessels' wharves, harbour-master's department, Strand Bank lands, new works, Port Trust Railway, port approaches, and dock revenues. The income of the port in the above departments, supplemented by a special toll on imports and exports, which it has been necessary to impose to pay for the dock, amounted in the year 1897-8 to Rs. 61,84,908, or five times that of the year 1872-73, the earliest for which accounts in their present shape are available. The items of railway, port approaches, docks, and special toll, of course do not appear in the accounts of 1872-3; without them the remaining items grew in

1897-8 to about twice and a half what they had been in the former year. I am glad to say that, up to the end of January last, the latest accounts which I have seen show an income for the year 1898-9 of no less than Rs. 51,64,980, or Rs. 1,31,291 more than up to the same period of the year before. The value of the block and reserve funds (without estimating anything for the valuable Strand Bank lands, which are rented from Government) amounted at the end of 1897-8 to Rs. 5,64,04,508. The total amount of outstanding debt due from the Port Commissioners was at the same period (allowing for investments made to meet debentures) Rs. 4,09,50,346, including Rs. 2,87,70,566 due to Government for the construction of the dock. Ninety-two and a-half lakhs had been obtained from the public, and lately another 12½ lakhs were borrowed. The three loans previous to the last were obtained at 4 per cent. and a premium of from Rs. 5 12 a. 6 p. to Rs. 9 per cent. was received. The present price of these stocks in the market is 106; the last loan was at 4½ per cent., and was issued at 107 premium. When money is required the offers are largely in excess of the sum needed. The credit of the Port Commissioners stands next to that of the Government itself; and it is only the general stringency of the money market which prevents these loans from reaching a higher price.

I regret that the limits of what is reasonable do not permit me to enter into details of the various arrangements which have been made from time to time by the Commissioners to meet the public convenience in the several departments. Not to speak of many minor works, they have doubled the extent of the jetties, and greatly improved them, and have built tea warehouses and petroleum jetties and sheds, and laid down moorings at Budge-Budge. Their greatest work has been the construction of the dock at an initial cost of nearly two millions sterling. Since this dock was completed, according to the original plans, they have made large and important additions, with the view of utilising it further and increasing its conveniences; especially (as I shall show later on) they have endeavoured to provide accommodation for the salt trade, and the expansion of the coal exports. They have much improved the lighting and the survey work; and the bad portions of the river are now incessantly examined, and the pilots immediately informed of changes. In 1897-8 the additions to the block consisted of many

items, and cost upwards of fourteen lakhs of rupees. The Commissioners have now under consideration other schemes of great importance, which I propose to lay before you, with such explanation as will, I hope, make their nature and object clear. These have to do with improvement in the river, and extension of the accommodation for vessels in port.

It will be remembered that in the days of the Portuguese the foreign ships did not go higher up the Hugli than Garden Reach. Though our own trade with Bengal through Balasore began in 1633, English ships did not attempt the navigation of the river till long afterwards. I have already mentioned the voyage of the *Lyonesse* in 1650, which was intended to proceed to Hugli. The agents at Madras discussed the project on her arrival, and "having" (as they say) "formerly understood that passage to be full of danger," unanimously voted against the ship's adventuring thither, and permitted her to go only as far as Balasore. The Court at home did not desist from urging their desire that their ships, instead of being discharged and grain-laden for England at Balasore, should be sent up the river, and their "business in the Bay" (as they expressed it) "brought into some decorum." In 1662 they agreed to pay 10s. per ton extra to the chartered ships for all goods that they should "take in within the said Barr of Ganges, and to be at the charge of Boats and Pylotts to attend up and doune the River, and in and out of the Barr." In the same year a Captain Elliott offered to take his ship up the Hugli, and pointed out that the Dutch ships of 600 tons performed this feat, which he declared to be "hazardless." This suggestion was commended to the local agents; but, though aware of the advantages to be gained, they sent no ship up the river, because they had no pilots. A small vessel called the *Diligence* was then built to assist ships in their navigation of the river, and in 1668 the Court renewed the offer of the bonus, and directed that "divers able persons" should be instructed as pilots, and that all persons in the vessels up and down the river, from the youngest to the eldest, should be "put upon taking Depths, Sholdings, setting of Tydes, Currents, Distances, Buoyes, and making of Draftes" (*i.e.*, maps) "of the river." They also, "for a supply of young men to be bredd up," entertained six apprentices on the encouraging salaries of £6 each for the first three years, £7 for the next two, and £8 for the last two. These magnificent allowances were to be

"their provision of clothes," so it is to be presumed that they were fed by their masters. Ten years later the Court directed the enlistment for this work of any that might be willing "among the soberest of the young mates or midshipmen," just as at the present day the Port Commissioners recruit for their harbour-master's department from young officers of ships; but these last are required to produce masters' certificates.

The first English ship to go up the Ganges was the *Falcon*, which, in 1678, conveyed to Hugli direct a cargo of bullion and goods valued at over £40,000. Eventually, as the river became better known, our countrymen became bolder; and in 1686, three ships, carrying from 50 to 70 guns each, ventured up to attack Hugli. Some 70 years later, Admiral Watson reached Chandernagore with ships of the line. These facts are interesting and important, for they tend to show that the Hugli has had a bad character for three hundred or more years, but that channels did exist so late as 150 years ago, which gave access, in cases of necessity, to sailing ships of considerable size, not only as high as Calcutta, but to places which could not now be reached by comparatively small vessels. There is, therefore, no doubt whatever of the deterioration of the river down to Calcutta; but no data exist from which this can be estimated, or from which we can draw any certain inference as to whether the process has reached its limit. I need hardly say that the Hugli is not an independent river, but one of the mouths of the Ganges, formed mainly by the confluence of the three offshoots of that great stream—the Bhagirathi, Jellinghee, and Matabhanga. The positions of the points of outlet of each of these vary much, from time to time, and their state and depth have also changed considerably under different conditions of the channel of the Ganges. Mr. Vernon-Harcourt (who, as I shall explain later on, specially studied the river) tells us, that in the case of the Bhagirathi, the inlet has varied since 1822, within limits no less than 23 miles apart. In olden times, these changes used to occur; for Rennell says that in the eight years of his experience (more than 100 years ago), this branch (the Cossimbazar river, he calls it) moved three-quarters of a mile. And I have found in the India Office some accounts still older—submitted in the early part of the last century—showing charges for the transhipment of saltpetre, which had come from Patna in large vessels into boats capable of passing down the Bhagirathi. These three

offshoots of the Ganges are collectively called the Nuddea rivers, and the ingenuity of the Bengal Public Works Department has been long taxed to the utmost to keep one or more of them temporarily open for boat traffic, which is very extensive. Their efforts have not always been completely successful, and it seems doubtful whether much, at least of a permanent nature, can ever be done to improve and control such inconstant streams. It is satisfactory, therefore, that Mr. Vernon-Harcourt has been led by the evidence before him to regard it as probable that all of them have improved somewhat of recent years. The main reason of the falling off of the river above Calcutta seems to have been the defection of the considerable stream of the Damuda, which used to flow into the Hugli, some distance above the town of that name, but is said to have suddenly, in the last century (I think in 1762), found a fresh outlet at Ulubaria, 16 or 17 miles south of Calcutta, and shortly afterwards at its present mouth (the Mundleghat of the old maps), nearly the same distance still lower down. I venture to hazard the conjecture that the consequent deterioration might have been greater but for the silting up of the rivers Jamuna, Bhoirab, and others, passing through the Nuddea and Jessore districts towards the south-east, which the Bengal Government, and still more, the local district officers, are constantly implored by the inhabitants to reopen. The Hugli can scarcely afford water for them, I fear. I do not think, then, that much can, or need, be done towards restoring the river above Calcutta. Reclamations opposite Calcutta have, we have been told, had a bad effect; but Mr. Vernon-Harcourt reassures us by saying that this has probably reached its maximum. The actual Port of Calcutta seems, therefore, not likely to fall off much unless conditions materially change.

What the Port Commissioners now have under their special consideration is that section of the river which extends towards the south as far as Diamond Harbour—that is to say, the river as distinguished from the estuary. In this section there have been frequent alarms, caused for the most part by temporary changes in the river bed; and there are portions which are always more or less troublesome, and in which there is no margin for deterioration. Of these the most important are the Moyapur Crossing, and the shoal which bears the name of the “James and Mary;” the latter is far the worse of the two, and is the one to which

the attention of the public, as well as the engineers, has been especially directed. I think it will be more interesting to you if I try to make this vital matter clear, than if I cover more ground in a vague way.

I have already mentioned the Damuda River and its present outlet into the Hugli. Almost opposite, but a little lower down, is a projection called Fulta Point. Some six or seven miles above Fulta Point, on the same bank (that is to say, the left bank) of the Hugli is Fisherman’s Point; and almost at an equal distance south is Hugli Point, which in old days was regarded at the beginning of the Hugli River, and was called Hugli River Point. The left bank has a well-marked concave bend each way from Fulta Point; that is northwards between Fulta and Fisherman’s Point, and southwards between Fulta and Hugli Point. The Hugli is nearly three-quarters of a mile wide at Fisherman’s Point, but broadens to about double that width about two miles above its junction with the Damuda. Exactly opposite Fulta Point it narrows again to the former width. It soon, however, broadens again, and by the time it reaches Hugli Point is over a mile wide. As it passes round Hugli Point there is a sudden turn at considerably less than a right angle to the left. Opposite Hugli Point (that is seven or eight miles south of the Damuda), the Hugli receives, almost at right angles, the river Rupnarain, which itself used to be called the Gunga or Ganges, and is believed to have been once the principal western mouth of the great river. The Rupnarain is over three-quarters of a mile broad at this junction, and much broader a little higher up. It is almost in a line with the Hugli below Hugli Point.

The Damuda and Rupnarain together, in the highest floods, are capable of bringing down rather more water than the Hugli above the Damuda can bring. So far as I can understand, the action of the Damuda on the reach of the Hugli below Fulta Point is generally beneficial; for the water brought down is carried across the river and helps to scour a channel in the concave bend below Fulta Point. The action of the Rupnarain on the part of the channel below its confluence with the Hugli appears also to be beneficial. But immediately above the confluence, and more or less in the middle of the river, lies the shoal which is known as the “James and Mary.”

An account of a journey made towards the end of August, 1676, by Sir Streynsham Master, agent at Fort St. George, mentions the violent

eddies at this point, but says nothing of a shoal. The earliest sailing directions, said to have been based on inquiries made in 1684, also mention the eddies but no shoal. Sir Henry Yule was, therefore, inclined to the belief that there was then no shoal. But Mr. Barlow, a very high authority, is much more cautious; he is disposed to think that, unless the conditions have much altered, the shoal existed; but he declines to dogmatise. It is worth notice that Master was travelling in a small sloop, and he expressly says that he passed this point at the top of the tide. The shoal, even if it existed, would thus have given him no trouble. At any rate, it certainly was there in 1694, for in that year the *Royal James and Mary*, a ship from the Spice Islands, was wrecked on it, and gave it her name.

The following brief account is taken from the very interesting report of Mr. Leonard, a Superintending Engineer specially deputed by the Government of Bengal to examine this shoal in 1865. The general character of the "James and Mary" is a sand about three miles long, and one-third of a mile in width, placed about the centre of the river, thus forming two channels, called the Eastern and Western Gut. Some parts of this sand are always so joined on to the bank as to reduce greatly the depth of water in both guts; but during the rains, when there is a large fresh water discharge down the river, it is so joined to the right bank as to quite close the Western Gut. Then, when the fresh water discharge of the river is very small, the sand is detached from the right bank, and so joined to the left as to close the Eastern Gut. Very often, while the changes are taking place, both channels are so bad that there is sometimes as little as six feet of water in the best of them. Mr. Leonard observes that, when one river flows into another, the consequence is that a shoal is formed above the junction and a deep channel below. In the rains, the Eastern Gut is scoured by the freshets and the ebb tide, and the Western Gut closes. In the dry season, the discharge from the Damuda is small, and the ebb tide runs, consequently, more under the right hand bank of the Hugli; then the Western Gut opens and the Eastern Gut closes. The sands forming the "James and Mary" are deposited mainly on account of the diminution of the velocity of the current of the main channel, caused by the great body of the water of the Rupnarain meeting the Hugli at nearly right angles; but the action of the

Damuda water has much to do with the shape and character of the shoal.

Various suggestions have been made for evading or removing this serious cause of danger, delay, anxiety, and expense. A mode of evading it, which has been suggested, and is at first sight obvious, is that of making a short canal, $4\frac{1}{2}$ miles long, at the back of Hugli Point, leaving the river just below Fulda Creek, and entering it again near Hospital Point. This scheme, which was regarded by its parent as "comparatively small and cheap," has been examined by the chief engineer of the port, Mr. Apjohn, who finds that the canal would have to be two miles longer than the estimate, that the initial cost of a narrow width would be $89\frac{1}{2}$ lakhs of rupees, and that of a broader canal would be nearly 146 lakhs, and there would be an annual charge of 2 lakhs and sixty thousand rupees for maintenance and working. A fatal objection to it is that the delay involved in putting a ship into the canal and taking her out, and her slow progress through it, would cause her to lose a tide, and probably to arrive in Calcutta 24 hours later than by the river.

Another proposition is to have a canal from Diamond Harbour to the dock. This would cost $152\frac{1}{2}$ lakhs, or 220 lakhs according to the width, and working and maintenance would add $4\frac{1}{2}$ lakhs per annum. The south-west monsoon blows very strong up the river towards Diamond Harbour, and would (I believe) cause some difficulty at that season. But the river would probably be preferred by ships of moderate and small size, since they would have the advantage of the tide.

A third scheme proposed is to have a ship canal from the dock to the Mutlah River, which lies to the east of the Hugli, and has a different outlet to the sea. On several occasions, especially when it has been feared that the Hugli is changing for the worse, it has been suggested that recourse should be had to the Mutlah; and there are doubtless some here who remember the disastrous attempts made some 25 years ago to create Port Canning on that river, and who have seen, as I have, the melancholy unused streets and tramway, the site of the "Victoria" Dock, and the two T-headed jetties which, I am told, are yet standing. The selection of Kidderpore as the site of the Calcutta Dock was influenced by the consideration that it might some day be conveniently made to communicate with Port Canning. And I think this was a wise precaution, for it is conceivable that the Hugli may

so fall off as to be no longer suitable for the larger vessels. But there are no signs of this calamity at present, and the establishment of a port on the Mutlah may perhaps be postponed till the necessity for it is more apparent. If such a port were established it would be impossible to economise much, if at all, on the Hugli, and at least the cost of lighting, surveying, buoying, and so forth (amounting, I am told, to about 2 lakhs per annum besides initial expenditure), on the Mutlah would have to be incurred by the port. The canal itself would be 32 miles long; with a bottom width of 75 feet it would cost 179 lakhs of rupees; or, if 200 feet wide, it would cost over 262 lakhs. Maintenance and working would require about 5½ lakhs per annum.

Proposals have been made to divert the Damuda River into the Rupnarain. Perhaps the removal of the Damuda current would have the effect of permitting the down current of the Hugli to cross the river at Fulta, and pass down the Western Gut, but the Hugli would, of course, lose the benefit of the Damuda water for this space. It has also been suggested that the Rupnarain itself should be diverted into the Haldia, which enters the estuary lower down. This would obviously be open to the same objection, besides others. Both these proposals have been considered, but no recent expert has advised their adoption. Whatever other reasons there may be in opposition, those of the expense (difficult to estimate, but certain to be enormous), and the disturbance of the tract of country concerned, are final. If the Damuda could be restored to its old bed at Noasarai, doubtless the Hugli would derive much benefit through many miles of its course. I believe that this matter has been looked into, but have not seen any paper on the subject; the results, however, cannot have been encouraging; and no expert (so far as I am aware) has thought it worth while to consider it in detail. I now come to more definite plans.

The question of ameliorating the navigation of the river Hugli was considered by a civil engineer, Mr. W. A. Brooks, in a paper read in 1865 at the Royal United Service Institution. The greater part of the paper had reference to the "James and Mary" Shoals. He describes these (much in the same way as Mr. Leonard) as consisting of a maze of shoals, varying in form and depth with every change of the condition of the river as affected by the preponderating influence, at the time, of either the

freshes or the strong flood tides of the south-west monsoon. He remarks that the object which should be steadily kept in mind by a engineer charged with the improvement of a navigation is to seek to lead the flood currents into the same channel which is taken by the ebbing current; and this, he says, can always be effected. The main feature of the navigation at the point in question consists, he remarks, in the ebb and flood occupying different channels, each alternately crossing at nearly the centre of the reach between Kurchi-bariah on the right bank, and Nila Khal, or crossing creek, on the left bank. Mr. Brooks discusses the feasibility of what he terms "the simple although expensive process" of straightening the navigation by boldly filling up the bight, or concave portion of the channel, abreast of the left bank of the river between Nynan and half a mile below Nurpur, thus forming a new foreshore. Such a work would have the effect of scouring away the point of land at Kurchi-bariah, and a nearly straight and safe navigation would supersede the very dangerous one which now exists. However, he rejects this plan because he considers it imperfect. It would leave untouched the tortuous navigation round Hugli Point, and would leave the strength of the flood current to set up the Rupnarain River rather than up the Hugli. He prefers the plan, which he deems simpler and probably much less expensive, of making a cut of 2,240 yards (a mile and a quarter) across the triangular neck of land on the left bank of the Hugli, the apex of which is Hugli Point, between the "James and Mary" and the Diamond reaches. The right bank of this cut would be concentric with the trend of the right bank of the river higher up between the mouth of the Damuda and Kurchibaria Point, and also with the trend lower down below the Rajnagar Point. Mr. Brooks suggested a narrow cut which, if opened out just before the great land floods, would, from the shortness of the new course, become rapidly the Hugli navigation, and in a few days be a broad and deep channel. To guard against too deep a scour the new concave bank should be faced, and possibly it might be advisable to construct a groin at Kurchibaria Point in continuation of, and concentric with, the concave curve of the right bank above that point. Detailed calculations are not given, but it is estimated that the cost would fall within £200,000.

The discussion on the paper seems to have been not very decisive, but the proposal was sufficiently plausible to obtain some support.

I do not know if it was ever laid before Government. I learn on expert authority that, even if the plan were successful, the cost would have been far in excess of the sum estimated. Mr. Brooks proposed to make the cut on the concave or shorter side, leaving the river to cut its own way on the convex side. But it is highly improbable that this would happen, for the river would try to cut on the concave side. I am told that if money were no object, and the Hugli could be forced to go as Mr. Brooks desired, there is no question that an excellent river would be the result; but these are postulates which cannot be granted. No succeeding expert has approved this plan, though it possesses the merits of ingenuity and of simplicity—at least on paper.

I have mentioned Mr. Leonard's deputation. After much enquiry and study of many river works in other countries, he submitted a valuable report, from which I have already quoted. In a preliminary paper, he suggested that an increased discharge might be obtained from the Damuda at Fulta, and his final advice was that the right bank of the Hugli should be improved at the junction, and a groin thrown out below that point. But the main feature of his scheme was the construction on the left bank of the Hugli of a mile of brushwood spur from Fulta Point, followed by a mile of training wall of burnt clay. The object of this was to throw the downward stream of the Hugli and Damuda combined into the Western Gut, so that it might alternate there with the flood tides. Mr. Leonard also laid great stress on the necessity for works protecting the mouth of the Rupnarain, which is gradually growing wider, and more in a straight line with the lower Hugli.

Sir Charles Hartley, to whom Mr. Leonard's preliminary memorandum was submitted, agreed as to bringing a greater flow from the Damuda, and advised the construction at the "James and Mary" of an "isolated work," a wall of rubble stone. The length should be estimated at 10,000 feet, but, in practice, he said, should stop considerably short of the extreme upper and lower limits of the shoal, and should only be continued thence for such lengths, and in such directions as experience might dictate. If this work were carried up to half tide level, it would not encroach on the tidal area, which he thought it very important to maintain, and would keep up a constantly good navigable channel. The work would form an artificial island, and probably the

necessary scouring would be effected by the current.

There was no immediate practical result from these discussions, though they tended to increase knowledge, and prepare the way for future engineers.

In the year 1895 the condition of the Hugli suddenly became such as to cause some inconvenience and greater alarm. This was no new incident in its history, and our experts hoped and believed—with justice, as events have shown—that it would not be long before the channel would recover its condition of comparative efficiency. The mercantile community very naturally hesitated to believe that nothing could be done, and it was suggested that an engineer, who had made the amelioration of rivers his special study, should be brought out to examine the Hugli and, if possible, make recommendations for its improvement. It was thought wise to consent, and since Mr. Vernon-Harcourt's well-known eminent qualifications pointed to him as suitable for this task, he was invited to undertake it. He came to Calcutta, and whether his conclusions are accepted or not, there is perfect unanimity as to the thoroughness and minuteness of his enquiries, and (I believe) as to the soundness of his views as to history and facts. All authorities concur in acknowledging the great value of his report, and all agree with him in his objections to schemes which had already been proposed.

His own proposals cover the improvement of the river in other parts, but I have only time to bring to your notice those which refer to the "James and Mary" Reach—the one eminently dangerous and inconvenient obstacle in the way of the navigation. He considers that dredging would on occasions be useful, but that this expedient alone would be of little or no effect. He holds that Mr. Leonard was right in desiring to lead the descending current gradually from about Fulta Point towards the Western Channel (or Western Gut as it is called), so that the freshets and the flood tides should be directed into one channel. But he thinks that Mr. Leonard's proposed training works, which were to be some two miles in length, would not go low enough down to secure this object, or to make the descending current adequately scour the western side of the central shoal to provide a large enough channel for the concentrated currents. And he objects to the proposed system of spurs, as one which later experience has discarded in favour of longitudinal training walls. In

making his own suggestion, he says that, for reasons given by him, it is evident that the improvement of the "James and Mary" Reach can only be effectually accomplished by training the channels of the freshets and ebb tide, from below Fulta Point, by a gradual bend into the Western Gut. Moreover, the width of the low-water channel must not be reduced anywhere within the limits of the channel through the narrow neck at Fulta Point, in order not to impede the progress of the flood tide up the deepened channel; and, for the same reason, the training wall should be kept at as low a level as practicable, consistently with its leading the descending current into the Western Gut. In accordance with these principles Mr. Vernon-Harcourt's proposal is that a training wall, slightly over four miles in length, should be constructed from Fulta Point nearly down to the outlet of the Western Gut. Being concave towards the river it would guide the freshets along it towards the Western Gut; and, by leading them against the sandbank in mid-river, would make them enlarge the Western Gut on its eastern side by scour. The training wall should be straight towards the lower end, so as not to narrow the channel unduly; and the lower end itself should be curved outwards from the channel, so as to prevent undue scour at the extremity by the sudden release of the confined current, to facilitate the outflow of this current in a suitable direction, and to afford an ample entrance for the influx of the flood tide. The height of the wall should be fixed at low water of ordinary spring tides, as the favourable concave line of the training wall, guiding the powerful freshets, should succeed in producing a sufficient scour to clear out the channel, being aided at first by a sand-pump dredger; and the lower the wall can be kept the less will it interfere with the tidal capacity of the reach. The cost of the work is estimated on the data assumed at Rs. 20,57,000. Such is Mr. Vernon-Harcourt's design, stated very nearly in his own words.

The Chief Engineer of the port (Mr. Apjohn), and the Deputy-Conservator (Captain Petley), in a joint note prepared for the assistance of the Port Commissioners, pay a just tribute to Mr. Vernon-Harcourt's "most exhaustive and able" report, and agree in thinking that, if such a training wall were constructed, it would probably have the desired effect: but they are of opinion that, if it were successful, the erosion of the opposite bank would be seriously increased if extensive protection works were not constructed; such works would not be diffi-

cult to construct, but would add materially to the expense. If the wall were a failure, the masses of weighted brushwood of which it was composed might find their way to the crossings of the channels, with disastrous effect. They differ from him in two most important respects. First, they judge from the scour caused by the wreck of the *City of Canterbury* (lost on the 17th January, 1896) that the 21 feet estimated as the average depth below low-water of the foundation of the wall ought to be increased to at least 34 feet. Secondly, they think that in tides running at between seven and eight knots, such as would at times be encountered in this locality, the work could not be carried out, unless the crest of the wall were raised above high water, so that the portion of the wall constructed might act as a base from which to extend it further. Supporting their opinion by examples, they proceed to argue that, unless the wall were constructed in this way, it would be necessary to resort to the expedient of a pile jetty along the line of the wall. They doubt the possibility of making such a jetty in such a bottom and such currents, but estimate that, if it be possible, it would cost not less than 44 lakhs of rupees. In their opinion the cost of the whole work would amount to 145 lakhs of rupees, and they are not confident that it would be successful. Mr. Vernon-Harcourt, I believe, has not been convinced by these objections. The Port Commissioners were thus perplexed by the disagreement of their very competent advisers—on the one side an eminent expert of wide experience, on the other two officers of marked ability and unequalled knowledge of local history and conditions. It was a relief to the Commissioners—I can answer for their former Chairman—that the river, becoming more favourable, freed them from the necessity for facing the responsibility of an immediate decision.

But the old tendencies remain, and the inconveniences and risks, even when the Hugli is on its best behaviour, are serious; and in these days of keen competition, merchants and shipowners are not satisfied with things as they are, if they can be made better. Every improvement in a river means bigger ships and greater economy, so that the Commissioners, as Conservators of the Port, must always be ready to consider important suggestions with attention and respect. Such a suggestion has now come from Mr. Lindon W. Bates, an American engineer, who has been consulted regarding very important works in the Scheldt

below Antwerp, and has devised and constructed two powerful dredgers for the Russian Government, to be used in the River Volga.

Mr. Bates, having had the advantage of studying the details collected by Mr. Vernon-Harcourt, lately visited Calcutta; and, though his stay there was very short, received all the help which the officers of the port could give him. He has thus considered himself in a position to make recommendations of his own for the improvement of the river generally, and especially of the "James and Mary" Shoal. He thinks the Port Commissioners well advised in not adopting Mr. Vernon-Harcourt's scheme of putting a half-tide training wall on the concave below Fulta Point. He says that nothing should be put into a river on its cutting bank; walls so placed are difficult to make and maintain, and all training works should be above highest water-mark. The true remedy is one which has only become possible by the powerful tools now available, and consists in the removal of Fulta Point; so that, in the place of the two concaves separated by Fulta Point, there should be one continuous concave from Fisherman's Point to Hugli Point. This involves the removal of a triangular piece of land, about three miles long on the base, and three-quarters of a mile from the base to the apex at Fulta Point. A rectangular tract of about double the area would have to be acquired for the deposit of the stuff excavated. An embankment would be thrown round this whole triangle, which is generally below the high-water of springs. Water would be admitted from the river, and would also be pumped up by two dredgers much larger and more powerful than those constructed for the Volga. These two dredgers would then be taken inside the embankment, and would excavate the triangle, depositing the stuff on the land taken up for the purpose. A shell would be left until the last, which would be removed at a favourable opportunity in the freshets season, so that a channel at least 600 or 700 feet wide would at once be opened under the new concave bank, and the point of the triangle would be removed as the normal width of the river was restored by training walls advancing its right bank into the flats on either side of the Damuda River; Hugli Point itself would also be slightly advanced. The effect of this, Mr. Bates says, would be to cause the deep water below the Point to move out into such a position that the deep channel under the concave bank would merge into it. The whole cost of all the improvements (of

which the "James and Mary" would account for perhaps 19-20ths) is estimated, if done by the Port Commissioners themselves, at 75 lakhs of rupees, including 24 lakhs for the two dredgers, the value of which is, however, taken to be 15 lakhs at the end of the work. The price of the land to be cut away would have to be added, but this would not be large. The work would take about five years. Mr. Bates also offers to undertake the works himself as a contractor, and carry them out for £840,000; or he would execute them, receiving no payment till they were completed and a specified minimum depth and width obtained on the several bars, when a lump payment of £1,000,000 would be made to him, and success and maintenance would be guaranteed by him for twenty years under certain terms of payments and penalties, according as the bars were better or worse than the agreed minimum.

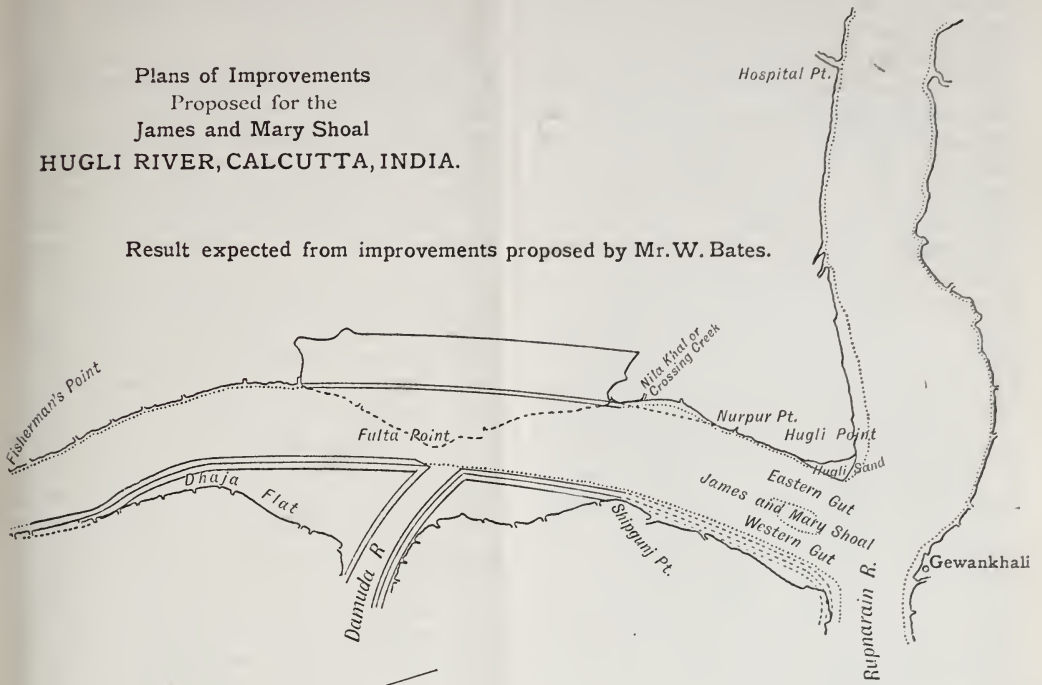

This scheme is approved by the Chief Engineer and the Deputy-Conservator; but the former officer suggests that it should be submitted to a committee of hydraulic engineers for thorough examination.

In the meantime there have been some expressions of doubt and disapproval. An anonymous writer in the *Englishman* newspaper, who has evidently much experience of the river, perhaps as a pilot, has discussed the proposal, suggesting caution, and advising that the western, rather than the eastern, channel should be assisted. In his view it is the flood-tide that does all the scouring in a tidal river; but nothing in the scheme can possibly compel a strong flood-tide to run for any time between Hugli Point and Nurpur Point; and whichever way the former is advanced, it can only create a worse eddy in the flood. The spring tides rush with great force, and, passing over the Hugli Sand, wash its loose and unstable material into the eastern channel, which presents itself at an angle of 50 degrees. There is nothing in Mr. Bates's scheme which can prevent this at a season when the flood-tides are stronger than the ebbs. It is the Rupnarain which causes all the difficulty; if this river did not exist, the flood-tides would be thrown in a regular manner across to Ninan; the Rupnarain "insists on getting a very large share of the flood's best efforts," and "the baulked tide fails, or partially fails, to keep the Western Gut open."

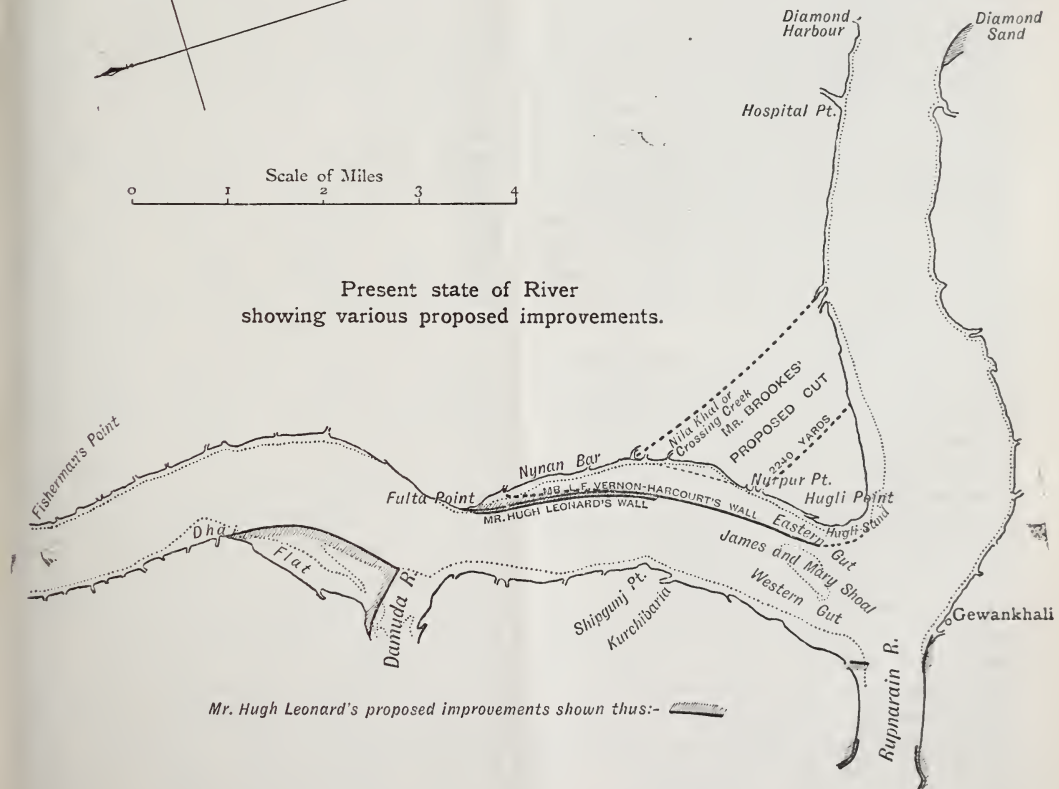

Mr. Vernon-Harcourt also has criticised Mr. Bates's proposals in a letter to the professional paper, *Indian Engineer*, expressed in terms

Plans of Improvements
Proposed for the
James and Mary Shoal
HUGLI RIVER, CALCUTTA, INDIA.

Result expected from improvements proposed by Mr. W. Bates.

Present state of River
showing various proposed improvements.

Mr. Hugh Leonard's proposed improvements shown thus:—

perhaps adapted to promote the vivacity of the discussion. He maintains his own position, that the great object to be aimed at for the removal of the "James and Mary" bar "is to guide the descending current and the flood-tide into a single channel, so as to put a stop to the successive opening out and silting up of each channel in turn, and to combine the present conflicting forces of freshets and flood-tide in deepening the same channel." This object will not be met by Mr. Bates's plan. It is true that the Ninan bar will permanently disappear, but in other respects conditions will be made worse; "for not only will the descending current be placed in more direct opposition to the course of the flood-tide at the lower end of the reach than at present, but the flood-tide current, which is now directed by the projection of Shipgunj Point into the ebb-tide channel below Fulta Point, would, after the dredging away of Fulta Point, by the removal of the ebb-tide channel further off from Shipgunj Point, not reach the channel along the new concave bank till about opposite Dhaja Flat, above the mouth of the Damuda. The projection of Hugli Point further into the river in the direction of Gewankhali, on the mouth of the Rupnarain, would have to be carried a considerable distance; and though such a diversion of the ebb channel might, during the freshets, lead that channel into the deep channel under the concave bank near Gewankhali, it would form an extremely awkward channel, with a sort of right-angled bend, much inferior to the present channel. On the other hand, the strong flood-tides in the latter part of the dry season, running up the river at right angles to a weak ebb, would form a bar, as at present, at the end of the Eastern Gut.

Mr. Vernon-Harcourt quotes, as an illustration of the fallacy of Mr. Bates's views, the method in which the river Weser, between Bremen and its mouth, has been successfully trained by the eminent engineer, Mr. Franzius. Since the above was written, I have been informed that Mr. Vernon-Harcourt has placed the Port Commissioners under an obligation to him by communicating his views to them direct.

I have seen the reply which Mr. Bates has sent to Mr. Vernon-Harcourt, with the request that he will publish it. After making one or two corrections in personal matters, he refrains from discussing the merits of the scheme, except before those who have to decide upon it, but says that he has shown it to the engineer, Mr. Franzius, to whose example Mr. Vernon-Harcourt has appealed, and also to

the principal hydraulic authority on the Scheldt, and that both those eminent specialists have signified their approval.

It is not mine "*tantas componere lites.*" An unlearned person might well be inclined to take refuge in the concluding words used by an engineer, Mr. Robertson, in noting on Mr. Leonard's memorandum: "The river Hugli is so large, the floods in it so great, the nature of the bottom so soft, and the quantity of silt which it brings down is so immense, that any attempt at improving even a single shoal should only be undertaken when it becomes a matter of absolute necessity." But, on the other hand, the maintenance and improvement of the navigation are of such vital importance to the Port of Calcutta and to the province of Bengal, that a scheme which appears to be mechanically practicable, and the cost of which, though large, is not prohibitive, ought not to be lightly thrown aside. I think that the Port Commissioners have blended caution with enterprise in deputing their Chief Engineer to see Mr. Bates's machines in operation, as well as to visit great works of river improvement in Europe and America. In company with two other former Port Commissioners, as well as Mr. Apjohn and Mr. Dawson, of the Bombay Public Works Department, I had lately the pleasure, by Mr. Bates's courtesy, of seeing one of his dredgers for the Volga working on the Scheldt, a few miles above Antwerp. There are two of these dredgers, precisely similar, which are intended to work side by side, but can work independently. The number of ingenious contrivances struck me with a sort of ignorant awe. I am told that these dredgers differ in two ways from the hydraulic, or suction dredgers, which have been successfully used in the Mersey. Instead of pumping the dredged material into hoppers, so that they may carry it away, they discharge it through a long pipe with flexible joints, carried each on a pontoon of its own, either to another part of the river, where it may be thrown without detriment, or to some suitable place on land. This expedient greatly increases the output. The second point is that, as they have to work in quiet waters, the silt is cut by a rotary cylindrical cutter, applied to the end of the suction-pipe and driven by a separate engine. This is said to give a great increase of power in dealing with all soils, and to make the action more steady and certain, giving the power to dredge a practically level bottom. Experience has shown that different parts wear with differing rapidity, and these can be renewed separately as required. We

saw the dredged silt removed to a distance of about 100 yards, but it can be taken four times that distance. Excavation was done at an estimated rate of 60 cubic metres per minute. The total power which can be exerted by the double dredger with its tender (or, as it may be termed, floating workshop) is 5,500 horse-power. The dredger for the Hugli would be much more powerful than these, and I may say that Mr. Apjohn has no doubt whatever that they would be able to do all the work required of them.

The objections raised to Mr. Bates's scheme are, however, not based on the ground of ineffectiveness of the proposed machinery, but on that of inappropriate river engineering, and I am disposed to think that a strong committee consisting of experts, not embarrassed by previously expressed opinions, might with great advantage be appointed to consider and advise upon this very important matter.

With regard to the estuary of the Hugli, all opinions seem to agree that no training works could be undertaken, except at a prohibitive cost, but that the very powerful dredgers now available might with advantage be used in this part. Mr. Vernon-Harcourt especially remarks that "dredging should be employed in the estuary for lowering narrow bases of abnormal height; for aiding the scour of the currents in the channel, and thereby increasing its stability as well as its depth; for facilitating changes in the course of the channel when they have become inevitable, or for opening up the portion of a channel which has become shoaled from temporary causes." For such services the two large dredges proposed by Mr. Bates for Fulda Point would (if suitable) be ready after the execution of the work suggested there. In the meantime it is satisfactory that all authorities appear to agree in holding that the channels of the estuary have not materially changed for the worse within the period for which we have any certain knowledge. So far back as the year 1844, the 12 branch pilots were consulted for the information of a committee considering the dock question. Eleven of them—men who had had the experience of 25 or 30 years—testified that there had been no deterioration. And I have just heard from the highest authority combining scientific with practical knowledge that, allowing for fluctuations from year to year, there is now in his belief a better river than there was in 1814. This is not, however, due to physical conditions only. Captain Petley—I need scarcely say that he is the authority to

whom I refer—tells me that, in his opinion, some fairly deep channel nearly always existed in the estuary and entrance to the river; but, for the want of knowledge, due to imperfect vessels and instruments, many vessels in former times used to be neaped, while under the present system of surveys and constant examinations, hundreds of vessels have been saved from this inconvenience. To this I may add—and I am confident that those present who know the Port of Calcutta will concur—it is to Captain Petley's own skill and constant watchfulness that this comparatively satisfactory state of things is largely due.

I now come to the question of increased accommodation in the port. The want of docks is not one which has lately made itself felt for the first time. So far back as the year 1769 one Benjamin Lacam perceived the desirableness of securing a place where large ships could be careened and repaired without having to go to Bombay, or other distant places. He was struck with the advantages presented by Channel Creek, east of Saugor Island, and succeeded in persuading the Government to give him a grant. Before he could do much in the way of improvements it was found that he was levying tolls on the traffic from Eastern Bengal, and the grant was revoked. He fought against this decision for forty years, and induced two Parliamentary Committees to be favourable to him; but, though he received credit for "faith, zeal, and enthusiasm," as well as a more substantial compensation in the shape of a large annuity, the authorities in India were firm; the grant was not renewed; and the principal memorial now left, so far as I know, is a record some inches thick of controversies conducted with all the freedom of language which characterised the discussions of those simple times. It is just as well; for, though at least one ship (the *Charlton*, East Indiaman, of some 800 tons) successfully passed "New Harbour," the creek is now no longer navigable for large ships.

This controversy must have tended to keep the subject of improved facilities in agitation; we find that various suggestions were made before long. Committees were more than once appointed, and schemes taken into consideration. A dock was proposed in the bed of Tolly's Nullah; docks were proposed severally at Akra, between Akra and Garden Reach, at Howrah, at the site now occupied by the jetties at Diamond Harbour, and at Kidderpore. All these sites were considered with more or less care; and none were accepted,

except the last. In this instance, the formation of a Joint Stock Company was suggested. Here the matter ended, until in 1881 (the question of increased accommodation having become excessively pressing), the Government appointed a committee to consider once more the question of constructing docks at Diamond Harbour. Their report was again submitted to a very strong joint Committee of the Port Commissioners and the Chamber of Commerce, which finally recommended the adoption of Mr. W. Duff Bruce's designs for the construction at Kidderpore of an inner and an outer dock, with a graving dock, a tidal basin, two entrances, and a boat canal communicating with Tolly's Nullah. After a long and careful discussion, both of principles and of details, by the authorities concerned, and taking the advice of experts, the Secretary of State (Lord Kimberley) decided that the inner dock should remain in abeyance, and the rest of the work should go on.

Accordingly, the land necessary for the complete project was taken up, and the scheme undertaken as modified. The cost, increased to some extent by unexpected difficulties and expenses, including discount and interest on loans, was nearly 288 lakhs of rupees, which was advanced, as required, by Government to the Port Commissioners. On the 21st June, 1892, the first ship entered the dock, but the hoped for trade did not come. It is true that in the first three months 117 ships passed the dock entrance; but of them 57 were merely on their way to the Commissioners' Graving Dock, or that of the Government, and many of the remainder were merely lying up, for want of moorings in the river; the total receipts amounted to only Rs. 32,107. The Commissioners did what they could by lowering charges to allure trade to the dock, but declined to recommend to Government any compulsory measures. In the meantime, the interest on the dock loan, amounting to Rs. 11,48,000 per annum, became payable from revenue, and to meet this charge it became necessary to reimpose port dues, which had been abolished in 1884, and were now estimated to produce Rs. 4,75,000, and also to levy a special toll on all goods landed or shipped within the port; this latter was expected to bring in Rs. 8,00,000.

In this melancholy condition of affairs a Committee of the Port Commissioners was appointed to find a remedy. Neither goodwill and industry, nor mercantile experience and capacity were wanting, but with the data then

before us the problem seemed insoluble, and a more lugubrious paper than our report I think I have never seen. We could not get over the facts that the steamers belonging to the regular lines, or "Liners" (as we call them), would not use the dock; and neither would consignees of imports take delivery of them there, nor had we any means of inducing the wheat and seed trade (which, as I have already shown above, is a very large item of the exports of Calcutta) to come to us. The only method which occurred to us of utilising the dock was to get the liners to discharge imports at the jetties and take in cargo at the dock; but there were objections, and the liners would not come.

The Government, recognising our difficulties, gave us a little encouragement, and the dock was kept open with a small establishment for such traffic as might present itself. By degrees the superior conveniences and appliances of the dock began to be appreciated, and in the year 1894-5 the income of the dock nearly equalled the working expenses; but the interest and the heavy municipal taxes were left as a burden on the port to be met from the port dues, the special tolls, and the general revenues.

Owing to increasing trade in Calcutta it began, soon after this, to be realised that the jetties were quite insufficient to accommodate steamers both discharging goods imported and taking in goods for export. Long delays occurred before vessels could obtain berths, and the space and appliances were altogether inadequate for the disposal of imports and exports simultaneously without confusion. At length, in concurrence with a suggestion of a Committee of the Chamber of Commerce, the Port Commissioners considered the question whether the jetties should not be confined to imports only, goods for export over the jetties being refused. This plan was extremely distasteful to exporters of fine goods, for whom it was obviously much more convenient that their wares should be put on board ship close to their own offices and warehouses.

There was much controversy: but the Port Commissioners, while regretting to be obliged to take a step which might be inconvenient to any branch of trade, regarded this as, on the whole, a less serious evil than the general loss and confusion which had begun to prevail at the jetties. They, therefore, in concurrence with a majority of the Chamber of Commerce and with the approval of the Government, decided to pass the order confining the use of the jetties to imports, though goods for export might still be received at the jetties and railed

to the dock for shipment. In the meantime berths at the dock had been used for loading ships with coal, which showed signs of becoming an important article of commerce. Other places were suggested to which coal could be taken, but all were open to serious objections. The Port Commissioners, in these circumstances, considered it necessary to make provision for dealing with this trade in addition to the general exports in the dock. They, therefore, determined to provide three special berths by deepening and widening a part of the canal which occupied a portion of the site proposed for dock No. 2. At the same time it was ascertained that Kidderpore was convenient for at least a portion of the salt trade; and the Commissioners, with the approval of Government, decided to give accommodation for this also opposite the new coal berths. Besides these arrangements other improvements were carried out, perhaps the most important of which were the extension of the railway facilities between the dock and the jetties, and the adoption of an expedient proposed by Mr. Apjohn, neither complicated nor expensive, by which the entrance lock was practically lengthened 83 feet, so as to admit the larger steamers to the dock. The result of these changes was the increase of the bulk of the imports to 89,111 tons in 1896-7 and 84,061 in 1897-8, and of the exports to 585,000 tons in 1896-7 and 1,140,464 in 1897-8. Of this last large total, 230,838 were jute; 44,327, tea; and 672,767, coal. The income, including receipts from the graving dock, had risen to Rs.11,81,731, and the working expenses (which include all charges for handling goods) to Rs.10,12,432, thus giving a balance of about one lakh and seventy thousand rupees towards meeting the municipal charges and interest, together amounting to 12 lakhs and 94,000 rupees. The income up to the end of January in the year just passed has risen to Rs.12,88,109, or more than 36 per cent. over that of the same period in the previous year. Ships of all lines now go to the dock, and many people are wondering how they could have done without it.

It will naturally be objected that what the dock has gained the jetties have lost; but the loss has really been much less than might well have been expected. The receipts at the jetties up to the end of January, 1899, are less by only two lakhs than the maximum which was attained two years ago, and actually exceed the receipts of the whole years 1893-4 and 1894-5, that is immediately before the

change of policy above described was determined on. I cannot give the expenditure of the broken period mentioned above in a form which would be useful for comparison; but, as such expenditure includes handling charges, it is necessarily large, and increases as the bulk dealt with increases. The policy of the Port Commissioners has certainly had a large measure of success in bringing the dock into use; the money spent in improvements and additional facilities has brought trade there. But it is now found that more, and much more, is requisite. Large as the quantity of wheat and seeds exported through the dock has begun to be, the handling of this trade can only be maintained, not to say increased, by providing all the accommodation that those interested can reasonably demand. Again, while even so lately as 1894, it was estimated by people engaged in the coal trade, that before many years 500,000 tons would have to be dealt with, we have seen that the quantity has already risen to between two and three times that quantity. It has, therefore, again been requisite for the Commissioners to improve their three berths into four, by making their T-headed jetties into a continuous jetty, and to propose to Government the construction of two more. The graving dock, too, is now being worked to its utmost capacity, and another is urgently required. A list of these and other necessary improvements, estimated to cost 29½ lakhs of rupees, has been submitted to Government. In some respects the task of the Port Commissioners would perhaps have been easier if the Secretary of State had permitted the construction of the second dock at once, but there are many circumstances pointing the other way, and, on the whole, there seems little room for doubt that, in the long run, the caution exercised will prove to have been for the advantage of the port. It is now, however, becoming evident that the question of constructing the other dock will have to be considered seriously. The work may be said to have practically been begun by making the four coal berths and three salt berths, and there is an urgent demand for two more of the former. In some quarters it is beginning to be doubted whether the Commissioners can make adequate provision for the coal trade at Calcutta, and I see that it has been suggested that the Mutlah river should be utilised. If this suggestion were adopted it would be absolutely necessary that Port Canning should be regarded as part of the Port of Calcutta, and that the Commissioners should remain, as they now are, conservators of

the Mutlah river. I have already indicated a portion of the annual expense which would be incurred in the exercise of this function. It would also be necessary for the Government to undertake the defence of the river, and to enlarge the administrative arrangements. I doubt if the result would be economy to either the Port or the Government. Nor does the measure seem to be necessary if sufficient facilities can be given in Calcutta. An obstacle in the way has hitherto been that, in order to construct the dock, it would be necessary to close the coal and salt berths. But this the Commissioners could not possibly afford. The powerful dredger which I have already described appears now to provide the means of solving this difficulty. It is capable of doing the necessary excavation berth by berth, as it is required, without disturbing the existing trade. The method of work would, it is said, be to dredge out the site of the dock wall foundation to the required depth, and the wall would be constructed by laying in the water blocks of concrete and brickwork. This being done, the remaining spoil excavated from the dock would be thrown in behind the wall to form the wharf. The saving on the old method is estimated to be 15½ lakhs of rupees. Having regard to the importance of dredging in the port, the Port Commissioners have ordered a single dredger of Mr. Bates's design, less powerful than either of those for the Volga, to be delivered in Calcutta for an amount in sterling which I cannot exactly recall, but which will be equivalent to about 3 lakhs of rupees; this is guaranteed to excavate and deliver at a distance of 1,000 feet, one million of cubic yards of spoil per month. I may mention that the whole dredging work done by the two old-fashioned instruments now in the port during the last two years of which I have seen the reports, amounted to 482,000 (or less than half a million) cubic yards. Now that the Commissioners will have this powerful machine at their disposal, I have little doubt that they will proceed with the dock extension as being necessary to accommodate the foreign trade, and free the port eventually from the burden of the special toll. The Commissioners have the land, and indeed are now paying interest on the ten lakhs or so which it cost. If they can get the whole foreign trade to Kidderpore, the economy in management is obvious enough; since, with the exception of the cost of handling goods, it will not be much more expensive to work two docks than one. It is a signal advantage that with the

new appliances no berth need be constructed till it becomes necessary. The jetties on the river bank, I believe, would always be very useful for coasting vessels and others which at present are little cared for. This improvement, it will be seen, is quite independent of the schemes for the "James and Mary"; but it has been estimated that if Government will advance the cost for both enterprises on the same terms as that of the original construction of Dock No. 1 and its appurtenances, repayment being deferred till after the existing debt has been liquidated, the whole debt would be extinguished by 1950. I regard it as most important that the existing trade of the port should not be burdened with further charges for interest on the cost of permanent improvements. The present generation has been, and still is, making large sacrifices for such improvements. To impose still heavier weights upon it would only have the effect of discouraging and embarrassing trade. But I have already exhausted you, I fear, though the topics relevant to my subject are well-nigh inexhaustible; and I must not enter into finance—a matter of which those directly interested will take good care. I will only say this: though I am the last person to suggest recklessness, the experience of the past has satisfied me that readiness to meet the requirements of the different branches of the trade, and in doing so not to shirk any reasonable expenditure, is the only policy which the Port Commissioners can adopt with any hope of ultimately freeing the port from its existing burdens.

On reference to Cesare dei Federici I find that I should have written "oil of zezelin," instead of "zezelin." Since it appears from Colonel Temple's remarks that the word "erba" is of some interest, I transcribe the passage from Cesari dei Federici in which it occurs:—

"... assai panni de erba, qual è una seta che nasce nei boschi senza fatica alcuna de gli huomini, solo quando le boccole sono fatte, e sono grosse, come ogni grossa naranza, hanno pensiero d'andare a raccogliere."

This description makes it quite clear that "erba" was tussur silk. C. C. S.

DISCUSSION.

Colonel R. C. TEMPLE, C.I.E., said this paper had been very interesting to him. If the author would allow him to be academical rather than practical, he might make one or two remarks on that side of the subject. Taking the old trades of Calcutta, Sir

Charles Stevens quoted Federici with regard to one or two articles. The first was what he called "zezelin, a kind of seed"; this was an Italian word, not an Indian one—originally *zerezolina*—and it had become the Anglo-Indian word *gingelly*, or sesamum oil, which the natives called *tīl*. Sir Charles had also quoted the same author for a much more interesting word—*erba*, which he said was tussur silk, and that was what it really was, as he had found out for himself after spending a good many hours in trying to trace it. It turned up in the old English travellers' books as *herba*, but it was not to be found in any dictionary. There was an early notice of it by Alexander Hamilton, the traveller, in 1708, who called it a sort of "tough grass," and so it had remained for many years. It was also quoted by Daniel Defoe in his "Wanderings" in 1725. Yule quoted it correctly in the Diary of William Hedges (1676) as *herba* or *tussur*, and now it appeared a century earlier in Federici's account in 1565. Sir Charles also noticed a third article of trade which was perhaps more interesting than at first sight appeared, viz., *jute*, which was supposed to be quite modern. Yule quoted *jute* as being first known in 1795, but he had found an old ship's captain who said that he landed bags of *jute* in 1746. What interested him in these particular three words was that he had been given to edit an old manuscript, the "Log of the ship *Wake*, kept by Captain Norton," who was directed to go round the coast in 1746, his object being to get to Madras, but he did not manage it, because it had been taken possession of by the French. That gave one some idea of what travelling was in those times. He started to go from Calcutta, and when he got to Pulicat he had to turn back because Madras was no longer English. But the interesting point just now was the navigation of the ship. They had heard this evening that there was a great difficulty in old days in getting up as far as Calcutta. This ship ostensibly started from Calcutta, but, as a matter of fact, she was laden at Kalpi, much lower down, on the 15th of August, and went by the buoys of the Upper and Lower Barrebulle, and by the buoy of the fairway. This particular fairway passage had not been known for the whole of this century. It was already unusable in the days of Horsburgh, in 1809. He then went across Balasore Bay to the Black and Juggernaut Pujoda, and then stuck close to land in sounding. The interesting point here was that in those days all these captains had a book called "The Pilot," which we should call "Sailing Directions." That told them that the 15th of August was the first day they could sail safely out of the river, and at that season, if they stuck close inland, and never got out of 30 fathoms, they got a current which took them down to Madras, whether there was a fair wind or not. That was the case now, and it showed that even as far back as that the navigation of the coast was well understood. They had also heard a good deal about Fulta Point, and he had been given lately to edit a manuscript letter, dated from Fulta

Point, which was of great interest to those who knew Old Calcutta. They had all heard about the Black Hole, and about that period. Now, when the English were going to be attacked, they met together and appointed a commander, Major Minchin, and as adjutant, one Captain Grant. These two worthies were amongst those who bolted from Calcutta on board a ship, and the manuscript in question purported to be a defence by Captain Grant of his conduct. It was dated from on board the *Success Galley*, 13th of July, 1756, from Fulta Point. As a matter of fact, the result of reading the letter would be to show that he was a greater poltroon really than history made him out to be. Turning to more modern times, he was glad to see Sir Charles had spoken very highly of the assistance given by the mercantile members of the Port Committee. He was for some years official President of the Rangoon Municipality, and *ex-officio* Port Commissioner for Rangoon, and, therefore, had great experience of the advice and assistance given to the officials by the mercantile members of those two bodies, and it gave him great pleasure to endorse everything Sir Charles Stevens had said on that point.

Mr. H. H. RISLEY, C.I.E., said Sir Charles Stevens spoke with high authority with regard to the Port of Calcutta, and hereafter when people came to look back upon the changes brought about under his management, they would say that these things happened—"Consule Planco"—when Sir Charles was Chairman. The two points which struck him as of special interest in the paper, were the beginning and the end, the beginning because it enshrined a curious bit of history—nothing less than the origin and growth of Calcutta itself. We are told how some of the native merchants began to desert Sâtgáon, and came lower down, and among others were four families of Bysakhs, and one of Setts. That literally marked the manner in which the native population had grown up. Before the fort and the factory were founded, there was no native population at all. Then there gathered round the factory people who made and sold cloth; the Bysakhs being the title of the great caste of weavers. The Sett, again, was a title of a trading tribe of Rajpoots, commonly known as Marwaris, and thus the people who dealt in money, and those who dealt in cloth gathered at Calcutta. It owed its origin to European enterprise, and around it, as a centre, the native population had by degrees grouped itself. He was also interested in the reference to Tolly's Nullah, which was the holy river of the Hindu. In Sanskrit, the name was Adigunga, or "the original Ganges," and even now it was regarded with the utmost sanctity. Two years ago, when they were in difficulties about the plague, one of the arrangements which had to be made was to find a place where the people were to be burnt. It was supposed you could not burn them in the ordinary ghauts. Then it was suggested that it should be done on Tolly's Nullah, and on consulting the natives

they were all very much pleased with the idea that this ghaut should be put on the banks of Tolly's Nullah. Apart from that, it struck one as a curious contrast, such as you saw all over the East, that the two names should still survive—the European name dating from Colonel Tolly, who excavated the Adigunga—and also the ancient Sanscrit name. Sir Charles had touched on one of the groups of large problems which would have to be settled; it was proposed to straighten out the Hugli, and also to make a second dock. Assuming there were no engineering difficulties which could not be overcome, both these matters required to be exceedingly well considered. He had seen papers recently from which it appeared that there was some sort of intention to commit the Government to make the second dock, without putting as clearly as might be that that was what was really intended. There were T-headed jetties at the coal wharves, and the proposal made was that certain new jetties should be constructed, not as T-jetties, but as a solid wall, the reason being that with a solid wall you could work hydraulic machinery, and with T-headed jetties you could not. But that really meant embarking on a new dock, and it was a proposal which ought to be faced and thoroughly well considered. In considering these points, they might expect the utmost possible assistance from the Chamber of Commerce, and he would add a hope that in delivering their opinion they would give it in such a fashion that there might be no doubt as to what they meant. Even with a new dock and a straightened Hugli, all the difficulties of the trade of Calcutta would not be overcome. There would still be the difficulty of railway communication with the docks. The more work there was at the dock, the more work there would be for the railway to do. It was a very narrow space indeed, and there were mechanical and financial difficulties. As far as he remembered, the estimate was 170 lakhs. Whether it was £70,000 for straightening the Hugli, and £100,000 for the dock, or *vice versa*, did not matter, but that was an engineering estimate, and those who had to do with such things always found that there was a margin, generally a large one, and invariably on the wrong side. Therefore, the question of the sinking fund charges on the outlay was a very serious matter, and the commercial element and the Government ought to realise very distinctly what they were doing when coming to a decision, otherwise the result might be that even a heavier demand would be imposed on vessels entering the port than was already the case, and it would still be cast in their teeth that the Port of Calcutta was the dearest in the world. A very revolutionary proposal occurred to him with regard to this, which he might mention. There had been a good deal of experience on the Continent in connection with the reconstruction of cities, not ports, but still the analogy served. What had happened in Vienna, Cologne, Mayence, and other places was this—the old fortifications became useless owing to the increased range of modern artillery, and

they were got rid of, and the value of the land thus made available had enabled them to finance all the magnificent improvements which took place. Now what was the use of the Fort of Calcutta at the present day? Would it not be possible to abolish the Fort, and to convert the whole of that strip into an area of useful land for commercial purposes? It would be of enormous value, and they would thus be enabled to get rid of the lift bridge, and quadruple the line of rails, and the whole thing might be financed out of the absolutely new value thus created. He recognised that this was a revolutionary proposal, which the military department would not listen to, but still it might be worth consideration. In conclusion, with regard to the plague in Calcutta, he had seen a good deal of it, the third case having occurred in the house where he was living. There was nothing more remarkable than the difference between the progress of the plague in Calcutta and in other places. Elsewhere you might say that, with hardly an exception, wherever a case had occurred it had been a centre of disease, but in Calcutta there was nothing of the sort. There had been sporadic deaths all over the town from time to time, but never anything that resembled a centre of infection. The disease had behaved so far exactly in the way that a friend of his, Dr. Douglas Cunningham, prophesied it would. He said he had no scientific reasons to go upon, but he did not believe there would ever be a bad time in Calcutta. He believed the conditions were such that for some obscure reason they were unfavourable to, and would kill the plague bacillus, and it was certainly remarkable that in the two outbreaks which had occurred the disease had behaved in exactly the way Dr. Cunningham prophesied. The trouble was not the plague, but the panic. The state of things in Calcutta in May, 1898, when a stampede of natives was going on, was most singular. Streams of people, mostly women, were making for all the ghauts on the river. If you stopped them and asked them where they were going, they said they were going home to the country, everybody was going, if they stopped they were all going to be inoculated. The one thing which at that time did more than anything to keep them in Calcutta at their work was the issue of certain blue tickets on which was printed "the bearer of this is not to be inoculated without his consent." It worked like magic, thousands asked for them, even his own servants, but still there was a very formidable exodus, the extent of which could not be exactly ascertained, but it could be gauged by one instance—the Indian Museum, one of the most popular institutions in Calcutta, which was visited by every native who came. He had statistics to show the difference in the attendance of natives at that museum for the two months, May and June, 1898, compared with the same months of 1897. In the non-panic months the total number of visitors amounted to 63,000, but in the panic months they dropped to 9,000. These figures, which were perfectly free from suspicion, inasmuch as they were taken

at a turnstile, showed the effect of a panic of that kind in paralysing trade.

Sir STEUART COLVIN BAYLEY, K.C.S.I., C.I.E., said it was too late to continue the discussion, even had he anything to say, but should there be anyone here anxious to assist in the discussion, he would remind them that the Secretary was always glad to receive the unspoken speeches of gentlemen to be added to the discussion in the *Journal*. He only rose to say how grateful they were to Lord Elgin for the honour he had done them in attending at this the last meeting of the Session. They had had many other distinguished persons in the chair, and many interesting papers, but no paper had been more interesting than the present one, and they had had no greater honour than to have Lord Elgin in the chair.

The CHAIRMAN said he was much obliged to Sir Steuart Bayley. It had been a great pleasure to him to be present and to hear the paper. Sir Charles Stevens had shown the great grasp of the subject, as he had ventured to predict, and it was his pleasing privilege as Chairman to move a cordial vote of thanks to him.

The vote of thanks having been carried unanimously,

Sir CHARLES CECIL STEVENS, in reply, said he had long known Mr. Risley as a financial expert, in which capacity he had enjoyed the benefit of his assistance. He was not unconscious of the financial difficulties to which he had referred, but, as he had said, that was a matter which might well be left to be dealt with by those who were personally and directly interested in the matter. He had perfect confidence that they would deal adequately with it, and, therefore, he had not ventured to make any recommendations himself.

Mr. W. S. SETON-KARR writes:—I wish to send a few remarks on the great question so ably discussed in the paper of Sir C. Stevens. I have, of course, no claim to speak as an expert or Engineer, but having some practical knowledge of the vagaries and changes effected by the Ganges and its distributaries in several of the districts of Lower and Central Bengal, such as Rajshahi, Fureedpur, Jessore, Nadya, the 24 Pergunnahs, and Hugli, I feel warranted in throwing out some suggestions. In the first place, I can state that, between the years 1842 and 1869 inclusive, or my period of active service in India, I never recollect a time in which some proposal or other was not under discussion, in the Press and in official correspondence, in regard to these rivers. There was, generally, a dread that this or that channel was silting up; and there were repeated proposals for dredging, improving, or widening the channels. It has always appeared to me that the enormous volume of water

caused by the melting of the snows in the hills, and the periodical heavy rains in the plains, must find its way to the ocean by some one exit or other; and that if one passage was obstructed, another, somewhere else, would be deepened or enlarged. At any rate, I do not make out that there is any indisputable evidence to prove that the obstacles to the free passage of large ships up the Hugli have increased since the beginning of this century; though fluctuations and changes must always give occasion for watchfulness and anxiety, while Engineers of great experience and ability seem to me to differ as to the precise remedy in each case. To my unscientific view it appears that in dredging and widening existing channels lies the best chance of success. The expense of canals and new short cuts would be very great, and I venture to think that we might confine ourselves to assisting Nature in her obvious efforts and in her own selected channels. I am quite aware that, by a general consensus of opinion, over the plains of the Lower Ganges the general level of the soil has been raised by the accumulation of silt and deposit within the last century, and that a similar rise has taken place in the beds of some Bengal rivers. Indeed, even at this distance of time and place, I could point to spots where the *jhil* has silted up, and the streams have lessened in volume in the last fifty years. Yet, I repeat my conviction that the periodical rainfall amounts to a volume of water not less than it was in the days of Warren Hastings, and that this downpour must find an outlet by some channel or other, into the sea. The mention of the river Bhairab, in the district of Jessore, reminds me that when I first knew that part of the country, in 1845-6, natives, advanced in age, averred that within their own knowledge, or in living memory, it was possible to get to the Ganges or one of its distributaries, by going up the Bhairab in a boat. This, both then and since, was quite impossible. Communication with the Sunderbunds below the station of Jessore was and is quite possible. As regards the Mutlah and Port Canning, I recollect that when the first venture was made some 35 years ago, it was pointed out that the transfer of heavy goods from ship to a terminus more than 20 miles distant from the town of Calcutta would, in all probability, cause the project to fail. On the whole, I should place reliance on dredging the Hugli, and in the New Docks, which seem to me a vast improvement.

Mr. MARTIN WOOD writes:—There can be nothing but praise for Sir Charles Stevens's painstaking, indeed, exhaustive history of the obscure, troublous rise of Calcutta, and the modern expansion of its port appliances. Yet when this story and description are looked at from the other side of India, and when the question of outlay from State funds comes in, a somewhat wider survey seems required than that taken in the paper itself, or in the few subsequent remarks that really touched the subject as a great

public works question of some imperial consequence. Those who, on the banks of the Hugli, regard it from the inside, are naturally impressed with the local sentiment, "here we are, and here we must remain." One must admit that it is scarcely conceivable that the immense aggregate expenditure incurred in the strenuous efforts to create a great port on a situation which, as Lord Elgin neatly implied, is one of the worst that could have been hit upon, shall not continue to be utilised, even at further expense. Those efforts, so graphically described by Sir Charles Stevens, are a record of tenacity and determination, mainly British from Job Charnock forward, to make the best of a bad job. Had Rudyard Kipling's ditty, quoted in the opening of the paper—

"As the fungus sprouts chaotic from its bed . . .

Chance-directed, chance-erected . . . on the silt,"

needed any matter-of-fact confirmation, that is found in this paper. So that, looking before and after, the bard, after all, has the best of the argument; thus "the popular notion of the origin of Calcutta," and of its fitness as a port for ocean-going vessels, holds the field. Though cited with quite a different object, the searching surveys and masterly judgment of Mr. Vernon-Harcourt, and other hydraulic engineers, seem to drive one to a feeling of hopelessness as to the practicability of making Calcutta an effective port for the ever-increasing bulk of modern vessels and international commerce. Very curious and interesting were the surmises, referred to in the paper, as to the rise and progress of the "James and Mary" shoal; but there the apparently irrevocable obstruction remains, and it must have been a counsel of despair when it was proposed to make an artificial island of it—though how to construct retaining walls on the silt will require a double-Dutch engineer to explain. However, adopting the spirit of Sir Charles Stevens's paper, it is forbidden for anyone to despair. Though the present Calcutta port cannot be superseded it may and must be supplemented. It needs an impartial stranger to see this for Calcutta folk cannot; and even the open-minded Bengal Civilian only looks askance in that eastern direction whence alone substantial relief can come. He shares the local sentiment that regards the Mutlah as a bugbear; but nature and physical facts must eventually overbear that shortsighted sentiment, though this derives its strength, as already intimated, from the habitual reliance of business men (many of them birds of passage) or what serves their turn for the time. But they need not shut their eyes to the eastern outlook as if the mere glance in that direction could shake the foundations of the stuccoed palaces around them, and undermine their godowns and the modern jetties on the Hugli; while, *pace* the revolutionary Mr. Risley, that historic memorial Fort William may be left intact. For the right way to grandly supplement the otherwise decaying port of Calcutta has already been entered upon. Once more the "chance-directed," the "chance-erected" Kidderpore docks have shown the way, with the canal behind them, for which Sir

Charles Stevens, with his usual completeness, gives the estimates. These are details which, though big enough, need not foreclose renewed efforts to solve the problem of the Port of Calcutta—while we will consent to use as little as may be the name of "Port Canning the forsaken." The comparison, from the standpoint of harbour engineering principles, may be stated almost in a single sentence. The Mutlah is an estuary with deep water close in shore, and can be easily adapted for the largest ocean-going vessels, which cannot much longer be dragged up the Hugli—a river with its fiercely-rushing tides, now and again overborne with devastating "bores," with its ever-shifting sandbanks, and its low-lying mud-made shores. The choice will have to be accepted, sooner rather than later, if the commerce of Bengal and north-eastern India is to increase, or even maintain its present volume.

Miscellaneous.

AUTOMOBILES IN FRANCE.

An interesting report on Automobiles in France has recently been made by the United States Consul at St. Etienne. He says that not a month passes without some new company starting up, and the variety of systems offered to the public is almost beyond the limits of nomenclature. Naturally, the reason of this keen competition on the part of the different firms is the constant demand of the public to possess the new mode of locomotion, and that, in spite of the costliness of the vehicles. It is now many years ago, shortly after the Franco-Prussian war, that MM. Dion and Bouton, who built engines more or less ingeniously devised to draw carriages, endeavoured to demonstrate the possibility of using steam carriages on the roads. But these motors were independent of the vehicles. The point in consideration was not only to have the motor apparatus form a part of the carriage itself, and of the smallest compass possible, but also to find a substitute for steam. Gas was tried, but was proved inapplicable and expensive; electricity, which Consul Brunot says he doubts not will in the near future supplant every other motive power, was not sufficiently practicable. The choice fell on petroleum, which, up to the present, appears to fully answer the expectations both of the carriage builders and the public. At first, however, the smell of the oil was very disagreeable, but this inconvenience has been almost totally suppressed by most builders, and satisfaction is general. The petroleum motor is a kind of gas motor, furnished with an apparatus for mixing immediately hydrocarbons with air; this apparatus is called a "carburettor." The first patent for petroleum vehicles was taken out in January, 1884, by Gottlieb Daimler, a German engineer. A year later he considerably improved his system, and almost immediately several

great automobile constructors abroad adopted it, and among others, in France, MM. Lavassor, Peugeot, and Rossol de Lille. The superiority of petroleum motors over steam was demonstrated in 1894, in the competition organised by *Le Petit Journal*. Out of twenty-one motor carriages which ran between Paris and Rouen, fourteen were petroleum and seven steam. All the former accomplished the journey without difficulty, while only three of the latter were able to arrive at their destination. Until quite recently, automobiles were only regarded as articles of luxury, but their practicability was so apparent, and impressed the public mind so favourably, that several commercial houses have adopted them for the transport of their goods, while a large cab company in Paris is running about 500 of them for public fares. All this goes to prove the great and increasing interest taken in the new means of locomotion. There are also one or two factors which will assist us to understand why automobiles can be adopted with facility in Europe, and why the idea has been readily seized upon by the French people. It is well known that France possesses the best road system in the world. The highways are admirably kept, and are as smooth as billiard tables, that is to say, the national modern routes. Before the Second Empire, the roads ran over hill and dale, irrespective of all obstacles; but under Napoleon III., who did so much for the improvement of communication, the engineers adopted the better plan of following the course of the streams, so that the roads are almost absolutely level, and, therefore, admirably suited for automobiles. Another factor which has its importance in the subject under consideration is that there is no restrictive legislation on this method of travelling. The automobile carriages are regulated by the same laws that appertain to every other vehicle. So long as the vehicles keep to the right side of the road, do not run at breakneck speed, and have their lamps lighted at dark, they are free to come and go at will. The carriages have generally three grades of speed—slow, moderate, and quick. The petroleum used is called the essence of petroleum, with a specific gravity of 700, and costs about 4½d. per quart. Some employ naphtha; this costs one halfpenny more per quart, and the cost of running is about three farthings per mile.

General Notes.

BERNE EDUCATIONAL EXHIBITION.—The Education Department has received from Berne an announcement that an Educational Exhibition will be held in that city next autumn. The authorities organising the exhibition will welcome exhibits illustrating education in this country. They are specially anxious for exhibits showing methods of physical training and the nature and organisation of school games. Communications from those willing to take

part in the exhibition should be addressed direct to the Director, Schweizerische Permanente Schulausstellung, Bern, from whom further particulars can be obtained.

ELECTRIC CABS.—The *Electrical Engineer* gives particulars of the improvements made in the London Electric Cab Company's vehicles, which are now on the road again. The electric motors have been increased in power from 2½-horse power to 3½-horse power. The motors are mounted on a hinged tray at the back of the cab, and, by means of india-rubber studs, jar on the motor and gearing is largely prevented. The driving gear is of the same general type as of the older cabs, and chain driving is still used. In order to reduce the wear on the driving tires, the brake has been made to act on the band wheel, instead of on the rubber tyre itself. Two of these band brakes are provided—one for each of the driving wheels—and in this way the life of the tires will be very largely increased. In addition to this, an electric brake is obtained by means of an additional step on the controller, which provides for five forward speeds and one reversing step in addition. The company is now generating its own current at the rate of 1d. per unit at the switchboard, as against 2½d. per unit during the day and 4d. per unit during the night, charged by the Electric Supply Company formerly. The batteries provided are only supposed to propel a cab a distance of 32 miles—which is far less than was formerly announced—but to keep on the safe side an average run of 25 miles with the one set of accumulators is to be recognised.

THE SUGAR INDUSTRY OF INDIA.—A return has been presented to the House of Commons showing for the years 1882-83 to 1898-99 inclusive (1) the quantity and the value of imports of sugar into India from Germany, Austria, and Mauritius; (2) the acreage of sugar-cane cultivation in the several provinces of India; (3) the quantity of refined Indian sugar exported from Bengal and the North-West Provinces to other provinces of India and to the native States; and (4) the quantity of Indian sugar, refined and unrefined, exported to Ceylon, to the United Kingdom, and to other countries. The quantity imported from Germany steadily increased from 1889-90 until 1897-98, when it reached a total of 1,203,309 cwt., but during 11 months of 1898-99 it was only 396,352 cwt. The supply from Austria was 3,087 cwt. in 1889-90, 945,745 cwt. in 1897-98, and 921,804 cwt. in the 11 months or 1898-99. The arrivals from Mauritius have not varied very much during the above ten years, and the figures for the 11 months of 1898-99 were 1,592,630 cwt., which is more than for any previous complete year. The total acreage under sugar-cane in India has fluctuated a little from year to year, with, on the whole, a tendency to increase until 1891-92, but since that year, when it reached 3,100,147 acres, it has fallen off, the area for 1897-98, the last year given, being only 2,675,763 acres. This latter figure includes, however,

an estimate for Bengal. The exports of refined sugar from Bengal to other parts of India had fallen off a good deal up to 1896-97, the last year for which statistics are available, but those from the North-West Provinces and Oudh to other provinces have been fairly maintained since 1886-87, though they have diminished since 1893-94. The shipments of sugar, refined and raw, to over-sea countries, including Ceylon, have fallen off very much during the 17 years under review, and especially since 1889-90. In that year the export to the United Kingdom was 1,168,354 cwt., in 1897-98 it was 447,070 cwt., and for the 11 months of 1898-99 221,816 cwt.—*Times*.

GERMAN EMIGRATION IN 1898.—The Imperial German Commissioner's report upon emigration in 1898, just published, shows that the bulk of the German emigration is in the direction of the United States. In 1898, 100,978 persons emigrated from German sea ports, viz., 60,486 from Bremen, 39,882 from Hamburg, and 610 from Stettin. Of these emigrants, 17,173 were from the German Empire, viz., 8,826 *viâ* Bremen, 8,170 *viâ* Hamburg, and 177 *viâ* Stettin. The greater part—83,805—were of other nationalities, among whom 38,493 were from Austria-Hungary, 27,853 from Russia, and 14,600 from the United States. The latter were by far the greater part Americans on their way back home, who, though carried by emigrant ships, did not belong to the class of emigrants. From Roumania 855 persons came; from Denmark 276; from other European countries there were still fewer. The principal goal of all emigrants is: the United States. To that country went 88,548; to British America 4,698; to the Argentine Republic 2,521; to Brazil 1,713; to Africa 1,886; to Australia 674; to Asia 302; to Chile 191, and to the West Indies 115. Emigration from German ports has upon the whole increased a little in 1898. The gain is, however, only in the number of non-German emigrants. The United States Commercial Agent at Bamberg says that only a small number of emigrants left in 1898 (as in former years) for the German colonies in Africa, and the efforts of the Hansatic Colonisation Association, formed in order to promote German emigration to Santa Catherina, in South Brazil, have also so far been attended with very scant success.

OIL FOR LAYING DUST.—The *Engineer* describes some experiments in the use of oil for the laying of dust on the line of the Baltimore and Potomac Railroad between Baltimore and Washington. It appears that the oil used is of a very high fire test, and of low gravity. It is said that these experiments have been most satisfactory, especially where the tracks are ballasted with gravel. The non-existence of dust reduces the wear and tear on the rolling stock, preserves the upholstery of the carriages, besides making travel much more comfortable and enjoyable. The oil is said to sink into the ballast on the first application to a depth of 4 in.; destroys vegetation in it,

and remains effective in every way for about a year. A second or third application penetrates below the cross-ties, and subsequent treatment is unnecessary unless a fresh ballasting is used. A specially constructed car for sprinkling purposes is made use of, and connected by a rubber hose with an ordinary tank car in which the oil is carried. The cost of oil per mile of single track is from £6 to £9, depending on point of delivery, and the quantity used is about 2,000 gallons. This is for the first application, and £1 to £1 10s. annually will be a sufficient expenditure for oil in subsequent treatment. About 1,000 miles of track in the United States have been treated in this way.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, JUNE 19...Geographical, University of London, Burlington-gardens, W., 3½ p.m.
Victoria Institute, 8, Adelphi-terrace, W.C., 4½ p.m.
Annual Meeting. Address by Sir Richard Temple.
- TUESDAY, JUNE 20...SOCIETY OF ARTS, 9 p.m. Conversazione at the Natural History Museum, South Kensington.
Statistical, 9, Adelphi-terrace, W.C., 5 p.m. Mr. A. W. Flux. "The Flag and Trade."
Photographic, 12, Hanover-square, W., 8 p.m. Mr. Redmond Barrett, "Retouching."
Zoological, 3, Hanover-square, W., 8½ p.m. 1. Hon. Walter Rothschild, "The Species of Cassowaries." 2. Mr. C. W. Andrews, "The Remains of a new Bird, *Prophaethon shrubsolei*, gen et. sp. nov., from the London Clay of Sheppey." 3. Mr. J. Y. Johnson, "The Antipatharian Corals of Madeira."
Colonial Inst., Whitehall-rooms, Whitehall-place, S.W., 8 p.m. Mr. Hugh C. Clifford, "Life in the Malay Peninsula: as it was and is."
- WEDNESDAY, JUNE 21...Meteorological, 70, Victoria-street, Westminster, S.W., 4½ p.m. 1. Dr. Robert H. Scott, "Heavy Falls of Rain recorded at the Observatories connected with the Meteorological Office, 1871-98." 2. Mr. R. C. Mossman, "Average Height of the Barometer in London." 3. Mr. Joseph Baxendell, "A New Self-Recording Anemoscope."
Geological, Burlington-house, W., 8 p.m.
Microscopical, 20, Hanover-square, W., 8 p.m. Mr. Jas. Yate Johnson, "Notes on some Sponges belonging to the Clonidæ, obtained at Madeira."
Mining and Metallurgy, Geological Museum, Jermyn-street, S.W., 8 p.m. 1. Discussion on paper by Mr. J. D. Kendall, "The Silver-Lead Deposits of the Slocan, British Columbia." 2. Mr. William Blackmore, "A New Type of Mechanical Calciner." 3. Mr. J. F. Wells, "Notes on the Occurrence of Mica in South Norway." 4. T. Graham Martyn, "Notes on an Improved Muffle Furnace for Burning Coke."
- THURSDAY, JUNE 22...Antiquaries, Burlington-house, W., 8½ p.m.
- FRIDAY, JUNE 23...Physical, Chemical Society's Rooms, Burlington-house, 5 p.m.
- SATURDAY, JUNE 24...Botanic, Inner Circle, Regent's-park, N.W., 3½ p.m.

Journal of the Society of Arts.

No. 2,431. VOL. XLVII.

FRIDAY, JUNE 23, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

ANNUAL GENERAL MEETING.

The Council hereby give notice that the One Hundred and Forty-fifth Annual General Meeting for the purpose of receiving the Council's Report and Treasurers' Statement of receipts, payments, and expenditure during the past year, and also for the election of officers and new members, will be held in accordance with the By-laws on Wednesday, 28th June, at 4 p.m.

(By order of the Council),

HENRY TRUEMAN WOOD,
Secretary.

CONVERSAZIONE.

The Society's annual *Conversazione* was held at the Natural History Museum, Cromwell-road, S.W., on Tuesday evening last, 20th inst.

The reception was held in the Central Hall of the Museum, by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman, and the following Members of the Council:—Captain W. de W. Abney, C.B., F.R.S., Mr. Francis Cobb, Major-General Sir John Donnelly, K.C.B., Sir Charles Malcolm Kennedy, K.C.M.G., C.B., Mr. James Sewell Neville, Sir Walter S. Prideaux, and Mr. W. L. Thomas.

The following portions of the Museum were open:—On the Ground Floor—the Central Hall, British Saloon, and Bird Gallery; on the First Floor—the East and West Corridors.

Promenade concerts were given by the String Band of the Royal Artillery (conductor, Cav. L. Zavertal) in the Central Hall, and by the Red Band in the Bird Gallery.

The number of visitors attending the *Conversazione* was 1,664.

EXAMINATIONS.

The results of the Examinations held at the end of last March are now ready, and an advance copy has been sent to each centre of examination.

Copies for gratuitous distribution to each candidate who attended the examination will shortly be sent to each centre. Additional copies can be obtained, price 6d. each.

The dates for the Examinations in 1900 will be Monday, Tuesday, Wednesday, and Thursday, March 26th, 27th, 28th, and 29th.

MEDALS.

The Council have awarded the Society's Silver Medal to the following readers of Papers during the Session 1898-99.

To PROF. GEORGE FORBES, F.R.S., for his paper on "Long Distance Transmission of Electric Power."

To C. H. BOTHAMLEY, F.C.S., for his paper on "Photographic Developers and Development."

To DIXON H. DAVIES, for his paper on "The Cost of Municipal Enterprise."

To JAMES SWINBURNE, for his paper on "Nernst's Electric Lamp."

To J. H. COLLINS, for his paper on "Cornish Mines and Miners."

To PHILIP DAWSON, for his paper on "Electric Traction and its Application to Suburban and Metropolitan Railways."

To WALTER HUNTER, M.Inst.C.E., for his paper on "London's Water Supply."

To SIR WILLIAM HENRY PREECE, K.C.B., F.R.S., for his paper on "Ætheric Telegraphy."

To COLONEL RICHARD CARNAC TEMPLE, C.I.E., for his paper on "The Penal System at the Andamans."

To SIR JOHN SCOTT, K.C.M.G., D.C.L., for his paper on "Judicial Reforms in Egypt in Relation to the Indian Legal System."

To ARCHIBALD LITTLE, F.R.G.S., for his paper on "The Yangtse Basin and the British Sphere."

To STEPHEN WEBB, for his paper on "Intarsia, or Inlaying."

To J. STARKIE GARDNER, F.G.S., for his paper on "The Revival of Tradesmen's Signs."

Miscellaneous.

SCIENCE AND ENGINEERING.*

We have gathered together from all parts of the kingdom to hold our second Metropolitan Engineering Conference; and we welcome here many who, temporarily at home, pursue their work in different parts of the Empire, or in foreign countries. We represent every department of engineering practice, and we are here assembled to discuss questions of great pith and moment affecting the applications of the fundamental principle of energy to further the interests and promote the comfort, health, and happiness of mankind. Engineering does not run in one groove, nor are its votaries Chauvinistic. We endeavour to benefit every race, and we welcome in our midst every nationality. We embrace in our sphere of operations the whole world. We desire to make our home in Great George-street the Mecca of Engi-

* Opening address of the President, Sir W. H. Preece, K.C.B., F.R.S., to the Engineering Conference, Institution of Civil Engineers, June, 1899.

neering; and in furtherance of this idea, I am bold enough to suggest that, at the next Conference, the Council should take measures to secure the presence of some of our members, delegated specially to represent Engineering in our Empire beyond the seas.

This Conference is not international, in the sense of that held at Chicago in 1893, or of that which I understand is contemplated in the year 1901 in Glasgow, in connection with the Exhibition which is to be held there, but it may well be Imperial. In whatever quarter of the globe we find ourselves, membership of this Institution has become a password; and the invariable support accorded to the Institution by its members in India and the Colonies, suggests the desirability of uniting them in a definite and formal manner with our proceedings on such occasions as this.

Conferences facilitate intercommunication among our members, and, by bringing us more into personal and social relations with one another, promote harmony, allay jealousy, and secure progress. Our weekly ordinary meetings are especially convenient for those who live in London; and the audiences are generally restricted to those occupied in the special branch of engineering under discussion at the moment; but these Conferences, in association with our annual *conversazione* and by combination with well-arranged excursions and visits to works, tempt many to come to Westminster who are rarely seen there, and facilitate the interchange of ideas between all the departments of our many-sided profession.

They disseminate knowledge by exciting discussion and extracting opinions from those who have acquired them from the only true master—experience—in every quarter of the world. Our weekly meetings receive and discuss papers selected from those submitted for approval, often of the character of probational essays. They open to the young and rising engineer a means of securing the attention and the support of the *patres conscripti* of his profession; but the discussions set in operation in these Conferences are based on short papers prepared for the purpose by those who have been selected as masters of their particular subjects, and invited by the Council to lay the foundation of our talks.

After very mature consideration the Council came to the conclusion that the objects of our gathering would be best secured by meeting biennially. The reasons that led to this conclusion are financial and administrative. If ever we secure another building—an event by no means improbable and not perhaps very distant, for the whole of this side of Great George-street has been absorbed by the new design for Government offices—I venture to hope that we shall realise the dream of Sir John Wolfe Barry, and have a hall large enough to hold our annual dinner and to receive the whole of our members and their friends in one evening at our *conversazione*—a hall that will vie in splendour with those of the Ancient Guilds of the City of London. No Guild and no Merchant Venturers' Society ever compared in

numbers and universality of operations with this Institution of ours—the home of an association that embraces every clime and knits together by physical agencies the whole world into one connected whole. Each morning's *Times* is the daily journal of the world; we learn by our work what took place yesterday everywhere.

Now we have to give up our own building to the *conversazioni*, and to throw ourselves upon the courtesy of our friends and neighbours for accommodation for the meetings of our various sections. The Mechanical Engineers have spontaneously offered us their new home, and there the sections dealing with machinery and electricity will meet. The Surveyors' Institution—before even their own formal occupation of the building—have given us the use of their meeting and council-rooms, where the sections dealing with railways, harbours, mines, and metallurgy will assemble. The Middlesex County Council have allotted to us their council-chamber and committee-room, where those interested in docks, canals, waterworks, sewerage, gasworks, and shipbuilding will gather and discuss.

The programme shows a plethora of important subjects for discussion. The visits to works will, we hope, provide objects of interest and instruction to every visitor. Their popularity is shown by the applications which have been received from over 1,000 members to take part in them, and on the first day nearly 500 claims had to be submitted to ballot—one-half of which, I am very glad to say, came from our members in the provinces. We are deeply indebted to those liberal and hospitable persons who have so kindly undertaken to meet our wishes in this essential feature of the Conference.

We found it inconvenient and unpractical to print and circulate the proceedings of our first Conference. We already receive four bulky volumes every year, and old members like myself find it necessary periodically to increase the dimensions of our libraries, and would rather experience a diminution than an increase in the number of our publications. The proceedings of the Conference are equivalent to one-and-a-half times the bulk of our annual ordinary meetings, and comprise three times the number of subjects ordinarily discussed in an institution Session. The proceedings are thrown open to the Press, and we hope that the enterprise of those admirable technical papers, that form such a credit to our industries, and such a benefit to our profession, will, by the completeness of their reports and the rapidity of their issue, render full publication on our part unnecessary.

The growth of engineering is illustrated, not only by the increasing number of affiliated institutions, societies, and members, but by the new fields of application which the advancement of knowledge and the progress of civilisation are opening up. At the present moment, in ten distinct associations, more or less intimately associated with our parent institution, there are some 22,700 paying members. *Science*, a

much abused term, is the systematised collection of the facts and laws of nature, and *Engineering* is their practical application to the use and convenience of man. There is a great tendency to put the cart before the horse; science has followed, it has not led engineering. It is their intimate association which is the foundation of all industrial progress. The war of the microbes, the latest development of biology, is a consequence of sanitary requirements. Our knowledge of the diffusion of molecules and the solution of solids have sprung from the investigation into the mechanical properties and constitution of iron and its alloys, and the disturbances of the æther are becoming familiar through the practice of the so-called wireless telegraphy. Facts are derived from accident, observation, or practice; laws are the result of research. Engineers have always appreciated science up to the hilt, but they wish that its special votaries were less dogmatic and more modest.

The fathers of our profession, whose names you see emblazoned on our walls—Smeaton, Cort, Watt, Telford, Stephenson—acquired their science by their own researches when professors were largely teaching nonsense, and text-books were full of errors. We, however, acknowledge our indebtedness to pure science by giving the place of honour over this chair to Newton; and by adding the name of the most accomplished experimenter of the age, and the most modest but clearest expounder of his own great discoveries—Faraday. I had the great satisfaction last Friday to present an illuminated address to the Vice-Chancellor of the University of Cambridge from this Institution, congratulating our honorary member, Sir George Gabriel Stokes, on attaining the jubilee of his professorship—a pure scientific worthy, ranking with those two great masters who have established and taught the principles that we practise. Of the three men who have been raised by our Sovereign to the peerage for their scientific attainments, we claim two—Kelvin and Armstrong on our roll—while Lister, who belongs to the nation, is also an honorary member of our Institution.

We are proud to enrol also among this class of member another peer, Lord Rayleigh, who, if he had not attained that rank by heredity, would certainly have earned it by his grand scientific work—work so accurate and so reliable that it has secured the faith of the British electrician.

The practice of the engineer as the great civiliser has been well eulogised by our distinguished honorary member, Lord Salisbury. The engineer not only immediately follows the military conqueror, but he sometimes even precedes the civil pioneer. Mr. Cecil Rhodes is opening up Africa by the “wonder-working wire.” In a few months there will be an unbroken line of telegraph from Cape Town to Lake Tanganyika. Peace and goodwill are messages thus distributed without fire, blood, or famine.

Before dismissing you to your different sections, to discuss the various questions allotted to you, I venture to allude to some questions that cannot well

be discussed in public, but which may form the subject of conversation among us.

The Lord Chief Justice's Bill for the suppression of illicit commissions is one welcomed by every member of this Institution, and it is most gratifying to find that no suspicion of improper practice has been adduced against our profession. We do, however, hear at times of a dangerous border-ground between consultation work and contracting, which is a pitfall to be avoided and to be surrounded by danger-signals. Again, occasionally, and fortunately rarely, we find the diploma of the Institution converted into an advertisement; this the Council strenuously protests against in the best interests of the entire body.

The examination system introduced just at the epoch of our first Conference, has proved a most unqualified success, and it has been welcomed by none more than by those who are subjected to its troubles. During the last Session, 107 candidates passed the Associate Membership examination, in addition to 31 who qualified by passing exempting examinations elsewhere, and 65 who satisfied the conditions of election by theses. Further, 53 passed the Institution examination for Studentship, whilst 167 qualified in that respect by passing various recognised examinations. Thus we added 423 new names to our roll—all of whom satisfied the examination standards. The Council feel that the system of examination has enhanced the intrinsic value of the diploma of the Institution, and that it has added materially to the dignity and responsibility of the profession. This diploma has become so valuable and so necessary to the practising engineer, that occasionally would-be practitioners improperly assume the title of member or associate. Fortunately criticism is too wide-awake, and the public interest too well served by all who are jealous for the prestige of their profession, to permit deceptions of this kind to escape speedy detection. The position of engineering has rendered it necessary for all new Universities—and especially for the Imperial University of London—to form a faculty of engineering, but the Council of this Institution has deprecated the idea of conferring degrees in engineering. Every engineer must acquire a knowledge of the scientific principles and the mental tools that form the bases and aid the operations of his profession, but he can be an engineer only by becoming an expert in its practice. Examination can test the former qualification alone, and this is what we have introduced. Practical training is not a matter amenable to examination. Hence we consider that degrees in science are quite sufficient to signify the successful completion of a University career, which should be strictly scientific; and that the diploma of the Institution should be the criterion of that professional qualification, which is the result of practice alone. And here may I mention that there is a tendency observable to avoid the condition that those admitted into our junior ranks shall be persons who are or have been *boni-fide* pupils of

corporate members of the Institution. Further, no one can be said to be regularly educated as a civil engineer unless he has passed through the ordeal of the training to be acquired in the workshop and the drawing office. It would be well, for the comfort of the Council, if those who rather lightly, and sometimes thoughtlessly, sign forms for election, would first inquire if the conditions printed on the back of every form were properly complied with.

Let us sincerely hope that this Conference of 1899 will be as successful, as pleasant, and as fruitful as that which took place in May, 1897.

DR. GEORGE SWINEY.

The following notes on Dr. George Swiney appeared some months ago in the *St. Pancras Guardian*. As little is known about this remarkable but eccentric character, to whom the Society is indebted for the bequest of the Swiney Cup, it has been thought well to reproduce them for the benefit of readers of the *Journal*:—

In the burial ground in Pratt-street there is a marble slab, enclosed in a frame of Portland stone, upon which the following inscription may, with some difficulty, be read—

HIC JACET
 GEORGIUS SWINÆUS, MED. DOCT.
 ANGLUS, SCOTUS, ET HIBERNICUS.
 VIXIT SIMPLICITER
 LUBENS OBIT
 12 KAL. FEB. MDCCCLXIV
 ANNO ÆTATIS SUÆ, L.

This stone marks the last resting place of Dr. George Swiney, a somewhat remarkable man, of eccentric habits, long resident in the parish. But for the fact that he left a sum of £10,000 to found a prize for an essay on jurisprudence, and for a course of lectures on geology, his name would have been forgotten long ago, though his extraordinary funeral made a deep impression on the inhabitants of the neighbourhood, and there are perhaps some still living who were present on the occasion. He lived for a time in Sidmouth-street, Gray's-inn-road, his will, dated May 7th, 1831, having been made there. Subsequently he removed to No. 9, Arlington-road, or Grove-street as it was then called, where he died on the 21st of January, 1844. The following account of his death and funeral appeared in the *Illustrated London News* of February 3rd, 1844, where his portrait is also given:—

“This eccentric person died under very extraordinary circumstances on Sunday week [Jan. 21st, 1844] at No. 9, Grove-street, Camden Town, where he had resided for 15 years. Strange stories are related of his birth, though he was acknowledged to be the son of the late Admiral Swiney. He was a relative of the great chemist, the late Sir Humphry Davy. His age was about 50, and not having shaved for the last two years, ‘his beard descending swept his aged breast.’ He lived in almost complete seclusion, his

house having but another inmate, a female, his house-keeper. He went abroad not more than four or five times a year. On Sunday morning becoming nearly insensible, his housekeeper called in Mr. Knaggs, surgeon, of High-street, who, having succeeded in rallying deceased a little, prescribed for him, but he would not take the medicine, and died shortly afterwards.

“The statement in the newspapers, that he died of voluntary starvation, is incorrect; his disease was of the heart, and to such an extent that the medical men present at the post mortem examination were surprised that he could have so long survived.

“Neither was Dr. Swiney of miserly habits, as has been related; he lived in a respectable street, and his house had every appearance of decent and cleanly comfort, without ostentation. His eccentricity bordered on insanity; so that his will is likely to become the cause of immediate litigation.

“Dr. Swiney died possessed of considerable property. He has willed £5,000 to the trustees of the British Museum for the establishment of a lectureship on geology, and a similar sum to the Society of Arts, out of which the first freeholder, whether in England, Ireland, or Scotland, that shall re-claim and bring into cultivation the largest amount of waste land is to receive one hundred guineas, to be presented in a goblet of equal value. This prize gift is to be renewed quinquennially. The testator has appointed five executors, gentlemen of high eminence in literature, art and science, to carry out his last requests.

“The provisions for Dr. Swiney's funeral were very eccentric. He was buried, according to his desire, on Monday last (January 29), in the cemetery of St. Martin's, Pratt-street. From the residence of the deceased to the burial ground, a distance of upwards of a quarter of a mile, the number of persons congregated to witness the funeral procession was so great that a large body of police of the S division, under Mr. Superintendent Carter and Inspector Aggs, were obliged to be present to keep anything like order. By the will three girls were to be chosen as mourners by the chief executor, and to each of them was bequeathed a legacy of £20, besides a similar amount to buy dresses for the three. About a quarter before two the funeral cortège made its appearance, and agreeably to the will of the deceased the coffin was covered with yellow cloth, studded with white nails. On getting into the street a yellow velvet pall, edged with white silk, was thrown over it. Immediately after the coffin came the three young girls, the eldest about 14 years, and the other two about 12 years of age. They were habited in white (according to the will), with violet coloured cloaks. Their head-dress consisted of straw bonnets, trimmed with white satin ribbon. The dresses had a most singular appearance, the wearers appearing more like a party proceeding to a wedding than mourners at a funeral. After these came the mutes, and then the real mourners, habited, not in yellow cloaks, as previously announced, but in the usual mourning habit. In this

order the calvacade proceeded to the burial ground, the crowd being so dense that it was with the greatest difficulty it could proceed, police-officers going first to clear the way. On reaching the ground there was hissing and hooting. The service appointed for the burial of the dead was read in a very impressive manner by the Rev. Mr. Chaplin, the officiating minister, partly in the chapel and the remainder over the grave. At the conclusion of the ceremony, despite the efforts of the police, the mass of people round the chapel was so great that the mourners were compelled to return in hired cabs to the late residence of the deceased. The mourners, of whom Dr. Cox was the chief, consisted of the executors and other friends of the deceased."

The conditions of the bequest of £5,000 to the Society of Arts were varied by a codicil, of the existence of which the writer of the above account was no doubt unaware, and a sum of one hundred pounds contained in a silver goblet of the same value is awarded every five years to the author of the best published work on jurisprudence.

The cup was executed from a design by Maclise, and although premiums were offered for a new design some years ago, none of the drawings sent in were considered satisfactory, and Maclise's design is still adhered to. Dr. Swiney left £100 to the poor of the parish in which he might die, a gold ring to the clergyman who should read the burial service at his funeral, and £50 for a slab of white marble to be placed for his grave. As I have already implied, the stone is much decayed, and the inscription might be re-cut. Perhaps the trustees under the Doctor's will, if they happen to see this, will take my suggestion into consideration.

AN OLD INHABITANT.

It may be added that some few years ago Dr. Swiney's monument was repaired at the cost of the Society of Arts. The slight repairs which were all that it was thought judicious to attempt at the time, have not sufficed to arrest the decay of the stone, and it is now intended to replace the old stone with a new one in facsimile. The attempt to preserve the old one had to be abandoned as hopeless.

ACETYLENE.

At the last meeting of the Royal Photographic Society, Professor Vivian B. Lewes read a paper on "Acetylene," which is reprinted in abstract as follows by the *British Journal of Photography*.

Dealing first with the history of acetylene gas, he said that in 1836 Edmund Davy, nephew of Sir Humphry Davy, read a paper before the Dublin Royal Society, in which he stated that, in the course of some experiments in which he distilled tartrate of potash, he obtained a residue which, when thrown into water, evolved a gas, that gas proving on analysis to be bicarburet of hydrogen, and he went on to

point out its properties, and concluded his paper by showing the marvellous illuminating power of the gas, and prognosticating that it would some day play a very important part in connection with lighting. On reading Davy's paper, it was evident that very little advance had really been made since its date with regard to acetylene, and the facts which he put forward formed as good an epitome of the characteristics and properties of acetylene as could be compiled to-day. After Davy's time, many experiments were made, and in 1859 Berthelot commenced some researches which led to the discovery, in 1862, that acetylene could be built up from its constituents. This was followed by the discovery by Wohler, a great German chemist, that calcium carbide could be made in the electric furnace, and that it was decomposed by water with the evolution of acetylene gas. It was not, however, until 1892 that these experiments were put upon a commercial basis, when a Canadian experimentalist, named Wilson, found, quite by chance, that calcic carbide could be made directly from lime and charcoal in the electric furnace, the same result being arrived at a few months later by the celebrated French scientist Moissan as a step in some of the most beautiful researches ever made. At that time the amount of electricity necessary to make a pound of carbide was very high, but subsequent improvements had rendered it possible to make one ton per year with one electrical horse-power.

Professor Lewes next described the ingot process of making calcic carbide, in use in England and America, and the running process by which arrangements are now being made for the production of about 30,000 tons per annum on the Continent. He remarked that many people thought that if the carbide had a very fine crystalline surface it was perfectly pure, and that if it appeared like grey pig-iron it was impure, but he said that these differences were entirely dependent upon the manner in which it was cooled, and that the latter was often more satisfactory in use than the former.

With regard to the precautions necessary in the storage of carbide, and which were sometimes thought to be vexatious, he said they were not unnecessary, and that in almost every country in the world where they were not insisted upon the history of acetylene had been marked by a considerable number of accidents.

Turning to the subject of generators, the lecturer first showed the method which he described before the Society of Arts in 1895, the calcic carbide being placed in a perforated zinc cage, and plunged into a cylinder filled with water, and the resulting gas being received in a floating bell; and he then classified and described the other methods which have been adopted for the generation of the gas, laying particular stress upon the importance of obviating undue heating in the generator as essential to the avoidance of danger.

The following method was given for ascertaining whether a generator was satisfactory:—Put a small piece of carbide into water, and examine the residue;

if the residue is white, or nearly white, the carbide is of good quality; then use some of the same carbide in the generator, and if, after the generation of acetylene is finished, the residual lime is white, there is no fault to find with the generator; but, if the residue is snuff-coloured, the temperature evolved by the decomposition of the calcic carbide was too high, and the generator is not a good one.

After discussing the various forms of burners suitable for acetylene gas, the Professor alluded to its richness in actinic properties, and its consequent value for photographic purposes, and said its cost would compare most favourably with that of other methods of artificial lighting, both for studio work and for printing.

He concluded by performing a pretty experiment to show that, when a light is applied to acetylene, it burns with a luminous and intensely smoky flame, and that, when a mixture of one volume of acetylene with one volume of air is ignited in a cylinder, a dull red flame runs down the cylinder, leaving behind a mass of soot, and throwing out a dense black smoke.

ELECTRIC RAILWAY CONSTRUCTION IN GERMANY.

Of the most important German cities, Aix La Chapelle, Brunswick, Chemnitz, Dresden, Hamburg, Hanover, Leipzig, Munich, and Stetten have almost completely abandoned horse cars and are supplied by electric roads. In the cities of Berlin, Breslau, Cassel, Cologne, Frankfort-on-the-Main, Düsseldorf, Barmen, Elberfeld, Königsberg (East Prussia), and other places, horse lines are being converted into electric roads, and most of these have suburban electric roads completed. According to the United States Consul at Düsseldorf a large number of electric lines are being constructed in the country districts about Aix la Chapelle, Bochum, Gelsenkirchen, Düsseldorf, Vohwinkel, Elberfeld, Barmen, Elbthal, Essen, Kraiss, Hoerde, Reisingebirge, Waldenburg (Silesia), Witten-Ruhr, and in the mining districts of the Saar (southern Rheinland), and in Upper Silesia. In thirty-five cities and districts, not mentioned in the above lists, electric roads were in the course of construction on 1st September last, in nine of which the roads were completed and put into operation before the close of the year; so that at the beginning of the year 1899 there were 77 cities and districts in the empire supplied with electric roads. In 35 of these places extensions were being made to the lines in operation on the 1st September, 1898, some of which were completed before the 1st of January. From a return which has been prepared on the subject it appears that there were on the 1st September last 888 miles of electric roads as compared with 595 miles at the corresponding date in 1897. There were in September last 3,190 motor cars as compared with 2,255 in 1897. Adding the roads put in operation since the 1st January, 1899, it is estimated that there are now 930 miles of electric

roads, with a total of 1,300 miles of tracks in Germany. From the city of Düsseldorf there are now four suburban electric lines completed. From Düsseldorf to Crefeld about 12 miles, from Düsseldorf to Rattigen about 8 miles, from Düsseldorf to Benrath about 6 miles, and from Düsseldorf to Kaiserwerth about 5 miles.

CARBONS IN BRAZIL.

The State of Bahia is said to be the sole seat of the carbon industry. The carbons have been found for years but there has been no market until the commencement of the present decade, when on account of their hardness they were sought by makers of so-called diamond drills. As the demand grew greater the supply decreased and prices rose. The region in which they are found is in the interior of the State and is reached only after a long and tiresome journey. It is necessary to go by boat from Bahia to St. Felix and then by rail to Bandeira de Mello. This is the edge of the diamond region and carbons are always found near diamonds. The United States Consul at Bahia says that the most productive region is further up the Paragassu river, and to reach it it is necessary to go overland by mule, following a rough and hilly pack trail for a couple of days. It is thought that diamonds and carbons are found all through this section, but on account of the rude methods of mining only the bed of the Paragassu and its tributary the San Antonio, and the side of a range of mountains called Serra das Lavras Diamantinas are worked. The carbons are found in a kind of gravel called *cascalho*, and this occurs in the river bed beneath the silt and on top of a stratum of clay; in the mountains beneath a stratum of rock and above the same stratum of clay, and in the surrounding country beneath several strata of earth. To obtain those in the river bed a place of not more than twenty feet in depth and where the current is not rapid is selected. A long pole is then planted there, and naked native divers go down this pole taking along with them a sack kept open with a ring. They first scrape away the silt and then proceed to fill the sack with the underlying gravel, removing all the gravel down to the clay. As soon as the sack is full the man above in one of the native canoes is signalled to. The bag is raised to the surface with the aid of the diver below, taken to the shore, and placed at a sufficient distance to prevent its being washed away by any sudden rise in the river. This operation is repeated day by day for the six months of the dry season. At the commencement of the rainy season when diving has to be suspended on account of the strong current and great depth of the river, the gravel is washed and examined for carbons and diamonds. The divers are very skillful and many of them can remain below for a minute at a time, there are some who stay as long as a minute and a half. The gravel becomes partly recovered by silt while they are at the surface, thus causing extra work, which would be

avoided by more modern methods. Places where there is greater depth of river cannot be worked at all. The other method of mining consists in drilling through the rock in the mountain side, and by a series of tunnels removing the diamond and carbon-bearing gravel. It is piled up in the dry season and washed during the rainy season by conveying the water down the mountain side in sluices. The greater part of the carbons is found in the mountains because they are more accessible there than at the river bottom. No mining of any importance is attempted elsewhere than above stated, except along the river bank, and little is done there because the water runs in as soon as the carbon-bearing gravel is reached, and with their rude methods the natives cannot remove it fast enough. The reason why no mining is attempted in other places is on account of the lack of water to wash the gravel after it has been raised; the idea has apparently never occurred to those engaged in this industry to use modern mining machinery, or if it did they have not the capital to invest. Carbons are found in all sizes; a very large one was picked up in 1894 on a road where the gravel formation was exposed, and was sold in Paris for 100,000 francs (£4,000). The most valuable ones are those weighing from one to three carats; the larger ones have to be broken, and there is always great loss as they have no line of fracture. Thus the largest carbon found, after being broken into saleable pieces, brought considerably less than £4,000, the cost price. About two years ago there was a local combination to keep up prices, but the chief promoter failed and there has since been no attempt to combine. The price that now prevails is due entirely to the great demand, small supply, and the laborious method of mining. The small supply is due to the crude methods. Frequently a couple of workers will obtain only three or four carbons as a result of their six months' work, and for these they demand and receive a good price. The large export dealers have their business at Bahia and agents in the mining regions, but as the miners keep themselves posted as to the market price the dealers are little more than commission houses.

AGRICULTURAL PRODUCTS OF TOGOLAND.

The principal products of Togoland (a German colony in West Africa, between the British gold coast possessions and Dahomey) are oil palms, coco palms, india-rubber, and coffee. The most important, from the European point of view, is the kola nut, to the cultivation of which great attention is being paid. Regulations have been issued to prevent the wanton destruction of india-rubber trees, and the dealers receive licenses from the Government. Only natives are allowed to collect this product, strangers being forbidden to ply the trade without a special license, which costs £50 a year. It is not allowed to give natives an advance on the year's

yield. According to a recent report by the Second Secretaries of H.M. Embassy in Berlin, the cultivation of the oil palm has not yet been undertaken by Europeans, and remains in the hands of the natives. Good building wood is supplied by the following trees:—*Chlorophora excelsa*, *borassus flabelliformis*, and *eryodendron anfractuosum*. There are six coffee plantations, the number of trees varying from 30 to 3,000. The yield is given as 4,300 kilogrammes (9,479 lbs.). Coco nuts last year were grown in five plantations, varying from 33 to 1,000 in each, and the yield given was 10,000 nuts. New undertakings are in view. In the mountains, five days journey from the coast, the natives are growing coffee with success, and plantations on a large scale, with European capital, will shortly be commenced. The india-rubber tree (*manihot glaziovii*) is grown in the coffee and coco nut plantations. It does fairly well, but suffers from a blight (*Loranthocos*) which does much damage. Cassave (tapioca), yams, maize, and earth nuts are also cultivated with success. An experimental plantation is carried on at Sebbe. It has been found that the trees which do best are mangoes, eucalyptus, banana, bixa orellana, oranges, and coffee. Mulberry trees do well in the rainy season, but three-quarters of them die in the dry season. A new garden is being started at Lome, where native gardeners are being trained. Coffee, manihot, *kikxia africana*, *inophyllum*, &c., are being raised from seed. The following annuals are being grown:—*Ricinus*, *sesamum indicum*, oil plants, maize, *andropogon*, and *corchorus capsularis*.

THE FISHERIES OF NEW SOUTH WALES.

There are stated to be no less than 60 different families of fish, comprising 348 species, frequenting the waters of New South Wales. The edible fish comprise 105 different species, and among the best known may be mentioned the following. The schnapper (*Pagrus unicolor*), the most valuable of all Australian fishes, is found along the whole extent of the coast, and is very abundant. It is a deep-water fish, found generally near rocky points or reefs running out into the sea. The schnappers "school," as it is termed, during the summer months, and are then most plentiful. The young fish, known as red bream, frequent the harbours and estuaries of the coast, but are never found in shallow water. The schnapper is caught by the hook, which it takes freely, as it will attack almost any bait. It sometimes attains a very large size, weighing as much as 30 lbs. The fish cures well, and is said to be equal to the finest cod, and is in every respect superior to ling. The nannigai is a deep-water fish, caught with the hook, and ranks high in public estimation as an edible fish. The supply, according to the Government Statistician of New South Wales, is not large, as the fish is not especially sought after, being chiefly obtained by fishermen in search of schnapper. The nannigai is

scientifically interesting as one of the oldest forms of bony fishes now surviving. The black rock-cod is considered one of the best of Australian fish, and is also a deep-water fish, never captured by the net. It grows to a large size, specimens from 35 lbs. to 40 lbs. being not uncommon, whilst fish weighing over 100 lbs. are met with in the markets. It is found more abundantly in the warmer waters of the north of the colony, where, as a rule, it attains larger proportions than to the southward of Sydney. In the vicinity of the islands lying off the New South Wales coast—the Seal Rocks, Solitaries, Elizabeth Reef, and Lord Howe Island—the black rock-cod may be taken in almost any quantity, and of the largest size. A fish of great size and beauty, known in Australia as the salmon, is found off the coast in prodigious quantities. It has no affinity whatever to the true salmon, and is inferior as an article of food. The flathead, a fine fish, of which there are several varieties, is captured both by the hook and net. It is of excellent quality, and ranks high among New South Wales fishes. There are four species of whiting found in New South Wales waters. The common sand whiting and the trumpeter whiting are both very abundant, but the other two species are more rare. The sand whiting is, perhaps, the fish most in demand in the metropolitan markets, where it is to be obtained all the year round. The jew-fish is the largest edible fish found on the New South Wales coast, attaining sometimes a length of 5 ft. It is found at all seasons, but most frequently during summer. The teraglin is of the same family as the jew-fish, though it does not reach an equal size. The air bladder is large, and of excellent quality, being of great value for the making of isinglass. The mackerel is obtained in enormous quantities off the coast, and sometimes even in the harbours. It is a good fish when eaten fresh, but it decomposes rapidly. The family of mugilidæ, or mullets, is well represented in Australian waters. The sea mullet is a large fish, often attaining a length of 2 ft., and a weight of 8 lbs. It is regarded by some authorities as unsurpassed in richness and delicacy of flavour by any fish in the world, and it visits the shores of New South Wales in countless numbers in the season when it is in the best condition. There are four species of gar-fish found on the New South Wales coast. The Sydney gar-fish is very abundant, especially towards the end of summer, making its appearance in shoals, sometimes of enormous size. The river gar-fish is even of better quality than the last-mentioned, but it is not so plentiful as formerly. The other species are seldom met with. There are numerous other varieties of fish found in the waters of New South Wales, many of which are very valuable as articles of food, but for the most part they are neither so numerous nor so easily obtained as those referred to. Destructive fishes are by no means rare, the shark family being largely represented, not only in the deep sea off the coast, but even in the harbours. The shark, however, is not absolutely valueless. The fins find a

ready sale in the Chinese markets; the skin also has some commercial value, while from the liver is extracted a large quantity of valuable oil, equal in every respect to cod-liver oil. Several varieties of fish which have long since disappeared from other parts of the world are still represented in New South Wales. Amongst these is the cestracion, or Port Jackson shark, whose teeth resemble those of the fossil acrodis found in the mesozoic deposits. During the season the Australian waters teem with herrings, the season of immigration being the last six months of the year. There are four species, but two only are of commercial importance. The most valuable of this family of fishes is the pilchard. The Australian pilchard in a fresh state is equal in excellence to the Atlantic pilchard, and there is every reason to suppose that it can be obtained in quantities sufficient to enable competition to be entered into with the bloater and sardine of Europe. The maray also passes northward at the same time as the pilchard, and in like prodigious numbers, but both species keep well away from the shore. The rivers of the colony produce some most excellent specimens of freshwater fish. The Murray, Murumbidgee, Lachlan, and Darling are the most plentifully stocked, the Murray cod (*Oligorus Mitchellii*) being perhaps the most highly esteemed of their fishes. The silver perch, and several kinds of the percidæ family, so highly prized for their delicacy, are plentiful in the rivers. Little systematic attempt has yet been made to acclimatise European varieties of edible fishes, although success would most probably attend any efforts in this direction, every difficulty having been overcome in Victoria, New Zealand, and Tasmania. Of oysters, two kinds occur on the coast of New South Wales—a large one considered to be a form of the English oyster, and popularly known as the mud oyster, and a smaller sort, the rock oyster.

THE GERMAN TOY INDUSTRY.

Although the little Thuringian town of Sonneberg, the centre of the modern toy industry, is commonly considered as the birthplace of toy making, it appears, according to a German trade journal, that the first attempts in the art were made by the village of Judenbach, situated further to the north-east. By reason of its favourable situation near the Nürnberg Sächsische Geleitsstrasse, a road much frequented ever since the 13th century, and the only means of communicating with Leipsic and Nuremberg, the village could always readily dispose of its crude wooden house and kitchen utensils, and later of its little chairs, tables, animals, cross-bows, swords, guns, and musical instruments. Even long after the art of making woodenware had been introduced in Sonneberg, Nuremberg was still the market for these peasant products, and continued to make the most of the transaction. Not without reason did the city call Sonneberg its Goldtöchlein (little gold

daughter). Not until the Thirty Years war had destroyed all the regular trade communications did the Sonneberg tradesmen themselves begin to travel about with their wares. The inhabitants of Judenbach, on the other hand, would never leave their native village in order to sell their products. While in Judenbach the toy industry did not attain great proportions, in Sonneberg the trade, as early as the 17th century, had grown to such an extent that when public markets were established in Frankfort-on-the-Main, the merchants of Sonneberg were granted equal exemption from taxes and duties with the merchants of Nuremberg. Till the 18th century toys were coloured with poisonous bismuth paints. An important step in the development of the industry was the endeavour to make those parts which were difficult to carve out of some doughy substance (rye flour, mixed with lime water). This substance, however, softened and mildewed when moistened. A decided advance was recorded only when Friedrich Müller, a citizen of Sonneberg, began to use *papier maché*, a substance of which he had heard from a French soldier. The figures were no longer modelled as before, but the plastic mass was now pressed into shape by moulds. By means of this new substance Sonneberg produced its wares with almost mechanical rapidity. Toys are no longer made in the peasants' houses, but in factories. The cost of these new wares was, moreover, considerably reduced—a most significant factor in the manufacture of toys. In the making of dolls but little progress was made. Not until a new method was introduced into Sonneberg, which came from China by way of England, can any great improvement be recorded. From the first Chinese dolls of 1852, with the movable limbs, strung together by cords drawn through the joints, developed the so-called "jointed dolls." In colouring the faces of these dolls, white lead, a poisonous paint, was long employed, until by legislative action its use was prohibited. Nowadays, the innocuous zinc oxide, and similar harmless colours, are used. The hair of dolls, after many failures of other materials, is now made of mohair and the fur of Angora goats. In this manner the toy industry slowly developed to its present state. How numerous are the varieties of toys now made may be inferred when it is considered that the design room of a Sonneberg factory contains from 12,000 to 18,000 designs. In order to maintain the position which they have reached, toy makers are compelled constantly to bring forth new models, and to adapt their products to the tastes and peculiarities of foreign purchasers. Years ago, the Chairman of the Sonneburg Chamber of Commerce proposed the collection of toys made by foreign manufacturers, in order that Sonneberg toy makers might thus be able to acquaint themselves with the wants and peculiarities of foreign markets. Such a collection of models has now been made, and does good service for the manufacturers as well as for the students at the various industrial schools of Thuringia. The toys at present may be

divided into the following groups:—1. Wares made entirely of wood, such as cross-bows, guns, violins, flutes, chess and draught boards, rattles, jumping mannikins, nutcrackers, soldiers, ninepins, rocking-horses, &c. 2. Articles made mostly of wood, such as doll-houses, kitchens, shops, furniture, punch and judy shows. 3. Mechanical toys. 4. *Papier maché* articles, such as harlequins, riders, caricatures of national types, animals covered with felt or leather, shepherd's houses, menageries, figures of Santa Claus. 5. Animals covered with fur. 6. Metal toys, such as tin figures, toy trumpets, weapons and theatres. 7. Figures and toys made of china, burnt clay, stone, and glass. Among these toys may be mentioned toy dishes, marbles, and articles of various kinds made of blown glass. 8. Christmas-tree decorations of glass, metal, and wax. In Lauscha wax is the material most used. 9. Dolls, with wagons, chairs, and swings. Besides Sonneberg, the towns and villages of Watterhausen, Friedrichsroda, Ohrdruf, Hildburghausen, Schleusingen, and Koburg are engaged in the industry. Toy factories are now scattered more or less over one-half of Germany; they are distributed from the Black Forest and the Palatinate of the Sudetic Mountains, and the province of Brandenburg. Of particular importance are the Erzgebirge of Saxony, which on account of their forests and abundant water power, have enabled the manufacturers of Saxony to produce many of the more common toys formerly made in Sonneberg. The most recent statistics show that Germany has exported toys to the value of 40,500,000 marks (£2,025,000), while in 1895 the value was only £1,500,000. Including the toys sold in Germany, the product of the entire German industry is probably worth 50,000,000 marks (£2,500,000), from which 750,000 marks (£37,000), representing the value of toys imported from foreign countries, must be deducted. Sonneberg undoubtedly produces half the toys made in Germany. The two largest buyers of German toys are the United States and England. In 1897 this country imported German toys to the value of 17,000,000 marks (£850,000). To the development of toy manufacture, and to the rise of doll making, is due the increase in the number of export houses in Sonneberg. In the sixties there were about thirty export firms. By 1880 the number had increased to forty-eight, and by 1896 to seventy. According to the latest statistics there are 40,829 persons engaged in German toy manufactures, of which number 44 per cent. are employed in Sachsen, Meiningen. In the region of Sonneberg about 34 per cent. of the population are engaged in toy making, not including those who in addition are otherwise employed.

General Notes.

HAULAGE IN MINES.—At a recent meeting of the Engineers' Club of Philadelphia, Mr. H. K. Myers

read a paper on modern mine haulage, describing the methods applied in American collieries. He estimated that the production of 200,000,000 tons of coal last year required 2,000 miles of railway lines in main roads and 5,000 miles in workings. This showed the importance of the problem of mechanical mine haulage. In order to compare a mule and a locomotive for mine haulage, the author has calculated that both the former and the latter can produce a maximum tractive effect of one-fifth, and an average of one-seventh, of its own weight.

PHOTOGRAPHY A TEST FOR REAGENTS.—Messrs. Lumière Bros.' process of development with acetone, &c., has been put to a novel use by them in detecting the presence of these bodies by their photographic behaviour. To apply the test, 25 c.c. of an aqueous or alcoholic solution of the substance under examination is mixed with double the quantity of solution containing 7 per cent. sulphite of soda, and $1\frac{1}{2}$ per cent. of pyrogallol or a similar hydroquinone solution, and applied to a plate acted upon by light. A similar test solution is diluted with an equal bulk of water, and applied also to an exposed plate, and the two plates are compared. The method is so sensitive, that it will detect formaldehyde (formalin) diluted 25,000 times, acetaldehyde 15,000, and acetone 2,500 times.

MINES IN SERBIA.—Mr. E. Hegner, says the *Mining Journal*, has contributed to the *Montan-Zeitung* an account of the coal-mining industry of Servia. Although Servia has more than enough coal and lignite for its needs, foreign coal is imported every year in increasing amounts. Not more than a dozen collieries are in operation, and most of these are worked in a very primitive manner. The Morava Tertiary basin, near Alexinatz, is described in detail. It is twelve miles long and five miles wide. It is traversed by the State Railway, and contains numerous seams of excellent coal, some of which have been worked for the past fifteen years. The average selling price of the coal is 6.25 francs a ton. The cost of mining per ton is:—Wages, 2 frs.; material, 0.25 fr.; transport to the railway, 1.70 fr.; royalty and administration, 0.45 fr.; total, 4.40 frs.

WOOD PULP.—The process of manufacturing mechanical wood pulp is described by Mr. W. A. Hare in a volume just received, containing papers read before the Engineering Society of the School of Practical Science, Toronto. Within the past two or three years there has been a marked impetus given to the pulp and paper industry in Canada. Wood pulp will, for many years to come, be used to supply the world's demand for a filler in the manufacture of paper, in many of the coarse grades of which it is the only constituent. It is not confined, however, to the manufacture of paper alone, but is made into many useful articles of daily service, the market for which is increasing rapidly. No country in the world is better adapted than Canada for the establishment and expansion of wood pulp manufactures; and a prosperous future may be anticipated for the industry.—*Nature*.

JEWISH COLONIES IN JAFFA.—The most advanced and fertile of the colonies in the neighbourhood of Jaffa, according to Consul Dickson, are the Jewish colonies. The vintage was very abundant last year, especially in the colony of "Richon-le-Zion." The following are, as nearly as possible, its returns of the manufacture of wine and cognac, given, unfortunately, in weight only:—Wine, 1,680 tons; cognac, 84 tons. Great hopes are entertained for further improvement in the quality of these wines, which are equal in flavour to many of the French wines. The settlers in the colony of "Petah-Tikva" have begun to plant a large part of their grounds with orange trees. It is estimated that the area destined for orange plantations is equal to that of one hundred of the average sized Jaffa gardens. The Agricultural School—"Mikueh Israel"—belonging to the "Alliance Israelite" of Paris, and situated on the carriage-road to Jerusalem, at half an hour's distance from Jaffa, is steadily progressing. There are always in this school about 100 resident pupils, who are boarded, clothed, and instructed at the expense of the "Alliance," and many of the pupils who finish their studies in this school are sent to Paris, and after they have ended their course of studies in the French capital go as teachers to the different schools maintained by the "Alliance." In this way the pupils have a promising career opened to them. The institution at "Mikueh" has devoted a large part of its ground to viticulture. The wine produced is extremely good, the last vintage having yielded 111 tons. The plantation of mulberry trees for the breeding of silkworms is also being extended.

THE MALAY PENINSULA.—According to a paper recently read by Mr. Hugh Clifford before the Royal Colonial Institute, in 1875 the revenue of Perak was only \$226,233, compared with \$2,776,582 in 1889, while the revenue of all the federated Malay States was only \$881,910 in 1880, against \$7,000,000 last year. All this revenue raised in the federal Malay States was devoted solely to the development of Malaya.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, JUNE 26...British Architects, 9, Conduit-street, W., 8 p.m.
- TUESDAY, JUNE 27...Photographic, Russell-square, W.C., 8 p.m. Reception by the President.
- WEDNESDAY, JUNE 28...SOCIETY OF ARTS, John-street, Adelphi, W.C., 4 p.m. Annual General Meeting. Colonial Inst., 9 p.m. Conversazione at the Natural History Museum, South Kensington. Sanitary Institute, 74A, Margaret-street, W., 8 p.m. Japan Society, 20, Hanover-square, W., 8½ p.m. Annual Meeting. British Astronomical, Sion College, Victoria-embankment, W.C., 5 p.m.
- THURSDAY, JUNE 29...Hellenic Society, 22, Albemarle-street, S.W., 5 p.m. Annual Meeting.

Journal of the Society of Arts.

No. 2,432. VOL. XLVII.

FRIDAY, JUNE 30, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS.**

The results of the Examinations held at the end of last March are now ready, and an advance copy has been sent to each centre of examination.

Copies for gratuitous distribution to each candidate who attended the examination will shortly be sent to each centre. Additional copies can be obtained, price 6d. each.

The dates for the Examinations in 1900 will be Monday, Tuesday, Wednesday, and Thursday, March 26th, 27th, 28th, and 29th.

Proceedings of the Society.**ANNUAL GENERAL MEETING.**

The Annual General Meeting, for receiving the Report of the Council, and the Treasurers' Statement of Receipts and Payments, during the past year, and also for the Election of Officers, was held in accordance with the By-laws on Wednesday last, the 28th inst., at 4 p.m. Sir JOHN WOLFE BARRY, K.C.B., LL.D., F.R.S., Chairman of the Council (followed by Major-General Sir OWEN TUDOR BURNE, G.C.I.E., K.C.S.I.), in the chair.

The SECRETARY read the notice convening the meeting, and the minutes of the last annual meeting.

The following candidates were proposed, balloted for, and duly elected members of the Society:—

Boyle, Sir Cavendish, K.C.M.G., 100, Piccadilly, W., and Georgetown, British Guiana.

Carter, William Leonard, 51, Aynhoe-road, Kensington, W.

Hozier, Colonel H. M., C.B., Lloyds, E.C.

Jennins, Henry Horwood, Crown Works, Leeds, and West-hill, Chapelton, Leeds.

Khan, Sultan Mohammed, Christ's College, Cambridge.

Nesbitt, Thomas Huggins, Vestry-hall, Mount-street, Grosvenor-square, W.

Phillips, George A., The Grange, Hever, Kent.

Sorabji, Shapurjee, 49, Leadenhall-street, E.C.

Syad Mahomed Latif, Khan, Bahadur, Shams ul Ulema, District Judge, Jalandhar City, Punjab, India.

Thornton, H. G. Blake, Constitutional Club, W.C.

Walker, Charles Maynard, 304, Fulham-road, S.W.

The CHAIRMAN nominated Mr. John Jewell Vezey and Mr. Carmichael Thomas, scrutineers, and declared the ballot open.

The SECRETARY then read the following

REPORT OF COUNCIL.**I.—ORDINARY MEETINGS.**

The business of the present Session—the 145th since the foundation of the Society in 1754—was commenced on the 16th of November last, when the Chairman of the Council, Sir John Wolfe Barry, in accordance with the usual practice, delivered an Opening Address. The Chairman took for his topic the Internal Traffic of London. He showed how rapidly it had increased and was increasing, and suggested various means for the alleviation of its present congested condition. The address, dealing as it did with a subject which was already much in the public mind, attracted a great deal of interest, and was largely commented upon in the newspapers. It has already borne useful fruit in the extension of police measures for the regulation of a certain amount of traffic, while it appears likely that further powers will be entrusted to the police with the same object. It is to be hoped that the constructive measures suggested by the Chairman for the improvement of the means of communication may also receive consideration, and be eventually carried into effect.

The first paper read after the Opening Address was by Professor Forbes, who dealt with the question of the "Long Distance Transmission of Electric Power." Professor Forbes had recently returned from a visit to Egypt, where he had been examining and reporting on the water-power which would be developed by the new works for the barrage of the Nile. He dwelt strongly on the importance of employing the various great sources of water-power known to exist, even suggesting as

feasible the utilisation of the Victoria Falls of the Zambesi. A proposal which he made to get over one of the main difficulties—the cost of the large copper mains required for distant transmission—by means of a mortgage on the copper, gave rise to a good deal of discussion.

Four other papers read during the Session dealt with various applications of electricity. At one of the meetings in February, Mr. James Swinburne introduced Nernst's Electrical Lamp to this country, and gave an interesting account of this new and remarkable invention, in which the carbon filament of the ordinary incandescent lamp is replaced by a thin rod of highly refractory oxides. Such a rod will remain incandescent in the atmosphere without appreciable waste, so that a surrounding vacuum is not required. The lamp is certainly very ingenious, and very simple. If the anticipations of its inventor are realised, it ought to work a revolution in electric lighting. Another application of electric power formed the subject of Mr. Philip Dawson's paper on "Electric Traction." Mr. Dawson gave a compendious account of the principles involved in this application of electricity, and of the application of these principles, so far as they have as yet gone both in America and in Europe. A little later there were two papers dealing with the older application of electricity—the conveyance of information, not of material substances—one by Mr. John Gavey on "Telephones," and one by Sir William Preece on "Aetheric Telegraphy." Mr. Gavey described the mechanism and organisation by which the telephone system has been brought to its present perfection, while Mr. Preece gave an account of the various methods, including his own, by which signals have been transmitted through space without the use of any communicating wire.

The various applications of engineering science received in this session a large share of attention. The first paper that may be classed under this head was the one on "Inland Navigation," by Mr. Vernon-Harcourt. The question of inland navigation is one which has been dealt with on various occasions by the Society of Arts, a special Conference having been held in 1888. Mr. Harcourt gave an account of the present condition of inland navigation in Europe and America, and compared it with the condition of things at home. He urged that the British waterways should form the subject of a careful and thorough inquiry, with a view to their development for the carriage of heavy goods, and also suggested that the Board of Trade

should be requested to collect complete statistics indicating the recent growth or decrease of traffic on waterways. The subject of "London's Water Supply" was treated by Mr. Walter Hunter. Mr. Hunter dealt with the case of the water companies, and showed how efficient and satisfactory their service to London is at the present time. At the meeting succeeding Mr. Forster Brown read a paper on "Coal Supplies," and suggested the measures which he thought ought to be taken, in view of the possible exhaustion of our coal, to place the country in a satisfactory economic and manufacturing position before the time arrived when the want of coal began to be felt. Another mining paper had been read a little earlier in the session by Mr. J. H. Collins, who gave a very complete account of the Cornish mines and their present condition. His opinion was that the mines in Cornwall only required further working capital to make them as profitable an investment as the perhaps more attractive, and certainly more popular mines in other parts of the world. The supply of liquid fuel, which formed the subject of a paper by Sir Marcus Samuel, may be treated as belonging to the same class as the papers just mentioned. Sir Marcus gave a very vivid idea of the enormous extension which has lately taken place in the use of petroleum for domestic lighting in the Far East and elsewhere.

Another set of papers may be grouped together as dealing with questions of a social or economic character. The first of these was the one read by Sir Albert Rollit on "Commercial Education." Sir Albert laid great stress on the necessity for improvement in commercial education, showed what had been done up to the present in that direction in this country, and indicated the lines on which he thought further development ought to follow. The next to be mentioned is Mr. Dixon H. Davies' paper on "The Cost of Municipal Enterprise." Mr. Davies treated a very difficult question with much skill, taking the side of those who looked upon municipal enterprise as an unwise interference with the development of private industry and trade, and asked for a Commission which might eventually provide the basis of legislation to indicate the limits which should be set upon such trading. The paper gave rise to an important discussion, lasting over a second evening. The third paper of this class was one on "The Law of Trade Marks," read by Mr. J. E. Evans-Jackson at the concluding meeting of the

session. Mr. Jackson pointed out that we had now had considerable experience in the working of the present law, and that the time had arrived when its revision and reform in certain directions was required.

Two papers dealt with foreign countries and their resources. Mr. W. T. Maud, who had served as special correspondent of the *Daily Graphic* during the Egyptian campaign, gave a graphic and interesting sketch of Egypt and the Soudan in 1897 and 1898; and Mr. James Irvine, who has previously contributed important material to the Society's transactions, gave an interesting account of the gold mines of West Africa, their present condition, and the developments which they required.

The remaining papers do not lend themselves to ready classification. At the second meeting of the session Mr. C. H. Bothamley read an excellent paper on "Photographic Developers and Development." It was a very clear and compendious account of the progress which has been made in this branch of photographic chemistry. Very few years ago there were but two substances upon which photographers could rely for the development of the latent image—one a salt of iron, ferrous oxalate, and the other the hydrocarbon compound, pyrogallol acid or pyrogallol. Since 1880, when Captain Abney introduced the use of hydroquinone, photographic developers have greatly increased in number, though it may be doubted whether the results of their use have shown any great advance. Mr. Bothamley gave, in a popular and intelligible form, an account of the various substances which are now employed, and, so far as they are known, the general reasons for their action.

At the first meeting after Christmas, Mr. W. Hunting read a paper on "Tuberculosis in Animals," pointing out how closely associated this disease is with tuberculosis in the human subject, and advancing the proposition that, without checking the one, it would be impossible to get rid of the other. A little later in the session, the Rev. J. M. Bacon gave an interesting account of his recent meteorological and other researches carried out in balloon ascents, researches which it may reasonably be hoped will have an important practical value. Mr. Wilton Rix, in his paper on "Leadless Glazes," dealt with one branch of a subject of the greatest importance to our manufacturing industries—the regulation of the use of dangerous materials in industries, so that injury to the workers may be avoided without undue interference with the industry

itself. An important industry, and though one of the oldest, yet one which is receiving considerable recent development, was dealt with by Mr. Bunyard in his paper on "Fruit-Growing in Kent." Mr. Bunyard's account of the present condition of this important branch of agriculture was satisfactory and full of hope for the future.

II.—INDIAN SECTION.

This Section has had another successful session. The standard of the papers, six in number, has not been inferior to that of previous years, while the discussions generally have been of exceptional interest and value. That the work of this department of the Society is appreciated, not only at home but in India, is shown by the large amount of attention the Section's meetings obtain from the Indian Press, and by the frequent applications for membership received from our Eastern Empire.

The session commenced on January 19th, when Dr. John Nisbet dealt with the proposal to continue eastwards the important railway now in course of construction from the Upper Burma capital to the Salween River, the object being to tap the trade of Yunnan, "presuming that there is any trade worth tapping." Dr. Nisbet thinks that it would be wiser to develop railways within the province itself, and to establish a connection with Assam, than to penetrate far in the direction of Western Yunnan. His doubts as to the commercial value of that region were shared by the Chairman, Sir Alexander Mackenzie, who declared that "it would be monstrous to expend the revenues of India in extending the railway beyond British territory into China." On February 9th the Chief Commissioner of the Andamans, Colonel R. C. Temple, read a paper giving a description of the penal system in force at that settlement, the largest establishment of the kind in the British Empire, and perhaps the largest in the world. Of the 12,000 "lifers" in the Andamans 250 are regarded by Colonel Temple as positively dangerous; the same number as requiring permanent imprisonment; and the remainder as capable of being brought to a considerable height of respectability by continuous education in self-restraint. They are employed in all sorts of industries, doing "anything that the labourers of a whole community do." "Leprosy in India" was the subject of a paper read on March 9th by Mr. H. A. Acworth, who

distinguished himself as Municipal Commissioner of Bombay—a post similar to a French prefectship—by establishing in 1890 the well-known Matoonga Leper Asylum, and who may claim to have originated the policy of segregation embodied in the Acts since passed by the Viceregal and Bengal Legislative Councils. Mr. Jonathan Hutchinson spoke in the discussion on Mr. Acworth's paper. On April 27, Sir John Scott, in his paper entitled "Judicial Reform in Egypt," gave the first account presented to a London audience of the "great work," to use Lord Dufferin's words, he carried out as Judicial Adviser to the Khedive; and on May 11, Mr. F. O'Dwyer contributed a comparison of the Punjab revenue system and that of two leading Rajput States of which he is the Settlement Officer. The Session concluded on June 1 with a paper on "The Port of Calcutta," by Sir Charles Stevens, who included a sketch of the circumstances that led to the establishment of the Bengal capital as an emporium, and an explanation of certain ingenious engineering schemes for overcoming some of the difficulties connected with the River Hugli.

For the sixth year in succession three of the meetings of the Session were held at the Imperial Institute.

III.—FOREIGN AND COLONIAL SECTION.

To this Section were contributed four valuable papers on matters of great and present interest. The first of the series was that of Mr. Archibald Little, on "The Yangtse Basin and the British Sphere," with which the session opened on December 6. Mr. Little, the highest living authority upon the subject, as the Chairman (Sir Richard Temple) styled him, described the basin of the Yangtse—the watershed of which comprises a third of China proper—as one of the richest, if not the richest, sub-tropical region on the world's surface, and as inhabited by a people as hard working as that of the United States, with which it has many points of analogy. On January 24, Mr. W. Fischer Wilkinson, who spent nearly the whole of last year in travelling about the mining districts of that portion of South Africa, named after the founder of the Chartered Company, set forth the results of his investigations in a paper, entitled "Rhodesia and its Mines in 1898." That the mineral wealth of Rhodesia will prove to be its only source of prosperity is not Mr. Wilkinson's view. In his opinion the future of the country

"is bound up with its pastoral and agricultural possibilities." The high veldt, with an elevation of 4,000 ft., is, he mentions, particularly suitable for farming. His impression, as an independent and impartial observer, is that settlers have every reason to be satisfied with the manner in which Rhodesia is being administered by the Chartered Company. On February 28, Mr. A. Hotz read a paper on "Persian Trade Routes," insisting, from his extensive mercantile experience, on the urgent need for replacing the existing inadequate and antiquated mule tracks with a network of proper roads. While Russia is bestirring herself to remedy this evil in the North, the attitude of England in the South is, according to Mr. Hotz, one of "indifference." Thanks, however, to private enterprise, something is being done, and a road from Schuster to Ispahan is now in course of construction. At the concluding meeting, on March 21, Mr. C. Rozenraad read a paper on the recent remarkable commercial development of Germany, the origin of which he traces to the foresight of Bismarck, particularly in his creation of the Imperial Bank of Germany.

IV.—APPLIED ART SECTION.

For various reasons considerable alterations had to be made in the original programme of this Section. Three of the papers announced for reading had to be withdrawn, namely, those by Sir William Richmond on "Craftsmanship," by Mr. George Lock on "Domestic Furniture," and by Mr. William Burton on "Maiolica." In place of these were substituted papers by Mr. Stephen Webb on "Intarsia or Inlaying," and by Mr. I. Hunter Donaldson on "The Artistic Treatment of Picture Frames."

In the first meeting of the Section, Mr. Edward F. Strange gave an account of the Centenary Exhibition of Lithographs, which, as is stated in another portion of this report, the Science and Art Department were at that time holding at the instance of the Council of the Society. Mr. Strange, after an instructive criticism on the works of the different schools, both foreign and English, laid stress on the value of lithography as a medium by means of which the artist's own work is exactly reproduced, and expressed the opinion that in spite of the recent revival of the art there was room for a much greater development. He hoped, therefore, that artists would devote more attention to it in the future. The second paper of the Section was on "Vitreous Enamels," by Mr.

Cyril Davenport. Mr. Davenport's paper dealt chiefly with the ancient examples which showed the art in its greatest beauty, and drew special attention to the high position which England had taken in the development of the art of enamelling. A special feature of the paper was its illustration by a series of very beautiful lantern slides, prepared by Mr. Davenport from originals principally in the British Museum.

Mr. Stephen Webb's paper on "Intarsia," above-mentioned, was the next in order. Mr. Webb gave a very interesting account of this beautiful minor art, and illustrated his remarks with some fine specimens of his own work. In his paper on "Picture Frames," Mr. I. Hunter Donaldson dealt with a subject of great importance to painters, but one which appears to have been very much neglected by them in the past. During the last and the greater portion of the present century the frame makers were allowed to supply the most tasteless productions, in the making of which they had entirely fallen away from the better taste of the 16th and 17th centuries. Of late certain of our chief artists have realised how much their pictures gain by appropriate and elegant frames. Mr. Donaldson's paper was supplemented by some very interesting speculations by Sir George Birdwood on the archæology of the subject. The last paper in the section was by Mr. J. Starkie Gardner, on "The Revival of Tradesmen's Signs." Mr. Starkie Gardner, to whom the Society has previously been indebted for very valuable contributions on the subject of art metal-work, dealt to a large extent with the work of the older craftsmen, who designed the wrought-iron signs which formed the exemplars of those which are now making their appearance in the streets of London.

V.—CANTOR LECTURES.

The first course of Cantor Lectures this session was delivered by Professor Vivian B. Lewes, on the subject of "Acetylene." It will be remembered that the application of acetylene for illuminating purposes was first described in this country in a paper read by Professor Lewes before the Society in January 1895. Since that date he has devoted a great deal of attention to the subject, and his lectures included the results of a great deal of original work. Coming, as the course did, so soon after the holding of the Exhibition of Acetylene Generators at the Imperial Institute last year, and the Report upon them by the Society's Committee, the lectures formed a most valuable

supplement to that Report, and there has been, since their publication, a great demand for them.

The second course was by Dr. Samuel Rideal, on the "Bacterial Purification of Sewage." In it Dr. Rideal gave his audience the latest results of the investigations which have been made with a view to the application of the recent extension of bacteriological knowledge to the solution of the important problem of sewage disposal. This problem has often been before the Society of Arts, and, indeed, it was the action of the Society in holding its Conferences on Public Health, in the years 1876, 1877, and 1878, that principally induced public attention to the subject. The records of the Society show, from time to time, what advances have been made; and the most recent advances were those described by Dr. Rideal in his lectures.

Mr. Sharp, in his course on "Cycle Construction and Design," dealt with a subject which is just now extremely popular. Mr. Sharp has given great study to the mechanics of the cycle, and there is, perhaps, no one better qualified to deal with the subject from a scientific point of view. His lectures embodied a great deal of valuable information, and may be said to have brought the subject of cycle construction down to the most recent date.

The last course of lectures was by Professor Henry Procter, on "Leather Manufacture," a subject of great practical importance, and one which may fairly be considered as a London industry. Although the practical treatment of skins in the process of making them into leather is not very different from that which was arrived at long ago by purely empirical methods, there have been great advances in the scientific knowledge of the subject, and consequent modifications in the methods of the process. Mr. Procter, who is Professor of Leather Industries at the Yorkshire College, Leeds, was able to give the Society the benefit of extended theoretical as well as practical knowledge of the subject.

VI.—JUVENILE LECTURES.

Two Juvenile Lectures were delivered by Professor Jeffrey Bell during the Christmas holidays. The subject was a zoological one, and may be said to have dealt with the mechanics of animal construction. They were well attended, and much appreciated by the audience of members and young people which listened to them.

VII.—ALBERT MEDAL.

The Albert Medal for the present year has been awarded by the President and Council to Sir William Crookes, F.R.S., for his extensive and laborious researches in chemistry and in physics, researches which have, in many instances, developed into useful practical applications in the Arts and Manufactures. Sir William Crookes was among the first to employ the spectroscope as an instrument of chemical research, and by its aid, in 1861, he discovered the metal thallium, the earliest of the series of the "rare metals." To his researches was also due the discovery of the various earths now so extensively employed in obtaining a large increase of light from illuminants. In 1872, he began the long series of experiments on radiation, of which the radiometer was the first outcome. This work on molecular physics in high vacua led to methods of producing extremely high vacua, which made possible the construction of the incandescent lamp. They also enabled the remarkable properties of the cathode rays (which are affording such important results in connection with surgery) to be discovered and developed. He has rendered important services to industrial chemistry, and long ago established a position as an authority on the chemistry of dyeing and calico printing. His work in connection with the chemistry of agriculture also requires to be noted. His services to pure science have been acknowledged by the award of a Royal Medal, and of the Davy Medal of the Royal Society; and it is the application of these researches to industrial uses which led the Council of the Society to submit his name to the President for the award of the Albert Medal.

VIII.—MEDALS.

The Council have awarded the Society's Silver Medal to the following readers of Papers during the Session 1898-99.

At the Ordinary Meetings:—

To PROF. GEORGE FORBES, F.R.S., for his paper on "Long Distance Transmission of Electric Power."

To C. H. BOTHAMLEY, F.C.S., for his paper on "Photographic Developers and Development."

To DIXON H. DAVIES, for his paper on "The Cost of Municipal Enterprise."

To JAMES SWINBURNE, for his paper on "Nernst's Electric Lamp."

To J. H. COLLINS, for his paper on "Cornish Mines and Miners."

To PHILIP DAWSON, for his paper on "Electric Traction and its Application to Suburban and Metropolitan Railways."

To WALTER HUNTER, M.Inst.C.E., for his paper on "London's Water Supply."

To SIR WILLIAM HENRY PREECE, K.C.B., F.R.S., for his paper on "Ætheric Telegraphy."

In the Indian Section:—

To COLONEL RICHARD CARNAC TEMPLE, C.I.E., for his paper on "The Penal System at the Andamans."

To SIR JOHN SCOTT, K.C.M.G., D.C.L., for his paper on "Judicial Reforms in Egypt in Relation to the Indian Legal System."

In the Foreign and Colonial Section:—

To ARCHIBALD LITTLE, F.R.G.S., for his paper on "The Yangtse Basin and the British Sphere."

In the Applied Art Section:—

To STEPHEN WEBB, for his paper on "Intarsia, or Inlaying."

To J. STARKIE GARDNER, F.G.S., for his paper on "The Revival of Tradesmen's Signs."

IX.—SWINEY PRIZE.

The prize left by Dr. Swiney, to be awarded on every fifth anniversary of his death, was awarded in January last, that being the 55th anniversary of the testator's death. It has to be given to the author of the best published work on Jurisprudence, and the award is made jointly by the Society of Arts and the College of Physicians. On the occasion of the first award being made, the question was discussed between the two bodies concerned as to what share should be allotted to Medical Jurisprudence, and an arrangement was arrived at that the award should be made alternately to Medical and to General Jurisprudence. This plan has been continuously followed. The question was raised as to whether it would be desirable to revise it; but after consideration it was determined that there appeared to be no reason to disturb an arrangement which had worked well for the past 50 years, and that it should be continued, with the understanding that if at any time the joint Committee of the Society of Arts and the College of Physicians, which was usually appointed to submit a book to the adjudicators, should be unable to find a work of the class whose turn it was to receive the award, which appeared to them to be of sufficient merit, they should be at liberty to recommend a book belonging to the other class. As has been already announced in the *Journal** the prize for the present year was awarded to Dr. J. Dixon Mann for his work on "Forensic Medicine and Toxicology."

* See *Journal*, vol. xlvii., p. 173, January 27, 1899.

A list of previous recipients will be found in the *Journal* of the 28th of October last.*

The prize is a silver goblet of the value of £100, with gold coin to the same amount. The cup has always been made by Messrs. Garrard from a design by Daniel Maclise.

Dr. Swiney is interred in the burial ground, Pratt-street, Camden-town, and it was lately represented to the Council that the monument over his grave was falling into disrepair. Some years ago it was renovated at the expense of the Society, but the stone is of a very perishable nature, and the slight repairs which the Council thought it wise to execute at the time were insufficient to arrest its further decay. The Council have felt that the duty of preserving the monument of one of its benefactors might fairly be undertaken by the Society of Arts, and they have therefore obtained the consent of the Vestry of St. Pancras to allow them to replace the stone, which is now almost perished, with a fresh stone in facsimile.†

X.—OWEN JONES PRIZES.

These prizes have now been awarded annually since the year 1878. Owen Jones died in 1874. After his death a committee was formed to collect subscriptions for the purpose of founding a memorial. The money thus obtained was partly expended in erecting a monument over his grave in Kensal Green, and the balance (a sum of £400) was presented to the Council of the Society of Arts upon condition of their expending the interest thereof in prizes to "Students of the Schools of Art who, in actual competition, produce the best designs for Household Furniture, Carpets, Wall-papers and Hangings, Damask, Chintzes, &c., regulated by the principles laid down by Owen Jones." The prizes are awarded on the results of the annual competition of the Science and Art Department.

Six prizes were awarded this Session, each prize consisting, in accordance with the regulations laid down for the administration of the Trust, of a bound copy of Owen Jones's "Principles of Design," and a Bronze Medal.‡

The next award will be made this summer, on the result of the present year's examinations. Six prizes have again been offered for competition.

XI.—PRIZES FOR DRAWING.

Since 1889, the Council have placed at the

disposal of the Royal Drawing Society, for competition among the candidates at its annual examination, 12 Bronze Medals, and, as usual, these medals were awarded for drawings sent in by students to the exhibition held by the Drawing Society in April last.

This Society is doing useful work, by its examinations and exhibitions, in encouraging the teaching of drawing in second-grade schools. Its operations are extending annually, and the Council believe that the assistance given to its operations by the Society of Arts by means of these medals has been usefully bestowed.

XII.—EXAMINATIONS.

It is very satisfactory to be able to state that the increase in the number of candidates for the Society's examinations still continues, indeed the rate of growth is larger than last year; 8,750 candidates entered this year, showing an increase of 1,114 over the number last year, 7,636. The figures for the past ten years are given in the following Table, which shows a continuous and steady increase. This indicates the estimation in which the Society's examinations have been held, and proves that they supply a want which is felt by the classes for whom they are intended. As the examinations commenced in 1854, they are now approaching the end of the first half century of their existence. At various times they underwent considerable modifications, but no alterations have been made in the scheme now for a good many years. They form the only scheme of commercial examinations which have achieved any practical success, and indeed they had achieved success before the recent demand arose for examinations in commercial subjects at all. They are founded on the principle that the surest basis for good commercial education is a sound general education. Although it is only to a small extent that the value of such education can be tested by examination, it is believed that the Society's examinations offer a useful test, and, at all events, they offer the only one which has yet been provided.

The 8,750 candidates worked in all 9,581 papers. For these the following certificates were awarded:—First-class, 796; second-class, 2,063; third-class, 2,833; while 3,123 failed to satisfy the examiners. In addition to these there were 427 certificates granted in elementary languages, and 339 in music. Putting these in the form of per-centages, we find the approximate per-centage of first-class was 8·3, of second 21·0, of third 29·56, while

* See *Journal*, vol. xlvi., p. 909, October 28, 1898.

† A note on Dr. Swiney will be found in the *Journal*, vol. xlvi., p. 660, June 23, 1899.

‡ See *Journal*, vol. xlvi., p. 797, August 26, 1898.

32.7 failed. These results are not unsatisfactory as compared with those of last year.

Year.	No. of Candidates.	No. of Papers worked.	No. of Centres.	No. of Sub-jects.
1890.....	2,315	2,474	79	14
1891.....	2,460	2,667	78	14
1892.....	*2,928	3,143	96	13
1893.....	3,702	3,916	109	13
1894.....	4,106	4,376	131	14
1895.....	4,777	5,108	146	14
1896.....	6,111	6,568	197	16
1897.....	6,919	7,513	221	19
1898.....	7,636	8,372	243	19
1899.....	8,749	9,581	260	23

* Total, with supplementary autumn examination, 3,351.

In recent years the per-centage of first-class certificates has fallen—last year it was 6.05. The per-centage of failures has varied from year to year—last year it was 26.1. As mentioned in last year's Report, it is evident that the increase in numbers has been accompanied by a decrease in quality, owing to the fact that in many cases the fees payable by candidates are paid from the funds now at the disposal of the County Councils, and that therefore a large number of candidates are induced to enter before they are fully prepared. No general attempt has been made to raise the standard, although it may perhaps be a fact that the standard tends slightly to rise. It is at all events a satisfactory point to notice that there is this year a very distinct increase in the better class of candidates, as shown in the larger number of first-class certificates taken.

Nearly all the commercial subjects show an increase. There is a slight falling off in the two musical subjects, and in Domestic Economy. In Harmony there are 167, as compared with 161 last year; but this slight increase is counter-balanced by the still greater falling off in Rudiments of Music, 341 having entered, as compared with 366 last year. For Domestic Economy there were 202 candidates, as compared with 206 last year. Turning to the subjects of a commercial character, it is to be noted that in Italian there is a falling off, only 18 candidates having entered, whereas there were 37 last year. Commercial Geography also shows a trifling decrease, 118 as compared with 120. All the other subjects show an advance. The largest subject of all is Book-keeping, in which 4,006 candidates entered—last year there were 3,730. The next

largest is Shorthand—2,214, against 1,791 last year. The next most popular subject is Type-writing, with 462 candidates, as compared with 433 last year. In English there is a considerable increase—254 against 189; and there is also an increase in Arithmetic—282 against 259, although this important subject is not as popular as it certainly ought to be. Economics attracted 34—an increase over the 27 of last year; and Précis Writing 28, also an increase over the 17 of last year. Of the language subjects, French, as might be expected, is the most popular—there were 398, last year there were 322. And there were almost as many for Elementary French, 395—a considerable increase over last year's number, 218. The next largest is German with 263, as compared with 227 last year. Spanish shows a steady increase—107 against 92—and in Elementary, 58 against 41. For Portuguese there were 39—last year there were 26. It is satisfactory to be able to note that this year for the first time there have been a few candidates in Russian and in Danish—7 in the former, and 5 in the latter language. Too much stress cannot be laid on the importance, to those who are being educated for a commercial career, of the study of the less well-known modern languages, and the Society has for some years past kept some of these languages in its programme, although year after year no candidates entered. It is to be hoped that now that a beginning has been made a larger number of candidates may take up this branch of study, and enter for the examinations in future years.

The examiner in Arithmetic remarks that this year's examination has been marked by a perceptible increase in the number of successful candidates for honours, 9 having achieved the high standard required for a first-class and 29 that for a second-class. These candidates sent up very good papers, briefly but lucidly expressed, the reasoning clear, the work accurate, and neatly written. Every question was satisfactorily answered by some one or other. Many candidates sent up answers, right or wrong, to every question on the paper. The number of failures has largely increased. This seems to be due to the influx of a number of candidates totally unprepared for an examination intended to test not only accuracy in the performance of arithmetical operations, but also knowledge of the principles of Arithmetic, and capacity to apply reasoning based upon those principles to practical commercial problems.

The examiner in English considers that the results of this year's examination are not up to the usual standard. Of the 254 candidates, no less than 77 failed, while only 24 evinced sufficient merit to justify the award of a place in the first-class. Mistakes in spelling are fewer every year, but there is as much need as ever for more accuracy in the use of grammatical terms, and for the exercise of more thought about the structure of sentences, and the due subordination of their several parts.

The examiner in Book-keeping considers that the results of this year's examination show a decided improvement upon those of 1898, though the per-centage of passes is less. To some extent this may have arisen from the alterations made in the plan of the questions set, but to a considerable extent it arises from improved knowledge and grasp of the subject. The plan of setting two exercises, independent of each other, proved a great improvement over the old plan, in which a candidate making blunders in the first part of the exercise, would be necessarily wrong in the second. The difference in the degree of preparedness shown by the candidates was, as last year, extraordinary. The best papers evidenced excellent and workmanlike knowledge, and a gratifying feature of the examination is the marked increase in the number of first-class certificates; 68·32 per cent. of the candidates passed, and of these 10·41 took first-class, 26·58 per cent. second-class, and 31·33 third-class. The failures amounted to 31·68. Compared with last year, this shows a considerable increase on the per-centage of first-class, and also a considerable increase in the per-centage of failures. The second-class per-centage remains about the same, and the third-class per-centage is smaller than last year.

The examiner in Commercial Geography states that the papers sent in this year are very much better than on any previous occasion since he has been examiner. The subject selected—the Commercial Geography of the British Empire—seemed to be popular, and had been studied in an intelligent way, though a large number of candidates failed to distinguish between the political unity and the commercial heterogeneity of the British Empire, a very large proportion being evidently unaware of the existence of tariffs directed by one part of the Empire against the other parts. On the whole the questions were well answered. The true nature of the examination seems to be becoming understood, and this year there

were fewer incompetent papers than in any previous year.

The sudden death of Mr. T. A. Reed, who had acted as examiner in Shorthand since 1889, following Mr. Frederick Pitman, who acted as examiner from 1882, when the examination was first established, threatened to cause serious delay in the publication of the results. Mr. Reed died after he had actually commenced the examination of the papers, but before it was completed. Fortunately, however, Mr. Allen W. Reed, who has for many years past assisted his father in the conduct of the examinations, was able to take the work up, and carry it through without any delay or inconvenience. He reports that though there has been an increase of 423 papers over the numbers of last year, there has been a larger proportion of failures than in the three preceding years, the first-class certificates being actually less in number than those of 1898; last year there were 68, but this year he is only able to recommend 53. These 53 papers are of a specially good character, some of them being really excellent examples of shorthand writing and transcription. The second-class papers also showed an improvement. With regard to the failures, it is noticed that a large percentage of those who presented themselves were quite unprepared for anything of the nature of a speed test. The majority of the failures appear to have occurred not from lack of knowledge of the theory of Shorthand, but from incapacity to write beyond a very low speed.

The examiner in Type-writing speaks highly of the character of the papers which have been sent in, although the lower-class papers showed relatively greater advance than the first-class. She remarks that the greatest difficulty is experienced by employers in finding first-class clerks, the young people who present themselves being half-educated or wholly uneducated. And, as in former years, the examiner lays great stress on the importance, in the case of those who are seeking a situation as a typist, of their qualifying themselves by a good general education.

The examiner in Economics considers that there was a great improvement in this year's papers as compared with those of 1898. The complaint he has had to make in previous years of the neglect of economic history is not now called for—this year's papers have to a large extent removed that reproach. On the whole this year's results are satisfactory, and considerably better than those attained in previous years.

The examiner in Précis Writing says that many of the papers worked show a marked improvement upon those worked in previous years. Some of the papers are very good, and many show a decided advance in the habit of thought and discrimination.

The examiner in French considers that the advanced papers are not quite so satisfactory as those of last year, which was an exceptionally good year. He is however able to recommend a good proportion for the first-class, and on the whole the results are satisfactory. In the Elementary examination while the actual numbers have increased the proportion of those who have passed remains about the same.

The examiner in German while noting the considerable numerical increase also reports an improvement in the general result. The majority of the first-class work was, as usual, very satisfactory, and some of the second-class work was also very good; but the majority of the candidates showed a lack of knowledge of German commercial, scientific, and technical terms.

The examiner in Italian notices that while the papers of a small proportion of the candidates are the best he has ever had to deal with, a great many of the papers are unfortunately extremely bad.

The Spanish examiner finds the number of inferior papers this year remarkably few, the candidates showing considerable capacity in their way of dealing with the commercial portion of the paper.

The examiner in Portuguese finds the work on the whole satisfactory, although the increase in the merit of the papers does not keep pace with the increase in their number. The technical portion of the paper is, as usual, rather weak.

The standard of the Russian examination was purposely kept low this year, in the hope of encouraging candidates who had probably entered after only a short course of instruction. But, in spite of this, the examiner found himself unable to pass more than one of the seven candidates who entered. To this one a second-class certificate was awarded. He, however, states that, considering the incomplete amount of preparation they had had, the work done by most of the other candidates was fairly good, quite sufficient to justify them in continuing their work in the hope of attaining success another year.

The same remark as to the standard applies to the papers in Danish. The papers sent in by one candidate were excellent, and the

examiner felt justified in awarding third-class certificates to the other four who had entered.

The examiner in Domestic Economy considers that the papers sent in year by year show a continuous and steady improvement. The papers this year reach a very high standard indeed.

The examiner in Music thinks that on the whole the results of the examination in the Rudiments of Music were good—some of the elementary papers were extremely satisfactory. As regards the examination in Harmony, though some of the papers, both for the higher and elementary certificates, were praiseworthy, there was a very large proportion of failures, especially in the higher class.

The Council have, as in previous years, to acknowledge the assistance they have received from many of the City Companies. The Clothworkers offered special prizes for certain of the language subjects, and the following Companies subscribed to the special Prize Fund, out of which money prizes are provided for the other subjects* :—Goldsmiths, Merchant Taylors, Mercers, Skinners, Leathersellers, and Salters.

XIII. — PRACTICAL EXAMINATIONS IN MUSIC, 1898.

The practical examinations in Music for 1898 were not concluded until the 13th July, too late for the results to be included in the last Report of the Council.† They were, however, published in the *Journal*.† The examination lasted for 15 days.

The system of examination was the same as that which has been carried on for the last three years. Candidates are asked to select for themselves which of four standards they choose to be examined in. Standard I. is easy, Standard II. moderately difficult, Standard III. difficult, and Standard IV. very difficult. For each standard a list of music is given, and a selection from this list is sent to the candidates six weeks previous to the examination. Candidates are expected to play pieces from the selected list, as well as to play a piece, or portion of a piece, at sight.

In all 539 candidates were examined, an increase of 147 over 1897; 5 of these took up two subjects, so that there were 544 examinations. Of these there were 515 passes and 29

* The Clothworkers' Company's Prizes are offered in Italian, Spanish, and Portuguese.

† See *Journal*, vol. xlvii., p. 845, Sept. 23rd, 1898.

failures. The failures in 1897 were considerably larger in proportion, being 44 in 405 examinations.

The following were the subjects taken up:—Piano, singing, violin, violoncello, mandolin, zither, and organ. 399 entered for the piano, of whom 376 passed and 15 obtained medals; 79 entered for the violin, of whom 75 passed and 15 obtained medals; 1 entered for the violoncello and passed; 1 passed for the mandolin; 4 entered and passed for the organ; 59 entered for singing, and 57 passed, 5 obtaining medals; 1 entered for the zither and passed.

Mr. John Farmer, of Balliol College, Oxford, and director of the Harrow Music School, acted as Examiner, Mr. Ernest Walker, M.A., Mus. Bac. Oxon., and Mr. Burnham Horner, as Assistant-Examiners.

XIV.—PRACTICAL EXAMINATIONS IN MUSIC, 1899.

The Practical Examinations for the present year have not yet been concluded. They commenced on the 26th June, and will be finished on or about the 12th July, after which a summary of the results will be given in the *Journal*. No alterations have been made in the system adopted in 1896, and continued since. In 1896, the first year in which the new system was tried, there were 376 candidates, and in 1897 there were 392, in 1898, 539, and for the present year 551 have entered.

XV.—ACETYLENE EXHIBITION.

The steps which were taken by the Council, at the request of the Imperial Institute, for the examination of the Acetylene Generators exhibited at the Institute last summer were detailed in the last Report of the Council. After the exhibition was opened, it was suggested that a further set of experiments should be carried out on the very representative collection of apparatus which had been brought together, and an application was made to the Society's Committee that they should continue their labours, and report on the working of the generators after they had been put to the test of a month's practical experience. The members of the Committee, at the request of the Council, were good enough to undertake this somewhat arduous duty, and arrangements were made for the practical testing of all the apparatus shown.

As the result of these tests a great deal of information was collected, which was eventually embodied in a Report, which was pub-

lished in February last. The Report itself was printed in the *Journal*.* It was also published separately, with appendixes giving particulars of the tests, diagrams of the apparatus and other information. It had been hoped that the report would have been ready sooner, but the mass of information which had to be dealt with prevented its publication being possible at an earlier date.

The Committee expressed their indebtedness to two of their members—Professor Vivian B. Lewes and Mr. Boverton Redwood—and they also acknowledged the value of the services of Mr. Duffield, who was engaged for the practical management of all the tests, and who carried them out with very great care and attention. The Council have reason to believe that the report has been of considerable value. There has been a large demand for it, and it appears to be much appreciated by those who are interested in this new method of lighting.

XVI.—EXHIBITION OF LITHOGRAPHY.

In the course of last summer a suggestion was made to the Secretary of the Society by Mr. Joseph Pennell that the Society of Arts should organise an exhibition of lithographs to commemorate the centenary of the invention of lithography by Aloys Senefelder in 1798, the year in which, according to all the evidence now available, the invention was perfected. The special reason for the Society of Arts being asked to interest itself in the matter was that it was the first to recognise the invention in this country by the award of its Gold Medal to Senefelder in 1819.

The proposition was in due course laid before the Council and was approved of by them. A committee was formed, and arrangements were made for holding an exhibition of lithographs in the Society's house. It soon appeared that such an exhibition would require far more space than is available on the Society's premises, and the Council, therefore, applied to the Stationers' Company to know if they would lend their hall for such a purpose. The Court of the Stationers' Company at once acceded to the application, but it was found that even with this assistance the cost of the exhibition would be considerable, and the Council, therefore, made a suggestion to the Science and Art Department that they should take charge of the proposed exhibition. After some consideration, the Department agreed to undertake the work, and it was

* See *Journal*, vol. xlvii., p. 289, February 24th, 1899.

announced in the *Journal* in September last that an exhibition of lithography would be held in the buildings of the South Kensington Museum on the west side of Exhibition-road. The committee which had already commenced the organisation of the work on behalf of the Society was asked to continue their labours on behalf of the Department, and some additions were made to it. The exhibition was opened on November 21, and remained open until the end of February. A large and widely-representative collection of historical and artistic lithographs was obtained, and there was also a small set of examples of modern industrial lithography exhibited at the request of various firms who made application for space. It included over 2,250 examples, and showed a larger number of artistic lithographs than had ever been publicly exhibited before.*

The Council feel much indebted to the authorities of the Department for acceding to their suggestion, and for carrying it out in so complete and admirable a manner.

XVII.—DETERIORATION OF PAPER.

In the last Report of the Council an account was given of the proceedings of the Committee on the Deterioration of Paper, and it was stated that the Report of the Committee on the subject would shortly be issued. This Report was published in August last. It contains, as well as the conclusions of the Committee themselves, two appendixes—one, an abstract of official publications bearing on the subject of paper, and issued by the German Imperial Testing Station, and the second a précis of the information and suggestions submitted to the Committee by their correspondents.

XVIII.—MUNICIPAL TRADING.

In the discussion on the paper on this subject, read before the Society by Mr. Dixon Davies, a suggestion was made that Her Majesty should be asked to appoint a Royal Commission to lay down the principles and limitations on which Parliamentary powers should be granted to municipal and local authorities, enabling them to embark in enterprises of a trading nature. This suggestion commended itself to the Council, which therefore addressed a memorial to the Home Secretary, asking for the appointment of such a Commission.

XIX.—INTERNATIONAL CONGRESS ON COMMERCIAL EDUCATION.

The International Congress on Technical Education, the last meeting of which was held in London, in 1897, under the organisation of the Society of Arts, met in Venice, on the 4th of May. The Secretary, Sir Henry Trueman Wood, attended to represent the Society, and read a paper at the Congress on "Commercial Education in England."*

The Congress confined itself on this occasion to the discussion of Commercial Education alone, whereas in former years it dealt principally with Technical Education. The International Congress held last year at Antwerp, dealing with the same subject, though it was attended by a large number of the same delegates, was not under the same organisation as that which arranged for the Congresses previously held in France and in London.

The meeting was well attended by delegates from most of the countries of Europe. The subjects discussed included the general organisation of Commercial Education and its relations with general education, the teaching of modern languages, and the results attained by the attempts which have been made to provide definite trade instruction in schools.

It was decided that no definite resolutions should be passed by the Congress, but the following conclusions were generally arrived at:—That pupils should pass into the schools of commerce from the primary schools, but that no teaching of a commercial character should be introduced into the primary schools; that the pupils leaving the schools of commerce ought to be so trained as to render them immediately useful in commercial life; that great attention ought to be paid to the teaching of modern languages, teachers, as far as possible, employing the language taught, not the language of the pupils, the teaching also being of a commercial character.

The Permanent Committee was asked to prepare a report on the commercial terms used in various languages, with a view to accurate equivalents being provided in the different languages. The committee was also requested to take steps to obtain a number of communications on the existing organisations for commercial instruction in different countries.

* A notice of the exhibition will be found in the *Journal*, vol. xlvii., p. 37, November 25, 1898; and a paper on it, by Mr. E. F. Strange, vol. xlvii., p. 245, February 10, 1899.

* The text of the paper will be found in the following numbers of the *Journal*:—Vol. xlvii. p. 573, May 19th, 1899; vol. xlvii. p. 590, May 26th, 1899; vol. xlvii. p. 624, June 9th, 1899.

With regard to future Congresses, it was resolved that after the Congress in Paris, in 1900, the Congresses should be held at intervals of either two or three years, and some other suggestions were made as to the work of the Permanent Committee in organising future Congresses.

XX.—CHADWICK TRUST.

The late Sir Edwin Chadwick, who died in 1890, left a considerable sum of money to establish a trust for the purpose of awarding prizes, establishing lectures, and taking other steps for the promotion of sanitary science. The Society of Arts was one of the bodies which were requested to nominate trustees, and on the formation of the trust Sir Douglas Galton was appointed, in 1896, the representative of the Society. His death having caused a vacancy in the representation, the Council appointed Mr. R. Brudenell Carter a member of the trust.

XXI.—MEMORIAL TABLETS.

The tablet has been set up, which, as stated in the Report of last year, the Council had decided to place on the house, No. 50, Wimpole-street, where Mrs. Elizabeth Barrett Browning, wife of Robert Browning, the poet, lived for some time, and from which house she was married.

The Council have also decided to erect a tablet on "Bolton House," Windmill-hill, Hampstead, for many years the residence of Joanna Baillie.*

XXII.—ELECTRIC LIGHTING OF THE SOCIETY'S PREMISES.

The premises of the Society of Arts have been lighted by electricity since the year 1883, in which year an engine and dynamo were put down, and the Meeting-room was lighted. The installation was afterwards completed by the purchase of a storage battery, and the lighting was extended to a portion of the offices. The cost of the installation was partly defrayed by contributions made by the following members of the Council:—Sir Frederick Bramwell, Sir Daniel Cooper, Sir Henry Doulton, Sir Edwin Lawrence, Mr. Matthey, Mr. Perkin, and Sir William Preece. The installation has worked

quite satisfactorily during the 16 years since it was inaugurated.

The arrangements which were necessary in 1883 to provide the electric light, have since been rendered more or less obsolete by the development in the public supply of electricity, and although the installation has given every satisfaction since it was first laid down, and has worked almost without interruption, the time has now arrived when it can be more economically replaced by a supply to be taken from the street mains. The subject has been under the consideration of a Committee of the Council during the session, and under their supervision the electric lighting arrangements have been thoroughly overhauled, and certain improvements and additions have been made. The work was satisfactorily executed by Messrs. Buchanan and Curwen, electrical engineers, and Mr. Graham Harris kindly undertook its superintendence as a member of the Committee. Arrangements have been made both with the London Electric Supply Corporation, and with the Charing-cross Electric Supply Company for a supply of alternating current in the case of the former, and of direct current in the case of the latter; the object of this arrangement being that either current might be available for experimental purposes. The old plant used for the generation of the current is already in part disposed of, and the price which will be realised for the whole of it will considerably diminish the cost of the alterations.

XXIII.—CONVERSAZIONE.

The annual *Conversazione* of the Society was held this year, as it was last, at the Natural History Museum, by permission of the Trustees of the British Museum. This is now the third time on which the building was placed at the disposal of the Society for the purpose, the first occasion having been in 1890.

As on the former occasions, special arrangements had to be made for lighting the Museum. As the building is not intended to be opened in the evening, it is not sufficiently lighted for the purposes of a *Conversazione*. For this reason only a small portion of the building is available. On the present occasion the only parts of the Museum used were the Central Hall, with its surrounding corridors and galleries, and the Bird Gallery, which occupies a portion of the ground floor of the western wing of the Museum. These galleries were specially lighted with the electric light, the expense of the installation being shared (as it was last

* A complete list of the tablets which had been set up at the time will be found in the Report of the Council for 1895-1896. *Journal*, vol. xlv., p. 681, June 26, 1896. Since that date, a tablet to Sir Harry Vane has been set up in Hampstead. See Council Report, 1897-8. *Journal*, vol. xlvii., p. 700, July 1, 1898.

year) with the Royal Geographical Society, the Royal Colonial Institute, and the Institution of Electrical Engineers—all of which Societies held *Conversazioni* in the building about the same date.

The usual arrangements for music and refreshments were made. Tickets were issued as on previous occasions to the members of the Society, and additional tickets were sold to members at the price of five shillings each. The Metropolitan District Railway Company were good enough to allow visitors who used the underground railway the free use of their subway leading from the South Kensington railway station into the grounds of the Museum. The total number of visitors attending the *conversazione* was 1,664.

As on previous occasions the Council have to thank the principal officers of the Museum for their help in carrying out the arrangements for the evening.

XXIV.—NEW COUNCIL.

The Vice-Presidents retiring from office at the expiration of the present year are :—The Attorney-General, Sir Edward Birkbeck, Lord Curzon, Sir Charles Fremantle, and Sir William Roberts-Austen. To fill their places, the Council have placed on the Balloting List the names of the following members :—Sir Steuart Colvin Bayley, Sir Owen Roberts, Mr. Ludwig Mond, Sir W. H. White, and Sir Edwin Lawrence. Sir Steuart Colvin Bayley has just completed his term of office as an Ordinary Member of Council, and Sir Owen Roberts, in accordance with the Bye-laws, resigns the office of Treasurer, which he has held for the period of five years. Mr. Ludwig Mond and Sir William White have not served previously on the Council. Sir Edwin Lawrence held office for some years, but has not been on the Council since 1876.

The retiring members of Council are :—Sir Steuart Colvin Bayley, Mr. M. Carteighe, Mr. Alexander Siemens, and Mr. J. S. Neville. To replace them the Council have nominated Professor Dewar, Mr. J. W. Swan, Sir William Preece, and Sir Edward Nelson. Professor Dewar and Sir William Preece have both served previously on the Council—neither Mr. Swan or Sir Edward Nelson have held office before.

To fill the vacancy in the Treasurership the Council propose the name of the Attorney-General. Sir Richard Webster, as the members well know, has long been a member of the Society's Council, having served a double term of office as Chairman.

XXV.—OBITUARY.

During the past Session the Society has lost many members who were closely associated with its work. Prominent amongst them is the name of Sir Douglas Galton—a past Chairman of the Council, a member of nearly 50 years' standing, and one who took the very warmest interest in the labours of the Society. The death of Sir William Anderson caused another great loss to the Society. He had been a member since 1883, had served on the Council, and as Treasurer of the Society, and contributed valuable lectures and papers to its proceedings. Sir Francis Dillon Bell, though for the last few years he had taken no part in the Society's work, was at one time a very active member, and served on the Council from 1884 to 1891. Sir Stuart Knill had been a member of the Society for 40 years, and served for four years as Vice-President. Sir John Fowler had not served on the Council, but had been a member of the Society for 50 years. The sad accident which in August last cut short the career of Dr. Hopkinson, deprived the Society of Arts of one of the most distinguished of its scientific members. Sir John Scott, though he took no active part in the Society's proceedings, took a great interest in them, and at one time was a constant attendant. Lord Herschell, who had been a member since 1890, though not very closely associated with the Society, took part in its discussions on some occasions, and presided over one of the meetings of the Indian Section. Dr. Obach will be remembered for the very valuable course of Cantor Lectures on "Gutta-Percha," which he delivered in the autumn of 1897, only a year before his death. Dr. Leitner read several papers of importance before the Indian Section. Mr. Andrew Chadwick, who succeeded his father as auditor to the Society, only held the appointment for six months before his death. Other members of the Society whose names should be mentioned are :—Mr. George Spottiswoode, the eminent printer ; Mr. J. M. Cook, of the well-known firm of tourist agents ; Mr. Jeremiah Head, the distinguished engineer ; Professor Hayter Lewis, a member of 30 years' standing ; Mr. J. J. Colman, who had been a member for 53 years ; Mr. John Phillipson, the well-known carriage builder of Newcastle ; and Captain W. H. Davies, the Managing Director of the Exchange Telegraph Company.

XXVI.—FINANCE.

The Annual Statement of Receipts and Ex-

penditure was published, in accordance with the Bye-laws, in the *Journal* last week. It shows the revenue of the Society for the financial year ending May 31st last, and the Society's liabilities and assets, its investments, and the Trusts standing in its name. It does not appear that any of the items require special explanation. The statement as a whole may be regarded as thoroughly satisfactory, since it compares favourably with the corresponding statements of recent years.

The sudden death of Mr. Andrew Chadwick, who last year succeeded his father, Mr. J. O. Chadwick, as auditor, caused a vacancy which the Council filled by the appointment of Mr. G. Walter Knox, of the firm of Knox, Cropper, and Company. Mr. Knox is a Past President of the Institute of Chartered Accountants, and has already been associated with the Society's work as its examiner in Book-keeping.

[Sir JOHN WOLFE BARRY having been obliged to vacate the chair during the reading of the report, Major-General Sir OWEN TUDOR BURNE presided over the remainder of the proceedings.]

The CHAIRMAN (Sir Owen Tudor Burne) moved the adoption of the report, and said everybody would agree with him that it was a very satisfactory and encouraging one; the Society's financial position had improved and the number of members was maintained. He thought this arose from two causes—first, that all the valuable papers read in that room were despatched in thousands to all parts of the world, and a great many new members joined the Society in consequence. The Society's work, however, was not confined to the reading of papers; it carried out much practical work also. The examinations had been carried on for half a century. The fact that there was a distinct increase in the number of better class candidates showed that the Society had done right in not raising the standard of the examinations, as it was feared would have to be done, in consequence of the numbers of less qualified candidates who came forward in recent years. He fully agreed with the statement in the Report that the surest basis for a good commercial education was a sound general education. The Society had been engaged in very useful work in connection with acetylene generators and the deterioration of paper, and also deserved credit for promoting the Exhibition of Lithographs. It was to be hoped that this exhibition would result in a great development being made in this particular art. The society had lost a long list of distinguished men during the year, and the Council deeply regretted the death of Sir Douglas Galton, and of Sir

William Anderson; but they hoped that younger men would come forward to fill up the gaps, and continue the long list of distinguished names associated with the Society.

Surgeon Lieut.-Col. J. INCE, in seconding the adoption of the report, said it was a most satisfactory report, and one felt that the Society of Arts was amongst the most flourishing societies of the country. The work in which the Society was engaged was of great importance and most penetrating, dealing as it did with the ordinary interests of the country, and he looked upon the Society as one of the most useful and most important of the nation. As regards commercial education, he said he must confess that he did not understand what commercial education was, or how the special duties of a clerk in a mercantile office could be taught. The keeping of books and making out of invoices involved a knowledge of arithmetic, and it was impossible for clerks to carry on correspondence with foreign countries unless they knew thoroughly the language of the country. In this respect he thought foreigners were ahead of us, perhaps on account of our occupying an isolated position. As an ordinary member of the Society, he desired to bear his testimony to the satisfactory state of the Society and to the admirable character of the report which had been submitted.

Mr. MARTIN WOOD said he should like again to draw attention to the time fixed for the holding of the annual meeting, he thought that if the meeting were held in the evening, it would be much larger and more representative. It was satisfactory to know that the number of members was kept up, and the Chairman's remarks about the influence of the Indian Section in securing new members from India were exceedingly encouraging. The Chairman had alluded to the success of the examinations, and the efficiency with which they are carried on, and he regarded them as of great importance, as their connection with provincial centres prevented the Society from becoming a purely London institution. He endorsed the Chairman's remarks respecting the losses by death which the Society had sustained, and especially with regard to Sir Douglas Galton. It showed them the need for increasing the personal influence of the Society in order to fill up the gaps. They must remember that things were moving around them, and that unless they were making distinct progress, it it would be equivalent to falling off. He should like to see the list of affiliated institutions extended, and inquired if something could not be done about increasing the number of honorary corresponding members, as it would keep up the Society's international interests.

Mr. W. GREEN suggested that the *Conversazione* should be held out of doors—say, in the Botanical Gardens. He thought more people would attend the *Conversazione* if the Council found a fresh place for it. He also suggested that the Council should

arrange some kind of an exhibition every year, similar to those held by the Arts and Crafts, such as exhibitions of wood work, metal work, furniture, and fabrics, as they would do an immense amount of good.

Mr. FRANCIS COBB said, with regard to Mr. Green's suggestion, that it was necessary to provide against bad weather, and that the Council, in selecting a place, always considered that there should be ample room to hold the *Conversazione* under cover, if necessary. As regards exhibitions, he would remind members that the exhibition of lithographs held last year was at the instance entirely of the Society, and was held at South Kensington because the room that was available in the Society's house was not nearly sufficient for the purpose. The Society had held many exhibitions, and exhibitions of the sort suggested were continually being held.

The CHAIRMAN said the Council were much obliged to Mr. Green for what he had said. His suggestions should receive consideration.

The adoption of the report was then agreed to.

The CHAIRMAN moved a vote of thanks to Sir Henry Trueman Wood, also to Mr. Wheatley, Mr. Room, and the other officers of the Society for the accurate, hearty, and loyal work which they did year after year.

Mr. J. J. VEZEY seconded the vote of thanks, which was carried unanimously.

The SECRETARY, in returning thanks for this expression of confidence in himself and in the other officers of the Society, referred to the recent death of Arthur Cowdroy, who had been a clerk in the Society's employment for thirty years.

The ballot having remained open for one hour, and the Scrutineers having reported, the CHAIRMAN declared that the following had been elected to fill the several offices. The names in *italics* are those of members who have not, during the past year, filled the office to which they have been elected.

PRESIDENT.

H.R.H. the Prince of Wales, K.G.

VICE-PRESIDENTS.

H.R.H. the Duke of Saxe - Coburg and Gotha, K.G.	Duke of Abercorn, K.G., C.B.
H.R.H. the Duke of York, K.G.	Captain W.de W. Abney, C.B., F.R.S.
Sir Frederick Abel, Bart, K.C.B., D.C.L., D.Sc., F.R.S.	<i>Sir Stewart Colvin Bayley, K.C.S.I., C.I.E.</i>
	Lord Belhaven and Stenton.

Sir George Birdwood, K. C. I. E., C. S. I., LL.D., M.D.	<i>Sir Edwin Lawrence, Bart., M.P.</i>
Sir Frederick Bramwell, Bart., D.C.L., F.R.S.	Sir Villiers Lister, K.C.M.G.
Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I.	Right Hon. Sir John Lubbock, Bart., M.P., D.C.L., F.R.S.
R. Brudenell Carter, F.R.C.S.	<i>Ludwig Mond, Ph.D., F.R.S.</i>
Right Hon. Viscount Cross, G.C.B.	<i>Sir Owen Roberts, M.A., D.C.L., F.S.A.</i>
Major-General Sir John F. D. Donnelly, K.C.B.	Lord Strathcona & Mount Royal, G.C.M.G., LL.D.
Sir John Evans, K.C.B., F.R.S.	Sir Thomas Sutherland, G.C.M.G., M.P.
Sir Charles Malcolm Kennedy, K.C.M.G., C.B.	<i>Sir William Henry White, K.C.B., LL.D., F.R.S.</i>

ORDINARY MEMBERS OF COUNCIL.

Sir John Wolfe Barry, K.C.B., F.R.S.	<i>Sir William Henry Preece, K.C.B., F.R.S.</i>
Lewis Forman Day	Sir Walter S. Pridcaux.
<i>Professor James Dewar, LL.D., F.R.S.</i>	<i>Joseph Wilson Swan, F.R.S.</i>
Joseph G. Gordon.	William Luson Thomas.
Henry Graham Harris	Professor John Millar Thomson, LL.D., F.R.S.
<i>Sir Edward Nelson, K.C.M.G.</i>	
Sir Westby B. Perceval, K.C.M.G.	

TREASURERS.

<i>The Attorney - General, M.P., G.C.M.G.</i>	B. Francis Cobb.
---	------------------

SECRETARY.

Sir Henry Trueman Wood, M.A.

On the motion of the CHAIRMAN, a vote of thanks to the scrutineers was carried unanimously.

Sir GEORGE BIRDWOOD proposed a vote of thanks to the Chairman of Council, Sir John Wolfe Barry. He said the Society had been very fortunate in its Chairmen, as the first men of the Society had always served the Society with the greatest benefit in all its interests, and it was no exaggeration to say that Sir John Wolfe Barry's services had been equal to those of any of his predecessors. He looked forward to the prospect of his remaining with them as Chairman for another year.

The resolution was seconded by Mr. FRANCIS COBB, and carried unanimously.

On the motion of Mr. W. LUSON THOMAS, seconded by Surgeon Lieut.-Col. J. INCE, a vote of thanks was passed to Major-General Sir Owen Tudor Burne for his services in the chair.

The CHAIRMAN acknowledged the vote of thanks; and the meeting then adjourned.

Journal of the Society of Arts.

No. 2,433. VOL. XLVII.

FRIDAY, JULY 7, 1899.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

EXAMINATIONS.

The results of the Examinations held at the end of last March have been published.

Copies for gratuitous distribution to each candidate who attended the examination have been sent to each centre. Additional copies can be obtained, price 6d. each.

The dates for the Examinations in 1900 will be Monday, Tuesday, Wednesday, and Thursday, March 26th, 27th, 28th, and 29th.

Proceedings of the Society.

CANTOR LECTURES.

BACTERIAL PURIFICATION OF SEWAGE.

BY DR. SAMUEL RIDEAL, F.I.C.

Lecture I.—Delivered January 16, 1899.

The primitive mode of disposal of effete matters consisted almost entirely in the very effective method which is still in use in dealing with the dead, namely, a committal to earth. Deuteronomy xxiii., 12, 13, enjoins that all excreta shall be covered with earth, following the natural instinct of many animals. It will be noticed that this instinctive effort to cover the dejecta is most prominent in the carnivora, in which the matters are most nitrogenous, and therefore more highly offensive, whereas in the herbivora, no such natural propensity is observed. In the case of pastoral populations depending on springs and wells, water was too scarce and valuable to be purposely polluted. Those residing on the banks of rivers also refrained, to a great extent, from casting their refuse into the streams used for their bathing

and drinking, and, having access generally to an ample amount of open and porous soil, employed, what we may call, the earth system. As soon as a portion of the population, for protection or convenience, became aggregated into settlements, it was early found necessary to set aside certain special places for the reception of refuse, hence the midden heaps that have been widely discovered in the neighbourhood of aboriginal villages. After a time for human excreta ditches or trenches were dug, from which the products of decomposition either sank into the surrounding soil, or found an outlet to some watercourse. In many cases trenches were at length filled in with earth, over which a rank vegetation grew, and the soil became gradually purified, a plan which is still followed in the case of temporary camps and in eastern villages. At a later stage, when the progress of civilisation necessitated the use, for washing and cooking, of a larger quantity of water, isolated inhabitants found it difficult to dispose of the liquids, therefore great pits were dug to receive them, and to keep the rain out were roofed over with beams and earth. At a still later period these excavations were lined with brick, arched over, and connected with the houses by brick or flagstone drains. No cement, as a rule, was used in the construction, as it was found that if the sewage sank into the earth less frequent emptying was required. Moreover, if the receptacle or "cesspool" were made air- and water-tight by cement, it was necessary to provide a vent for the large quantity of gas that was generated in the decompositions. The author can record a case where a cemented cesspool in the north of England regurgitated a large quantity of sewage into the cellars of the house, although the pit had been recently erected, and was by no means full. In other cases unventilated cesspools have filled the basements of dwellings with sewer gas.

For houses in isolated positions the cesspool, till lately, was the only available means of sewage disposal, and architects and others spent considerable time and skill upon the design in the early Victorian period, when sanitary progress first drew attention to its importance. I give the following as an example of its successful use, which is interesting on account of its being antecedent both to the French "Automatic Scavenger," to be described in a subsequent lecture, and to the modern "Septic Tank":—

In 1858, a large school in Derbyshire, situate on the top of a lofty hill, surrounded by

its own land, but at a distance of two miles from a small river which ran through other property, had to provide for the sewage of 250 to 300 persons, and the drainage from a farm. The water supply was adequate for ordinary needs, but not sufficient for water carriage of the sewage. A very large cemented brick pit was constructed underground, and arched over, at the back of the buildings and 200 yards from them. Into this the whole sewage passed continuously. When the floating gauge indicated that the pit was full the whole contents were pumped out from a point near the bottom, and discharged by pipes over cultivated slopes, finally filtering through a gravel and chalk soil into a moderate-sized reservoir in a clayey valley at the foot of the hill, where it mixed with water derived from springs and a rivulet. The mixed water was clear and bright, except for an occasional turbidity from the clay. At the periods of emptying no nuisance occurred; sometimes a faint, earthy odour was noticed when the wind was in the direction.

But in towns, the crowding together of cesspools renders a large area of soil waterlogged with black and fetid matter, which undergoes little or no oxidation; while the periodical clearing out may be an offensive, and sometimes dangerous, process. At Hampstead, for instance, in a sandy soil, cesspools were formerly almost universal, and were thickly distributed, so that the earth, and often the basements, were heavily infiltrated; it is needless to say that most of them have now been removed. A striking example of the pollution of a deep well by leaky cesspools occurred at Liverpool in 1872. The Dudlow Lane Well, in the new red sandstone, 443 ft. deep, by continuous pumping had dried up all the private wells in the neighbourhood; these were afterwards used as cesspools. As a result, the water in the deep well became polluted, and in a few years after its construction it had to be closed. On diverting the drainage from the cesspools the water was so improved that it was considered safe to resume its use.

For these reasons it became necessary to organise a regular system of drainage by sewers. But the difficulty was still not overcome. In the ramifications of these canals a good deal of leakage occurred. The construction of traps to intercept the gases, and of ventilators to remove them, was for a long time, and in many parts still continues to be, very imperfect; in fact, the ventilation question is only now showing signs of solution. The

greatest difficulty, however, arose when an outlet had to be found for the immense volume of the sewage of modern towns. To discharge it untreated into rivers, unless of many times the capacity of the sewage and well oxygenated, converted the stream itself into an open sewer. It will be in the memory of many Londoners how black and offensive the Thames was formerly between the bridges, and even in 1894 the Seine near Paris was so polluted that Dr. Billings observed, "Bubbles of gas from the putrefying slime at the bottom escaped from the dark surface, and no fish could live in it," affording an example of a bacterial process working naturally, but imperfectly and under improper conditions. The Irwell, at Manchester, in 1892, was practically sewage, as the following analysis by Hepworth Collins (*Transactions Sanitary Institute*, 1892, p. 196) will show:—Total solids, 160·6; consisting of organic 59·6, mineral 101·0, suspended solids 29·6, ammonia free and albuminoid 0·900, chlorine 11·9; oxygen absorbed 4·90.

EFFECTS OF DILUTION.

On the other hand, with conditions that are favourable, the purifying action of rivers is known to be very great. Towns on the banks of rivers of considerable width, and having a fairly constant volume and velocity during all seasons, have discharged their raw sewage into the stream for many years, and investigation has proved that a few miles below the outlet of the sewers there is little or no trace of pollution.

Many chemists believed that sedimentation was the main cause of any self-purification in river water. But any extensive improvement by mere sedimentation would be on the wrong lines, and should not be permitted, as it would result in a filling up of the river bed and formation of dirt banks which become foul. If, on the other hand, suspended organic matter is slowly removed to the river bed and is there attacked, in the absence of air and light, by the organisms naturally fitted to the purpose, the products will dissolve and become available for the water bacteria in the river. In a paper read at the British Association at Bristol in 1898 on "Standards of Purity for Sewage Effluents," I discussed the conditions for safe discharge into a flowing stream, pointing out that "methods had been found which, by natural agencies, allowed us to carry the purification to a rational and harmless stage, when such factors as time, light, volume of oxygen, and various life of a river will be more than sufficient to deal with the effluent."

Pettenkofer, from investigations on the river Isar, at Munich, has concluded that if the sewage never amounts to more than 1-15th, or 6·7 per cent. of the river water, and the velocity of the latter is at least equal to that of the former, the raw sewage may be poured into the river without causing pollution.

In America, from the results of actual observations on rivers, under the direction of the Massachusetts Board of Health, Rudolph Hering fixes a limit to the amount of free ammonia permissible in a stream, and finds that if the flow of a stream is less than $2\frac{1}{2}$ cubic feet per second per 1,000 persons (or one gallon per minute per person), "an offence is almost sure to arise," but when the flow is greater than 7 cubic feet per second per 1,000 persons, then safety is assured. "In other words, when the free ammonia is greater than 0·12 parts per 100,000, the conditions are probably objectionable." These limits correspond to about 50 volumes of river water to average sewage in this country. Mr. Stearns, the engineer to the Massachusetts Board, concludes that if the average amounts to more than 1-40th, or 2·5 per cent. of the river water, it cannot be discharged into the river in its raw state; if it amounts to less than 1-40th, and more than 1-130th, it is doubtful; if less than 1-130th, it may be admitted without any doubt in its raw state into the river. These conclusions are, of course, empirical, and have not been generally accepted; they would be greatly affected by the amount of solid matter present in the discharge. It must be remembered that the sewage in America is much more dilute than in this country, that the rivers have greater volume, and that the limit is much higher than we have found necessary in England.

It is possible, however, to form an estimate as to the amount of sewage which can be dealt with by a flowing stream, if one remembers that the bacteria, always naturally abundant in river water, are able by the aid of the oxygen dissolved from the air to consume more or less rapidly the organic matter. It is evident that the volume of the sewage and the oxygen required by the organic matter in it as measured by permanganate—*i.e.*, the "oxygen consumed"—should bear some relation to the flow of the river and its aeration. But, in addition to this, it is also desirable to take into account the amount of available oxygen as nitrate and nitrite, since it has been proved that, always with the help of bacteria, the oxygen of nitrates and nitrites is available or the burning up of organic matter.

From these factors the following formulæ may be deduced. Where X is the flow of the stream, O the amount of dissolved oxygen, S the volume of effluent, M the "oxygen consumed" by the latter, N the available oxygen as nitrate and nitrite, C the ratio between the amount of oxygen in the stream and that which is required to oxidise the organic matter in the effluent, then the equivalent will be—

$$XO = C(M - N)S.$$

Where the sewage is fresh, and no nitrates have been formed—

$$XO = CMS.$$

If N be less than M, $M - N =$ the deficit of oxygen in the effluent, requiring to be supplemented by the free oxygen in the river: such an effluent will throw a burden on the river, and cannot be considered in a satisfactory state, and it will be a question of volume and other circumstances whether it can be permitted to be discharged at all. This may be determined by the consideration that if the available oxygen of the river, XO, be greater than the demand $(M - N)S$, there will be a chance of the stream dealing with the inflowing liquid, but if the reverse be the case, foulness will necessarily accrue.

In the favourable cases where bacteria and algæ are active, and the oxygen of the river is able, by their help, to deal rapidly with the incoming residues, the minimum ratio between the volume of the stream and the volume of effluent that could be allowed to be discharged into it would be indicated by the value of C in the above equation, which would also approximately denote how far the population might increase before the proportion could be seriously disturbed. The minimum figure will be reduced by the nitrites or nitrates of the river water itself, or the free oxygen which may be present in the effluent. River water often contains about 90 per cent. of its nitrogen in the oxidized form, and when saturated, holds about 700 c.c., or, approximately, one gramme of dissolved free oxygen per 100 litres. These materials for purification require to be supplemented by the agency of the natural bacteria, which, with the almost unlimited exposure and admixture in a flowing river, we may assume as certain to be present. Hence, in theory, comparatively few volumes of a river water will supply the requisite oxygen, which explains the well-known fact that in the lower reaches of a river the dissolved impurity is only a fraction of what has entered in its upper course. Dupré states that, on an average, dilution with thirty

volumes of fully-aerated river water prevents sewage from fouling, and ultimately purifies it. Even a less proportion, in my experience, has been effectual.

For one town then, on the banks of a large river, or even several towns, if they are sufficiently separated to allow natural recovery and aeration of the stream, the elementary method of discharging the untreated sewage into the water direct has been successful in the past, with the proviso usually required that by screening, sedimentation or precipitation, the suspended solids should be prevented from forming mud-banks and deposits of black sludge on the river bed.

Exeter, for example, a town which is now interesting from its association with the septic tank system, has also the historical position of being the first city to be sewered, and to discharge the combined sewage, untreated, into a river. As the volume of the Exe is about forty times that of the sewage, at the recent inquiries no chemical evidence of pollution a few miles below the city was obtainable.

But in countries thickly populated there is no such opportunity for the recovery of the river. Given even twenty-four hours for the completion of the natural process, the river would arrive at the next town denuded of its oxygen and in an unfit state for the reception of more sewage. The result has been such a condition as I have already mentioned in connection with the Seine and Irwell. Hence it is, as a rule, necessary for the sewage to be prepared before it can be allowed to be discharged, and the methods for so doing constitute our present subject.

It will be noticed that the characteristics of sewage are the converse of a pure running stream; and this is true, not only from the chemical point of view, but also when one studies the normal flora and life in the two. In a well oxygenated river the water bacteria are mainly aerobic, and carrying out their life-work of oxidation of the nitrogenous and carbon compounds presented to them. In a sewage, on the other hand, dissolved oxygen is usually absent, or, if present, soon disappears on standing, so that the organisms capable of living in this environment must perform their life-work without free oxygen. The water bacteria have been studied for many years, and those commonly occurring in river water are well known. Sewage organisms have only attracted attention during the last few years, and bacteriologists are now engaged in identifying the flora of different sewages, with especial

reference to the changes which they effect in the chemical constitution of their environment. It would seem, therefore, from the outset, that if these sewage organisms have any useful part to play, similar to that which they naturally do, in any modern system of sewage disposal admixture with river water, in which an entirely different set of organisms live, or exposure to the air, must be avoided. We have seen that in the two earlier methods of disposal, viz., committal to earth and the cesspool, absence of light and air were obvious conditions obtaining in both; and now, with our modern knowledge, we can say that these two conditions were favourable to the life-work of the organisms concerned in the destruction of the organic matter. With the introduction of the water-carriage system a departure from these conditions was made, and the difficulties which have since arisen can, in most cases, be attributed to a violation of one or other or both of them. When sewage is discharged untreated into a river, as we have just seen, sewage conditions or river conditions will exist after admixture, according to the ratio of the admixture. As sewage conditions involve absence of light and air, they will continue at the bottom of the river unnoticed if sufficient river water is present to mask these initial changes which must take place. If the river be a small one the sewage conditions may predominate, and constitute a nuisance which is all the more marked because the changes involved take place unobserved (out of the air) and unseen (in the dark).

It will be out of the scope of the present lectures to enumerate the characteristics of any of the water organisms concerned in the chemical changes taking place in a running stream. It is evident, however, that they normally can deal with the food supply presented to them, and the whole of the life of the stream is determined by their activity. At the present time it is becoming daily more possible to detect whether a river water has a flora which in any way departs from the normal, so that evidence of sewage pollution may now be ascertained by a careful examination of the types of water organisms present. Thus, for example, recent work on the organisms present in London sewage by Dr. Houston, for Dr. Clowes, the chemist of the London County Council, has established the following facts:—

Bacillus fluorescens liquefaciens and *B. fluorescens non-liquefaciens*, were generally, but not always, discovered. The bacteria causing fluorescence do not seem to be so

prevalent in the London sewage as in that from other sources. Both the above are frequent in natural waters.

Proteus.—The species most abundant was not the typical *Proteus vulgaris*, but liquefying and gas-forming protean forms were very numerous.

B. coli communis is constantly present in very great numbers. This organism is absent, at all events in any numbers, from pure waters. Varieties of the *Coli* group are also abundant.

Of spore-bearing bacteria, the spores of *B. subtilis*, *megaterium*, *mycoides*, and *mesentericus* were frequently found. These are chiefly notable for their great vitality and resistant powers, but are also met with in natural waters.

B. enteritidis sporogenes (Klein), was constantly present: it is believed to be causally related to diarrhoea. Cultivations of it are extremely virulent.

Unfortunately, many of the organisms enumerated also occur in river waters which presumably are pure, so that their value for diagnosing the presence of sewage in water is only of slight value. Dr. Houston, however, points out that the *B. enteritidis* of Klein is so characteristic of sewage that its presence in a river water may be regarded as a sure sign of the addition of sewage. This organism, like other typical sewage organisms, thrives in the absence of air, and is recognised by its coagulating effect upon the organic solids of milk, a property which the ordinary water bacteria lack.

Seaside towns usually discharge their sewage on the foreshore near low-water mark, but a great portion is returned by the tides, and the serious nuisance often occasioned has led to agitation against this practice. Sea water is not a satisfactory medium for the purification of sewage, partly because it contains a comparatively small number of water bacteria, but mainly because the tidal disturbances prevent sedimentation of the suspended organic matter, which allows, as we have seen, the organisms which live in the absence of air and light to do their necessary work.

A partial return to earth-disposal was seen in the adoption of irrigation, but the experience gained on sewage farms, and the study of nitrification by bacteriologists, have shown that, in the case of land treatment, different soils have very varying efficiencies. Thus the earlier experiments seemed to show that the "cleansing" power of a soil was determined entirely by its physical condition, porosity,

freedom from clogging, water-retaining power, &c.; whereas at the present time we know that the composition of the soil and its bacterial condition modify the results. In some soils nitrification either does not take place at all, or goes on with extreme difficulty. Crude sewage discharged direct on land rapidly coats it with a felted layer of black decomposing matter, which hinders the access of oxygen, chokes the plants, and soon creates a nuisance, unless the soil is exceptionally sandy or porous as in the neighbourhood of Berlin.

Great diversity of opinion existed as to the best vegetation for a sewage farm. Root crops and Italian rye grass found favour on some farms, while osier beds met with success on others, and owed a portion of their usefulness to their acting as a mechanical strainer. At Sutton, in recent years, peppermint has been found profitable, whilst sunflowers have been advocated as a suitable quick-growing crop. But the results were above all dependent on the soil. Thus Dr. Frankland, in 1870, speaking of a sewage farm at Barking, remarks on the slowness of nitrification, while with regard to a loam from Dursley, in Gloucestershire, he found that it surpassed all others experimented on in its power of purifying sewage, as it had a cleansing power of nearly 100,000 gallons per acre per day. We now know that the presence of carbonate of lime, or of gypsum, is favourable to the growth of nitrifying organisms, and the Dursley soil contained 8.1 per cent. of CaCO_3 , while that at Barking had less than 2 per cent.

I had lately to determine the merits of alternative sites for a sewage farm in the Midlands. The average amounts of water in the three soils were 6.75, 1.90, and 3.05 per cent., while their comparative nitrifying power, as shown by their action on dilute urine, was 17, 50, and 36, which is almost exactly in inverse ratio to the amount of moisture, showing the powerful adverse retarding influence of a water-logged soil.

The unsatisfactory results on sewage farms led to the opinion that the sewage should be first prepared, and a "combined system" of treatment was prescribed almost universally by the Local Government Board. The details of different processes of screening, filtering, sedimentation, and the use of precipitants are beyond the scope of these lectures. It is sufficient to say that the removal of suspended matters, and a greater or less reduction of

those dissolved, was attained, it was then considered, mainly by physical or chemical means.

One cannot, however, omit to draw attention to the almost universal adoption in this country of different methods of chemical precipitation after the River Pollution Commissioners issued their report. This was in great measure due to their finding that chemical precipitation effected the removal of the greater part of the suspended organic matter, and of some of the dissolved organic matter. This result was seized upon as a practical method of dealing with the sewage problem, as the effluent after such chemical precipitation was obviously less foul than the raw sewage. It was forgotten almost entirely, however, that the Commissioners, in the same report, distinctly state that just as good results could be obtained by upward filtration; in other words, if the sewage were allowed its conditions of absence of air and light, it could be brought into solution and towards purity. It was also not recognised at that time, that chemical precipitation, while removing the suspended polluting matter, would also remove the concomitant bacteria from

their sphere of usual action, and thus prevent any desirable changes naturally brought about by them. Likewise also, it was not realised that heavy doses of chemicals were likely to be inimical to these beneficent bacteria to such an extent that they might be killed or their work arrested.

The conclusion of the Massachusetts Board, in their report of 1890 (p. 788), showed that "it is quite impossible to obtain effluents by chemical precipitation which will compare in organic purity with those obtained by intermittent filtration through sand." It would thus seem that for nearly 20 years the almost universal practice of chemical precipitation had been wrong in principle, and that the example set by Merthyr Tydvil in 1871 should have been followed. This town then contained 50,000 inhabitants, and the sewage, after treatment with lime, was subjected to intermittent filtration through 20 acres of porous soil drained from 5 to 7 feet deep, under the superintendence of Mr. Bailey Denton. From the analyses made by Sir E. Frankland in 1871-2, I have prepared the following averages, adding also his "proposed standards of purity."

	Dissolved Solids.	Organic Carbon.	Organic N.	NH ₃	N as Nitrates and Nitrites.	Total combined N.	Cl.	Suspended Solids.	
								Mineral.	Organic.
"Proposed Standards"	Unlimited	2.0	0.3	Unlimited	Unlimited	Unlimited	Unlimited	3.0	1.0
Sewage after liming	52.0	2.44	0.9	2.7	.017	3.18	5.98	11.8	21.6
Filtrate	33.2	0.14	0.03	.063	.273	.348	2.74	trace	trace
Subsoil water	19.4	.106	.011	.004	.061	.075	0.9	—	—

The figures show that the sewage has undergone dilution with more than its volume of subsoil water, and probably with some rain, as the mean dissolved solids of the sewage and subsoil water are about the same as those in the effluent, while the chlorine in the effluent is less than half that in the sewage. But even with this allowance, the result justifies Frankland's pronouncement that "the effluent water on all occasions was purified to an extent much beyond that required by the standards of pollution suggested by us as those below which refuse liquids should not be permitted to enter rivers." The analyses are of further interest at the present time, as we can see from them that:—

The reduction of the total nitrogen, by about 75 per cent. (making allowance for dilution), is not accounted for by the somewhat meagre production of nitrate and nitrite.

Since the sewage "gradually sank into the soil as it flowed," this improvement can only be partially due to volatilisation of free ammonia, of which soils, as is known, are very retentive.

The large reduction in organic nitrogen was doubtlessly occasioned in part, at first, by its absorption by the soil, but as the analyses extended over nearly a year and half, and the later ones showed the same changes, this mechanical absorptive action must be excluded as an unimportant item.

The explanation is to be found in the life of the bacteria growing in the soil, and acting by various processes in which a large quantity of free nitrogen and lower oxides of nitrogen is generated from both ammonia and organic matter, and evolved as gas. In fact, the whole process, instead of being, as it was considered at the time, partly mechanical and partly chemical, was in its essence bacteriological.

Even under favourable conditions the results of irrigation are dependent upon the degree of skill with which the work is directed. When sewage is poured over clay-land which cracks in dry weather to the depth of the underground drains, it escapes in such weather almost immediately from the field in an imperfectly purified condition. When allowed to flow over an uneven surface, or without a regulated flow, it is certain to form stagnant pools in which the plants are injured, or only rank weeds are produced. All the uncertain conditions with which a farmer has to deal are complicated by the stream of sewage. Although the opposition almost invariably encountered in the establishment of sewage farms, on account of the nuisance often occasioned and the expected injury to health, does not seem to be well-founded where the management is efficient, the hope of return of capital has had in nearly all cases to be abandoned, on account of the initial cost of the necessary land and the poor return from the crops grown. For these reasons the insistence of the Local Government Board on a final treatment by land has met with very severe comment, especially since it has been shown to be practicable by bacterial agencies to accomplish the object with less attention, space and cost, and with more regularity. At the same time all these rudimentary methods which have been described have depended for the final stage of purification on the assistance of a river, or of porous land.

Miscellaneous.

POTTERY AS A HISTORICAL DOCUMENT.*

When I was invited to open this Exhibition, I was asked to deliver an address on the history of pottery. Although I had at hand, to help me, the late Professor Middleton's admirable article on "Pottery" in

* Address delivered by Sir George Birdwood in opening the Industrial Exhibition at Clough Hall, near Stoke-on-Trent, Thursday, 22nd June.

the *Encyclopædia Britannica*, and Messrs. Sparkes and Sandys recently published volume on *Potters: their Arts and Crafts*—that was rather an unmanageable subject to deal with in about twenty minutes, and what I have determined to do is, before dealing with the present position and future prospects of the potting industry in Staffordshire, to say a few words on the overwhelming magnitude of the debt of the whole civilised world to the potter's craft, in providing us with the very earliest, the most continuous, the fullest, and the most authentic, of the contemporary records that have come down to us from "the dark, backward, and abysm of time" of all the historical states of Antiquity. Pottery was the oldest and most enduring of the arts, and with basket-making and weaving, marks in every country the first dawns of civilisation. All the initial civilisations have arisen in great river basins, such as the basins of the Ganges, the Tigris and Euphrates, and the Nile; and this has been due not only to the supply of water for irrigation, but of clay for potting.

CHALDÆA.

Chaldæa, later known as Babylonia, was architecturally and artistically, if not also commercially and politically, entirely a creation of the potter. Juvenal (x. 171) says that "Babylon was a city protected by potters;" Ovid (*Met.* iv., 58), that "Semiramis raised up the proud walls of Babylon with baked bricks;" and Ezekiel (xxiii. 14), that "men [were] pourtrayed upon the walls of the palaces of Babylon, the images of the Chaldeans pourtrayed with vermilion." The modern excavations of Layard at Nineveh and Babylon, and of Dieulafoy at Susa, have confirmed these literary references to the immemorial tradition of the prodigious production of bricks and other fictile wares in Babylonia, and of the perfection there attained in the decoration of public buildings with tiles, and large slabs graven, or incusted, or moulded with illustrations of current events, and painted over in enamel with the most brilliant colours. But the most remarkable creations of the potters' craft in the valley of the Tigris and Euphrates are the tablets, inscribed in cuneiform characters with the chronicles of the rulers of Assyria and Babylonia, and with the religious conceptions and beliefs, and the memoranda of the daily lives and business transactions of their people. The record tablets of Assyria provide an unbroken and minutely detailed chronicle of the declining decades of the Old Empire, and of the whole period of the New Empire to its confused close, that is from B.C. 900 to 667. For Babylonia the chronicle texts reach continuously back from the 6th century B.C., to beyond King Khammarubi, who first brought all Babylonia under one rule, B.C. 2376-33. But casual tablets carry us far beyond the latter date. A cylinder of Nabonidas, B.C. 556, assigns to a predecessor, Naraim Sin, a date of 3255 years before his own, *i.e.*, the date of B.C. 3755. At first this abysmal date was received with natural scepticism; but some years ago an American exploring

expedition unearthed at Nippur, at a depth of 30 feet below the surface of the soil, the platform of a temple all the bricks of which were inscribed with the names of Naraim Sin and his father Sargon I; while below this platform they excavated the *débris* of older buildings, down to the depth of another 30 feet; the inference being that the oldest buildings constructed on the spot cannot be assigned a later date than B.C. 7000. At all events the pottery of Babylonia affords conclusive evidence of the actual beginnings of art and artistic culture in Mesopotamia centuries anterior to B.C. 4000. But not only the whole chronicle history, but the whole religious literature of the Babylonians has come down to us indelibly scripted on these imperishable burnt tablets, of which almost every city, the ruins of which have so far been explored, appears to have possessed an edition of its own.

EGYPT.

Pottery in Egypt goes back to as primæval a period as in Chaldæa, and at a very early date reached the highest perfection in the form of unglazed bricks, unglazed and glazed tiles, glazed scarabs, and other images of the gods, richly-enamelled plaques, and painted vases. The pyramid builders of the IV. Egyptian Dynasty, B.C. 3751-3998, were the contemporaries of Sargon I. and Naraim Sin in Chaldæa. Very beautiful also are some of the doorways, built up of enamelled tiles, of the tombs and temples of the XIX. Egyptian Dynasty, in the 13th and 14th centuries B.C.; and very valuable in many ways was the Egyptian fashion of representing in their vase paintings every type of the human races known to them, with the details of the clothing and jewelry worn by them, and of the arms they carried. In this respect we are indeed under as deep an obligation to the Egyptian potter, as to the Assyrian sculptors of the so-called "Nineveh Marbles." But the history of Egypt was never intentionally recorded in pottery, as was that of Babylonia; and we only become dependent on pottery for Egyptian history where the stone monuments of the country have disappeared, as in the Delta; and the only light we obtain from the vast mounds of broken tiles and vases that exist there is casual and disconnected. The earlier Egyptian dynasties ruled from capitals without the Delta, from Memphis (just at its apex) to Elephantine, throughout which prolonged tract the river Nile is huddled in on either side by rocky hills, precluding therefore any temptation to destroy the earlier monuments for the construction of later buildings. On the other hand, the XXVI. Dynasty, founded by Psammetichus I., in the 7th century B.C., had its capital at Sais, well within the Delta, where nearly all the stone monuments set up by Psammetichus I., and Pharaoh Necho, and Pharaoh Hophra, and their successors, have been used as quarries for providing the Arab devastators of Egypt with materials for building the cities of Rosetta, Damietta, and Cairo. On the other hand,

the Delta being rich in clay, it became from a very early period a great centre and market of the potters' industry; and the site of the Greek colony founded at Naucratis during the reign of Psammetichus I., has been identified, and its internal economy, and external trade, and its whole history traced, by means of the painted and lettered potsherds found among its ruins. This city, so rich in the remains of the fictile arts and crafts of the Greeks, is also deeply interesting to all Englishmen, as the first fruit of the free trade policy, initiated by Psammetichus I., of throwing Egypt open to foreign settlers. The similar policy adopted, in the same 7th century B.C., by Nebuchadnezzar II., gave its first great impulse to the sea-borne traffick of Babylon'a with Persia, Arabia, Western India, and the East Coast of Africa: and this enlarged commercial intercourse between the countries of the Indian Ocean, gradually joining hands, across the isthmus of Suez, with the active mercantile enterprise pursued by the Greeks, in succession to the Phœnicians, along the coasts of the countries of the Mediterranean sea, at last that great historical trade was established between Southern Europe and Southern Asia, which flourished almost uninterruptedly from the 7th century B.C., to the rise of the devastating Saracenic power in the 7th century A.D.

GREECE.

As the "go-a-ducking Phœnicians" were the first intermediaries in the trafficking between the peoples of the Mediterranean countries, and were later supplanted in this coasting trade by the "cogging Greeks," the latter were until very recently supposed to have received the first inspiration of their arts from Egypt and Anterior Asia: and one of the greatest services rendered by the potter to the history of art has been to prove, within the present generation, that while Hellenic art certainly received certain impulses, and a variety of decorative motives, from both Mesopotamia and Egypt, these existed in Greece, centuries before the Dorian invasion [*circa* B.C. 1100], a highly developed indigenous art, which, in the traditions it provided of the close study of nature, and of refined technical methods, laid the solid foundations of the Hellenic art of Greece, as it began to assert its independent individuality between the 8th and 7th centuries, and reached its perfection in the 5th and 4th centuries B.C.; and that the influence of this pre-Hellenic art of Greece not only dominated the immigrant Hellenes, but asserted its influence over Europe, far beyond the limits of Greece, to the very shores of the Baltic Sea and the German Ocean.

In 1868, Schlieman made his marvellous discoveries in the prehistoric mound at Hissarlik in the Troad, and in the prehistoric ruins at and about Mycenæ in the Argolid. These discoveries included not only figulines, but all sorts of objects of art, of which the most sensational were of course the jewelry of elaborately wrought gold. Schlieman thought he had broken into the Treasuries of Priam and Atreus,

and laid bare the very bones of Agamemnon. But he had done something much more important in the elucidation of the history of European art, for his discoveries—confirmed as they were by the discovery of similar figulines at Ialysus in Rhodes, in the islands of Thera, Naxos, and Paros, and throughout the Cyclades, in Cyprus, in the Mycenaean cemetery at Thebes, in the Temple of Apollo at Delphi, in the neighbourhood of Athens, and, sporadically, over all Greece—demonstrated that an indigenous civilisation, capable of the highest artistic achievements, had preceded the primitive Hellenic civilisation of Greece, and that in its beginnings it must have extended back to the very verge of the neolithic night of Europe; and that after it was suddenly blotted out by the Dorian invasion of Greece, *circa* B.C. 1100, the tradition of it still remained a living artistic force in Greece, and irradiated the stories of the *Iliad* and the *Odyssey* with their after-glow. This Mycenaean or, as it is now called, Ægean art, culminated in the 15th century B.C., and was therefore contemporary with the later Pharaohs of the XVIII. and the earlier Pharaohs of the XIX. Egyptian Dynasties. Its ornamentation is characteristically marine, and some of its conventional motives were conveyed, in the course of the prehistoric amber trade of Europe, into the countries of the Baltic Sea and German Ocean, where, centuries afterwards, they reappeared as “The Three Legs of Man,” and “The Celtic Knot.” The jewelry is, as already said, wrought with the utmost skill, while the pottery, in the best baked ware, is found fully developed in colour, glaze, and varnish. In the *Iliad* and *Odyssey* many of the lesser objects of industrial art are mentioned as the work of the Phœnicians; but the nobler ones are ascribed to the gods, that is to the forgotten and mythologised artists and artificers of “Mycenæ the Golden [πολύχρυσος].” The *Iliad* and the *Odyssey* were, indeed, the only links between the Ægean art of prehistoric Greece and the Hellenic art of Phidias and Praxiteles, until the recent excavations of the Acropolis, below the *débris* of the buildings re-erected on the sacred hill after the destruction of Athens by the Persians, B.C. 520, led to the discovery of the immense collections of the remains of primitive Hellenic art that had lain there buried and undisturbed for over two millenniums. After this date there was a rapid evolution of Hellenic art, the chronology of which, from first to last, is always to be most clearly and fully traced in the fictile wares of the Greeks, that is in their painted vases, which, including many of the so-called Etruscan vases, also afford us the most complete descriptions we possess of the costume, manners and customs, and whole social life, and also of the religion and mythology of the Greeks.

ROME.

Glancing at the native pottery of Italy, in so far as it throws any light on the ancient history of that country, I would briefly refer to the excavations of the

terramarine village of Castellazzo di Fontenallato, where a rustic crematorium was found, having beside it a platform with a number of urns, containing the ashes of the dead, arranged on it in a four-square order, with dividing cross gangways, after the ground-plan of the villages of primitive Italian, and all antique cities. This is one of the most pathetic and suggestive relics of primitive Europe. I will only add, under this head that, the remains of Roman pottery indicate to us more exactly than any of the literary records of even so comparatively late a date, what were the real limits of the Roman Empire, so far as its intimate civilisation spread beyond the boundaries of Italy.

BRITAIN.

There was a vigorous native art in Britain before the Roman conquest of these remote and fog-banked islands, an art of the nature-loving Ægean type, and undoubtedly indirectly inspired by the Ægean art of Mycenæ; but such was the predominant force of the Roman invasion on southern and south-western Great Britain, that our indigenous rustic pottery was at once replaced by the so-called Samian ware, the fashion of which was imported, as Pliny tells us, from the island of Samos into Etruria, and was afterwards imported by the Romans into whatever still savage countries they carried their ever-victorious standard. But our native industrial arts found a timely and safe refuge in Scotland, and Ireland, where the practice of them slowly developed those distinctive Celtic arts, which as Rome declined and at last fell, re-issued from their reinvigorating retreats, and, as modified by Byzantine [including so-called Saracenic] art, flourished for centuries over all Western and Northern Europe, and even reacted on the arts of Byzantium.

THE FUTURE OF BRITISH POTTERY.

The advances made in British pottery during the past 150 years has been remarkable, and the improvement in its artistic quality since the Great Exhibition of 1851 has been truly wonderful. That exhibition gave an extraordinary impulse to all the artistic industries of the United Kingdom, excepting jewelry; and in none of these industries have the resulting effects been so beneficial and momentous as in pottery; the redeeming grace of our pottery, in all its numberless local variations, being the distinctively British love of nature, and of the study of nature in the harmonious combination of decorative forms and colouring, which can nowhere be artificially combined more felicitously than in pottery. Never was the pottery industry of this country more healthful and active than at the present time, and there is before it an immediate future of unbounded prosperity. Its artistic superiority, in its simple naturalness and dexterous *technique*, over the pottery of all other European manufacturing countries, was being everywhere recognised, and the demand for all classes of British pottery was every

year increasing in the United States, and the other English-speaking nations of the New World and the Old. Apart from this, pottery was coming into growing demand for many purposes to which it had never before been generally applied in this country. The National Liberal Club, in Whitehall-place, London, was an illustration of the pleasing effects to be obtained by covering the walls of ordinary living-rooms and house passages with enamelled tiles. In the Brompton-road, London, a house is now being completed, the whole front of which is covered with enamelled tiles of deep-toned brown. Nothing can be more magical than the play of the slanting shafts of the light of sunrise and sunset on these tiles. The Birkbeck Bank in Southampton Buildings, off Holborn, London, is being entirely renewed in polychrome pottery, not only the ornamentation, but the entire architectural construction, so far as it appears externally, of the building being rendered in variously and vividly coloured enamelled terra-cotta. Of course, pottery readily yields itself to excess of elaboration in decorative details, and some will possibly feel that this has happened with the Birkbeck Bank, both in the plastic ornamentation and the colouring of the building; but, none the less, it is a hopeful illustration of what can easily be done to render the streets of London, and other smoky cities of the United Kingdom, as clean, and bright, and cheering in the future, as at present they are dirty, dull, and depressing. The greater part of London, and of Manchester, might rapidly be rebuilt in enamelled terra-cotta, and with the finest effects of both foreground and distance, and with the most charming flamboyance of softened colouring along the skylines. In Lambeth both scenic stoneware and earthenware are now being largely introduced in the internal decoration of public houses. The tap-room of one of them has lately been lined with a polychrome representation of the Lambeth bank of the Thames one hundred years ago, showing the house as it then stood. Nothing could be more attractive. There is, of course, no limit to the potential demand for enamelled tiles and decorative stoneware for these and similar applications. The internal decoration of St. Paul's also at once suggests how profitable it would be for the potters of this country to take up the manufacture of earthenware and stoneware, if not of glass, mosaic cubes or "tessere," for the external and internal decoration of public and even private buildings. A great outcry has been raised against the decoration of St. Paul's with mosaic. The practical answer to it is to visit the Cathedral as the work progresses, and I am glad to say that it is progressing without interruption, and to see it in the varying lights and shades of dewy morn and dusky eve and unclouded midday. Words cannot describe the stately splendour of the magnificent and enchanting vision that rises before you in the choir—divine in art of colour and design; and when the whole work is completed, this achievement of the

self-denying piety of the Dean and Chapter of the Cathedral, and of the genius of Sir William Richmond, will be regarded in all future time as the crowning architectonic glory of Victorian reign. That the outcry against it should have received any semblance of official support is nothing short of a national scandal.

I have said nothing of the use of unglazed tiles and unglazed terra-cotta mouldings in house building and decoration. There are two highly ornamental chimney-pieces, of dull brick-red terra-cotta, almost as hard, to all appearance, as unpolished jasper, in the Council Reading Room of the India Office, which deserve more attention from architects and decorators than they have received; and the Science Schools, at South Kensington, and the Natural History Gallery (British Museum), opposite to it, are two notable examples of buildings of unglazed terra-cotta. But the objection to its use in both these examples is that it is intentionally made to simulate stone, with the result of painfully disillusioning the admiring student of the noble architectural frontage of the latter building when once the imposition is exposed. The deception in this building is the more difficult of detection owing to the "bonding" of the terra-cotta blocks after the manner of stone masonry.

There is another application of pottery, in the production of bright, showy trinketry. The Egyptians were great adepts in it, enhancing the brilliance of the variegated enamels used in the first firing, by leaving depressed points on the surface of the objects [usually of a prophylactic, phalacterial, or talismanic character], into which fragments of richly-coloured glass were fixed, and fused by a second firing. Gaily painted, and carefully modelled in the minutest details, this dainty trinketry was in design and subtlety of artifice a triumph of the potter's craft and, indeed—to say so without offence—of his craftiness. Stoke might do much in this way to cut out Birmingham, and there would be nothing of the tarnish of "imitation"—of "Brummagem"—about such figural jewelry.

THE ARTISTIC EDUCATION OF THE ARTISAN.

To secure this future, the indispensable requirement was to advance in every way the technical and artistic education of the British potter. That is too large a subject to treat fully in bringing my remarks to a close. I will only say on the point that, it is as true of pottery as of all other artistic industries, it is indeed more true, as clay responds so readily to one's mental suggestions, that the skill of the artisan can be perfected only in the education—the drawing out—of his artistic ideals; and that two things are essential to this. The first is to intimately familiarise the potter with the best examples of his art, and, above all, with the masterpieces of the Greek potters. One has to insist on this in an unhistorical age, in which men are apt, in their degrading ignorance of tradition, to rely too exclusively on their technical proficiency, and overweening conceit of themselves. The second essential, and still greater thing, is

fortunately, innate in all the Aryan races, and deeply implanted in the British races, and that is the simple love and diligent study of nature; the love of our green hills and dales, of the bright flowers of our fields and lanes, the birds that fill our rejoicing skies with song, and the shells and other strange sea things the surging waves wash up on our shores, the colours of sunrise and sunset, and the jewelled constellations of the midnight heavens. The love of these things must be fostered in every way; for, quoting from Longfellow, whose *Keramos* this exhibition and its neighbourhood have vividly recalled to my memory:—

“Art is the child of Nature; yes
Her darling child, in whom we trace
The features of the mother’s face,
Her aspect and her attitude,
All her majestic loveliness
Chastened, and softened, and subdued
With a more attractive grace,
And with a human sense imbued.
He is the greatest artist then,
Whether of pencil or of pen,
Who follows Nature. Never man
As artist or as artisan,
Pursuing his own fantasies,
Can touch the human heart, or please,
Or satisfy our nobler deeds,
As he who sets his willing feet
In Nature’s footprints, light and fleet,
And follows fearless where She leads.”

PATENTS IN 1898.

The report of the Comptroller-General of Patents for the year 1898 has just been issued. For the first time since the Act of 1884 came into force, there has been a distinct falling off in the number of applications for patents, the applications in 1898 numbering 27,659 as against 30,952 in 1897, a decrease of 3,293 or 10·7 per cent. In the year 1895 there was a falling off as compared with the previous year, but the difference at that time was a little more than 300. The Comptroller considers the rapid growth in the number of applications which took place in 1896 and 1897 was to be attributed to the activity of the cycle industry, and that there is little doubt that the decline in that industry has caused the present decline of numbers.

As the 1884 Act has now been in operation for 14 years, the earliest patents granted under it have run out their full time. It appears that 5·5 per cent. of the 1885 patents have been maintained for the full 14-year period; the proportion of the previous year, 1884, was 4·5 per cent. The average percentage of patents granted under the 1852 Act which ran for their full term was 6 per cent., so that the conclusion may fairly be drawn that the reduction of initial fees in 1884 has only slightly diminished the average value of the patents sealed, while it has added considerably to their number.

Of the total number of applications, 17,389 come

from England and Wales, 1,395 from Scotland, and 502 from Ireland. There are only three foreign countries from which large numbers of applications come—2,629 from the United States, 2,599 from Germany, and 1,133 from France. There are only eight other countries from which as many as 100 applications come.

An elaborate Table, printed as an appendix to the report, shows the different classes under which inventions may be arranged for the period 1884-97. Later figures cannot be given, on account of the time which may elapse before the acceptance of a complete specification following on an application. There has been a great increase under certain of the chemical classes, attributed to the development of the acetylene industry, which is also responsible for a large increase under lamps. In the following classes the number of patents is said to be practically stationary:—Agriculture, guns and ammunition, sanitation, ships, and textiles. There has been a decrease as regards iron and steel, cutlery, and steam - engines, and a considerable increase in advertising, electric lamps, and photography. Since 1884 the inventions relating to the cycling industry have increased sixfold, but the advance in 1896 was barely maintained in 1897. The numbers for 1898 are not yet fully available, but it is believed that the extraordinary inventive activity in this industry has reached a climax, and now gives signs of abatement. As might be expected, an unusually large number of valueless inventions appear to be included in this increase. Of 6,000 applications made in 1897 in connection with cycles, only 2,300 were completed—much less than the average. An increase in air and gas engines is attributed to the number of inventions for oil engines intended for motor cars. Here, however, there is a decline in 1897, which appears to be continued in 1898. Among minor industries, hat-making and tobacco show substantial increases, and sugar and watch-making substantial decreases. Since the passing of the Workmen’s Compensation Act the number of applications relating to guards for preventing accidents with machinery has very largely increased. Immediately after the railway accident at Wellingborough Station, caused by a luggage truck falling on to the line in front of an express train, there was a great increase in inventions for railway platform luggage trucks. As showing the relation between passing events and the course of invention, it is mentioned that the publication in a London morning paper of a letter relating to the waste of horse-feed in London was followed within five weeks by 34 applications for patents for nosebags for horses, the average number per annum being about 12.

THE DIFFRACTION PROCESS OF COLOUR PHOTOGRAPHY.

Nature, for the 29th of June last, contains an excellent article by Professor R. W. Wood, of h:

University of Philadelphia, on the ingenious process which he has devised for obtaining the effect of colour in photographs by means of diffraction.

His process is really a modification of the three-colour process of Ives and others, but it has the advantage that only one picture is required, and that copies of the picture can be multiplied. The necessity for coloured screens for viewing the picture is also done away with. If a lamp, a grating, and a lens are arranged in front of a screen, the result will be an image of the lamp on the screen, with spectra on each side. If a small hole is made, say, in the red part of one of the spectra, a person looking through the hole will see the grating illuminated with red light. The position of the spectra depends upon the number of lines to the inch with which the grating is ruled—the finer the ruling, the further removed from the central image are the coloured bands. A finer grating than the one originally employed will, therefore, throw green light upon the hole, instead of red, and a still finer grating will illuminate the hole with blue light. If two overlapping gratings, of which one throws the red light and the other the green on the hole in front of the lens, the spectra will overlap, and the effect to the eye, looking through the hole, will be that the closer-ruled appears green, the coarser-ruled grating appears red, and the overlapping portion yellow—the result of the combination of red and green light. If the third grating is added, the part where all three overlap will be white, produced by the mixture of red, green, and blue light. If a glass plate be ruled with a design, say of a tulip, in which the blossom is ruled with 2,000 lines to the inch, the leaves ruled with 2,400 lines, and the flower-pot 2,750 lines, such a design, when placed in front of the lens, and looked at through the hole, will give the effect of a red tulip, with green leaves, growing in a blue pot.

The principle can be further elaborated and applied to photography. For this purpose three negatives, such as are used to produce a coloured picture in Ives's chromoscope, are required—that is to say, three negatives taken respectively through red, green, and blue coloured filters. Positives are made from these in the usual manner. A plate bearing a film of bichromatised gelatine is placed under a 2,000-line grating, and on the top of the grating the positive, obtained by means of red light. A sufficient exposure is then given. The grating and the red positive are removed, the 2,400 grating and the green positive substituted, and a second exposure made. The same is done for the blue, and the plate then developed. When dried and placed in front of the lens, it appears as a coloured photograph on being viewed through the hole in the screen. In practice, Professor Wood says that he prefers to make two printings on one plate, and the third on another, mounting the two with the films in contact. Once the original picture is made, it can be multiplied indefinitely.

To view the pictures, the only apparatus required is a lens mounted in front of a small screen, perforated with an eye-hole through which the pictures are

looked at. Viewed without the lens, the picture is perfectly transparent, and is merely "a diffraction grating on gelatine with variable spacing." The pictures can be projected if a very intense light is used, but great amplification cannot well be obtained.

Theoretically, one of these diffraction pictures can be obtained in the camera on a single plate. This has been done for a single colour, but there are practical difficulties in realising it for all the colours.

Those who are interested in the subject will find fuller details in the *Nature* article, which is illustrated. Without illustrations it is not easy to make the process intelligible.

General Notes.

CENTRAL SCHOOL OF ARTS AND CRAFTS.—An Exhibition will be opened to the public at the Central School of Arts and Crafts, 316, Regent-street, opposite the Polytechnic, on Monday, July 10th, and remain open throughout the week, from 12 noon to 8.30 p.m. daily. The work done by students includes:—Book-binding, silversmiths', goldsmiths', and jewellers' work, chasing and engraving, enamelling, stained glass, ornamental lead work, stone work (by architects), woodcuts in colour (by a method based on Japanese practice), embroidery, wood-carving and gilding, &c., also modelling and designs for various processes. Admission will be free. The school was established in November, 1896, by the Technical Education Board of the London County Council, to meet a definite want, viz., to provide for apprentices, journeymen, and others, engaged in the more artistic trades, such training, subsidiary to the workshop, as each student may require in relation to his special craft. Admission to the school is, within certain limits, restricted to those actually engaged in these trades, and no attempt is made to provide for the amateur student of drawing and painting. The school is well equipped with all appliances for carrying on practically the crafts embraced, and with fine examples of old work to serve as a stimulus. The staff is composed of specialists, working under the general direction of Mr. G. Frampton, A.R.A., and Mr. W. R. Lethaby. The third session of the school is just completed, during which nearly 600 students have been in attendance.

VICTORIA AND ALBERT MUSEUM, SOUTH KENSINGTON.—Miss Helen Mary Gulson has recently presented to the Museum a collection of Spode porcelain, comprising vases, cups and saucers, &c., in memory of her uncle, the late Mr. Josiah Spode, of Hawkesyard, Rugeley, Staffordshire.

Journal of the Society of Arts.

No. 2,434. VOL. XLVII.

FRIDAY, JULY 14, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****CHAIRMANSHIP OF COUNCIL.**

On Monday, 10th inst., at their first meeting after the annual election, the Council elected Sir John Wolfe Barry, K.C.B., F.R.S., as Chairman for the ensuing year.

The various Committees were also re-appointed.

Proceedings of the Society.**CANTOR LECTURES.****BACTERIAL PURIFICATION OF SEWAGE.**

BY DR. SAMUEL RIDEAL, F.I.C.

Lecture II.—Delivered January 23, 1899.

A partial recognition that natural purification of organic matter was due to living organisms was arrived at early in the present century, when Cagniard de la Tour discovered that yeast was a living plant, and Schwamm demonstrated that putrefaction was due to something in the air which heat could destroy, and that meat would putrefy in calcined air. It was suspected therefore that organisms were the actual cause of decay and putrefactive change, but the powerful advocacy of Liebig and his school of the so-called "Catalytic" theory delayed the general acceptance of the "germ theory" for more than thirty years. It will be recollected that in the catalytic theory it was believed that some organic substances, in the act of undergoing decomposition, possessed the power of causing the alteration and decay of other organic substances in contact with them, and this mechanical, as distinct from a biological, explanation, held its own until Pasteur proved that fermentation and putrefaction did not take place in the

absence of living organisms, which he divided into aerobic, or thriving in presence of oxygen, and anaerobic, or growing without it. Their life history and characters have since been elaborated by Koch and a number of other observers. On the other hand, the well-known purifying action of soil, beyond the mere mechanical straining, was, up to a late date, considered to be purely chemical, and due to oxidation. E. Frankland, in 1872, had pointed out that "a filter must not be considered as merely a mechanical contrivance, the process carried on being also chemical." This was true, but the necessity of the co-operation of life in the processes was at first almost ignored, more especially as in nitrification, one of the most important of the actions, no accompanying special organism had been discovered. We now know that this was due to the fact that the microbic group responsible for nitrous and nitric changes would not grow in the gelatine or other media ordinarily used for cultivations. The researches of Warington, P. Frankland, Schloesing, Winogradsky, and others, resulting in the isolation of nitrifying and denitrifying organisms, removed the difficulty, and, in 1872, the Berlin Sewerage Commission reported that sewage matter was converted into nitrates, not by a simply molecular process, but by organisms present in natural sewage and soil. Muntz, Müller, Marie Davy, and others also demonstrated in various ways how the purification of sewage was accomplished by bacterial action.

Sorby, in 1883, remarked on the very large proportion of the detritus of fæces which was lost in the river, owing to the action of "countless thousands of living creatures," and Dupré, in a report to the Local Government Board in 1884 on the results of his experiments on aeration, stated that "the consumption of oxygen from the dissolved air of a natural water is due to the presence of growing organisms, and that in the complete absence of such organisms little or no oxygen would be thus consumed." In May, 1886, Dupré proposed "to cultivate the low organisms on a larger scale, and to discharge them with the effluent into the river, as the power these lower organisms had was remarkable."

In the following January, Dibdin, speaking at the Institute of Civil Engineers, on the precipitation of sewage, observed that "One object claimed for the use of an excessive quantity of lime, and also for some other substances, is that they destroy the living organized bodies, such as bacteria, &c., which

gave rise to the phenomena known as putrefaction. . . . As the very essence of sewage purification is the ultimate destruction, or resolution into other combinations, of the undesirable matters, it is evident that an antiseptic process is the very reverse of the object to be aimed at."

In this connection the same authority has remarked that "very alkaline effluents, such as those produced by the use of lime in excessive quantities, are very liable to putrefy instead of becoming purified by oxidising organisms."

In 1887, the Massachusetts State Board commenced their well-known series of experiments on the purification of sewage by filter beds, showing the effects of intermittent filtration with the aid of aerobic bacteria, and working out details of various porous materials, size of grains, thickness of strata, influence of time, temperature, and different methods of procedure. The results were on rather too limited a scale to be exactly comparable with practice, but the general deductions have been amply confirmed by the success of larger sewage works on biological principles both in Europe and America.

It soon became evident that if a filter bed were worked continuously, it rapidly choked, and putrefaction occurred in the interior owing to a deficiency of aeration, so that on the aerobic plan it was necessary to work intermittently, draining out the liquid, and allowing the entrance of air during regular intervals of rest.

Otherwise it was necessary to have "very slow motion of very thin films of liquid over the surface of particles having spaces between them sufficient to allow air to be continually in contact," a condition, however, which did not prevent the sand filters from becoming overburdened and also greatly limited the amount of sewage treated. In the Massachusetts Report of 1890, the process is compared to a combustion, and was found to be most rapid in the summer months. The same Report gives useful information on the methods of analysis, besides observations of the number of bacteria and algæ, and valuable descriptions of the species found in the effluents. It must be remembered that sewage in America is usually weaker and of greater volume than it is in Europe, on account of the more abundant supply of water.*

The sewage of Lawrence City, in the Massachusetts investigation, had been run on the filters without any previous purification, or even settlement. On the other hand, our sewage of London had undergone a previous preparation, by being treated with 1 grain per gallon of ferrous sulphate and 4 grains of lime, the precipitate of sludge being then conveyed in boats to be discharged at the mouth of the Thames. It was hoped that the clarified liquid, after the precipitation, could be discharged into the river direct without creating nuisance. But it still contained about 10 parts per 1,000, or 7 grains per gallon of suspended solids, and was by no means free from odour. The Royal Commissioners of 1884 had decided that the liquid could not be discharged at the outfalls as a *permanent* measure, and required further purification by application to land.

In 1866 an experiment with London sewage as applied to land had already been made at Barking. The Metropolis Sewage Company obtained a concession to treat the sewage of North London, amounting to about 2,000 tons in 9 or 10 hours, on five or six acres of grass land on a light gravelly soil. The experiment was not a success, either culturally or with regard to the cleansing of the effluent. But when we come to the 200,000,000 gallons daily of London sewage, it will be obvious that the requisite area of suitable land is entirely unattainable. This being recognised, and an extension of chemical treatment and precipitation having proved to be inadequate as well as costly, the Main Drainage Committee of the County Council in 1891 determined on a series of experiments at Barking outfall, on the lines of the Massachusetts researches. From the preliminary investigations with small filters, it was considered that coke-breeze was the most suitable material, although burnt ballast was found to nearly equal it in purifying efficiency. Sand and gravel effected a greater clarification, but the removal of dissolved organic matter, as measured by the reduction in the oxygen consumed, given in Mr. Dibdin's Report, was considerably less than with the coarser materials. Moreover, there seemed a tendency for the effluent to become putrid, owing to deficient aeration from the closeness of texture, while the filter required frequent scraping and renewals. The average rate of working, including periods of rest, was 411,000 gallons per acre, or 250 gallons per square yard, in 24 hours. For eight hours a day the effluent ran continuously, the filters being kept

* The daily consumption of water per head in New York is 92 U.S. gallons; in New Jersey town and cities, 92 gallons; in Philadelphia, 143; in Los Angeles, California, 200; in Alleghany, Pennsylvania, as much as 247 gallons. (10 U.S. gallons = 7 imperial.) (Mason.)

full; the filter was then emptied, and allowed to rest for 16 hours.

The figures given by Messrs. Dibdin and Thudichum, who conducted the experiments, are as follows:—

Clarification, as measured by the units of depth required to obscure standard mark:—Burnt ballast, 1; coke breeze, 1; pea ballast, 1¾; sand, 2¼.

Reduction of Organic Matter (oxygen consumed):—Burnt ballast, 43.3 per cent.; sand, 46.6; pea ballast, 52.3; coke breeze, 62.2.

The report adds significantly “the number of organisms in the tank effluent before filtration, and in the filtrates, was found to vary very considerably, *those in the filtrate being generally present in larger numbers*; but it soon became apparent that the presence of a large number of organisms was evidence of the activity of the process of splitting up the organic compounds in the sewage matters passing through the filters. Here it is clear that the main purification was bacterial, and only the beginning of a further resolving change to be carried on in the river. It would undoubtedly have been an advantage if the biological process so initiated could have been allowed to develop a further stage in the filter, but the prescribed object of the experiments was the attainment of the highest rate of speed consistent with such purification as would remove the obvious objectionable characters such as odour, colour, and liability to putrefaction.”

The further experiments with a one-acre coke breeze filter at Barking are well-known. As at Massachusetts, it was found that continuous running resulted in clogging and a foul effluent, and that to obtain the best results the commencement must be made with small quantities

of liquid, the filter, which was composed of 3 feet of coke breeze and 3 inches of gravel, being at first merely filled and emptied twice daily, with a view to obtaining an active bacterial bed. Daily determinations were made of the oxygen absorbed, albuminoid ammonia, and nitrates. At the end of a month, when the highest efficiency was reached, amounting to 83 per cent. purification, the quantity of effluent was increased by stages to one million gallons daily, while the time of rest was shortened. The filter was finally worked on the system which has been found the best at Barking, Exeter, and Sutton, namely, alternate filling, resting full, and emptying, with a periodical entire rest empty for complete aeration. At Barking, the filling occupied two hours, the standing full one hour, the emptying five hours, so that three cycles of eight hours were completed each day. From 10 p.m. on Saturday till 6 a.m. on Monday the filter rested empty, making a period of 32 hours each week. This weekly rest involves the storage of the crude effluent in reservoirs for the corresponding period—a practice which has many objections. At Exeter, where the flow through the septic tank is continuous, and no reservoirs are employed, the cycles are continued, by means of the automatic gear, throughout the entire week. Should a filter show signs of exhaustion, which occurs at long intervals, or rarely through accident, it is thrown out of use for one or two weeks till recuperated.

The one-acre filter is still in use. It is reported that after five years' working it is free from clogging, and its working capacity is not impaired. Its depth is now being doubled, to see whether any increase of efficiency will ensue from a deeper layer.

TABLE I.—AVERAGE ANALYSES FROM ONE-ACRE FILTER (DIBDIN).

Parts per 100,000.

Date.	Average per acre per day.	Oxygen absorbed in 4 hours.		Albuminoid ammonia.		Nitrogen as nitrates.		Per cent. purification by oxygen absorbed.
	Gallons.	Effluent.	Filtrate.	Effluent.	Filtrate.	Effluent.	Filtrate.	
April 7th to June 9th, 1894 ..	500,000	5.85	1.23	.593	.138	.182	.340	79.3
Aug. 3rd to Nov. 9th, 1894 ..	600,000	5.18	1.42	.565	.158	.032	.200	79.6
Nov. 1894 to March, 1895....	1,000,000	5.87	1.33	.545	.160	.565	1.00	77.5
April 8th to April 20th, 1895..	1,000,000	5.00	1.26	.514	.146	.204	1.10	75.4
May to Sept., 1895.....	1,000,000	6.62	0.91	—	—	—	—	80.7

At the period when it was believed that the purification of sewage was almost entirely effected by chemical processes of oxidation, attention was divided between chemical methods of oxidation by materials like the manganates, permanganates, chlorine, and others, which proved in practice to be expensive and not final, and mechanical devices for freely exposing to air, or even forcing it continuously or intermittently into the liquid. The patents are very numerous, and include the use of perforated screens, weirs, cascades, and the use of air heated, charged with vapour, or under pressure. Electrolysed sea water, and other electrical processes have also been tried without much success. Many of these have been started with an idea that the final products might have a sale which would help to balance the cost of the process. But since this hope has not been realised, chiefly on account of the great dilution, even a strong sewage only containing about 100 parts of total solids in 100,000, or 0·1 per cent., a great part of which is worthless inorganic matter, and only about 20 to 30 parts per 100,000 of nitrogen in all forms, with an even less proportion of other substances of value, it soon became evident that the only expenditure which could be incurred was that which was rendered absolutely necessary for sanitary reasons. Therefore the introduction of the natural, and to a great extent, automatic process, was an immense advance. Yet while exclusive attention was given to the aerobic organisms, various schemes were proposed for the artificial aeration of the filters.

Under Lowcock's system, as described in a paper read before the Institute of Civil Engineers in 1893, air was forced under an average pressure of $4\frac{1}{2}$ inches of water, either continuously or at intervals into the body of the filter, which was constructed at first of gravel, and afterwards, at Wolverhampton, of coke breeze. It is claimed that the filtering area required is thus reduced to 3·8 acres per million gallons, and that the percentage purification of the sewage is "considerably over 90 per cent." At the same time, the expense of pumping air must needs be very great.

About the same time Waring, in America, proposed a method of forced aeration which differs from Lowcock's mainly in the separate treatment of the sludge by means of "aerators." The system, which is somewhat complex, was first installed at Newport, N.Y., in 1894.

This city was sewered under the combined system, and the liquid became frequently

admixed with sea water entering the sewers, the effect being an increase of the suspended solids by precipitation of soap and other matters. This precipitation has been often noticed in tidal reaches, and has resulted in the formation of banks and deposits on the bed. It would seem that the lime and magnesia present in ordinary waters do not secure the removal of all the higher fatty acids as the greasy scum seen frequently in sewers. From examination of the soluble part of sewage I have found that soda salts of oleic and other fatty acids are still present, especially in towns with a soft-water supply, owing probably to the influence of the ammonia formed. These soluble soaps are decomposed and precipitated by the high amounts of calcium and magnesium salts existing in sea-water, so that the sewage of Newport contained unusual amounts of soap curds.

The sewage first passed through a settling chamber for road detritus, and was thence pumped alternately through either side of a divided tank containing a shallow bed of coarse broken stone to arrest the coarser solids. "The impurities in the section thrown out of use disappeared rapidly in its interval of rest."

The liquid next passed slowly through four straining tanks filled with stones and gravel, whose function was said to be "mere mechanical sedimentation." As soon as these became clogged a plug was drawn, and the sludge emptied into a separate "aerating tank," filled with stones and gravel, where air was driven constantly through the mass, and as soon as active bacterial action had set in the sludge was rapidly dissolved.

Air was also forced through the straining tank till it was again in condition for use. Apart from the complexity of the system, we have here, in place of the regular intermissions for rest and aeration as used in England, a continuous working, assisted by forced aeration, with its accompanying expense, at longer intervals, the compensating point being claimed that a larger volume of sewage can be treated. The action here is obviously entirely aerobic, but as we shall see later, can be obtained better by a preliminary anaerobic treatment.

Following the success of the Barking experiments, an installation on the same principle was started at Sutton, Surrey, at the beginning of 1894. The filters were of different materials, but again showed coke breeze to be the best, with burnt ballast as a good second, the latter being very simply constructed by digging out

the clay to form a pit about 3 feet deep, and filling it up with the same clay after burning, the cost of a filter of this kind, having an area of rather more than one-tenth of an acre, being given as less than £100, including all charges. It will be remembered that the cost of the Barking one-acre coke filter was stated as £2,000.

Up to this time the filters had been fed with an "effluent;" that is, a sewage prepared by straining, partial chemical precipitation with lime and ferrous sulphate, and sedimentation. In November, 1896, it was determined to abandon precipitation and to prepare the crude sewage, after the removal of the grosser particles by screens, by running it into a "bacteria tank" containing coarse burnt ballast, previously inoculated with a liquid containing the bacteria which had been found effectual. The fluid from the tank was further purified, as formerly, by coke breeze filters.

After three months' working Mr. Dibdin was able to give a satisfactory report. The oxygen consumed by the organic matter was reduced by the tank 66 per cent., and by the filter beds to 86.5 per cent. The solids in suspension were reduced by the tank 95 per cent., and by this and the filter 99.6 per cent., while the filtrate was practically clear, had no objectionable

odour, and did not putrefy on keeping. The process has continued to the present time with satisfactory results, except when the filters were overtaxed, "some of them," as Mr. Dibdin reports, "having been purposely worked up to a rate of nearly three million gallons per acre per day, with the result that the bacterial action was evidently checked, as shown by a decrease in the production of nitrates and an increase in the quantity of organic constituents in the effluent. As the result of careful watching, however, no permanent harm was done, as the filters were immediately restored to their usual condition, when they proceeded to give good results."

This remark points to the conclusion that when there is reliance on presumably aerobic filters and organisms for combined liquefaction and nitrification, indiscriminately, in the same receptacles, the result is apt to be variable, and to depend on "careful watching," an inference that is borne out by Mr. Dibdin's figures as given in his later report of analyses during 1896 and 1897.

The average results in his Table I have calculated, for the purpose of comparison, to a uniform chlorine content of 12.84 parts, which is the average given for the Sutton crude sewage.

TABLE II.—SUTTON SYSTEM (parts per 100,000).

	Cl.	Oxygen absorbed in 4 hours.	N as nitrites.	N as nitrates.	Free NH ₃ .	Albuminoid NH ₃ .	Suspended matter.	Residue on micro-filter millimetres per litre.
Crude sewage ...	12.8	6.49	.021	None	12.53	1.13	85.76	3000
Tank effluent.....	12.8	3.06	.301	.751	3.85	0.60	5.1	213
Filtrate from coke breeze	12.8	1.19	.087	1.99	1.25	0.316	1.35	23

These figures show the following percentages of purification :—

	Oxygen absorbed.	Free NH ₃ .	Albuminoid NH ₃ .	Suspended matter.
By the "bacterial tank".....	53	69	47	94
By the coke filter	29	21	25	4.4
Total purification	82	90	72	98.4

It will be observed that the chief purification occurs in the bacterial tank, and that a large proportion of it consists in the removal of the

suspended solids. The following are further particulars of the Sutton Works :—

The bacteria tanks are three in number, con-

tain $3\frac{1}{2}$ ft. of burnt clay ballast, and are 183 square yards in area. The times required are:— Filling $\frac{3}{4}$ hour, resting full 2 hours, emptying $1\frac{1}{2}$ hour, resting empty 2 hours. Two or sometimes three cycles are completed per day, according to the flow.

The population of Sutton is 13,000, and the daily dry weather flow of sewage, on the separate system, is 350,000 gallons. At present only part of the sewage is treated bacterially. The beds have been working for the last three years, the coarse bed dealing with the screened sewage at a rate of about 100 gallons per square yard per day, and the fine bed at a rate of about 150 gallons per square yard per day; 10 acres of beds are therefore required to treat 3,000,000 gallons of sewage per day after it has been properly screened.

During the two hours of resting full, a mixture of organisms, of which I believe a great proportion are anaerobic, as indicated by the large production of nitrites, are liquefying the sludge. It was estimated that in the three tanks 80 tons of dry matter had been thus reduced from November, 1896, to December, 1897. During the period of resting empty, the aerobic bacteria are supposed to be at work, although, according to Mr. Dibdin, no air enters except that drawn in while emptying out the liquid. The subsequent coke breeze filter is intended, under the same conditions, to be entirely aerobic and nitrifying. Here also the presence of nitrites may be remarked.

It will be noticed, further, that the Sutton sewage has already been broken down to a very considerable extent, as shown by the 12.53 parts of free ammonia, and only 1.13 parts of albuminoid.

An automatic rotary screen is used to intercept the coarser matter before the sewage is applied to the tanks. The amount of this intercepted material is stated in Mr. Thudichum's recent paper (Soc. of Engineers, Dec. 5th, 1898) to be about 30 barrow loads per day per 1,000,000 gallons. Mr. Thudichum also remarks that "practical points requiring further investigation are the trapping of sand, the duration of life of the coarse beds, and the degree of fineness for the screens. In the septic (Cameron) tank everything organic may be permitted to enter."

At Oswestry the Sutton system was adopted in the beginning of 1898. The material for the beds was obtained by screening from an old refuse tip, from which, according to the engineer, everything excepting hard carbonaceous matter had disappeared. The coarser portions

are used for the "primary" filters, $4\frac{1}{2}$ feet deep, corresponding to the Sutton "bacteria beds," and the intermediate portions for the "secondary" filters, 4 feet deep, intended to be equivalent to the Sutton coke breeze. This screened refuse costs about 1s. 3d. per cubic yard in the filter beds, and is believed to be already charged with organisms. The crude sewage is not passed at once on to the beds, but is previously clarified by subsidence in settling tanks. The report states that about half the sludge settles in these tanks, and is removed weekly, mixed with the dust screened out of the town refuse and sold as manure. The population of Oswestry is 10,000, the dry weather sewage 300,000 gallons per day, and the water supply 20 gallons per head. Total costs of works (when completed) £1,800, annual working expenses about £80.

Other experiments carried on during the past twelve months with the Sutton method on the sewage of Leeds at first showed considerable difficulties owing to "sludging-up" of the beds, but by increasing the periods of rest so as to allow the retained organic matter to be dissolved, and by the introduction of finer screens which remove a greater portion of the suspended solids (sludge) to be otherwise dealt with, more satisfactory results are being obtained.

It is remarked, however, in the Leeds report, that if the resting period were too prolonged, "the large increase of capacity gained by rest was, to a great extent, lost within a short time" (p. 33). Thus, after a suspension of 38 days, the capacity was reduced in a fortnight from 56,500 to 45,800, or 10,700 gallons. I would venture to suggest as a reason that the long aeration had destroyed or enfeebled the anaerobes, and that the liquefaction was therefore suspended until an anaerobic state was restored.

Colonel Harding (the Lord Mayor) and Mr. Hewson, the City Engineer, who together drew up the report, conclude as follows:—

"The question is raised as to whether an experiment should not be made without delay to ascertain the effect of the septic tank treatment for the destruction of the solids in suspension; also to see how far an open (?) septic tank, or upward septic filtration through coarse material, covered with a layer of sand, would be effective in destroying the sludge, and so far relieving the filter beds."

With Leeds sewage, the experience gained shows that 400,000 gallons per day can be dealt with on $\frac{1}{2}$ acre of coarse bed and $\frac{1}{2}$ acre of fine

bed, or 1 acre per day in all, after the grit has been removed in a settling tank, and the grosser solids (paper, fibre, &c.) screened off. This gives a minimum of 50 acres of beds for 20,000,000 gallons; but in order to have spare beds, it is recommended to have 70 or 80 acres, or say 4 acres per 1,000,000 gallons.

Leeds, under the old system, would have to deal with 300 tons of sludge per day, or say 100,000 tons per annum. By settling the grosser solids, the suspended matter could be reduced, according to the same report, from 37·2 grains per gallon to 25 grains per gallon, and the filter beds would not then sludge up. This leaves, however, about one-third of the total quantity, corresponding to the 100 tons of sludge per day of the present precipitation process still to be disposed of.

DUCAT FILTER.

Colonel Ducat, with a view of introducing automatically a larger supply of oxygen, has devised a filter with walls composed of perforated tiles, or of drain-pipes laid horizontally, so that air can have free access to the body of the material without pumping. The bed is coarse-grained above and fine below, and the action is intended to be exclusively aerobic, as atmospheric oxygen in excess is brought in contact with the contents at once without giving any period of anaerobic incubation, and therefore presents some points of resemblance to the Waring process already mentioned. I have pointed out elsewhere that in towns with old and long sewers, or where storage is practised, the liquids may have already received sufficient hydrolytic resolution to be quite prepared for a strong aeration such as this filter supplies. The system is under trial at Hendon, and also experimentally at Sutton.

This is illustrated by an analysis furnished by Dr. Houston:—

	Oxygen absorbed.	Free ammonia.	Albuminoid ammonia.	Oxidised nitrogen.
Sewage, Oct. 14th, 1898	14·72	8·7	1·6	—
Filter effluent, ditto	0·78	0·3	0·094	·477

The high free ammonia and the low albuminoid shows that the sewage has already undergone the preparation I have mentioned. The nitrification of the effluent, indicated by the "oxidised nitrogen," has not proceeded as far as might have been expected, notwithstanding

the very large loss of ammonia. The oxidation of the carbonaceous matter to carbonic acid is also most marked.

GARFIELD COAL FILTER.

Dr. Bostock Hill, in a paper at the Leeds Sanitary Congress in 1897, gave a very favourable account of the use of fine coal for the filtration of effluents which had been previously chemically precipitated, at Wolverhampton, Lichfield, and other places. The sewage of Wolverhampton is heavily polluted with chemicals, that of Lichfield contains a large amount of brewery refuse. Dr. Hill observes that "the action of coal is different from that of other media in that analysis shows a far greater difference in the oxygen absorbed before and after filtration than in the organic matter as measured by albuminoid ammonia."

"As far as is known any kind of coal will do, but it should be as clean as possible, and the depth should not be less than 5 feet." At Lichfield the first layer, over the drain pipes, is $\frac{1}{2}$ -in. cube coal, then a little $\frac{1}{4}$ -in., afterwards $2\frac{1}{2}$ feet of 1-8th inch cube, and $2\frac{1}{2}$ feet of 1-16th inch, ending with 6 inches of 3-16th coal dust. The liquid is supplied continuously for 12 hours, with 12 hours rest, and the rate is a 1,000,000 gallons per acre per day. The effluent is said to be bright and clear. He adds that "as a result of 12 months working the efficacy of the coal has increased. At first it would appear that the action is a chemical one, because the oxygen absorbed is at once directly affected; afterwards, however, nitrates are produced in considerable quantities, so that probably there is then a double action, chemical and bacteriological. The interior of the filter, after many months, has nothing but a slight earthy smell." This filter was introduced by Mr. Garfield in the summer of 1896.

Mr. Fowler, in his report of the Davyhulme experiments, in 1897, confirms the results of previous observers that coal and burnt clay filters, when worked continuously, rapidly become clogged, and that improved results are obtained with intervals for rest and aeration. He considers coal to be superior to burnt clay.

In the experiments with Manchester sewage the liquid dealt with was usually an effluent which had been treated with chemicals, such as lime and sulphate of iron or alumina, a procedure which robs the liquid of its natural bacteria, or inhibits their action. The work of bacteria is repeatedly recognised, and yet,

even where, as at Accrington, Oldham, and other places, a treatment is adopted which is called biological, merely as a supplement to chemical and mechanical processes, we meet with such phrases as "Both the tank effluent and the cinder filtrate were tested for nitrites and nitrates practically without result" (Oldham); "There is practically no formation of nitrates in the filters at Swinton;" at Accrington, "nitrification in final filter none;" at Salford, "the large excess of lime present acts as a *temporary sterilising agent*." We cannot be surprised, therefore, that nearly all the effluents were found liable to subsequent putrefaction, or at the result that the anaerobic changes which had been suspended by the treatment, are resumed imperfectly and irregularly in the Ship Canal or the rivers.

In December, 1897, a Rivers Sub-Committee of the Manchester City Council visited representative sewage works at Barking, Friern Barnet, Sutton, Oldham, Swinton, Chorley, Glasgow, Salford, Hendon, and Accrington. In March, 1898, their report was approved and a deputation was appointed to wait on the Local Government Board. The conclusions of the Committee are shortly:—

1. That filtration by land is altogether impracticable.
2. That no practicable system of precipitation by chemicals alone has been laid before them which will meet the requirements of the Mersey and Irwell Joint Committee.
3. That the method most reasonably practicable and available is the biological filter or bacteria bed, such as may be seen in operation at many of the places visited.

After some delay and correspondence, two bacteria beds of coke breeze were completed at Davyhulme on September 14, 1898, under the superintendence of the three experts appointed—namely, Baldwin Latham, Percy F. Frankland, and W. H. Perkin, junr. The working capacity of each filter is 5,000 gallons, and the liquid to be purified is taken direct from the sewer and passed into a settling tank for an hour before proceeding to the first or coarse filter. After remaining in the latter for one or two hours, "according to circumstances," the partially purified sewage is transferred to the fine filter, where it again rests for a period of one or two hours. Each filter requires three-quarters of an hour for filling, and the same time for emptying. Samples are taken every five minutes during emptying, and mixed for analysis. The figures show, as in other cases, that an improvement

occurs as the filters mature. At first, the beds were filled once a day with settled sewage and twice with crude, and under these conditions the capacity of the coke filter remained constant. With regard to trade refuse, Mr. Fowler reports that iron pickle (ferrous chloride), dye refuse, carbolic acid, and sulphocyanides from gas liquor, are all removed or oxidized, that "in no case has the presence of manufacturing refuse showed a marked tendency to make the purification less effective" (an opinion also shared by Dr. Perkin), though "it is probable that with purely domestic sewage the yield of nitrate would be larger."

The three experts also state in their report that "the bacteriological system, without the use of any chemicals, notwithstanding the peculiar nature of the Manchester sewage, will purify that sewage, and yield an effluent which will comply with all the requirements of the Mersey and Irwell Joint Committee, and will, in our judgment, be the means of greatly improving the waters of the Ship Canal."

The Local Government Board held an inquiry at Manchester, on January 12th and 13th, 1899, with reference to the application of the City Corporation to borrow £160,000 "for purposes of sewerage and sewage disposal." It was explained that Manchester had tried filtration by land and chemical treatment, but neither of these had been satisfactory. Eleven tanks had now been constructed at Davyhulme, each 300 ft. long by 100 ft. wide, and 6 ft. deep, with a united capacity of 12 to 15 million gallons, equal to half a day's dry weather flow. The population of Manchester was 520,000, and was increasing at the rate of 4,700 per annum. The tanks were originally used as chemical filters, the treatment and removal of sludge costing about £17,000 a year, the chemicals alone reaching £90 per week. It was then proposed to utilise these tanks for settling the raw sewage, which would subsequently pass through sixty acres of double contact beds filled with coke breeze. An effluent would then be introduced without the use of land, which would practically conform to the present requirements of the Mersey and Irwell Joint Committee. It is also stated that if the "double contact" did not suffice, they would employ a "third contact." The inquiry was adjourned for further details. The first contact beds of 30 acres were to be constructed of coarser material than the second 30 acres of second contact beds.

From a later report it appears that nitrifi-

eration has at length been attained, the highest result being 0·68 of nitric nitrogen, but the average only reaching 0·27. In the Tables given they are called "double filtration" experiments, and as a fact they are neither anaerobic nor properly aerobic as the poor result in nitrification shows. Better results, as we shall see later, could probably be obtained by making the first filtration more anaerobic and by ensuring better aeration in the second filters. It will also be noticed that sedimentation in tanks is required by Manchester as essential for the proper working of the contact beds. This sedimentation, therefore, is the equivalent of the screening adopted by Mr. Dibdin, at Sutton, and the chemical precipitation of the earlier experiments before passing on to the one acre filter bed in the London County Council experiments.

[NOTE.—The adjourned inquiry was concluded on May 1st, 1899, when the experts gave satisfactory reports of the working of the experimental beds since January. On learning that the effluent was passed into the Ship Canal, the Local Government Board inspectors observed that "pending the report of the Royal Commission, the Board was not prepared to depart from what it has laid down as to the provision of land for the treatment of effluent." The Corporation have shown that 300 acres of land could be made available below the filter beds, if necessary.]

Miscellaneous.

AGRICULTURAL EDUCATION IN FRANCE.

A considerable amount of attention has been given in France to what may be termed general agricultural education. Agricultural teaching, of a more or less rudimentary order, has been made obligatory at elementary schools, and a small garden for practical illustration has been attached to many of these institutions in rural districts. The Commercial Attaché to H.M. Embassy at Paris says that the instruction given at elementary schools has produced most beneficial results. In one particular case the teacher, by the introduction of new methods, has about doubled the average production of wheat. Special professors also form part of the staff at 76 of the boys' superior primary schools, at 2 similar schools for girls, at 72 colleges, and at 12 lycées. These figures relate to the year 1898. This general instruction may be divided into distinct sections; firstly, that given by the departmental professors; and, secondly, that given by the special professors. In accordance with the provisions of the law of June

16, 1879, a travelling professor of agriculture has been appointed to each department. These professors are selected by open competition, each post being made the subject of a separate and special examination bearing upon general agriculture, viticulture, arboriculture, horticulture, and the sciences connected with those subjects, in their application to the conditions obtaining in the particular department in question. The examiners are nominated by the Minister of Agriculture, and include—the Inspector-General of Agriculture, the Inspecteur d'Académie, a professor of chemistry or of physics, and a professor of natural sciences. The two latter must be chosen from amongst the staff of either the Institut Agronomique, or of one of the national agricultural schools, a professor from the nearest veterinary or medical school, three agriculturists chosen from amongst the members of the departmental agricultural association, and a member of the general council. The candidates must be at least 25 years of age. These professors are, owing to the two-fold nature of their duties, partly under the Ministry of Agriculture, and partly under the Ministry of Public Instruction. The expenditure for their salaries is therefore shared equally between the two Ministries. They are divided into four classes, with salaries as follows:—First-class, £180; second-class, £160; third-class, £140; and fourth-class, £120. The duties attached to these positions may be divided into two distinct sections—(1) general instruction of adults—in the service of the Ministry of Agriculture; (2) teaching in the normal schools—in the service of the Ministry of Public Instruction. The tuition for adults takes the form of lectures, delivered in different parts of the department. The number of lectures given by each professor during the year must not be less than 26, but it would appear that the minimum is generally exceeded. The lectures are intended to enlighten landed proprietors, farmers, and others, as to the best agricultural methods, the applications which can be made of scientific discoveries, &c., in a word, to assist them in reaping the greatest possible profit from their land. The subjects treated naturally vary greatly according to the needs of the population of each department; the lectures, however, possess one characteristic in common, they are of an essentially "popular" type. The lecturer also, at the close of each lecture, places himself at the disposal of his audience, with the object of advising them individually regarding special questions, and of elucidating any points touched upon in his discourse which they may have failed to grasp. The most powerful aids to this class of teaching are found in the "experimental" and "demonstration" fields. The first serve for experiments respecting the adaptability of different kinds of plants and crops to various soils, for the testing of chemical and other manures, &c. The second, though the most important, are in a measure subsidiary to the first. Here the professors making use of their knowledge of the general conditions obtaining in the department,

and of the results of their personal experience, aim at producing the best possible crops, in order to convince the sceptical of the success of their methods by ocular demonstration. This form of teaching is highly thought of by competent authorities. M. Tisserand, who was Minister of Agriculture, remarks:—"The results are certain; one may without fear say that the demonstration fields have been amongst the powerful factors in increasing our agricultural production." In the departments where this system has been inaugurated the average number of experimental fields is said to be between eight and nine, and of demonstration fields between 35 and 40. In both cases the fields are usually a little over an acre in extent. The cost of organising the system and of maintaining it is provided for partly by Government subsidies, partly by departmental grants, and partly by the subscriptions of agricultural associations. In his capacity of teacher at the normal schools, the professor gives two lessons a week during the winter terms to the combined second and third year pupils. These lessons treat of agriculture, zootechnics, and horticulture. The theoretical teaching is supplemented by practical work in the gardens, the experimental fields, &c., and by various excursions. These classes were instituted in order to enable teachers at primary schools to give elementary instruction in agriculture, and the law concerning departmental professors contained a provision that such courses of tuition should begin within three years of the nomination of the professors. The special professors already mentioned have much the same duties as the departmental professors, so far at least as the instruction of adults is concerned, and are in this respect subordinate to them. The difference in their functions has been thus defined by M. Tisserand: "The task of the first (departmental professor) is to teach the agricultural classes, that of the second (special professors) to inform them." The special professors are attached to superior primary schools, to colleges, and to lycées. They hold agricultural classes in these establishments, and deliver two lectures a week in winter, and one in summer for adults. Their teaching is confined to the "arrondissement" in which the institution to which they are attached is situated. Candidates for these professorships must be twenty-five years of age, and possess either the diploma of agricultural engineer, or that of a national agricultural or veterinary school. The posts are, according to a new regulation, to be awarded by an examination having retrospective effect in the case of those nominated merely on the strength of their diplomas. The examination would appear to be very complete. It includes the theory of agriculture and kindred subjects, the application of various sciences thereto, several practical tests, the writing of a report, and the delivery of a lecture. The instruction given in the schools is spread over two years, and consists of two lessons per week. During the first year the pupils are taught agriculture and horticulture; during the second, zootechnics, rural economy,

and book-keeping. The special professors are divided into four grades. Promotion from one grade to another can only take place after three full years' service. The exceptional grade is exclusively composed of men of at least 15 years standing, of which five have been passed in the first-class. The salaries are as follows:—Exceptional class, £136; first-class, £120; second-class, £108; third-class, £96. The results attained by these two classes of professors, particularly the departmental professors, would seem to have been such as amply to justify their cost to the State. In conclusion, attention should be called to the agricultural stations and laboratories which, though not properly coming within the sphere of educational establishments, render considerable service to the agricultural population. They are, for the most part, departmental institutions subsidised, to a varying extent, by the State. They numbered 59 in 1893, in addition to 6 of special type attached to the Institut Agronomique in Paris. The laboratories make analyses of manures, soils, products, &c., upon demand, and against a fixed rate of payment. The agricultural stations, on the other hand, have been instituted more with a view to the carrying out of scientific and practical experiments of general utility to the inhabitants of the districts in which they are situated, such as the detection of fraudulent practices in connection with manures, seeds, &c.; they are intended, moreover, to be centres of information, both for the professors and for the public, in regard to all the latest scientific and practical improvements connected with agriculture in its widest sense.

OYSTER CULTURE AT SPEZIA.

The first attempts to cultivate oysters at Spezia were made in 1887, and after a few years the industry developed so rapidly that the production rose from about 150,000 oysters in 1891 to more than 6,000,000 oysters in 1898. The method practised is the same as at Taranto, with several modifications rendered necessary by the difference of situation, temperature, &c. According to the British Vice-Consul at Spezia, the method consists of suspending twigs of lenticus in the months of May, June, and July, in about 40 feet of water, on the inner side of the "diga" or breakwater, across the gulf, which is about nine miles from the town. These twigs serve as "collectors" for the embryos and are kept suspended there for one or two months. When the twigs are sufficiently laden with young oysters they are removed to the "sciaja" or enclosures, where the twigs are cut into short pieces, inserted crosswise into the strands of ropes of esparto grass, and again suspended in water varying from nine to twenty-one feet deep. The oysters are kept there for twelve or fifteen months, and when they are developed and fattened enough they are taken to the depôts closer inshore. Here they are separated from the mussels clinging to them,

and the twigs, scraped, sorted, and packed in baskets (with their mouths upwards to retain water), and despatched by rail to Genoa, Turin, Milan, and other Italian markets. Those kept for local consumption and for re-sorting are placed in baskets of iron wire and kept hanging in shallower water. The "sciaja" or enclosures are on the eastern side of the bay, at a little distance from the Stagnoni shore, and consist of rectangular spaces, enclosed and crossed by four or five rows of stout piles of pine wood—sometimes coated with pitch—driven into the bottom of the sea, and emerging about three feet above the surface. These piles are connected together by ropes of grass from which the strings of oysters (known as "pergolari") hang. Close to the tops of the piles short branches are attached obliquely, pointing outwards, from which thick nets are hung that completely surround the "sciaja," and prevent predatory fish destroying the oysters. There is also a "sciaja" at La Grazie Cove, on the western side of the bay. Latterly an innovation has been introduced in the method of suspending young oysters in the fattening enclosure ("sciaja"), and this consists of placing cement between two layers of oysters, each layer having two oysters, making a group of four oysters. These groups thus stuck together are inserted into the strands of the rope, one above the other at short intervals, and suspended in deep water; this prevents any of the oysters being washed away and lost. One thousand oysters are estimated to weigh 40 or 50 kilogrammes (say, about one hundredweight). The average prices at which oysters are sold are—first quality, 32s. per thousand; second quality, 20s. per thousand; and third quality, 13s. per thousand. The industry has suffered somewhat from a rumour spread in the neighbourhood that the oysters contained the germ of typhoid. This led to investigations by order of the sanitary authorities at Rome, and the publication of a report stating that there was no ground for the rumour.

THE FIBRES OF THE PHILIPPINE ISLANDS.

By far the most important of the fibre plants growing in the Philippines is Manila hemp, or *abaci*. At first sight this plant might be taken for an ordinary plantain, or banana tree, but its fruit is much smaller than the banana, and is not edible. According to a recent report of the United States Department of Agriculture, the Manila hemp crop comes chiefly from the provinces of Albay and Camarines, on the island of Luzon and from the islands of Marinduque, Leyte, Cebu, Mindoro, Samar, Mindanao, and the southern part of Negros. The finest quality of the fibre is called "lupis," or "quilot," and is of a pearly lustre. Other grades are distinguished by their colour and consistency. Nearly the whole crop is placed on foreign markets. The average yearly ship-

ments amount to nearly 1,000 tons, and form the most important item in the Philippine export trade. The United Kingdom and the United States receive the largest shipments, although considerable quantities are also sent to Spain, Australia, China, and Japan. Cotton occupies a peculiar position in the Philippines. It was the first raw fibre used locally in the manufacture of textile fabrics, but it has recently lost much of its former importance, partly because of the excessive taxation that has for some time been imposed on the textile industry of the islands, but principally because of the competition of British fabrics. The cotton plants cultivated in the Philippines are chiefly of the herbaceous varieties. They yield a fine white staple, of superior quality and strength. One variety, however, known under the name of *cayote*, produces a cinnamon-coloured fibre. There is also a species called *bubuy*, that grows like a shrub; the fibre it produces cannot be employed in weaving, but is used in stuffing mattresses, pillows, cushions, &c. Another textile plant that occurs is the *amiray*; this plant is found only on the Batanes Islands, north of Luzon; it closely resembles ramie, and yields a fine white fibre of great tensile strength. Various other fibre plants are found in the Philippines, such as the *pita* (a kind of aloe), the *balibago*, the *dalanot*, or tree nettle, the pineapple, and the *cabon negro* (a species of palm tree), as well as many other varieties more or less unknown outside the archipelago.

POULTRY BREEDING IN BELGIUM.

The breeding of all kinds of domestic animals, for profit or pleasure, was for centuries more advanced in Belgium than in any other European country. Poultry is bred throughout Belgium—in some localities for eggs and meat—in others for meat alone. According to the United States Consul at Brussels, the breed most in favour for general purposes is known as the "Land Van Orlst." The hens, somewhat resembling the pencilled Hamburg, are prolific layers. The eggs are large, of good flavour, and produce the earliest "poulet au lait," which is marketable when six weeks old, or, when grain fed, at three months. The young cocks mature early, and become fat before three months old, or they are kept at liberty on the farm until after the New Year, and sold during the months of January, February, and March at high prices. Large quantities of eggs and young fowls are exported to the cities of Northern France. The breed *par excellence* for the table is the "Conconde Malines," better known in trade as "poulet," or "poularde de Bruxelles." When the chicks are about three months old they are put in coops of special construction, preparatory to fattening for market. The coops or cages are 24 inches high, 20 inches wide, and stand upon four legs, 3 feet in height. The bottom is made of laths, and the top is an adjustable board, to allow the free circulation of air. The

front consists of laths, placed at a distance of from 2 to 2½ inches apart. The receptacle for food is a triangular-shaped wooden box. Each coop accommodates about twenty chickens. After the fattening period expires the coops are thoroughly cleaned, and exposed to the air for not less than fifteen days before receiving other chickens. The length of time necessary to fatten varies from four to five weeks. The best age for fattening is when the chicken is from three to three and a half months old. Younger than this they cannot endure captivity, and when older they cannot become accustomed to it. The food consists of ground buckwheat, mixed with milk, forming a kind of paste, not too liquid, which is given twice daily, very early in the morning, and at about four o'clock in the afternoon. About noon, pure milk, or milk mixed with a little water, is given. If the fowls refuse to take the food they are not forced to eat, but are removed from the coop and killed, otherwise they grow thin and lose their market value.

General Notes.

CHINESE COINS.—The collection illustrating the coinage and currency of the Chinese empire, brought home by Lord Charles Beresford from his recent mission to China, has been lent by him to the Victoria and Albert Museum, South Kensington. This collection includes a series of silver taels of various sizes, in the form of cast ingots in the rough, with a pair of scales, with brass and ivory weights for estimating the value, and some fragments used as small change. There is a set of dollars of different nationalities which pass in China, among them being the new British dollar, first issued in 1898, and coined in India. Among the copper coinage is a collection of 10,000 cash, strung together in bundles by means of the central hole which is a characteristic of Chinese copper coins, representing £1 in English money. This exhibit has been placed in the Chinese Section in the Cross Gallery, behind the Imperial Institute. The entrance to this gallery is through the Indian Section, Victoria and Albert Museum.

INDIAN TEA.—The Indian Tea Association of Calcutta have recently published detailed figures showing the distribution of tea from Calcutta to various places outside the United Kingdom, thus affording an amount of information which, if taken advantage of, may lead to the development of some new markets. The total shipped to these markets was 18,657,841 lbs. 1898-9, against 14,532,618 lbs. 1897-8. The most important places where Indian tea goes direct are shown in the following list (in lbs.), and in addition to the large markets of Australia, "Indian Ports," and North America, Turkey has taken a considerable quantity, as well as Persia, Arabia, Germany, and Russia. The destination of the large quantity headed "Indian Ports" is not

precisely known, but probably a large proportion of it goes from Bombay to some of the Asiatic markets in the neighbourhood of the Persian Gulf:— Australasia 6,293,950, Indian Ports 3,919,018, N. America 3,232,027, Turkey 1,994,507, China 883,295, Germany 526,418, Persia and Arabia 1,504,845, Russia 49,958, Egypt 127,946, Straits Settlements 34,299, Africa 34,436, France 26,294, Norway 8,480, S. America 1,000, Austria 4,145, other places 17,223, total 18,657,841 lbs.

ELECTRIC LIGHTING IN BRUSSELS.—Statistics show that in 1893, 3,030 lamps met the requirements of consumers of electricity in the city of Brussels. At the present time, according to Consul Roosevelt, there are 66,000 lamps. In consequence of the constantly increasing use of electricity, the city has been obliged to enlarge its works. It is now proposed to acquire five new vertical machines of 1,000 horse-power to be placed in works already supplied with five horizontal machines of 500 horse-power. The city also has electrical works established in the railway station, but owing to the steadily increasing use of electricity, the production is insufficient to meet public demands. It was at one time proposed to erect a large electrical power-house just beyond the city limits; but, as it was shown that about 15 per cent. of the current would be lost, the proposition was rejected. The most practical method now seems to be the creation of new stations as the exigencies of the situation may demand.

MILITARY MOTOR CARS.—The *Times* describes a motor vehicle for military purposes, designed by Mr. Frederick Simms. This "motor scout," as it has been named, consists of a quadricycle fitted with a 1½ horse-power petrol motor, which can propel it at any speed up to about 18 miles an hour for a distance of 120 miles, or further with a reserve supply of petrol. It is convertible, carrying either two persons or one person and a light Maxim gun. In the latter case, the gun is mounted in front over the leading wheels and so arranged that it can be fired either to the right or left or straight ahead with the vehicle going at full speed, while in a tray below there is room to store 1,000 rounds of ammunition within easy reach of the rider. Another type of "war motor car" designed by Mr. Simms is much larger and heavier, is armour-plated all over, and has a ram both in front and behind. The armament consists of two quick-firing Maxim guns, carried in two revolving turrets. The steering is managed by means of mirrors, and it is claimed that the crew need never expose themselves outside the protection of the armour. An electric search light is provided, the dynamo being worked from the main engine (16 horse-power nominal). The tires with which the wheels are fitted are such as will enable the vehicle to travel over very rough ground. A third type designed by Mr. Simms is a military railway inspection car, also armour-plated and carrying a Maxim gun. All three vehicles are built to the order of Messrs. Vickers, Sons, and Maxim.

FRIDAY, JULY 21, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS.**

The results of the Examinations held at the end of last March have been published.

Copies for gratuitous distribution to each candidate who attended the examination have been sent to each centre. Additional copies can be obtained, price 6d. each.

The dates for the Examinations in 1900 will be Monday, Tuesday, Wednesday, and Thursday, March 26th, 27th, 28th, and 29th.

Proceedings of the Society.**CANTOR LECTURES.****BACTERIAL PURIFICATION OF SEWAGE.**

BY DR. SAMUEL RIDEAL, F.I.C.

Lecture III.—Delivered January 30, 1899.

Almost all of the processes for sewage treatment already described have been of a mixed or compound character, and not purely bacterial. And to a great extent this accounts for the numerous failures, either through expense, or irregular working, with such a variable liquid as sewage. Even when it was recognised that nearly all the destruction of effete matter was accomplished by minute organisms, there was a natural reluctance to trust entirely to the action of bacteria, from fear of the multiplication of pathogenic forms. Numerous attempts have consequently been made to sterilise sewage by chemicals, or heat, or electricity, or else to reduce the amount of solid matter by precipitants or filtration. The result of such treatment was a double product; first, an effluent, soon becoming putrid, owing to the subsequent inevitable entrance of more bacteria; secondly, a mass of sludge that required a further expen-

sive treatment. The Royal Commission of 1882-84, after deciding against the discharge of crude sewage into any portion of the Thames, had prescribed "some process of deposition or precipitation, the solid matters to be applied to the raising of low-lying ground, or to be burnt, or dug into land, or carried away to sea." The latter course was resorted to as the only one that was thought available for London. In the case of towns like Bradford and others, at a distance from the sea, this course would be obviously impossible.

The one-acre filter at Barking is still only a part of a process that includes also the cost and complication of a preliminary precipitation, and a subsequent transport of the sludge to the mouth of the Thames. The mixture of chemical and mechanical treatment is even now in practice in a large number of places.

If we recall what was said in our first lecture as to the cesspool, it will be remembered that the natural process consisted in:—

1. Liquefaction of the insoluble matter, and modification of the dissolved matter, in a closed space, therefore mainly by anaerobic bacteria.

2. Oxidation afterwards by the help of aerobic bacteria during passage through a porous medium like land. We have seen how an active smaller area, such as that of a coke or ballast bed, can be substituted with economy and more regular working for at least a part of the necessarily large area of land.

I have always been of the opinion, and have often urged in previous papers, that the anaerobic change is an integral part of the preparation, and that the neglect, and even avoidance of it, has been a frequent cause of failure. As Rudolph Hering aptly remarks, "The aerobic process, when applied to organic matter in suspension, is slower than the anaerobic process. It takes a long time for solid particles of organic matter to disappear as such, when the conversion depends on the oxygen contained in the water. It takes a short time when it is brought about by anaerobes, which produce conditions causing liquefaction. The reverse seems true in the case of organic matter in solution, because the aerobic bacteria, and conditions favouring a thorough aeration of liquid sewage, will remove a much greater amount of organic matter from the water in the same time than if it is left to the action of anaerobes."

Therefore, the processes should be properly and systematically conducted in natural sequence. Any mixing or confusing in the

order, any artificial interference, or attempt to work distinct reactions simultaneously in the same receptacle, will lead to uncertainty and irregularity in the results. I shall have again to revert in my last lecture to this principle of differentiated bacterial action. At present we have mainly to deal with the preliminary anaerobic liquefaction.

It has long been known that in the slow filtration of sewage, more particularly when the direction was upwards, so that little or no mixing with air occurred, very considerable changes in the organic matter were brought about, entirely unconnected with oxidation. Thus in an experiment of Frankland's as early as 1870, when a strong London sewage was made to traverse, "continuously upwards so as to exclude aeration," a layer of sand, the analysis of sewage and effluent given is the more instructive as the meaning of it was not understood at the time.

PARTS PER 100,000.

	Crude sewage.	Effluent.
Solid matters in solution,	64.5	80.5
Organic carbon	4.39	3.23
Organic N.	2.5	1.4
NH ₃	5.5	4.6
N as nitrites and nitrates.	None	.328
Total combined nitrogen	7.0	5.5

That is to say, the anaerobic bacteria have acted in the usual way:—

1. They have dissolved 16 parts per 100,000 of the solid matters or sludge, thereby increasing the solids in solution from 64 to 80.

2. Some of the ammonia has been changed into, almost certainly, *nitrite*.

3. 1.16 parts of carbon (25 per cent.) and 1.5 parts of nitrogen (60 per cent.) have been eliminated as non-ammoniacal gases, methane, N, and nitrogen oxides, with probably some CO₂.

We shall see later that this is exactly the process that goes on in the Exeter septic tank. In Frankland's filter the arrested suspended matter slowly disappeared just in the same way as organic substances do when dug into the ground or buried beneath the surface. The action at first is simply a process of *hydrolysis*, or combination with water, whereby the complex organic molecules of insoluble organic matters, like fibrin or cellulose, break up and dissolve as simpler compounds, with at the same time a liberation of much of the

carbon and nitrogen in the form of various gases. And this first, or preparatory, stage, not only goes on without the presence of air or oxygen, but is actually hindered by it, that is to say, it is effected by the agency almost entirely of anaerobic microbes.

I find that a certain amount of confusion is likely to arise from the application of the words aerobic and anaerobic in two slightly different meanings—one with reference to the chemical changes that occur, the other with regard to the organisms that produce them. The words simply meaning "living with air," and "living without air," the chemist has applied the term "anaerobic" to changes occurring by life in which free oxygen took no part, simple changes by hydrolysis, or the addition of water, like that of urea into ammonium carbonate, of sugar into alcohol and CO₂, or of albumen or cellulose according to the anaerobic equations we shall presently meet. In this sense, the word "anaerobe" implies an organism that effects its changes in surrounding matter without oxidation. But a bacteriologist often uses the term, anaerobe, in the sense of "obligate anaerobe," *i.e.*, one that not only does not require oxygen, but is actually inhibited, or even killed, by its presence. The obligate anaerobes, as is shown by our table of bacteria in sewage, are, though exceedingly active, comparatively few. The "facultative" anaerobes on the other hand, those that can live either with or without oxygen, are much more numerous, as being the ones most suited to a liquid which contains little or none of the gas, but may at any time become oxygenated. Thus yeast, which was classed by Pasteur as "both an aerobian and an anaerobian," *i.e.*, as facultatively anaerobic—when in presence of excess of oxygen multiplies vigorously, but does not act as a ferment, whereas in sugar solutions containing no oxygen, it multiplies with less activity, but the fermentive character is most marked, the yeast attacking the sugar, and obtaining any oxygen it requires from it, or from the water present. Boussingault found that normal fermentation could be carried on *in vacuo*, and was greatly promoted by removing the CO₂ and alcohol as fast as they were formed, and thus preventing their retarding action. In the same way with bacteria, a better result is attained when the liquid products are continuously removed, as in the bacterial tanks of Cameron and Moncrieff, and the nitrifying trays of the latter, than where periods of stagnation occur, as in the intermittent system.

In a paper I read, published in the *Journal*,* I described in detail the chemical processes involved in the transformations, so far as they were known. As even now these are often not sufficiently kept in mind, I may recapitulate some of the main points, with a few later observations.

After remarking that the anaerobic changes occurred naturally in the mud-banks of estuaries, under the surface of the water of rivers, and at the bottom of stagnant pools, where the well-known "marsh gas" (mainly methane, CH₄) is produced, I observed that "in nearly all cases of destruction of organic matter this preliminary disintegration takes place before the final oxidation of the elements." I need hardly remind you that *hydrolysis*, or the breaking up of bodies by the action of water, is familiar in chemistry—and that it frequently results in the dissolving of matters previously insoluble, as in the conversion of starch or cotton fibre into dextrin and sugar, or of solid albuminoids like animal fibre or horn into various soluble products, with or without the assistance of acids, alkalis, or heat.

Very similar changes, mainly hydrolytic, are accomplished by the large class of organic substances called "enzymes," which, though not living, are products of animal and vegetable life. These enzymes have been defined by Lehmann and Neumann as "chemical bodies, which in minimum amounts and without being used up are able to separate large amounts of complicated organic molecules into simpler, smaller, more soluble and diffusible molecules." The definition is not quite accurate, as the milk ferment, for instance, actually coagulates casein, or renders it insoluble, but it gives an idea of the immense power that these enzymes possess, and the economy of their use as distinguished from ordinary chemical or mechanical means. Their importance to us is shown by the fact that a large number of them are the products of bacteria or other fungi, and are powerful agents in their resolving action. By their means a bacillus is not only able to act in its immediate neighbourhood, but also at a considerable distance, through the soluble ferments it forms and disengages. To most of them the termination "*ase*" is applied, as *diastase*, *glucase*, or generally *amylases*, which decompose starch; *lipase*, which hydrolyses fats; *cytase*, which dissolves cellulose, and probably numerous others, which are generated by

organisms, and take part in the preliminary liquefying changes of sewage. For example, the enzyme (Rideal and Orchard, *Analyst*, Oct., 1897) produced by *Bacillus fluorescens liquefaciens*, when separated from the organism by a Pasteur filter, is capable of causing liquefaction of gelatine. Dr. Armstrong distinguishes between *zymosis*, or fermentation of organisms, and *enzymosis*, or change by enzymes or unorganised ferments. By the aid of the latter, bacteria are able to produce effects which are quite out of proportion to their size or even to their numbers. Enzymes are also developed by moulds and other fungi.

It must be repeated that these phenomena of resolution take place independently of the presence of oxygen and even more rapidly in its absence, and that even where the organic matter is partly converted into final stable oxidised compounds, the oxygen of the latter is not derived from the air, but is that which was originally present in the organic matter, or in the water taking part in the reaction.

I have previously instanced as a type of anaerobic hydrolysis, the case of albumen. Summing up all the changes in one equation, and taking the simplest empirical formula, we should have:—

giving us all the gases which are commonly met with in these decompositions, and *leaving no residue of solid matter*.

But the large amount of hydrogen that is liberated shows that there is an oxidation *at the expense of the oxygen of the water*. Thus I have found the gas evolved in the septic tank at Exeter to have the following composition:—

	Per cent. by volume.
CO ₂	0·6
CH ₄	24·4
H	36·4
N	28·6
	—
	100·0

This is very similar to the fermentation described by Wood and Wilcox as produced by *Bacterium furfuris* in the manufacture of leather. This bacterium does not attack cellulose, but only starch and nitrogenous matter. They found a sample of the gas evolved to contain:—

CO ₂ and traces of H ₂ S..	25·2 per cent.
Oxygen	2·1 ,,
Hydrogen	46·7 ,,
Nitrogen	26·0 ,,

* *Journal*, vol. xlvii., p. 81, December 17, 1897.

Formic, acetic, butyric, and lactic acids were produced. These in sewage would combine with ammonia. I have lately found in a septic tank effluent salts of acetic, butyric and phenylacetic acids.

On the other hand, *Bacillus amylobacter*, which is strictly anaerobic, dissolves cellulose and evolves gases, the equation being given by Hoppe Seyler as—

The greater part of the carbonic acid remains dissolved as carbonate of ammonia, while the hydrogen, from its easy diffusibility, escapes

from the tank more rapidly than the heavier gases. No sulphuretted hydrogen was found in the septic tank gases, the sulphur remaining in solution mainly as methyl mercaptan, $CH_3 HS$. The normal decomposition of urea into carbonate of ammonia and water is an example of a simple hydrolysis which produces no free gas, thus:—

The following Table shows the weight of oxygen required to convert some typical organic compounds into the final products that are actually found:—

Substance.	Empirical formula.	Per-centage composition.				Oxygen required by one part to convert it into—	
		C	H	N	O	CO ₂ , H ₂ O, & N	CO ₂ , NH ₃ , & H ₂ O
Albumin	C ₈ H ₁₃ N ₂ O ₃ ?	53·4	7·1	15·8	23·7	1·754	1·48
Gelatin	—	50	6·6	15·3	25·1	1·61	1·33
Starch, cellulose, and woody fibre	C ₆ H ₁₀ O ₅	44	6·2	—	49·4	1·184	1·184
Ammonium amidoacetate (Am- monium salt of glycocine).... }	C ₂ H ₅ N ₂ O ₂	26·1	8·76	30·43	34·78	1·043	0·53
Urea	CH ₄ NO ₂	20	6·7	46·7	2·66	0·803	0

Every eight parts by weight of oxygen absorbed from water would involve the liberation of an equivalent, or one part by weight of hydrogen, so that the above weights, if increased by one-eighth, give the weight of water taking part in the hydrolysis. At present it is difficult to say whether the first or second of the transformations given in the last two columns should be encouraged. As a matter of fact, both usually occur in practice.

It is obvious that the first or more complete change is one in which the gases evolved would be entirely without odour, but the N, being in the free state, is lost: in the second or less complete anaerobic change, the gas will have an ammoniacal odour, and would be offensive if allowed to escape into the air. The effluent also will contain combined N in the form of NH₃ and compound ammonias, and make it absolutely necessary to insure that adequate nitrification should follow. The final effluent then theoretically contains all the original organic N in the form of nitrate, which is available for plant nutrition.

The "by-product" of these re-actions is a varying but small quantity of dark pulverulent matter resembling the humus or peaty substances of soil. This mixture of bodies of somewhat indefinite constitution, although containing nitrogen, is innocuous from its very

stability. It partially subsides and gradually disappears, while the suspended portion may cause turbidity and colour in the liquid, which are removed in the subsequent oxidation by porous aerobic media.

As compared to the voluminous "sludge" of chemical or mechanical treatment, the anaerobic liquefaction leaves only a small quantity of this earthy matter which requires no special provision.

The "cesspool" or anaerobic preliminary treatment is however by no means novel, as it is on record that an early attempt was made in France to carry out systematically this form of treatment. Rudolph Hering has given an abstract of an article in the "Cosmos. Les Mondes" of December, 1881, and January, 1882, on the "Mouras Automatic Scavanger," described as a "mysterious contrivance," which has been used for 20 years, or since 1860. It consists of a closed vault with a water seal, which "rapidly transforms all the excrementitious matter which it receives into a homogeneous fluid, only slightly turbid, and holding all the solid matters in suspension in the form of scarcely visible filaments. The vault is self-emptying, and continuous in its working, and the escaping liquid, while it contains all the organic and inorganic elements of the faeces, is almost devoid of smell, and can be

received into watering carts for horticultural purposes, or may pass away into the sewer for use in irrigation." As to the theory of the action, it is said, "May not the unseen agents be those vibrions or anaerobies which, according to Pasteur, are destroyed by oxygen, and only manifest their activity in vessels from which air is excluded"?

Observations with a glass model showed that "Fæcal matters introduced on August 29th were entirely dissolved on September 16th, while even kitchen refuse, onion peelings, &c., which at first floated on the surface, descended after a time and awaited decomposition. Everything capable of being dissolved acted in a similar way, and even paper wholly disappeared."

It is further said, "The principle on which M. Mouras bases the action of his machine are that the animal dejecta contain within themselves all the principles of fermentation or of dissolution necessary and sufficient to liquefy them, and to render them useful in their return to the soil, and without appreciable loss."

A later article of January, 1883, by the Abbé Moigno gives formulæ for the dimensions of the tank, estimating its superficial area as preferably 1-10th metre, or about 1 square foot per person. The Exeter tank, I may remark in passing, works out to about 0.6 square feet per person. The article also specifies that "for the complete solution of the floating solid matter a period of thirty days should be

allowed," giving $\frac{130}{30}$ M as the the total average

amount of suspended matter present in the tank at any instant when M is the weight of organic matter present in the volume of sewage dealt with per day. The size of the tank required is therefore not so large as to be impossible with sewages containing an ordinary amount of organic matter, but as the effluent from such a tank without further nitrification has practically all the properties of liquid sewage, it probably accounts for the fact that

the "Automatic Scavenger" did not attract more general attention at the time. Mr. Scott-Moncrieff's early experiments seem to have originated from his observation of the rapid liquefaction of organic matter in long lengths of sewers. He began on a practical scale in 1891 by constructing at Ashted a bacterial tank into which the crude sewage was admitted from below and gradually passed upwards over the surfaces of a bed of stones. He found that the liquefaction of the solids was so effective that the whole sludge of seven years from a household of ten persons was absorbed on nine square yards of land, causing no distinction in appearance between this soil and that surrounding. The space beneath the under grating of the tank had a capacity of less than five cubic feet, and would obviously have filled up in a short time but for the liquefying action that had taken place.

In 1892 his process was examined by Dr. Houston, and later by Dr. Sims Woodhead and myself. Dr. Houston's report of 1893 is practically the first literature on the purification of sewage as a whole bacteriologically, without deposition or chemicals and with hydrolysis by micro-organisms of the grosser organic matter as a precedent to further treatment, a point which is not mentioned in the Massachusetts reports.

In this way the difficulty of the production of sludge was completely disposed of. I have shown how a great part of this, during or after liquefaction, disappears as gases. It is obvious, however, that the remaining liquid will retain the ammonia which has been produced by the hydrolysis, together with residues of nitrogenous and carbonaceous dissolved matters, so that judged by ordinary standards of analysis, this liquid, in the first stage, will show somewhat large amounts of carbon and nitrogen. As examples of some effluents from Moncrieff's anaerobic tanks, derived from heavy domestic sewages during the early stages of experiments, I may quote the following analyses made by C. G. Groves for the Thames Conservancy, and by myself:—

PARTS PER 100,000.

Date.	Analyst.	Suspended matter.	Dissolved solids.	Cl.	Ammonia.	Albuminoid NH ₃ .	Oxygen consumed.
May 7th, 1895	Groves.	Trace.	101.0	10.4	15.0	0.8	5.4
June 1896	Groves.	„	112.0	21.0	7.0	0.8	3.9
July 1897	Rideal.	„	191.5	59.4	9.0	0.7	8.2

With reference to the first sample, Groves remarks that it contains a *large amount of easily decomposable nitrogenous organic matter in solution*. This great instability of the organic compounds that come over from cultivation tanks is the principal feature of the process.

With the object of obtaining an oxidized effluent, Moncrieff then duplicated the tanks and used them alternately with periods of aeration and rest. The effluent obtained was clearer, and had less odour, but showed practically no nitrification. That the liquid was ready for natural oxidation was shown by the fact that when at Towcester in 1893, the effluent was passed into a small brook, the water actually became clearer below the discharge than above it. Efforts were then directed towards carrying on this final change within the apparatus. It was first tried to obtain nitrification by passing the effluent through the "nitrifying channels," consisting of half drain pipes joined in line by cement, and filled with coke. But the result was not commensurate, for the reason that the right organisms were not developed. During the transit, the liquid was largely exposed to the light, whereas it is known that the bacteria forming nitrates thrive best in the dark. It was noticed that denitrifying organisms, which are not so sensitive, had actually in some cases reduced existing nitrates, as pointed out by Dr. Houston in the Ashted experiments. How the difficulty was afterwards overcome by the construction of the nitrifying trays will be described in the last lecture.

Up to this point there was still a belief that hydrolysis and aerobic nitrification could be carried on successfully in the same tank. At Aylesbury air was forced in by a steam jet, with this object in view, but the result was unsatisfactory.

It was concluded finally that all the nitrogenous organic matter must be as far as possible broken up into ammonia before being oxidised to nitrates, and that these two reactions should be carried on in separate areas, the one under anaerobic conditions, and the second with free admission of air but not of light, when the distinctly nitrifying bacteria should be free to work without being interfered with by conditions favourable to other organisms, or by these latter organisms themselves. In very strong sewages there seems almost no limit to the capacity of the hydrolytic ferments to break down nitrogenous matter into ammonia. Thus Marchal found that one of

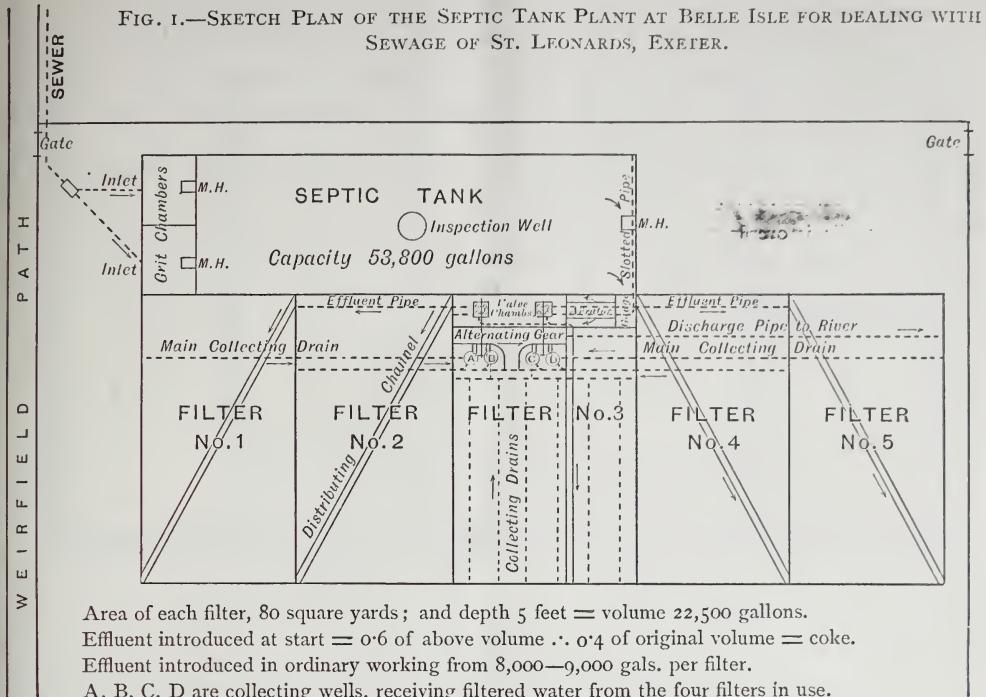

the organisms that effects this function, *B. mycoides*, could thrive in a medium containing two parts in a thousand of caustic potash, equivalent to 660 parts per 100,000 of free ammonia, and in septic effluents in the first stage I have found as much as 30 to 40 parts per 100,000 of NH_3 .

But it was found, on the other hand, that there was a limit to the amount of anaerobic change if nitrification is to be carried to a successful issue.

Thus, in recent experiments at Caterham, dealing with a heavy sewage containing 18 parts of Cl per 100,000—the entire discharge from the barracks—the preliminary process was pushed much further than usual, to try if it were possible to carry the anaerobic fermentation too far, with the object of ascertaining the most favourable point, by estimating the free ammonia, and finding what amount gave the best results in nitric nitrogen. Exceptionally anaerobic conditions were introduced, by means of inverted open-mouthed glazed earthen vessels, about 400 in number, piled in a tank 20 ft. by 10 ft. by 9 ft. deep, and kept down by weights. Each pot became filled with gases of the character I have described, devoid of oxygen, so that there were a large number of surfaces on which zooglæa colonies of bacteria could quietly develop in contact with the percolating sewage. The result was an effluent containing 126 parts per 100,000 of dissolved solids, 35 of free NH_3 , and 5.3 of organic nitrogen. The liquid was now highly toxic to any but anaerobic organisms, and absolutely refused to nitrify. When diluted, however, with a few volumes of natural water it rapidly became purified.

In 1895, Mr. Cameron, City Surveyor of Exeter, introduced his "septic tank" process for the treatment of a portion of the sewage of the city, comprising about 2,000 persons, on the combined system, yielding about 50,000 gallons of sewage. After passing through a grit chamber where gravel brought down by the rains was detained, the liquid containing all the organic solid matter emerged into a closed tank, through which it slowly passed. The details are well known and are indicated in the illustrations. (Fig. 1.) The present tank has a capacity of 53,800 gallons, therefore holds approximately a day's supply, hence the time of remaining in the tank is about twenty-four hours. In this way the sewage becomes mixed and averaged, and the bacteria have a chance of working during the passing through the 65 feet length of flow, which the sewage

FIG. 1.—SKETCH PLAN OF THE SEPTIC TANK PLANT AT BELLE ISLE FOR DEALING WITH SEWAGE OF ST. LEONARDS, EXETER.

Area of each filter, 80 square yards; and depth 5 feet = volume 22,500 gallons.
 Effluent introduced at start = 0.6 of above volume. ∴ 0.4 of original volume = coke.
 Effluent introduced in ordinary working from 8,000—9,000 gals. per filter.
 A, B, C, D are collecting wells, receiving filtered water from the four filters in use.
 By means of the alternating gear, each filter in rotation is filled, discharged, and aerated automatically.

traverses at the rate of a little more than 2 feet per hour. No obstruction is present, and the entire space is available, differing from what we have seen of tanks partially filled with stones or coke. In the latter the dimensions must either be larger in proportion, or the sewage must pass at a greater rate, the bacteria also are not so freely distributed through the liquid. From the inspection chamber it is seen that a leathery scum from 2 to 6 inches thick, according to the position, collects on the surface and renders the whole anaerobic. Below this is a zone of fermentation, in which the sewage is mainly clear, but bubbles of gas keep the liquid in a state of quiet admixture. At the bottom of the tank there is a layer of the dark peaty matter, previously referred to, which is so small in amount that during a period of a year's working, it does not require to be removed. The organic matter in it is gradually broken up by the bacteria, the inorganic matter is raised by the gases and gradually carried off in the flow, so that its quantity does not sensibly increase. On October 13th, 1898, I found this peaty matter to contain about 68 per cent. of mineral, 32 per cent. of organic matter, and 2.4 per cent. of nitrogen.

According to Adeny's researches it seems to be necessary for the subsequent nitrification.

The flow through the tank is continuous, therefore requires no attention for Sundays or night. The inlet and outlet are submerged so as to minimise the disturbance of the contents. At the far end of the tank a transverse iron pipe, about a foot below the level of the liquid, with a slot on the under surface extending its length, forms an exit for the effluent, which passes over a V-gauge, and then falls in a thin stream over an aerating weir, to restore aerobic conditions. It then flows through distributing channels on to filters of coke breeze or clinker similar to those at Barking and Sutton, four of which are used at a time, and one kept in reserve. An automatic gear devised by Mr. Cameron regulates the cycles of filling, resting full, emptying, and aeration, so that here again no attention is required. (Fig. 2.) The Local Government Board inquiry of 1897 approved of the system being applied to the whole of the city, of a population of 46,000, with the usual proviso as to land. The daily flow is 1,064,610 gallons, and for this, six tanks 181 ft. by 35 ft. by 7 ft. deep, with a capacity of 262,422 cubic feet, will be provided, in which the suspended solids will dissolve. Eight filters of a total

FIG. 2.

Cycle for Four Filters, Nos. 1, 2, 3, and 4, Discharging into Four Collecting Wells, A, B, C, and D.

At starting, let filter No. 4 be already full and resting, and No. 1 filling.—Period I.

When No. 1 fills, it overflows into tipper C, discharging No. 4, putting down outlet valve of No. 3, and admitting effluent to No. 3.—Introducing Period II.

When No. 3 fills, it overflows into tipper B, discharging No. 1, putting down outlet valve of No. 2, and admitting effluent to No. 2.—Introducing Period III.

When No. 2 fills, it overflows into tipper D, discharging No. 3, putting down outlet valve of No. 4, and admitting effluent to No. 4.—Introducing Period IV.

When No. 4 fills it overflows into tipper A, discharging No. 2, putting down outlet valve of No. 1, and admitting effluent to No. 1.—And so on.

Diagram of Overflow Pipes.

Position of Gear.	PERIOD I.				PERIOD II.				PERIOD III.				PERIOD IV.			
	A	B	C	D	C	A	B	D	A	B	C	D	D	A	B	C
Filter No.1 ...	Filling				Resting Full				Emptying				Aërating			
Filter No.2 ...	Emptying				Aërating				Filling				Resting Full			
Filter No.3 ...	Aërating				Filling				Resting Full				Emptying			
Filter No.4 ...	Resting Full				Emptying				Aërating				Filling			

area of $2\frac{1}{2}$ acres, or 13,600 sq. ft. each, having a depth of $3\frac{3}{4}$ ft. of crushed furnace clinker on 6 in. of coarse gravel, and a working capacity of $2\frac{1}{2}$ million gallons a day, operating with the alternating gear as before, will deal with the tank effluent. (Fig. 3.)

It will be seen that Mr. Cameron, like Mr. Scott-Moncrieff, carefully differentiates between the hydrolytic or solution process, and the subsequent oxidation required for final purification. Dr. Sims Woodhead has shown that while the anaerobic organisms are more numerous in the tank, a number of liquefying aerobic organisms are still present, and increase on passing over the aerating weir. The filters are, of course, aerobic.

The changes occurring in the tank are rather complex. Analyses were made by Dupré, Perkins, and myself, in 1896 and at sub-

sequent dates, and by Dibdin and Thudichum, and Pearmain and Moor, in 1897. From these it appears that the total dissolved solids are increased somewhat, but not in relation to the organic *débris* that has passed into solution. A large proportion has undergone the hydrolytic decomposition which we may represent in two forms:—

1. Producing nitrogen, methane, a small quantity of hydrogen and carbonic acid, as in the general equation already given:—

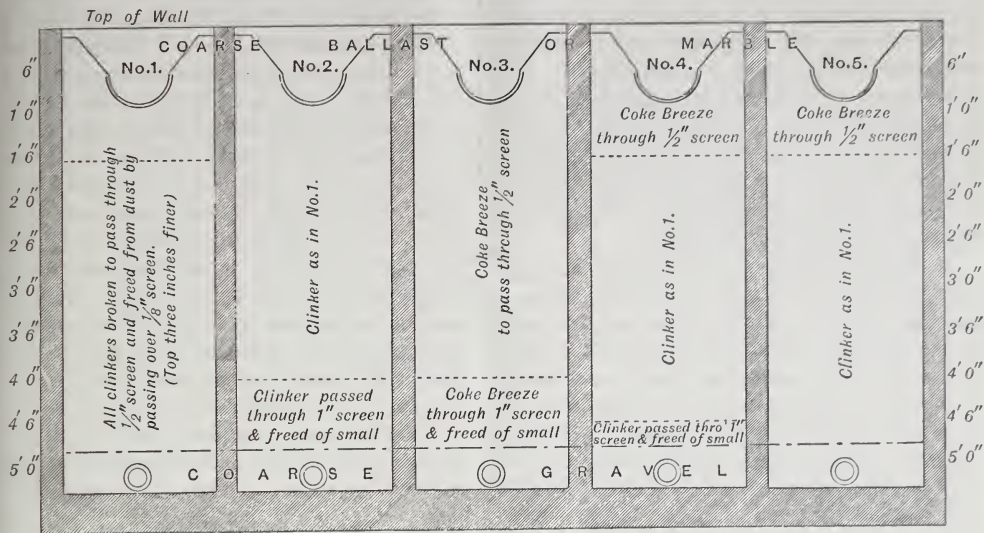

2. Producing ammonia, CO_2 , and a large quantity of H:—

Both species of reactions go on simul-

FIG. 3.—SECTION SHOWING ARRANGEMENT OF FILTERING MATERIAL AT BELLE ISLE.

taneously, along with others, according to the species of bacteria. The result is the production of a large quantity of inflammable gas, which can be drawn off by a pipe and made serviceable for heating.

The ammonia and the major part of the CO₂ remain in the solution, which contains on an average 33 per cent. more of free NH₃, 29 per cent. less of organic matter as measured by the oxygen consumed, and 46 per cent. less of albuminoid ammonia. The organic matter is now in a readily oxidizable state, and passes on to the second or aerobic part, in which it is dealt with by the filters. A large amount of carbonic acid is produced in the filters by oxidation of the organic matters, and is driven out in the stages of filling. I found in one case nearly 7 per cent. of CO₂, which is equivalent to 400 gallons per day. The residue of the nitrogenous matters is mainly changed into nitrates, averaging about one part of nitric nitrogen per 100,000.

The following Table shows the per-centage purification produced by the Exeter process, as stated by different observers at the inquiry in 1897, measured by the reduction of albuminoid ammonia and of the oxygen consumed:—

	Albuminoid NH ₃ .	Oxygen consumed.
Dupré	84.9	88.3
Perkins ..	64.4	78.7
Dibdin and Thudichum....	63.2	80.9
Pearmain and Moor	80.0	90.0
Mean	73.6	84.0

My own figures for the separate stages of purification, published in 1896, were, in per cents. of the crude sewage:—

	Albuminoid NH ₃ .	Oxygen consumed.
By tank	46	29
By filters	31	53
Total	77	82

The installations at Yeovil and other places have proved that the septic tank process is not affected by manufacturing refuse. The smoothing and diluent effect in the volume of sewage, and the room for precipitation and neutralisation by the ammonia, seem to obviate these difficulties.

Three other points in the Exeter Local Government Board inquiry require comment. One was the action of the grit chamber. On entering this the heavy particles of gravel and sand at once sank, while the organic refuse, which in fresh sewage always floats, passed over the submerged wall, 7 feet from the entrance and 12 inches below the surface of the liquid, into the main portion of the tank. The result is that no solid sewage remains in the grit chambers, and the gravel may at intervals be dredged out without disturbing the contents of the tank. This is not at all parallel to the action of screens or straining filters, which also arrest the solid organic matters, thereby forming a subsidiary sludge.

The second point is as to the stay in the tank. The flow of the liquid through the tank in dry weather occupies 24 hours or more, and

in wet weather may be reduced to 7 hours. During that time, it is, as we have seen, profoundly altered by the action of the anaerobic bacteria. But the more intractable portions of the solid matter remain much longer: they are entangled by the active zooglœa scum on the surface, or may slowly sink to the bottom: in both cases they are dissolved by the bacteria and join the liquid, so that the scum and the sediment, though showing some fluctuations, remain about the same volume.

A third important point was raised at the inquiry and is one which requires more than a passing mention. It is as to the pathogenicity of the product after anaerobic treatment, since it has been suggested that whilst cultivating the bacteria necessary for the destruction of the organic matter in sewage, the pathogenic organisms present in the crude sewage will not only survive but may possibly multiply and so cause the effluent to be dangerous to health. It is important, however, to remember that the bacterial processes are not novel, but are identical with those which obtain in nature, so that effluents from sewage farms are strictly comparable with filtrates obtained after either a "coarse bed" or an anaerobic treatment.

Mr. Groves, in his evidence before the Water Commission last week, hoped that the Local Government Board would not depart from their past position with regard to the land treatment, as from the typhoid statistics for London, he argued that the present method of dealing with sewage was satisfactory. Although with any new scheme, it is difficult to obtain any direct evidence as to its ultimate effect upon a river water which is subsequently to be used as a drinking supply, one must recollect that under existing circumstances the removal of all kinds of bacteria from the river water is attempted by those who desire to use such water for drinking purposes, so that even assuming that bacterial systems tend to increase the bacteria in the river, they do not make any new departure necessitating a re-consideration of our methods of water purification. Even if an anaerobic treatment alone resulted in an effluent which possessed toxic properties disastrous to a small river, it must be recollected that no process is at present suggested which does not involve a full and efficient aerating filtration as a final method of purification, and it is the pathogenicity of such filtrates upon which information is wanted. Satisfactory evidence on most of the systems is now available, from which I think we are justified in concluding that even if towns on a

river like the Thames adopted bacterial schemes, the pathogenicity of the London water supply would not be adversely affected.

With intermittent fine bed filters following coarse bed or chemical treatment, as at Leeds and London, fish have lived in the filtrates. At Exeter, Dr. Cartwright Wood examined the tank effluent, the filtrate, and the river water before and after admixture. The broth inoculated with these fluids, and incubated for 48 hours, had no effect upon rabbits or guinea-pigs, when 2 c.c. were injected subcutaneously.

When incubated for 11 days, the tank effluent and the water at Belle Isle contaminated with the untreated town sewage, were found to be morbidic, but the filtrate and the water at Salmon Pool weir, some little distance below the town, contained so little morbidic material of any kind, that even with this severe test both animals remained alive and perfectly well.

Dr. Woodhead, in his report, concludes "that none of the organisms themselves found in the tank effluent are capable, in the quantities present or in which they can grow even in broth, of setting up any morbid changes."

With regard to typhoid fever, Lawes and Andrews some years ago showed that some liquefying organisms have a germicidal effect upon typhoid bacilli, so that their sojourn in a septic tank or their arrest in an anaerobic upward filter, with such organisms diminishes instead of increases their chance of survival. Dr. Pickard, of Exeter, has proved this fact again experimentally by introducing an emulsion of the typhoid bacilli into a septic tank, when he found that instead of increasing they rapidly diminished, until after 14 days less than 1 per cent. of the number introduced were surviving. The same investigator also proved that the filtration was also efficient in removing typhoid bacilli, as he found that filtration as conducted at Exeter removed about 90 per cent. of typhoid bacilli from sewage inoculated with this organism. The passage of a tank effluent containing no typhoid through the same filter yielded filtrates containing only about 1 per cent. of the bacilli introduced in the first filtration, showing that the environment was unsuitable for their development, even if their absence from the filtrate was due partly to a straining action.

Dr. Houston with the Ducat filter has shown that with sewage containing one *B. coli* per 100,000 c.c. a filtrate is obtained which contained no colonies resembling this organism in this quantity. And that sewage containing be-

tween 1,000 and 10,000 spores of *B. enteritidis sporogenes* per c.c., retained after filtration less than 10 per c.c., whilst the aerobic bacteria causing liquefaction of gelatin were likewise reduced from 22 to less than 1 per unit.

In my own work I have proved that the spores of *B. enteritidis sporogenes* survive, as might be expected, the septic tank treatment, but Houston has shown, as stated above, that 99 per cent. can be removed if the tank be followed by a well aerated filter.

Before this evidence of the comparatively innocuous character of the filtrates from bacterial systems was available, I pointed out that subsequent chemical treatment could be used for sterilising the filtrate if necessary. Such reagents as may be conveniently employed may be called "finishers," as the resulting purified sewage is satisfactory, both from chemical and bacterial points of view. Chlorine is one of such reagents, and the late Dr. Kanthack has established the fact that with one grain to four gallons of the tank effluent, or to five gallons of filtrate, with a period of contact of about five minutes, the number of bacteria can be reduced from any number (even millions) to 10-50 per cubic centimetre, and that no pathogenic organisms were found in any of the numerous samples of Maidenhead sewage finished in this way. I found at the same inquiry that on adding 1.77 parts of available chlorine per 100,000, although about half the amount immediately combines with any organic matter present, if the aerating filter has not worked efficiently, the micro-organisms, by contact with the remainder, are gradually killed, so that plate cultivations of such sewage taken after 14 minutes showed no growth with three and a half days' incubation.

Miscellaneous.

THE PRACTICE OF PROFESSIONS IN JAPAN.

Anyone who wishes to practice law in Japan must pass the examination which is held once a year, and must obtain the permission of the Minister of Justice, and then he can practice in the Supreme Court and other Courts. The United States Consul-General at Yokohama says that a minor, a bankrupt who has not completed the obligation of compensation, a person convicted of a theft or fraud, an official, or a public or private employé is debarred from obtaining such permission. A practitioner must join a guild of lawyers in the district where he intends to settle, and he must observe its rules and regulations. The

registration fee is 20 yen (about £2), and the sum of 10 yen (about £1) is to be paid as a fee at the time of examination. Violations of the provisions to be observed by the members of its Bar is punishable by censure, by suspension of avocation for not more than one year, or by a fine of not more than 100 yen (about £10). In the case of a graduate of the law college of the Imperial University, he is exempted from passing the examination, but is required only to apply for a license for practising. The profession of veterinary surgeon can be followed only by one who has obtained a licence from the Minister of State for Agriculture and Commerce. Those enumerated below may obtain the licence— One who has passed a veterinary examination, and holds a certificate; one who holds a diploma of a Governmental veterinary school, or a certificate that he has passed a special course of the veterinary department of an agricultural college; one who holds a certificate that he has passed a special course of the veterinary department in a public or private school, the curriculum of which has the approval of the Minister of State for Agriculture and Commerce; one who holds a graduation certificate of a governmental or public veterinary school in a foreign country. A licence fee of 1 yen (about 2s.) must be paid; a renewal of licence on account of loss can be made upon the payment of 50 sen (about 1s.). A suspension of business for not less than five days, and not more than 50 days, or entire prohibition of occupation, may be adjudged (if there be any offence with regard to veterinary practice or improper conduct) by the Minister of State for Agriculture and Commerce, according to the circumstances of the case. This prohibition may be rescinded after three years have elapsed if deemed desirable, in which case the practitioner must apply for a fresh licence. A fine of not less than 5 yen (about 10s.), nor more than 50 yen (£5), will be imposed upon one who has practised veterinary medicine or surgery without obtaining a licence. A fine of not less than 2 yen (4s.), nor more than 25 yen (£2 10s.), will be imposed upon one who practices while he is under suspension. A penalty of not less than 1 yen (2s.) nor more than 1.95 yen (about 4s.) will be imposed upon a veterinary surgeon who shall have refused to comply with the request of others for professional services, without sufficient reason for his refusal. The Minister for Agriculture and Commerce may issue a provisional licence to a person who has none of the qualifications enumerated above, but whose antecedents merit such favour, by limiting the area of operation and the period of practice, upon the recommendation of the chief of the Hokkaido Cheo, or of a governor of any prefecture where veterinary surgeons are scarce. Any person who desires to practice medicine must pass an examination before a committee annually appointed by the Minister of State for Home Affairs. The fee for a licence to practice is 20 yen (£2). The alumni of the medical college at Tokyo Imperial University, and

of the medical departments of the first, second, third, fourth, and fifth high schools, and one of the medical schools of Osaka, Kyoto, and Aichi, are entitled to practice without passing the examination, the only requirement being to apply for, and obtain, a licence. A physician who shall have committed any offence, or one who has been guilty of improper conduct in a professional way, may be suspended or prohibited from practice by the Minister of State for Home Affairs, after full inquiry has been made by the central Sanitary Board. After study of at least two years, one who desires to practice dentistry can apply for examination, which is held annually. This must be passed before he can procure a licence, the fee for which is 8 yen (16s.). The penalty clause that applies to physicians is also enforced in the case of dentists. One must be over 20 years of age, pass the examination, and obtain a licence from the Minister of State for Home Affairs, before he can practice pharmacy. The licence fee for practising is 3 yen (6s.). He can make up medicine only in accordance with a prescription of a physician, in which the name and age of the patient, name of medicine, quantity, directions for use, quantity to be taken by the patient, date, and name of the physician, are described. A prescription for a poisonous or astringent medicine must be signed by a chemist and be kept for a period of 10 years. One who practises the business of pharmacist without obtaining Governmental sanction will be punished by a fine of not less than 10 yen (£1), nor more than 100 yen (£10).

Correspondence.

PORT OF CALCUTTA.

In my paper on the "Port of Calcutta" [*Journal*, June 16, p. 628, *et seq.*], I quoted in paraphrase a copy of a letter which Mr. Lindon W. Bates wrote to Mr. Vernon-Harcourt in correction of some statements regarding his Hugli River Improvement Project, made by the latter in an article attributed to an Indian journal. I wrote that "he (*i.e.*, Mr. Bates) says that he has shown it to the engineer, Mr. Franzius, to whose example Mr. Vernon-Harcourt has appealed, and also to the principal hydraulic authority on the Scheldt, and that both those eminent specialists have signified their approval."

I am informed by Mr. Bates that this statement is not correct, so far as Mr. Franzius himself is concerned, and that the project has not been submitted to him personally. The words on which I based my sentence are:—"My Hugli plans have been submitted to the principal hydraulic authority on the Scheldt, and to the authority you quote in Bremen during the past week, and they have given me the assurances of their full approval."

I understood "the authority" in Bremen to be Mr. Franzius. It appears, however, that Mr. Bates,

who had discussed the matter with Mr. Franzius' chief of staff in Bremen, intended these words in a less personal sense; they were not meant for publication (as I had supposed) like the special corrections, but to intimate to Mr. Vernon-Harcourt himself that the authorities which he had invoked in his letter to *Indian Engineering* were in fuller accord with his (Mr. Bates's) application of the principles of modern river regulation to the Hugli than with the projects heretofore proposed.

It is, therefore, obviously only just to all concerned that this explanation should be published; and I do so with the approval of Mr. Bates, who has called my attention to the matter, and to whom I have shown this letter.

I desire that the paragraph beginning "I have seen the reply," on the first column of page 644 of the *Journal*, may be considered as cancelled.

C. C. STEVENS.

General Notes.

THE ORIGIN OF FINE PEARLS.—Some hold that fine pearls are the result of a disease in the oyster, and others that they are caused by the shellfish coating intrusive bodies, such as grains of sand, insects, and even small fishes, with nacre, so as to make them agreeable to its soft flesh. According to a paper of M. Leon Diguët, presented to the Académie des Sciences, Paris, recently, there is a distinction between fine pearls and intrusive bodies coated with nacre, which renders both views more or less right. It is true that foreign bodies entering the shell, and probably irritating the mollusc, are coated with nacre, and sold as pearls, often of peculiar and fanciful shape. They occur between the "mantle" and the shell, but are usually, if not always, attached to the shell by a neck of the pearly matter. These "pearls of nacre," as M. Diguët calls them, have not the fine iridescence of the true "Orient" pearl, but only that of the shell or mother-of-pearl. They are the result of an accidental intrusion. On the other hand, the true spherical pearl of Orient lustre is formed in any part of the shellfish except the mantle, and has no connection with the shell itself. It is a pathological calcification or "stone," and seems to arise from parasites. It begins in a small sac of humour, which becomes gelatinous, and calcifies in a series of concentric layers. A pearl thus formed is composed of crystalline matter, and a substance resembling conchioline in alternate layers. At its heart is a cavity holding organic matter and calcareous crystals, with remains of organised creatures, presumably the parasites which have provoked the malady in the shellfish. In course of time the sac in which the pearl is made becomes thin, and the mollusc, breaking it easily, can eject the pearl.—*Times*.

CANTOR LECTURES.

BACTERIAL PURIFICATION OF SEWAGE.

BY DR. SAMUEL RIDEAL, F.I.C.

Lecture IV.—Delivered January 30, 1899.

There is an early part of the transformation which we have not hitherto noticed. When faecal and other solid matters are first discharged, the earliest changes must be aerobic, because of the free oxygen dissolved in the water and contained in the air. The effect is mainly the same as the last stage, i.e., the organisms acting in a normal manner upon those simpler constituents like ammonia, which must obviously already exist in small quantities, and into which the process itself afterwards resolves the main ingredients of the sewage. Nitrates in small quantities are consequently often observed in discharges which are moderately fresh.

As soon as the free oxygen has been exhausted, these oxidation changes come to an end, and the bacteria which require air in part disappear, and in part remain quiescent to resume their functions at a later stage. On the other hand, the anaerobic organisms will commence to multiply, the nitrate will be reduced to nitrite and this to nitrogen, according to reactions we shall explain later, and the liquefaction and hydrolysis changes will proceed. This is usually the condition when the sewage arrives at the works, and the first, or anaerobic stage of the treatment proper, commences.

In the second stage, aeration is to be encouraged as much as possible, so that the aerobic bacteria may act, and ammonia and carbonic acid be produced, with the help of some of the anaerobic forms.

In the third stage, with provision of a still larger quantity of oxygen, the nitrifying group will get rid of the remaining products.

The phenomenon of symbiosis—that is when

one or more kinds of bacteria act together and effect decompositions which neither of them could do separately—shows that it is not necessary to aim at securing individual species, which indeed would be impossible in practice, if the complexity of the flora of sewage be considered.

Dr. Sims Woodhead found in Exeter crude sewage the following number of organisms per cubic centimetre (about 20 drops):—

Anaerobic	{ Liquefying, 300,000 (some fluorescing and many of them gas-producing). Non-liquefying, 700,000.
Aerobic (facultatively anaerobic)	
	{ Liquefying, 500,000. Non-liquefying, 3,000,000 to 5,000,000.

Dr. Houston, in London sewage, finds about 4,000,000 to 5,000,000 of bacteria, of which about 500,000 are liquefying.

On the other hand, in a mixture of species, some are crowded out, and being unable to act, finally disappear. Such is the fate, as we saw in the last lecture, of pathogenic organisms, which preferably grow at blood heat, and do not find themselves under favourable conditions at low temperatures, and among a swarm of competing others.

If, however, successive zones or habitats be arranged under slightly varying circumstances of aeration or otherwise, groups of species will establish themselves to the exclusion of others, and sewage passing through will find itself exposed to a natural cycle of change. Such an arrangement takes place in the top and bottom layers of the septic tank, and still more in the "bacteria tank" of Scott-Moncrieff, where the stones become coated with zooglæa layers of different organisms at successive points. The same system he carries out further in the oxidising filter, to be described later.

This differentiation of the organisms leads us to a consideration of the chemical reactions that occur, and the bacteria which produce them.

The fermentations occurring in the first or hydrolytic part of the process may be chemically classified, as follows:—

1. The solution and decomposition of albuminous bodies.
2. The fermentation of urea.
3. The fermentation of the amido-compounds formed from the albuminous bodies.
4. The formation of organic acids, and the fermentation of their salts.
5. Cellulose or methane fermentation.
6. The hydrolysis of carbohydrates.

7. The formation of small quantities of sulphur compounds, like H_2S , mercaptan, &c. This, from the odour of the products, often attracts the most attention.

These, as a rule, are conducted by bacteria, mould and yeasts not being commonly found in sewage, indeed, their presence, according to Andreasch, is distinctly prejudicial to normal bacterial action.

The following is a list of some of the sewage bacteria which have been found by various observers:—

BACTERIA OCCURRING IN SEWAGE.

NOTE.—L, liquefying gelatine; NL, not liquefying; SL, slightly liquefying.

Obligatory Anaerobes.

Spirillum rugula, L (very active, spore bearing, gives rise to a faecal odour).

Sp. amyloferum (in absence of air acts as a vigorous ferment).

Bacillus enteritidis sporogenes. (Klein. See Lecture I.)

B. amylobacter, L (*Clostridium butyricum*).

B. butyricus (Botkin), L (gives much gas).

(*B. subtilis* is aerobic, and rapidly consumes oxygen, so is dormant in the first stage.)

Facultative Anaerobes or Aerobes.

B. putrificus coli, NL (decomposes albuminous substances with liberation of ammonia, whether air is present or not).

Spirillum plicatile, serpens, undula, tenue, and volutans.

Vibrio saprophilus, aureus, flavus, fluorescens, NL (in sewer mud).

B. mycoides, L } Produce NH_3 from nitrogenous
Proteus vulgaris, L } organic matter, and denitrify.

B. fluorescens putridus (similar, produces trimethylamine).

B. fluorescens liquefaciens, L, and *non-liquefaciens*, NL. See Lecture I.

Micrococcus ureæ, NL; *B. ureæ*, NL (convert urea into ammonium carbonate, the latter the most energetically). Flüggé has also described a *M. ureæ liquefaciens*.

B. mesentericus, L (several varieties in London crude sewage).

Proteus mirabilis and *Zenkeri*, L.

B. megaterium, L; *liquefaciens*, L; *magnus, spinosus*.

Streptococcus liquefaciens coli, L, and *mirabilis*, NL.

B. saprogenes, I., II., III.; *pyogenes* and *coprogenes fetidus*.

B. acidi paractici.

B. lactis aerogenes, NL (produces CO_2 and H).

B. coli communis, NL (produces much gas, mainly H).

Cladothrix dichotoma, L.

Proteus sulphureus, L (produces H_2S and mercaptan).

Bacterium sulphureum, L (liquefies gelatine and casein, produces H_2S). Found by Sims Woodhead in Exeter sewage.

Beggiatoa alba (secretes granules of sulphur, formed, according to Winogradsky, by oxidation of H_2S , and finally turned into sulphuric acid by the plant).

The following forms reduce nitrates to nitrites:—

B. vermicularis, liquidus, ramosus, aquatilis (grows luxuriously in ammonia solutions), besides *mycoides* and *Proteus vulgaris*.

The following were found by Jordan in the sewage of

St. Lawrence, Massachusetts:—*B. cloacæ*, L; *ubiquitus*, NL; *reticularis*, SL; *circulans*, L; *hyalinus*, L; all reducing nitrates. *B. superficialis*, SL, not reducing.

I must content myself with a few comments on some of the species. First, we must notice that as sewage contains little or no oxygen, nearly all these species must be at least facultatively anaerobic, and the decompositions they engender are hydrolytic. Consequently it is a mistake in the first stages to introduce air, which merely hinders the anaerobic changes. Any attempt to induce early nitrification before solution is effected, results in the production of nitrites and not nitrates.* The same non-recognition of anaerobic liquefaction leads to the difficulty with the solids blocking the filters, and to the compulsory resort to screens, sedimentation, or even to an idea of preliminary precipitation, all of which produce their equivalent of sludge. During the "resting full" period of the filters the changes are really anaerobic, during emptying and resting empty the aerobic bacteria are at work. Therefore if sole dependence is made on such filters, the process is a mixed and variable one, and the result is shown in deficient nitration.

The Vibrios in sewer mud do not liquefy gelatine, but act probably on the carbonaceous vegetable matter.

Bacillus ureæ is said to be more energetic in converting urea into ammonium carbonate than the associated *Micrococcus ureæ*.

The putrefactive fermentation of albuminous bodies is caused by a large number of species, of which the forms from London sewage, mentioned in the first lecture, are among the most frequent. The first action is parallel to ordinary digestion, that is the so-called *peptonization*, or conversion into a soluble form. The peptones are then split up, amido-acids like leucin, tyrosin, &c., are formed together with a number of substances of the aromatic group,† the amido-acids further break

* *Bacillus mycoides, liquidus, vermicularis, ramosus, cloacæ* (Jordan) *aquatilis*, and others powerfully reduce nitrates to nitrites, and account for the absence of nitrates in sewage.

† Oscar Emmerling found that *Streptococcus longus*, in liquefying fibrin, produced peptones, and then ammonia,

TABLE OF FERMENTATION OF ORGANIC ACIDS.

(For simplicity the sodium salts are taken though the lime salts are rather more fermentable.)

Salt fermented.	Cause of fermentation.	Products.
Formate ...	"Bacteria from sewage slime."	Acid sodium carbonate, NaHCO_3 , carbonic acid and hydrogen.
Acetate ...	Ditto.	Acid sodium carbonate, NaHCO_3 , carbonic acid and methane, CH_4 .
Lactate ... Undergoes four different fermentations.	"Thin bacillus" (Fitz). "Other species of bacteria; short aerobic butyric bacteria" (Fitz).	1. Propionic acid, and as bye-products, acetic and succinic acids, and alcohol. 2. Propionic and valerianic acid. 3. Butyric and propionic acid. 4. Butyric acid and hydrogen.
Malate ... Different fermentations.	Bacteria, not described; "Thin bacilli."	1. Chief product—propionic acid; bye-product—acetic acid. 2. Chief product—succinic acid; bye-product—acetic acid. 3. Butyric acid and hydrogen. 4. Lactic acid and CO_2 .
Tartrate ...	Different species of bacteria.	1. Chief product—propionic acid; bye-product—acetic acid. 2. Butyric acid. 3. Chief product—an acetate; bye-products—alcohol, butyric and succinic acids.
Citrate ...	"Small, thin bacilli."	Acetic acid in large quantities, with small quantities of alcohol and succinic acid.
Glycerate ..	Micrococci; medium-sized bacilli.	1. An acetate, with small quantities of succinic acid and alcohol. 2. Formic acid, with some methyl alcohol and acetic acid.

[Under active microbial fermentation all eventually pass into CO_2 and H or CH_4 . The CO_2 is partly free, and partly as bicarbonate of the base. Acetic acid is generally the penultimate product, therefore the common production of methane. Any amides of the acids are hydrolysed, with liberation of ammonia].

up into fatty acids and ammonia. Tyrosin yields indol, skatol, phenol, and acids related to benzoic (*Spirillum rugula* and the *B. coprogenes* group develop a strong faecal odour, probably owing to this reaction).

The breaking up of organic acids is described in the following Table, adapted from a summary of the varieties of septic fermentation, by Dr. E. Herfeldt, of Bonn.*

The volatile bases produced in the fermentations are, in the ordinary method of analysis, put down as "free ammonia," which includes not only the ammonia really existing in the free state, but also that combined with the

mono- and tri-methylamine, tyrosine, leucine, fatty acids to caproic (except valeric), succinic, and a collidine, or pyridine derivative (Berichte, 1897, xxx., p. 1863).

* "Centralblatt für Bakt.," Jan. and Feb., 1895; "Journ. Soc. Chem. Ind.," May, 1895.

organic acids as salts, as well as such compound ammonias as react with Nessler test. Many years ago Young pointed out that in the usual mode of distillation, volatile nitrogenous matter escaped which was not recorded by Nessler. I have often also indicated that the conventional procedure in the Wanklyn determination gives an "albuminoid ammonia" far short of the fixed organic nitrogenous matter, which probably accounts for such low figures as 0.34 (with 13.8 of chlorine), 0.24 (with 10.3 of chlorine, &c.), for raw sewages in the recent Manchester and other reports. The Kjeldahl process, on the other hand, gives theoretically the whole of the ammoniacal and organic nitrogen.

In a septic tank effluent I lately found, by fractionation of the hydrochlorides:—

	Parts per 100,000.
Actual ammonia	3.48
Monomethylamine, CH ₃ NH ₂ ...	0.844
Trimethylamine.....	traces

the original having given 4.6 parts of "free ammonia," and (by Kjeldahl) 1.98 parts of fixed organic nitrogen, with a chlorine content of 6.2.

Trimethylamine has a fishy smell, which is very marked in some sewages. *B. ureæ*, *B. prodigiosus*, and *B. fluorescens putridus* develop this compound during putrefaction; Amylamine and other volatile bases are also found. The chief importance of the group lies in—

1. Their volatility and odours;
2. Their removing carbon as well as nitrogen;
3. The toxic nature of some to the organisms of nitrification. Therefore—

(a) The preliminary liquefaction should be conducted in a closed chamber;

(b) The amines must be removed by a nitrous or other oxidation in the second part of the process, before reaching the nitric organisms.

The same remarks apply to:—

The Sulphur Fermentation.—Dr. Sims Woodhead found *Bacterium sulphureum* in the Exeter tank. It liquefies gelatine, casein, and other albuminoids, and produces sulphuretted hydrogen. Several observers did not however find H₂S in the tank gases. I have found that a mercaptan (methyl hydro-sulphide) and other ethereal compounds are undoubtedly present in small quantities. They are very soluble, and fairly easily oxidized.

Most of the sulphur, however, enters into combination with the iron present in the sewage, forming insoluble ferrous sulphide and giving a black colour to the suspended matter. When the black matter is acted on by acids, sulphuretted hydrogen is evolved and the substance becomes brownish, just as when strongly acid effluents from factories are discharged into ditches or on to the black mud banks of neglected rivers, a liberation of sulphuretted hydrogen occurs. In the tank, however, the ferrous sulphide is protected by the ammonia; on reaching the oxidation stage it is converted into a basic ferric sulphate, forming an ochreous coating on the materials, which considerably assists in the transfer of oxygen.

Anaerobic fermentation is called by the Germans *true putrefaction* (Faulniss), while aerobic is termed *mouldering* (Verwesung).

In the first, hydrolytic processes, in the second oxidation, prevail.

DISSOLUTION OF CELLULOSE AND FIBROUS MATTERS.

Mitscherlich in 1850 proved that cellulose was dissolved by fermentation, and Van Tieghem in 1870 describes the most active organism as *B. amylobacter*, anaerobic, and derived principally from the intestines of animals. Tappeiner fermented cotton-wool and paper-pulp in a weak nitrogenous solution, and obtained CO₂ and methane in neutral, and CO₂ and H in alkaline solution. Hoppe-Seyler in 1886 found only traces of soluble residues, and concluded that at first a soluble carbohydrate was formed by the action of water, and that this was then split up into carbonic acid and methane—

If more water took part, less CH₄ and more H would be obtained.

Van Sensus in 1890 proved the fermentation of fibre to be anaerobic, that it was occasioned by a symbiosis, or concurrent action of *B. amylobacter* with *butyricus* and other organisms, and that gaseous products of the above character finally remained. He isolated an enzyme which dissolves fibre, and also a group of these "resolving bacteria" from mud, stomach contents, and decaying vegetable matter.

In laboratory experiments with different kinds of cellulose, paper, cotton-wool, &c., in water inoculated with sewage organisms, I have observed gradual liquefaction with the production of inflammable gases.

The changes occurring in silos and in manure heaps, may be noticed as examples of the anaerobic breaking down of cellulose and fibrous matters.

The fragments of vegetable matter which pass down sinks, occasion considerable nuisance when an attempt is made to remove them by screens, or on the top of a coarse filter. They act objectionably in three ways:—

1. They set up acid fermentation and corrode iron.
2. Many of them (*e.g.* cabbage leaves) contain sulphur compounds, and evolve very offensive odours.
3. They form a pulp which blocks the strainers.

Under anaerobic conditions in a closed space

they rapidly rot away and disappear, their pectose first dissolving, and then their cellulose, while the ammonia takes up the acids.

FERMENTATION OF OTHER CARBOHYDRATES.

Starch, different sugars, and gummy substances undoubtedly enter into sewage. But their hydrolysis is so rapid, that very little trace of them is found after a short period. Those fermentations, like the alcoholic, which are occasioned by higher fungi like yeasts and moulds, do not present themselves. The changes are mostly lactic, by *B. acidi lactici*; or butyric, by *Clostridium butyricum* or *Bacillus butyricus* (both anaerobic), giving, besides the respective acids, carbonic acid, hydrogen, and water.

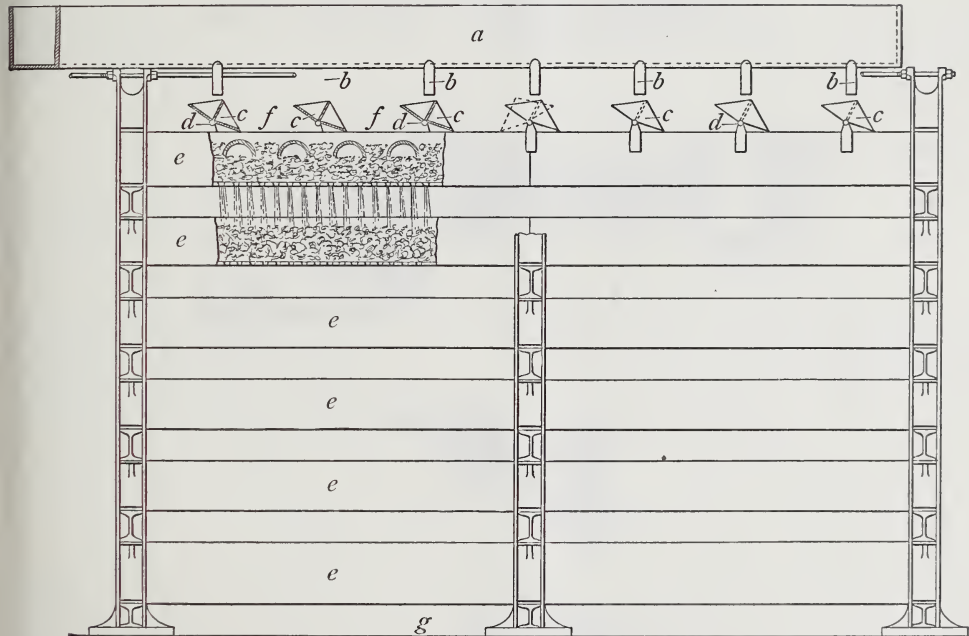

DECOMPOSITION OF FATS.

Soap-suds and greasy matters give rise to considerable trouble in the mechanical treatment of sewage. At Bradford the refuse of

weight and bulk, but also the difficulty of drying. The Corporation will eventually follow the example of Leeds, and adopt a bacteriological method.

In a bacterial tank the grease is first emulsified by the ammonia. There are several bacteria that attack fats in presence of nitrogenous substances (Sommaruga, Zeits. Hyg., xvii. 441), breaking them up into the simpler acids of the fatty series, like acetic and butyric, which in their turn are finally resolved into CO₂ and H. Many common moulds also act on fats, notably the ordinary green mould, *Penicillium glaucum*, which Hanriot found to contain an enzyme "lipase," besides emulsine and other ferments. Moulds are not commonly present in the anaerobic stage, but occur in the second, or limited aeration. Ritthausen and Baumann found that a great destruction of fat occurred by the action of moulds and bacteria in a substance containing proteids as well; the substance they experimented on was rape-cake.*

FIG. 4.

wool-scouring has been the chief difficulty for years. The sewage has been precipitated chemically by ferric sulphate, but, in addition to the large quantity of chemicals required, and the unsatisfactory character of the effluent, the very large quantity of grease in the sludge obstructs the filter presses, and renders it impossible to reduce the water below 95 or even 98 per cent., which not only increases its

There are also ferments existing in fungi and most vegetables, called by Bertrand "Oxydases," which are capable of acting on phenol and the aromatic compounds in the second stage.

We may now summarise the order of the changes as follows:—

* "Landw. Versuchs. Stat.," xlvii. 389, 1896. The subject does not seem to have been much investigated.

	Substances dealt with.	Characteristic products.
INITIAL. Transient aerobic changes by the oxygen of the water - supply, rapidly passing to:—	Urea, ammonia, and easily decomposable matters.	
FIRST STAGE. Anaerobic liquefaction and preparation by hydrolysis.	Albuminous matters. Cellulose and fibre. Fats.	Soluble nitrogenous compounds. Fatty acids. Phenol derivatives. Gases. Ammonia.
SECOND STAGE. Semi-aerobic breaking down of the intermediate dissolved bodies.	Amido - compounds. Fatty acids. Dissolved residues. Phenolic bodies.	Ammonia. Nitrates. Gases.
THIRD STAGE. Complete aeration: nitrification.	Ammonia and carbonaceous residues.	CO ₂ , H ₂ O, and nitrate.

fault being caused by mixing all the different bacteria in one or two large filters.

By using a series of smaller, separate areas, and passing the effluent continuously and progressively through them, with ample opportunity for the access of the air where it is required, the organisms gradually choose their own conditions, and allied groups gather together at different levels as coatings on the filtering material. In the later sections the nitrifying organisms are almost alone, and are therefore able to exert their full activity. In this way Mr. Moncrieff has secured a much higher nitrification than has been attained by the other processes.

This he has accomplished by spreading the "tank effluent" by tipping troughs or distributors over the uppermost of a

It has been already pointed out that in ordinary bacteria beds these reactions are

FIG. 5.—SEWAGE FILTER TANK (Scott-Moncrieff).

somewhat fortuitously reversed and confused, according to the periods of filling or rest, the

series of "nitrifying trays." (See Fig. 4.) The plant in use at Ashted for a domestic

sewage consists of nine perforated trays containing coke, supported vertically over one another at about three inches apart. Each tray has an effective area of one square foot and contains seven inches of coke, broken to one inch diameter. It requires only from eight to ten minutes for the liquid to pass through all the trays. (Fig. 5.) In the early part of last year, after the apparatus had been running continuously for three months, I collected on two occasions samples from the different trays and examined them separately.

The rate of flow was approximately measured as follows:—

	Flow observed. Per sq. foot.	Equal to gallons per acre per 24 hours.
Jan. 25, 1898.	1 litre in 15 minutes.	884,600
Feb. 8, 1898.	1,140 c.c. in 12 mins.	1,253,400
Mean ..		1,071,500

The results of analysis are given in the Table:—

PARTS PER 100,000.

	I.		II.		III.	
	0	9	0	9	0	9
Chlorine	9.0	7.5	6.3	6.4	5.5	5.5
Ammonia	11.5	0.25	4.25	0.755	4.0	0.42

(1) Oxygen consumed	94	93.3	91.6	93
(2) Oxidation of nitrogen.....	93.7	84.3	96.7	91.6

The progress of the nitration is indicated in the annexed curve (Fig. 6, p. 726), on which I may offer the following remarks:—

1. The nitrate has developed with extraordinary rapidity. This may be seen from the

following Table, which gives in the first column of each heading the original results and the chlorine; in the second, the results calculated to a uniform 10 parts of chlorine, to admit of comparison:—

TABLE OF COMPARATIVE NITRATION.—PARTS PER 100,000.

	Garfield: Manu- facturing.		Garfield: Domestic.		Dibdin: Sutton.		Cameron: Excter.		Scott-Moncrieff.					
	I.	II.	I.	II.	I.	II.	I.	II.	I.		II.		III.	
Chlorine	22.4	10	11.0	10	12.8	10	7	10	7.5	10	6.4	10	5.5	10
N as Nitrite.....					.067	.052	trace.	trace.	trace.	trace.	.06	.09	.034	.062
N as Nitrate					1.53	1.20	1.06	1.51	9.0	12.0	5.98	9.35	4.34	7.9
Oxidized N	1.67	0.75	0.95	0.86	2.20	1.25	1.06	1.51	9.0	12.0	6.04	9.44	4.37	7.05

2. The formation of nitrite is much less marked; it rapidly reaches a maximum and then declines.

3. The free ammonia has been almost completely oxidized; at the same time it was noticed that the original yellowish colour,

black suspended matter and sewage odour had disappeared.*

* It is stated that "by transposing the trays so as to upset the natural survival of organisms in the sequence, the whole process was arrested, a high-coloured and inferior effluent being the immediate result, and one or two days were required to re-establish the conditions that had been disturbed."

FIG. 6.—NITRIFICATION IN BACTERIAL TRAYS (Scott-Moncrieff System).

The following figures give the oxygen relations which I found for the first and last trays:—

PARTS PER 100,000.

	Dissolved Oxygen. cc. per litre.	Oxygen consumed by organic matter.	Available oxygen.
Jan. 28th—			
Original	—	9.54	minus 9.57
Last tray	—	0.39	plus 20.1
Feb. 8th—			
Original	0	9.05	minus 9.05
Last tray	6.34	0.44	plus 12.99

The organic matter has been very greatly reduced for so brief a time of contact. The effluent is now in a state of rapid natural purification by means of its "available oxygen," a term I some time ago proposed for effluents rich in nitrates. We know by

the researches of Warington, Munro, Adeney, Gayon and Dupetit, and others, that the oxygen of a nitrate is utilised for the burning up of organic matter, *provided the latter has been properly fermented*, as in this case it has. In my own experiments I have found that the large loss of nitrogen so often noticed was not accounted for by nitrous acid, ammonia, nor by nitrogen gas. Gayon and others have observed the production of nitrous oxide, which being soluble is not evolved and has no doubt been overlooked by many observers. Therefore, to be on the safe side, I have allowed four atoms of "useful oxygen" to every two molecules of nitric acid, according to the equation:—

Deducting from this the "oxygen consumed" figure, as representing the organic matters which are fairly easy of destruction,

I call the surplus "available oxygen," ready to be drawn on to complete the purification. In the above case the quantity is obviously far greater than would be supplied by any process of mere aeration, hence, as I have previously stated,* "such an effluent could be easily 'finished' by a fine filter without fouling the latter, or could be beneficially applied to a small area of land, or mixed with a river of moderate volume not only without pollution, but possibly with an actual benefit to the stream."

The *Noton Shelf Filter* is described in the Manchester Rivers Committee report† as "a framework supporting four lattice shelves . . . on which the filtering medium, consisting of layers one foot deep of blue furnace cinders, is laid." It was attempted by this means to nitrify a chemically-precipitated effluent, but the report states that "but little purification is effected."

At Church, Messrs. Whittaker and Bryant allow the sewage to pass through open precipitating tanks, using 1 ton of lime per 1,000,000 gallons. The sludge so formed is either pressed or allowed to putrefy in the tank itself, which becomes covered with a leathery scum as in the closed septic tank. The effluent is distributed by a sprinkler on to the surface of the nitrifying filter, together with a small jet of steam, so that the filter is kept at a temperature to ensure the fullest activity of the bacteria. The filter is 9 feet deep, and is filled with coke broken to a 2½ inch ring, and works like the tank continuously, provision being made for a steady stream of air passing through the drains at the bottom up into the centre of the bed.

Major Bennett, the borough engineer of Southampton, has introduced at the Portsmouth Sewage Works a system including an anaerobic bacterial tank, followed by an aerobic or oxidation bed, which is reported to have been dealing "with a large volume of strong sewage for the past six months with remarkable results." It claims several advantages.

I will now give a brief summary of the changes through which the organic nitrogen of offensive matter passes on its way to the final inorganic products. The formation of transition substances and of ammonia we have already noticed, also the copious production of nitrogen gas, which in part is the direct secretion of certain bacteria, but more largely

is the result of interactions, such as the following:—

Nitrosification, or the production of nitrites, and secondarily of nitrogen and its lower oxides, by *partial* oxidation, as it occurs in the second stage of bacterial purification. Wherever we find a final filter acting badly, either from deficient aeration, or other cause, the fault is at once indicated by the appearance of a high proportion of nitrites, as *nitrosification* is not nearly so delicate a process or so difficult to initiate or control as *nitrification*, or the production of nitrates, which it would naturally precede. Thus Winogradsky found widely distributed in soil an organism *nitrosomonas*, converting ammonia into nitrite, and another, *nitromonas*, later called *nitrobacter*, changing nitrite into nitrate. P. F. Richter isolated a coccus of medium size, which in 20 minutes produced a very intense nitrite reaction *in fresh urine*, and in addition reduced nitrate to nitrite, a retrograde change which I have already remarked as common to many bacteria, and characteristic of crude attempts to introduce nitrification before the sewage is properly hydrolysed and prepared. Some of my own experiments on this point are detailed in the "Journal of the Sanitary Institute," vol. xix., part iv., and have been already referred to. Nitrosification proceeds most rapidly in the presence of diffused light and of a moderate amount of air. It will be noticed that it is a characteristic stage reached in the earlier of Scott-Moncrieff's trays and in many processes the purification goes no farther, when nitrification is not subsequently active.

The amount of oxygen required for the processes of nitrification and nitrosification is shown in the following Table:—

One gramme of nitrogen requires:—

For production of	Grammes of oxygen.	Litres of oxygen.	Litres of air.	Litres of oxygen-saturated water at 7 cc. per litre.
N ₂ O ₃	2·85	2·0	10·0	286
N ₂ O.....	1·7	1·2	6·0	170
N ₂ O ₂	1·13	0·8	4·0	114
N ₂ O.....	0·57	0·4	2·0	57
N.....

So that to nitrify in an effluent, five parts of nitrogen per 100,000 (1 gramme in 20 litres) will demand about half its volume of air, or

* "Journ. San. Inst.," vol. xix., part iv.
 † March, 1898.

about fifteen volumes of fully aerated water. This explains the comparative failure and frequent collapse of filter beds in large masses, especially if the fluid is a raw sewage or a merely screened or precipitated effluent without preliminary hydrolytic change, as with every 100,000 gallons of sewage, about 50,000 gallons of air must be continuously supplied.

Contrivances like fountains, cascades, and weirs can only raise the dissolved oxygen to the saturation point of about 7 cc. per litre, or

The change is therefore accompanied by a great loss of nitrogen, and a disappearance of odour. It takes place in the resting-full period of filters, and causes disappearance of more nitrogen than carbon.

Nitrification proper, or the production of nitrates, is due to one or more organisms capable of growing in culture solutions which are practically free from organic carbon. But, under natural circumstances, they act in succession to nitrous organisms, and in the presence of organic material, which they do not, however, by themselves decompose.* Some of the difficulties of the subject have been cleared up by Adeney's researches, who, by cultivation in known solutions, has eliminated disturbing factors. His conclusions are:—

1. In inorganic solutions, containing ammonia, nitrous organisms thrive, but nitric organisms gradually lose their vitality.
2. Nitrous organisms cannot oxidise nitrites to nitrates in inorganic solutions.
3. Nitric organisms thrive in inorganic solutions containing nitrites.
4. The presence of peaty or humous matter appears to preserve the vitality of nitric organisms during the fermentation of ammonia, and establishes conditions whereby it is possible for the nitric organisms to thrive simultaneously in the same solution as the nitrous organisms.

In an effluent which is properly prepared and well-aerated, nitrification can often be encouraged by seeding with a small quantity of a fertile garden soil.

The conditions of nitrification have been often stated but may be recapitulated.

700 gallons per 100,000; although useful, if simple, like the aerator at Exeter, they are quite inadequate.

The nitrosification change is, however, very valuable in the second stage, as getting rid of the transition products, ammonia, amido-acids, and the amines by double decomposition into water, or hydroxy-compounds (which are afterwards broken up by fermentation) and nitrogen gas. As simple instances we have:—

(a) In every case the formation of ammonia by some other organism precedes the appearance of nitrous or nitric acid.

(b) Some fixed base must be present to combine with the acid formed. Therefore in a sewage farm, if the soil is devoid of lime it must be added. Ordinary sewage contains fixed alkali derived from washing soda, and any acid discharges are generally neutralised by this and by the free ammonia. E. Chuard found that nitrification may occur in an acid medium, but that it was very slow.* Hence in strong manufacturing effluents a treatment with lime may be necessary before nitrification will take place.

(c) The solution must not be too strong, nor too alkaline. Warrington found that a 12 per cent. solution of urine was the highest strength nitrifiable, and that the maximum alkalinity corresponded to 36.8 parts per 100,000 of N as ammonia carbonate, equal to 44.6 parts of ammonia. These are strengths which only under special circumstances would be approached in sewage. In the runnings from urinals, stables, &c., dilution would be necessary.

(d) Darkness and free admission of air.†

* *Comptes Rendus*, cxiv., 181.

† At this point I may incidentally draw attention to a curious fact. In nearly all published analyses, the chloride in the effluent is slightly lower than that in the corresponding sewage. Muntz pointed out that in nitrification, bromides and iodides were oxidised to bromates and iodates. Chili saltpetre (nitrate of soda), which has been produced by natural nitrification, almost invariably contains chlorates and perchlorates, sometimes amounting to 7 per cent. of the former and 5 per cent. of the latter; they are supposed to have been formed by bacteria. Dr. Tidy, some 20 years ago, found a loss of chloride in waters running over aerating wooden shelves, and suggested that it might be due to the formation of chlorates. (*Journ. Soc. Chem. Ind.*, Dec. 1898, p. 1160).

In natural soil, Warington proved that nitrification rapidly diminishes after 3 feet, and that there is no nitrification below 6 feet. Thudichum states that the maximum limit of depth for the best results from filter beds is 3 feet to 3½ feet. "Beds have worked well at 4 feet to 5 feet, but the alteration of a bed from 3½ feet to 5 feet was accompanied by some reduction in the quality of the effluent." And yet it is proposed to double the depth of the Barking filter from 3 feet to 6 feet.

Denitrification.—Two organisms were isolated from sewage by Gayon and Dupetit in 1886*, which, in the presence of organic matter, decomposed nitrates evolving nitrogen and nitrous oxide. They proved that the whole of the N was evolved, and that all the O of the nitrate united with the carbon of the organic matter to form CO₂, part of which united with the base to form acid carbonate.

Ampolla and Ulpiani, in 1898,† describe two bacteria which act similarly, giving, as they state, complete decomposition of the organic matter and nitrate to CO₂ and N, without intermediate production of nitrite. Sugars, fatty and amido-acids were equally broken up, thus:—

Thus 5 of oxygen are utilised, instead of 4, as in the production of N₂O. This is an illustration of what I have said about "available oxygen," and the reason why an effluent that has been properly fermented and heavily nitrated is capable of rapid self-purification, and also of improving the condition of a river into which it may be discharged.

Adeney, in fact, introduced a process in which he added artificial nitrate of soda at the third stage to accomplish by this denitrification the final removal of any organic matter present, but as we have seen that the effluent is naturally nitrified by properly constructed filters, the expense of an artificial supply can be avoided.

This brings us to the question of *what is a satisfactory effluent?* In a paper at the last meeting of the British Association at Bristol,‡ I discussed the various standards that had been adopted at different times. The popular permanganate test for "oxygen consumed" is open to the objections that:—

1. So many modifications have been introduced in procedure that the figures obtained by different observers are seldom comparable, as instanced in the recent discussion at Manchester.
2. It mainly measures the carbonaceous matters which are not the most noxious.
3. It is incomplete even in measuring these, since many of them are very resistant to permanganate if used, as ordinarily, at low temperatures. For this reason I prefer to work at a higher temperature, namely, that of a water-bath at 80° centigrade, giving 2½ hours.
4. The influence of nitrites, which are abundant, as we have seen, in certain stages of purification, of high chlorides, and of iron and manganese salts derived from a chemical treatment, has not been satisfactorily eliminated, even by the adoption of time-limits, such as 3 minutes 15 minutes, 2½ or 4 hours.

Still more delusive is the *albuminoid ammonia*. Its absolute amount has little or no meaning, the main question being the *quality* of the matters yielding it, and the nature of the accompanying substances.

I have noticed that many dilute putrid sewages of offensive character have shown less albuminoid ammonia than the condemnatory limits of existing standards, and conversely, many effluents in a healthy state of self-cleansing have exceeded the arbitrary margin that is sometimes laid down.

Incubation tests, as adopted in the Manchester report, maintain the effluent for five days at 80° Fahr., and determine the oxygen absorbed in three minutes before and afterwards, also noticing any change of odour. The result is still arbitrary, as an effluent is not intended to be stored by itself, but when finished, to be discharged at once into water, which is moving and aerated.

In the above paper I also reviewed the standards of several local authorities, and pointed out that in these conventional limits no account was taken of the respective volumes of the effluent and the stream into which it discharged, nor of the local conditions and subsequent use of the stream for drinking purposes. Standards founded on the number of bacteria are also of little value, although only a low number of organisms of the *Coli* group should be permissible, with an absence of dangerous pathogenic forms.

In the first lecture I explained a formula for estimating the volume of a given effluent that

might be permitted to pass into any particular stream, founded on the ratios of oxidation.

I have on many previous occasions pointed out that a "calculation of the *ratio* between the different forms of nitrogen furnishes a clearer idea of the history and character of an effluent than a mere consideration of its amounts." Besides the formation of free ammonia in the transition or preparatory stage, and the conversion into nitrite and nitrate at a later period, we have seen that there is a considerable dispersion of organic nitrogen in the form of innocuous gases. I believe I am the first to propose an expression for the measurement of this important phase of the purification, obtaining the data from the

RATIO OF THE CHLORINE TO THE TOTAL NITROGEN.

In perfectly fresh excreta, taking the solids and liquids together, the total fixed nitrogen somewhat exceeds the chlorine. This proportion will remain practically unchanged when diluted with water containing only the ordinary small amount of chlorine, as long as the nitrogen remains in fixed forms. Therefore, the ratio is applicable to fresh sewages generally, independent of dilution, but will be immediately altered by the production of gas.

Let Cl and N be the parts of chlorine and nitrogen respectively, the "residual ratio" will be :—

$$R = \frac{N \times 100}{Cl}$$

or in case of great dilution, with a high chlorine W, in the water supply :—

$$R = \frac{N \times 100}{Cl - W}$$

The simpler formula is usually sufficient. In the original excreta the number R will be somewhat over 100; in fairly fresh sewages it will be about 100; in bacterial effluents, on the other hand, the fall of R will indicate the gaseous dispersal of nitrogen. With chemical or mechanical treatment R will fall owing to the abstraction of matter as sludge. Where heavy nitrification has been the main feature, there may be little or no fall, this afterwards occurring rapidly in the process of *denitrification*, when the effluent is admixed with other water.

Notices.**PRACTICAL EXAMINATIONS IN MUSIC.**

The practical examinations in Music were not concluded this year until the 12th July, too late for the results to be included in the Report of the Council. They lasted for 13 days.

The system of examination was the same as that for last year. For instrumental music certain standards are given, and candidates are asked to select for themselves which of these standards they choose to be examined in. The standards range from easy to very difficult music, and for each standard a list of music is given for study, and for the pianoforte examination a selection from this list is sent to the candidates six weeks previous to the examination. For other instruments the pieces can be at once chosen from the general list. Candidates are then expected to play or sing the pieces which they have prepared, and in the third and fourth standards to play a piece, or a portion of a piece at sight, in addition.

In all 529 candidates were examined, a decrease of 9 as compared with last year; 3 of these took up two subjects, so that there were 532 examinations. Of these there were 508 passes and 24 failures.

The following were the subjects taken up:—Piano, singing, violin, viola, violoncello, mandolin, and organ. 419 entered for the piano, 399 of whom passed and 1 obtained a medal; 66 entered for the violin, of whom 56 passed and 5 obtained medals; 2 entered for the violoncello and passed; 1 passed for the mandolin; 5 entered and passed for the organ; 38 entered for singing, and all passed, 5 obtaining medals; 1 entered for the viola and passed.

Mr. John Farmer, of Balliol College, Oxford, and Director of the Harrow Music School, acted as Examiner, Mr. Ernest Walker, M.A., Mus. Doc. Oxon., and Mr. Burnham Horner, as Assistant-Examiners.

Miscellaneous.*THE HILL FORESTS OF WESTERN INDIA.**

It would be impossible, within the time prescribed for this paper, to attempt even a cursory description of the State forests in all parts of British India, or to render adequate justice to the work of the Indian Forest Department. I propose, therefore, to direct your special attention this evening to a limited area only in Western India, where the operations of the Department may be regarded as more or less typical of its general work. But, first, I should like to refer to some considerations which determine the applicability of a system of scientific forestry to any particular country, and to trace in outline the history of the measures adopted by the Government of India for the conservancy of forests in districts where scientific forestry is likely to secure permanent advantages to the people. I will also put before you some statistical information which may help to give an idea of the progress so far made.

It is obvious that in some parts of the globe it would be of no advantage at all to increase the existing forest areas, or to try to grow forests where no forests have ever yet grown. The increase of vegetation in some countries might indeed be a positive evil to the inhabitants. It might reduce the temperature of the air and of the soil where it is already cold enough for human comfort, as in places nearer to the Poles than we are; or it might increase the rainfall in sea-bound regions which are damp enough already; or it might unduly reduce the area of cultivation in thickly populated countries where people are mainly dependent on their own lands and crops for sustenance. Or, again, the afforestation of new lands might not be required for the production of fuel, or of materials for building ships or houses, or for railways or machinery, in countries already well supplied with peat or coal or iron, or other substitutes for firewood and timber. And, lastly, employment on forest industries might not be a matter of public concern in places where other industries sufficiently occupy the time and intelligence of the people.

But India is not a country where such considerations prevail. Dr. Schlich, Professor of Forestry at the Royal Indian Engineering College at Cooper's Hill, in his admirable "Manual of Forestry," prepared ten years ago at the instance of the Secretary of State for India, primarily for the use of the Forest Branch of the College, tells us that, as a rule, the nearer we are to the equator, the more important becomes the forest question. In a hot country, with distinct wet and dry seasons, forests may be necessary for the mitigation of extreme heat and dryness during a part of the year, and for the regulation of the flow

* A lecture, by H. M. Birdwood, C.S.I., LL.D., M.A. (late Member of Council, Bombay, and Vice President of the Bombay Natural History Society), given at the "Greater Britain" Exhibition, on the 4th July, 1899.

of water in springs and rivers. The climate of a continental country may be improved by forests, and a mountainous region is, according to the same authority, more in need of forests than a low-lying country, because forests tend to prevent landslips and avalanches, and the washing away of soil from hill sides, and the consequent silting-up of rivers; also they check the force and suddenness of destructive floods. In hilly countries, as elsewhere, forests provide protection from storms for men and beasts and birds.

Now India is distinctly a hot country, though in the northern provinces extreme cold is also felt in winter. It possesses, over a great part of its area, well-defined wet and dry seasons, dependent on constant causes recurring from year to year with the progress of the sun above and below the equator. Except on the sea coast, it possesses a continental climate, or, rather, several types of continental climate; and though there are vast plains within its boundaries, it is intersected by many mountain ranges, and even its plains and table-lands are broken by isolated hills and hilly tracts. It is clearly a land in which it would be suicidal to neglect the great question of forest conservancy. And yet it is only during the past fifty years that the vital importance of the question has been realised in British India. Early in the present century a timber agency was indeed established on the west coast; and in 1839-40, the Government of Bombay prohibited the cutting of teak trees on State lands. In 1843, Mr. Conolly, the collector of Malabar, made extensive plantations of teak at Nilambur, but no systematic plan for the maintenance of wooded lands for the supply of timber and other produce, or on account of their beneficial influence on the climate and public health, or for the protection of the soil or human dwellings from the violence of storms, and, in short, no plan for the regular administration of forests on well-ascertained principles was adopted till several years afterwards, when the danger of continued neglect could no longer be concealed.

There can be no question that, at one time, a very large part of the earth's surface was covered by forest growth, the destruction of which has affected the drainage of the soil and even its external configuration. Local climates have probably also been affected, though such causes as the drainage of marshes and the operations of husbandry are also believed to have contributed to such a result by altering the hygrometric, thermometric, electric, and chemical conditions of the atmosphere. As observed by Mr. George Marsh, in his suggestive treatise on "The Earth as Modified by Human Action," "it is but recently that, even in the most populous parts of Europe, public attention has been half-awakened to the necessity of restoring the disturbed harmonies of nature, whose well-balanced influences are so propitious to all her organic offspring, and of repaying to our great mother the debt which the prodigality and the thriftlessness of former generations have imposed on

their successors." As regards India, the evidence disclosed by ancient writings seem to show that it was covered to a great extent, at one time, by forests. Dr. Schlich thinks that the country was more fertile then than it is now, and the climate less fierce; and he refers to the testimony of the great Chinese traveller, Fa-Hian, who described the climate as neither cold nor hot. Subsequently, as settlers began to occupy fertile valleys, forest lands along the banks of the great rivers were more and more cleared for cultivation. Such a proceeding was inevitable, and it would be idle to regard it as an interference with the order of nature, for, so long as it merely met the actual needs of human beings, it was really in aid of those harmonious methods by which, during countless centuries, the earth has been fitted for human habitation. But man must now take his part in the further development of those methods, if the great end in view is not to be defeated, and if successive generations of men are to pass on the inheritance they have enjoyed, not unimpaired merely, but improved to the best of their power. Such a conception of human duty was, however, unknown to the nomadic tribes, who, according to Dr. Schlich, for a period of more than 750 years, carried on the work of destruction, not only in fertile valleys, but alike on hills and plains, as they moved from one pasture ground to another. In his preface to the catalogue of the Indian exhibit at the International Forestry Exhibition held at Edinburgh in 1884, Sir George Birdwood says that it was the destruction of vegetation over wide extended areas at the time of the troubles following the decline of the Moghal Empire which thenceforward rendered India liable to desolating droughts and the consequent calamity of often recurring famines. "In the course of time," says Lieut. Col. F. Bailey, formerly Superintendent of Forest Surveys and Acting Inspector-General of Forests in India, and now Lecturer on Forestry in the University of Edinburgh, "not only were large areas entirely cleared for cultivation and for village sites, but more numerous flocks and herds, driven for their daily food into the jungles, led to the impoverishment of a forest belt of ever-increasing width around the occupied tracts." During the hot season, dry grass, fallen leaves, and dead wood were set on fire in order to clear the ground for a fresh growth of grass for cattle, and also to simplify the pursuit of game. But such practices, with those of overcutting and digging up roots for fuel, soon destroyed the protective forest growth, and heavy rains then washed away the soil. Cows and bullocks could no longer be kept in good condition on the scanty herbage that remained, and the villagers began to keep large flocks of goats, "against whose hoofs and teeth," as Lieut.-Col. Bailey remarks, "it is well known that forest growth cannot contend." The village goats are still formidable foes to young plantations, though, in the estimation of Sir Clements Markham, "the uneducated man," in his dealings with forests, goes far beyond the goat in his capacity for mischief.

It would be satisfactory to be able to say that a wiser policy prevailed after the establishment of British rule. But, unhappily, that was not the case for many years. "With the advent of British rule," says Dr. Schlich, "the destruction of the forests became more fierce than ever." The extension of cultivation "at the cost of the still existing forests" was carried out for many years "without any inquiry as to the ultimate effects." With the introduction of railways a further impetus was given to cultivation in the immediate neighbourhood of railway lines and stations; and, with the steady increase of prosperity under a settled Government, the demands for timber and firewood increased enormously throughout the country; and thus the reduction of forest areas went on with all its attendant evils. In illustration of the evils which attend and follow the reckless destruction of forests, especially in hilly regions, Lieut.-Col. Bailey cites the case of the outer Himalayan spurs in the Hoshiarpur district of the Panjab, where, as the rock is very friable, serious damage has been caused by denudation. Within the memory of living men, these hills were well covered with forests or tall grass, and the hill streams ran evenly in well-defined channels. But the natural vegetation has now almost entirely disappeared, the hills are crumbling away, and loose rocks and stones are carried down by the streams, which are often several hundreds of yards wide, and deposited in the plains below. "Thus, not only have the hills themselves become a dismal and profitless waste, but the fertility of extensive areas of cultivation near their base has been completely destroyed by the stony deposits laid on them."* Similar causes have produced similar effects in other parts of India. I can myself speak of some of the districts to the south of Bombay, between that great western ramp of the tableland of the Dekhan—the range of the Sahyádrí Ghâts—and the sea; a narrow, hilly tract of land, known as the Konkan, and traversed by numerous streams having their sources in the Ghâts. Within living memory many of the hills were well wooded, and some of the streams were navigable by larger craft than any that can now make their way to the towns and villages on their banks. Here, as elsewhere, disastrous results have followed the destruction of forests. The mould which, in the shelter of the jungle, had been formed during centuries on the rocky surface of the hills—to which it had been bound by a living network of fibrous roots—became exposed to the full force of the monsoon rains. The average annual rainfall, near the sea, amounts to about 80 inches, and gradually increases till, about 30 miles inland, at the ridge of the Ghâts, which forms the watershed of the rivers flowing eastwards and westwards, it reaches an average of about 280 inches in the year. A wide view of these Konkan hills is obtained from the hill station of Mahabeshwar, on the crest of the Western Ghâts, at a distance of about 80 miles in a south-easterly direc-

tion from Bombay, and I well remember a conversation I once had there with Mr. Allen Shuttleworth, who for many years held, with distinction, the office of Conservator of Forests, from which he has lately retired. Like other officers of his Department, he was full of zeal for his work, and spoke in indignant terms of the folly and the mischief of which the evidence lay before us in sun-baked summits and barren sides of hills which, not very long ago, were clothed with all the glory of tropical vegetation. It is not easy to appreciate all the mischief that has been done. The silting up of waterways alone means commercial loss to the whole country side. It also means agricultural and pastoral loss to those from whose possession the soil itself has slid away, past recovery. In many places in the Southern Konkan district good soil is only now found in depressions on the surface of the laterite rock of the district, from which it could not be washed away. The whole community must suffer also from the increased cost of fuel and timber.

It is easy, in the light of our present knowledge, to condemn the heedless policy of the past, but I doubt whether it is for us in England to cast the stone. Though England has done a great deal towards the education of scientific foresters, we have the testimony of Sir Joseph Fayrer that it makes one almost ashamed, when travelling almost anywhere on the Continent, to see how comparatively well the woods are cared for there, and how they are neglected here. "There were miles and miles," he is reported to have said, "especially in the north, where there were only little bits of cover here and there, thoroughly neglected and of no use at all, except, perhaps, as shelter. There was no knowledge and no care, trees were planted and left to grow, or be blown down by storms, and there was practically no re-planting."* Such a remark would not, I think, be applicable to any rural district of British India at the present day.

It was not, however, until the increasing difficulty of meeting demands for public works indicated unmistakably the existence of a timber famine, that the Indian Government realised the gravity of the situation. According to Dr. Schlich, the remedial measures at first adopted were only "half-hearted." But when their insufficiency was made clear a special State Department was organised. The efforts which preceded that event were not, however, unimportant or without effect on subsequent arrangements. Indian botanists had long urged on the Government the necessity for establishing a regular system of forest administration and preventing, in the public interests, the continued destruction of public property of enormous value; and the dawning of a new era was marked by the appointment, in 1847, of the late Dr. Gibson, to be Conservator of Forests in the Bombay Presidency. The most important duty assigned to him was the maintenance of the supply of teak for ship-building to the Government dockyard in Bombay, and his work as a pioneer of practical forestry was of

* Lieut.-Col. Bailey on "Forestry in India." *The Scottish Geographical Magazine* for 1897, p. 576.

* *Journal of the Society of Arts*, vol. xliii., p. 107.

special value in Western India, where he was familiarly known as "Daddy Gibson" and is still remembered, with affection, by the people of the Junar district above the Ghâts, where he had his head-quarters. As early as in 1847 the well-known name of the late Dr. Hugh Cleghorn, who has been described as the father of scientific forestry in India, appears in a report on the proposed conservation of forests in Mysore. In the following year our Chairman, General Michael, who was then Lieut. Michael of the 39th Madras Infantry, and has been described by Sir Joseph Fayrer as the father and pioneer of practical forestry in India, was entrusted by the Government of Madras with the organisation of an establishment for working and conserving the public forests near Coimbatore and Cochin. He opened out forest roads and timber slips down the mountain passes and cleared belts of brushwood to preserve young saplings from fire. Indeed, in the Anamalai teak forests, he made "the first recorded attempt to protect Indian forests from injury by annual jungle fires."* Also by giving employment to the hill tribes he secured their co-operation in his plans. In the discussion on a paper on Forestry read by General Michael before the Society of Arts in December, 1894, Sir George Birdwood referred to certain attempts in the same direction made about the same time in Bombay and Tenasserim, which however met with no success, partly because they were on too ambitious a scale, and partly because the ancient forest rights of the people were not sufficiently considered. "General Michael," he said, "set to work in a more modest manner and in a far more conciliatory spirit and after six years his exertions, which completely broke down his health, were crowned with such success that the Court of Directors in London at once took up the subject warmly and rapidly extended the Madras system of conservancy all over India and as much of Farther India as was under their rule." I trust our Chairman will forgive my quoting these words in his presence. I have felt myself bound to quote them in justice to my subject and in deference to you who look to me for a full statement of facts. In the same discussion General Michael was referred to by Sir Joseph Fayrer as "certainly one of the great benefactors of India."

No account of Indian forestry, however summary, would be satisfactory without a reference to his services. It was the enthusiasm born of a love of woodland life, innate in such men as Dr. Gibson and himself, and the out-of-door experience acquired by them and others, whether as foresters or sportsmen, and interested as such in every phase of forest craft, which really prepared a firm foundation for the stately fabric of scientific forestry raised by their successors.

It was from the city of Edinburgh, with its grand botanic gardens, and its long array of men of science, prominent among them, in our own time, in connection with much that relates to the science of forestry,

being Professors James Hutton Balfour and Bayley Balfour, that the effective impulse was received which determined the further development of the Forest Department. In 1850, the British Association met in Edinburgh and appointed a Committee to consider the probable effects, from an economic and physical point of view, of the destruction of tropical forests. In the following year the Committee presented at Ipswich a report which embodied the general conclusions and recommendations arrived at, and demonstrated clearly the importance of preserving every condition tending to maintain an equilibrium of temperature and humidity, of preventing the disappearance of indigenous forests from the wasteful habits of the people, and of taking the requisite steps for extending forest produce. The weighty evidence adduced by the Committee and the broad views enunciated by them so impressed the Court of Directors that, within a few years, regular establishments were sanctioned for the Madras Presidency and British Burmah. In 1856, Dr. Cleghorn took up General Michael's work, and was appointed Conservator of Forests in Madras, with Captain Douglas Hamilton and Lieutenant Beddome as his assistants, who in turn succeeded him in the office of Conservator after his transfer, first to Bengal, where he gave most efficient aid to Dr. Brandis in carrying out forest conservancy, and afterwards to the Panjab. According to Colonel Bailey, Dr. Cleghorn checked the destructive practice of temporary cultivation in the Madras forests, notwithstanding the opposition he encountered. He was ultimately successful "because his well-known desire to promote native interests inspired the rulers of the country with confidence in his proposals." In 1856 also, Dr. Brandis (now Sir Dietrich Brandis, K.C.I.E.) was appointed superintendent of Forests in Pegu, and six years afterwards was placed on special duty with the Government of India. He was the first Inspector-General of Forests to the Government of India, and held the office till 1881, when he went on special duty to Madras. His book on the Forest Flora of North-Western and Central India is a standard work, greatly prized by Indian botanists and foresters. "From the time of his appointment," says Sir George Birdwood, in his preface to the catalogue of the Indian exhibit at the International Forestry Exhibition, already referred to, "the successful future of forest conservancy in India was assured. . . . He, in fact, by his great capacity, his wise recommendations, and his personal example of enthusiastic devotion to duty, has made the Forest Department of India what it now is." We owe to Dr. Brandis, among other important services, the suggestions for the various Indian Forest Acts, which, while strengthening the hands of the Government, have secured to the people the maintenance of all the ancient rights and privileges inherited by them from time immemorial; and also the inauguration, in 1866, of arrangements for the annual supply of trained officers to discharge the duties of assistant conservators of forests in India. At first, these officers were

* Lt.-Col. Bayley on "Forestry in India," *The Scottish Geographical Magazine*, for 1897, p. 576.

educated in France and Germany. In 1876 the student candidates were withdrawn from Germany and stationed at Nancy, under an English officer. In 1885 Dr. Schlich (who had succeeded Dr. Brandis on his retirement) organised the Forest Branch of the Royal Indian Engineering College on its present footing at Cooper's Hill.

While candidates with special qualifications for the higher grades of the Forest Department are, with some exceptions, now recruited from England, it is obvious that there must be much important work connected with the executive charge of the forest ranges, into which the larger divisions are split up, the disposal of which the Government of India must entrust to officers trained in India itself. The class of Forest Rangers has been described as the "backbone" of the Department. Candidates for this branch of the forest service are trained at the Imperial Forest School at Dehra Dun, which is attended by students from all parts of India. A certain number of forest appointments has also been guaranteed annually by the Government to the students of the College of Science at Poona. A protective service of Forest Guards is also employed for the purpose of patrolling forests and ensuring compliance with forest regulations. The members of this branch of the service receive no professional training.

The Indian Forest Service, thus organised, has been able not only to meet the demands of India, but to help other countries also. Ceylon, New South Wales, New Zealand, the Cape, Mauritius, Jamaica, and Cyprus, as General Michael, in his paper on Forestry, tells us with just pride, have all borrowed officers from India to put them in the way of organising conservancy and working their forests economically. The head of the Forest Department at the Cape and the Conservator in Ceylon are both Indian forest officers. The United States of America have also recognised the value of the work done in India by lately deputing an expert to study the methods there in force.

The forests to which the Indian Forest Act of 1878 is applicable include "reserved forests," which are State property, or over which the State has certain rights; "village forests," assigned or yet to be assigned by the Government to village communities from reserved forest areas; "protected forests," which, as regards the proprietary rights of the State, are on the same footing as reserved forests, but are subject to less stringent supervision—only certain kinds of timber being protected and all private rights of cultivation, pasturage and wood-cutting within the protected area being respected; and, lastly, "private forests," which are controlled only to such an extent as is necessary for their regulation or protection for certain special purposes. The Forest Department has also the control of State plantations of timber trees.

The area of British India, exclusive of the Native States, is about 960,000 square miles; and of this area more than 79,000 square miles had been con-

stituted as reserved forests before the end of the year 1896-97. About 9,000 square miles were "protected," and nearly 26,000 square miles were tabulated as "unclassified." The total area under the control of the Forest Department amounted, therefore, to about 114,000 square miles, inclusive of about 1,100 square miles leased from Native States. Of this area, which is only about 7,000 square miles less than that of the British Isles, about 32,000 square miles are closed to all animals, and about 41,000 to browsing animals only. I am unable to give any exact statistics as to village forests and private forests, but it has been estimated that the area of private forests and forests belonging to corporations and endowments is about equal to that of the State forests, and that the total area of forests of all kinds is about 25 per cent. of the total area of British India. In Great Britain and Ireland the corresponding per-centage is only 4. The corresponding figures for Europe and the United States of North America are 31 and 17 respectively. In European countries the highest per-centage is reached in Servia, where it is 48; in Russia and Sweden it is 42; in Austria, 33; in Hungary, 29; in Germany, 26; in Norway, 25; and in Turkey (including Bulgaria, Bosnia, and Herzegovina), and also in Roumania, and Italy, 22. In Switzerland, Spain, France, Greece, and Belgium, it lies between 19 and 15. In Holland it falls to 7, in Denmark to 6, and in Portugal to 5. Great Britain and Ireland thus show the lowest per-centage of all the countries named, while India comes seventh in the list, being bracketed with Norway.*

The area of plantations directly under the Government of India and the Government of Madras is said to extend to 41,000 acres. In the Bombay Presidency the afforestation of waste tracts has been pushed with vigour, but I am unable to give the acreage. One of the plans adopted by Mr. Shuttleworth, in the central division,—as he has personally explained to me on the site of some of his operations on the hills near Poona,—has been to sow the seeds of all kinds of forest trees and shrubs broadcast on the ground. The results of the annual sowings have been satisfactory except in seasons when the rainfall has failed at the close of the monsoon. Hill tops and stony valleys which, 20 years ago, were bare and unsightly, are now well covered with innumerable saplings and most refreshing verdure. Similar results have been obtained on many of the rocky hills of the Dekhan.

The review of Forest Administration in British India for the year 1896-97, by Mr. B. Ribbentrop, C.I.E., Inspector-General of Forests, shows that, in that year, which is the latest for which I have any report, the State forests yielded more than 47,000,000 cubic feet of timber, nearly 100,000,000 cubic feet of firewood, nearly 135,000,000 bamboos, and minor produce to the value of nearly 3,250,000 rupees.

In the same year the exports from British India to foreign ports included 64,221 tons of teak wood,

* Schlich's "Manual of Forestry," vol. i., p. 54.

valued at nearly 7,000,000 rupees; sandalwood, ebony, and other ornamental woods, worth nearly 600,000 rupees; and such minor produce as caoutchouc, lac, lac-dye, cutch and gambier, myrobalams and cardamoms, worth about 21,000,000 rupees.

The total value of exports, which reached nearly 28,500,000 rupees, was less by 6,500,000 rupees than the total value for the preceding year, the decrease being due almost entirely to the disastrous effects of plague and famine.

The gross revenue realised from forests during the year 1896-97 amounted to nearly 18,000,000 rupees, the surplus over expenditure having been 8,000,000 rupees. More than 17 per cent. of the gross revenue represented the estimated value of forest produce given away free or at reduced rates to right-holders and free grantees. When it is remembered that, before 1848, the forest revenue, which was treated as a branch of the land revenue, was very trifling, the progress made in the past 50 years is very remarkable. But, as most truly observed by Sir George Birdwood, in the paper from which I have already quoted, "the annual revenue which forest conservancy has as yet provided is utterly insignificant when compared with the capital value of the Indian forests redeemed by the British Government from certain destruction."

It would indeed be strange if such results had been achieved without opposition. I have already spoken of the conciliatory course adopted with obvious advantage by some forest administrators towards those whose privileges were affected by the stringency of the new regulations. Villagers on the outskirts of forests had for generations cut firewood and grazed cattle therein and cleared patches for cultivation without hindrance. The policy aimed at has been to stop the exercise of privileges incompatible with the continued existence of forests and to allow others as far as possible. But the necessity for a restrictive policy at all, while necessarily distasteful to rightholders, was not readily accepted as right by the local officers of the Indian Civil Administration, with whom it has always been an honourable tradition to seek above all things the happiness and contentment of the people. They were unable to look with favour on measures which seemed to indicate an excess of zeal on behalf of the State and to be in needless derogation of privileges long enjoyed without much apparent injury to public interests. It has been suggested that, though the accumulated mischief, caused by neglect of conservancy during a long series of years, is incalculable, yet it is not possible always to detect any appreciable damage done in a particular locality during a short period. Such a consideration alone might partly explain the tendency to reject as idle the fears of experts and to resent measures savouring of harshness and productive of discontent. In course of time, as forest management became stiffened and matured, friction was undoubtedly developed and gave rise to difficulties. One of the purposes of the Forest Act of 1890 was to give effect to recommendations for reconciling legitimate local demands with

State requirements which were made by the Bombay Government on a consideration of the Report of a Forest Commission appointed with the object, as publicly declared by Lord Reay, of substituting "co-operation for antagonism, confidence for distrust, contentment for disturbance." The Bombay Government has recognised the principle that the central authority in forest matters, so far as the interests of the people are concerned, shall be the Commissioner of the Civil Administrative Division, and that the Forest Department cannot be regarded as the rival of the Revenue Department in respect of such matters. You will not expect me to give any details in illustration of the practical working of this principle. The result has been to bring the Forest Administration into closer union with the general Civil Administration of the country, to remove many causes of complaint, and to place forest work altogether on a sounder footing.

The particular area of which I spoke at the beginning of this paper is within easy reach of the City of Bombay. It includes hilly tracts of country on either side of the range of Western Ghâts, in the Dekhan and Konkan respectively, between the latitudes, roughly speaking, of Bombay and Satara. As compared with other forest areas elsewhere in the Presidency, it is by no means remarkable, so far as the production of valuable timber is concerned; but it is of interest as illustrating generally the methods of the Forest Department; and it is of special interest to the inhabitants of Bombay and many other cities in the plains, as it includes the two popular hill stations of Matheran and Mahableshwar, which owe much of their value as health resorts to their pleasant woods and abounding undergrowth of beautiful shrubs and flowering plants and ferns, which everywhere keep the ground cool, and the air sweet and fresh. Both in climate and splendour of wild woodland scenery they furnish an instructive contrast with those hills of the same tract which have suffered from the destruction of forests in the manner I have already described. An account of the forest flora of Matheran and Mahableshwar will apply generally to similarly preserved portions of the Western Ghâts and the adjoining regions; and, in the time that is left us, it will be sufficient perhaps if I deal only with the flora of these two hills. Their vegetation is not indeed identical. Dr. Theodore Cooke, formerly principal of the College of Science at Poona and an accomplished botanist, who always found his "pleasure in the pathless woods" whenever he could escape from college lectures, has estimated that, exclusive of grasses, about 140 flowering plants are found at Matheran which have not been seen at Mahableshwar, and 130 at Mahableshwar which have not been seen at Matheran. Some of the conditions which regulate the distribution of plants are not indeed equally operative at both places. Mahableshwar is about 70 miles nearer the equator than Matheran. The latter is an isolated hill rising from the plain of the Konkan, midway between the Ghâts

and the sea; whereas Mahableshwar is further from the sea, and is, to all intents, a part of the range of Ghâts. The highest point of Matheran is about 2,500 feet above the sea-level; whereas the Mahableshwar plateau is at a general elevation of 4,500 feet above the sea and rises at one point to 4,700 feet. These differing conditions are not without their effect. Some plants are found at Mahableshwar which will not thrive on the lower mountain top. Some Matheran plants, on the other hand, find the higher levels of Mahableshwar beyond their range. I will give a few instances. The most casual observer is struck by the wonderful undergrowth of brake-fern at Mahableshwar and of the arrow-root plant—which in October and November blooms on almost every square yard of the jungle—and by the beautiful profusion of the *Osmunda* fern, mixed with clustering roses and willows, along the upper stream of the Yenna river. At Matheran the brake-fern is scarcely known. In a few years it will be extinct, if it is not already so; for being rare it has been the prey of thoughtless fern-hunters and cannot defy their onslaughts. It would be impossible for any number of fern-hunters to destroy it at Mahableshwar, and so it is left alone. Even if unmolested at Matheran, it drags on at best but a feeble existence. The site is too low for it, the lowest limit of its range in the latitude of Bombay being apparently a little more than 2,000 feet above the sea-level. The *Osmunda*, again, is not known at Matheran, nor is the Willow (*Salix tetrasperma*), nor the Arrowroot (*Hitchenia caulina*), though other allied plants of the order *Scitamineæ* are plentiful enough. On the other hand, there are some well-known Matheran trees, such as the Kumbha (*Careya arborea*), the Malia or Indian ebony (*Diospyros assimilis*), and the Chandára (*Macaranga Roxburghii*), which do not grow on the Mahableshwar plateau at all. But after full account is taken of all divergences, it is found that many plants are common to the two hills. Such a coincidence is favoured by the practical identity of their geological formation, and by the circumstance that there is no great difference in the range of their mean temperature at different seasons and in their rainfall. Both Mahableshwar and Matheran are huge masses of trap, capped by a thin layer of laterite. Both are within sight of the sea. Both are swept by the same dry winds in the cold weather, and by the same monsoon storms, and both enjoy the full benefit of the monsoon rains. The average mean temperature ranges at Mahableshwar from 63·3° Fahr. to 71·7°, and from 67·8° to 73·5° at Matheran. The average annual rainfall at Mahableshwar amounts to 281·4 inches, and at Matheran to 224·7 inches. Under such concordant influences, it is not surprising that a marked similarity should be apparent in the general outward forms of vegetation on the two hills, due to the frequent presence of the same characteristic plants on both. Everywhere at Mahableshwar, as at Matheran, we find the Myrtle tribe represented by endless woods of the beautiful Jambul tree (*Eugenia*

Jambulana), the Melastomas by the Anjan or Ironwood (*Memecylon edule*), the Laurels by the Pisa (*Litsaa Stocksii*), and the Madder tribe by the thorny Gela (*Randia dumetorum*), a small tree, generally a shrub, with numerous stiff branches, armed with spines, and large fragrant white flowers, which turn yellow before they fade. There is the same undergrowth of shrubs and herbaceous plants, the natural orders of *Leguminosæ*, *Acanthaceæ*, and *Compositæ*, being specially and numerously represented. There are many showy climbers, trailers, and creepers, and Orchids and Dendrobiums common to both hills; while everywhere the little silver fern covers with equal impartiality every sheltered bank and rock. Some years ago, before leaving India, I prepared for the "Bombay Natural History Society's Journal, with the aid of several competent botanists, a catalogue of the flora of Matheran and Mahableshwar. I cannot pretend that it is a complete list, for the simple reason that during the four rainy months of the year, when most herbaceous plants are at their best, the hills are practically inaccessible to Europeans; but in addition to the hill flora it includes some of the more conspicuous plants on the higher levels of the road from Poona to Mahableshwar; and the list of forest trees, which are conspicuous at all times, may perhaps be accepted as complete. It may interest you to know that of the 733 names included in the catalogue, about 125 are the names of trees or sub-trees, as distinguished from shrubs, creepers, grasses, ferns, and undergrowth generally. Of the trees probably not more than ten species have been introduced, and about 115 species are probably indigenous. They constitute but a small proportion of the indigenous trees found throughout India, the number of which exceeds 2,000 species, but they give some idea of the diversity of forest vegetation in the limited area under consideration, if we bear in mind that the number of species of indigenous trees in Great Britain is only forty.*

The trees which have been distinctly introduced are the Peach, which is cultivated at the hill station of Panchgani, near Mahableshwar; the Stringy Bark (*Eucalyptus obliqua*), which does not take kindly to Mahableshwar, the rainfall there being evidently too heavy for it, but does better at Panchgani,—which, at a distance of only ten miles from Mahableshwar, has a much lower rainfall—though not nearly so well as on the Nilgiri Hills; the *Cinchona succirubra*, which again has not been a success, as on the Nilgiri Hills and elsewhere; the Cassowary tree, or Beefwood (*Casuarina equisetifolia*), which has been extensively planted at Panchgani, but much prefers the lower lands nearer the sea, and especially the sandy beaches of the Konkan coast; the Oak (*Quercus robur*), of which, however, there are very few well grown trees; and the Mulberry (*Morus alba*), which was probably brought from China.

Among the more important or more conspicuous

* Lieut.-Col. Bailey on "Forestry in India." *The Scottish Geographical Magazine* for 1897, p. 572.

trees which may be regarded as indigenous are two species of *Garcinia*—the wild Mangosteen (*Garcinia indica*) and the Gamboje tree (*Garcinia ovalifolia*); and two species of *Sterculia*—the *Sterculia urens*, from the wood of which native guitars are made, and the Goldar (*Sterculia guttata*), conspicuous by its large, peach-shaped fruit, covered with scarlet down; the Silk-cotton tree (*Bombax malabaricum*), which attains a great size, and is a tree of strange beauty when in full bloom, with its large, showy, rose-red flowers; the Kásu (*Elæocarpus oblongus*), with leaves turning red in autumn, and clusters of flowers with white-fringed petals and reddish-brown sepals; the Frankincense tree (*Boswellia serrata*), which is plentiful on the Ghát road between Poona and Mahableswar; and another balsamiferous tree, the *Canarium strictum*, yielding a gum, burnt as incense by the hill people at their religious services, and much sought after on account of the rarity of the tree, of which I have found only one specimen at Matheran, to my lasting wonder at its presence there, in a thick wood, far from its congeners, and hemmed in by countless aliens; the *Garuga pinnata* (belonging also to the same natural order *Burseraceæ*), the bark of which is used in tanning; the Indian Satin-wood (*Chloroxylon Swietenii*), an excellent wood for cabinet work of the better kind; the Indian Red-wood or Bastard Cedar (*Soymida febrifuga*), the bitter bark of which is used as a substitute for cinchona bark; two species of the Jujube tree (*Zizyphus*); the Koshimb tree (*Schleichera trijuga*), on the young branches of which lac is produced in many parts of India; the well-known Mango tree (*Mangifera indica*), which is found wild on many hills, though sometimes said to have been introduced by the Portuguese monks from Brazil; the "Flame of the Forest" (*Butea frondosa*), which has given its name,—Palas—in the vernacular,—to the memorable plain of Palási, commonly known as Plassey; the Blackwood tree (*Dalbergia latifolia*), of which is made the elaborately-carved furniture, which at one time was much prized in Bombay; the beautiful Indian laburnum (*Cassia fistula*); the *Acacia Suma*, from the wood of which Catechu is manufactured; and yet another beautiful representative of the order *Leguminosæ*, the *Laeli* (*Albizzia stipulata*), a very conspicuous tree at Matheran, with clean stem and spreading branches, finely pinnate leaves, and large acacia-like flowers, with numerous, white, lilac-tipped stamens; the Ain (*Terminalia tomentosa*), a valuable timber tree; the Myrobolam tree (*Terminalia Chebula*), which is found in great abundance on Mahableswar, the fruit—the Chebulic Myrobolam of commerce—being largely exported, coming indeed, for the whole of India, third on the list of exports of forest produce, as regards valuation, and second, as regards quantity; the Jambul tree (*Eugenia Jambolona*), already referred to, which may be regarded as the most characteristic tree of both Matheran and Mahableswar, impressing as it does, most effectually, its grace of form and beauty of colour on all the landscape and shading the ground everywhere with a cool

canopy of sweet-scented leaves; another tree, also of the Myrtle order (*Careya arborea*), which has been already referred to; the Ironwood (*Memecylon edule*), which has also been referred to and is also a characteristic tree of both hills, with its dark shining leaves, like the leaves of the Camellia; the Benteak tree (*Lagerstroemia parviflora*), which yields a wood of excellent grain for the cabinet-maker; the Kánt Kumbal (*Sideroxylon tomentosum*), a tough, hard grained tree, as its name implies; the *Bassia latifolia* or Mowrah tree, from which Mowrah liquor is made in other parts of India; and yet a third tree of the Sapodilla order, the Bokul (*Mimusops Elengi*), with dark green foliage and honey-scented flowers; the *Diospyros assimilis*, one of the Indian ebonyes; the *Kaola* (*Symplocos Beddomei*), with blossoms scented like the hawthorn and blue berries; the wild Olive (*Olea divica*); the Wáras (*Heterophragma Roxburghii*), a tall tree of the Bignonia or Trumpet-Flower Order, with grey pinnate leaves and clusters of showy white bell-shaped flowers; the Teak tree (*Tectona grandis*), the most important of all the forest trees; the Shewan (*Gmelina arborea*), the pale yellow, close-grained wood of which is used for planking, furniture, the panels of doors, &c.; the wild Nutmeg (*Myristica attenuata*); and 15 species of the Laurel order, all notable and some of them very beautiful trees, the two most notable being the *Litsæa Stocksii*, already referred to, a shapely laurel rising to a height of 20 feet or more, and generally assuming a pyramidal tapering form, and displaying whorls of pale bluish leaves—a very characteristic tree of both hills—and a species of Cinnamon (*Cinnamomum Tamala*), of which I have found only four specimens, all at Matheran, a striking and handsome tree, though of no great size, with tufts, when first bursting into leaf, of small, pink, transparent leaves, which afterwards lengthen and become pointed at both ends, and have marked ribs or nerves, and are dark and shining above, and when dried turn to a rich brown, and yield a spicy scent when crushed. These, with several species of trees of the Spurgewort order (*Euphorbiaceæ*), which is well represented on both hills, and includes the *Macaranga Roxburghii*, already referred to, and readily recognised by its large ovate and peltate leaves, and the *Hasána* (*Bridelia retusa*), a good timber tree; and of the genus *Ficus*, which includes the well-known Banyan tree, the sacred Pipal, the Sycamore tree of the Bible, and other Figs, not so well known; the stately and fine foliaged Jack tree (*Artocarpus integrifolia*), with its enormous fruit, allied to the Figs, the Willow (*Salix tetrasperma*), and the Fish tail palm (*Caryota urens*)—the only palm included in my catalogue—make up a fairly full list of the more conspicuous of the forest trees on the two hills.

I wish I could convey to you something more than a dim conception of the beauty and perennial charm of these Indian woods. But that is beyond my power. It will be enough for me, and I shall be

quite satisfied, if, by my narrative, imperfect and meagre though it be, I shall have helped you in any degree to appreciate the value of the great work done by those who have preserved and improved the forest tracts of British India to the lasting benefit of the State and the people.

Some lantern slides will now be shown, illustrative of forest scenery and particular forest trees. I would also direct your attention to some specimens of forest wood on the table, which have been selected and polished by Messrs. John Roberts and Company, of Bombay, being woods in common use for cabinet work.

In proposing a vote of thanks to the lecturer for his highly interesting and instructive paper, the CHAIRMAN (General Michael) said that, as Mr. Birdwood had paid him the compliment of alluding to him, personally, in connection with the early efforts of the Madras Government to introduce a workable system of forest conservancy into India, he might perhaps add a few words to what Mr. Birdwood had said. There are few men, he said, now left alive among the Indian services who knew or could remember—as he did—what the state of affairs was, as regards forests, half a century ago, when the Madras Government made the effort spoken of. In those days hundreds of acres of primeval forests used to be ruthlessly cut down and burned by the inhabitants, for the sake of a few scanty crops of millet. Timber merchants used to be allowed to go into richly wooded tracts and work their wicked will. No thought seemed to be taken of the hereafter. But in 1848 an experimental establishment was organised for the protection and the economical working of one of the most valuable tracts of forest in the far south of the Madras Presidency. Mr. Birdwood had stated that, after seven years of somewhat uphill work, a pronounced success, both financial and preservative, was achieved, and the ball was thus set rolling. Success was the one thing needed to cause the Court of Directors of the East India Company to take the matter up warmly—conservancy measures and establishments spread rapidly all through India—and with what result? In 1848 the forests of India were fast being ruined by neglect and reckless waste, and the revenue was practically *nil*. By 1898 all existing forests were not only saved and put under good care, but he (the Chairman) was afraid to say how many thousands of acres or square miles had been planted or reafforested, and the net annual revenue stood at £1,000,000 sterling, or more. By that time also most of our colonies and dependencies, and even the United States, had taken a leaf out of India's book, and had established forest conservancy departments. Of course, this gigantic success is due to the measure having reached Imperial proportions. Madras can only take credit for a share of it, but she is justly entitled to look back with satisfaction to her pioneering scheme having been started on a sound basis, and to its having thus proved a success. Too

much stress cannot be laid on the value of two principles on which the work was begun—firstly, that full and liberal recognition and respect for the ancient communal rights of the people should always be maintained, and secondly, that, in carrying out forest conservancy, preservation of the natural resources should be the first consideration, and the acquisition of revenue a secondary one. The ancient rights of the people over forest land is a matter with which it is vitally necessary to deal in a liberal spirit. The early records of the Indian Office show that on this rock both Bombay and Tenasserim split when conservancy was first attempted there. This same rock has frequently cropped up since—as all forest officers know well—and a most dangerous one it is—because if once the local people think they have been badly or illiberally treated they have a thousand and one methods of showing hostility to the Department, and, maybe, to the Government itself. It was highly satisfactory to see that Lord Roberts, in the political part of his autobiography, took a clear-sighted view of this very question, and sounded a note of warning against undue over-riding of ancient forest rights, as a probable fertile source of discontent in India. He thanked Mr. Birdwood warmly on behalf of the meeting.

ROYAL MINT REPORT.

The twenty-ninth annual report of the Deputy-Master and Comptroller of the Mint for 1898 has lately been published, from which it appears that the number of pieces struck in the Operative Department on account of Imperial and Colonial coinages during the year amounted to 98,099,217, exceeding the largest number struck in any preceding calendar year by 2,261,402 pieces.

The real and nominal value of the Imperial coinages issued during the year, as compared with the year 1897, and with the mean of the ten years 1888-97, was as follows:—

	1898.	1897.	Mean of ten years, 1888-97.
Gold	£5,780,446	£1,178,437	£6,318,754
Silver	£1,312,306	£982,001	£1,188,885
Bronze	£84,555	£107,230	£69,790
Totals...	£7,177,307	£2,867,668	£7,557,428

The sterling issue in 1898 is thus considerably above that of last year in value, although about £400,000 less than the average of the preceding ten years, owing to the large re-coinages which have recently taken place in gold, the silver and bronze issues being also above the average. The demand for Colonial subsidiary coin was again very large, having risen from 35,154,000 pieces in 1897, to 39,896,607 pieces last year.

In the early part of the year 1898 the question of making good the deficiency of weight on the light gold coin sent in by the Bank of England since March, 1892, under the provisions of the Coinage

Act of 1891, had to be dealt with. Up to the 30th of September, 1897, that deficiency amounted to 134,294·800 ozs., representing at the Mint value a sum of £522,910 7s. 7d. As the market price of gold was at that time considerably below the Mint price, it appeared the best course to purchase the weight of gold required in the open market, and to convert it into coin. Messrs. N. M. Rothschild and Sons undertook to procure the gold required within a short period of time, and the whole weight was accordingly delivered into the Mint at a cost of £522,630 11s. 11d., an average price of 77s. 10d. per ounce, including brokerage. The first delivery took place on the 17th of February, and by the end of the month the larger part of the purchase (£417,698)

was completed—the balance was delivered at intervals between the 1st and 14th of March. The gain to the Coinage Fund was £279 15s. 8d. on the transaction.

The nominal value of the worn silver coin withdrawn from circulation in the United Kingdom during 1898 amounted to £346,096 13s., making, with that withdrawn from the Colonies, a total nominal value of £377,456 10s. 4d. The total weight of the silver coin withdrawn was 1,229,795·23 ozs., showing a loss of £39,262 16s. 7d., equal to 10·4 per cent. on the nominal value.

The following are the particulars regarding the several denominations of sterling silver coins issued during 1898, exclusive of Maundy money:—

Denominations.	United Kingdom.		Colonies, &c.		Total.	
	Value.	Number.	Value.	Number.	Value.	Number.
	£		£		£	
Crowns	45,850	183,400	800	3,300	46,650	186,600
Half-crowns	166,650	1,333,200	77,700	621,600	244,350	1,954,800
Florins.....	133,150	1,331,500	181,770	1,817,700	314,920	3,149,200
Shillings	226,300	4,526,000	268,700	5,374,000	495,000	9,900,000
Sixpences	114,150	4,566,000	35,260	1,410,400	149,410	5,976,400
Threepences	30,600	2,448,000	30,980	2,478,400	61,580	4,926,400

The nominal value of the bronze coins issued during the year was £84,555, a reduction as compared with the preceding year, when the value amounted to £107,230. More than half the issue took place in the last three months of the year, when the demand for new coin is always active, the issue for the first nine months of the year having amounted to £41,295, and in the last three months to £13,260. The following are the particulars of coins issued:—

	Number of pieces.	Value.
Pence	14,961,600	£62,340
Halfpence ..	8,738,400	£18,205
Farthings ..	3,849,600	£4,010
	27,549,600	£84,555

BELGIAN VICINAL RAILWAYS.

In a notice as to last year's working of Belgian Vicinal (or Light) Railways, it was observed that "the receipts during the beginning of the present year (1897) show a tendency to increase in still greater ratio than those of 1896;"* and indeed the result has not belied that expectation. Last year the total receipts of all these light lines, from all sources, attained the figure of 7,939,433 frs. 80 c. (£317,577 7s.), against 7,955,591 frs. 25 c. (£282,223 13s.) in 1897, while the

corresponding disbursements were 5,336,172 frs. 23 c. (£213,446 18s. 1d.) and 4,742,297 frs. 23 c. (£189,691 17s. 10d.) respectively: thus showing the mean coefficient of working to be 67·21 per cent. for the two years. Out of 9 lines that carry passengers and not goods, 8 show increased receipts, while there was only a falling off in those of the Ostend suburban service of the Ostend-Nieuport-Furnes Line; and out of the 58 lines which carry goods as well as passengers, 47 show an increase and only 11 a diminution in the receipts, there being an increase on the whole collectively, especially as regards passengers.

When the comprehensive project of these light lines—laid for the most part by the side of ordinary roads—was first started, there was a general fear that with the necessary relaxing of the precautions adopted on regular railways, accidents would be very numerous; but this fear has not been realised. Last year the total distance run was 7,980,597·84 kilometres (4,959,002 miles), showing an increase of 50½ per cent. as compared with that in 1891; and during this period the increase in the number of fatalities has only been 21·71 per cent., although that in the number of persons injured has been 75 per cent. Moreover, the accidents attributable to deafness, drunkenness, and suicide have appreciably diminished; but, strangely enough, accidents that have overtaken persons imprudently attempting to cross the line in front of a train in motion more than doubled last year as compared with 1897. Out of the 33 fatalities which occurred last year on Belgian vicinal

* See *Journal*, July 8, 1898, vol. xlvii., p. 718.

airways, twelve were due to crossing the line in front of trains, nine to deafness, drunkenness, or suicide, six to attempts at entering or leaving a train in motion, two to circumstances not exactly determined, and occurring to persons neither travelling on the line nor engaged in the service, and one each to getting on to the platform railing, passing from one carriage to another, the work of shunting, and a train running off the rails.

Out of the 75 lines opened for traffic at the beginning of the present year (against 70 at the beginning of 1898), 43 show more favourable results of working, 42 paying a higher dividend last year than in 1897, and one of them showing a larger profit, which goes to set off previous losses, while in the case of another line, in the province of Luxemburg, its increased earnings have not only permitted of paying off past losses, but have even gone towards the payment of a dividend. There now only remain two lines that figure in the account "Loss in working;" and this loss, which was 62,166 frs. 92 c. (£2,486 13s. 6d.) at the beginning of last year, became reduced at its close to 51,067 frs. 46 c. (£2,042 14s.). Such loss, as well as future losses that may be incurred in working lines made in outlying districts that would in all probability, but for this powerful organisation, remain unprovided with railway accommodation for many a year to come, is abundantly provided for by the general reserve fund of the several lines, the total amount of which increased during the same period from 712,737 frs. 93 c. (£28,509 10s. 4d.) to 884,504 frs. 93 c. (£35,380 3s. 11 $\frac{3}{4}$ d.) during the course of last year, and also the individual reserve funds of the several lines, the total amount of which increased during the same period from 468,136 frs. 36 c. (£18,725 9s. 1d.) to 589,669 frs. 66 c. (£23,586 15s. 9d.). Moreover, during the last three years not a single line of the 75 opened for traffic has incurred a loss; and, among the 69 lines that have been worked for more than a year, 31 pay a higher dividend than that guaranteed; nine a dividend of more than 3 per cent.; ten, one of more than 2 $\frac{1}{2}$ per cent.; and eight, one of more than 2 per cent.

During last December, after the Société Nationale des Chemins de fer Vicinaux had been in existence about fourteen years only, the concession was obtained of the two-thousandth kilometre of line, an occasion which was marked by a spontaneous demonstration by the *employés* of gratitude to the general manager, M. C. de Burlet, who has held that post from the commencement, by a banquet given to all the functionaries and *employés*, at which several members of the Government were present, and by the distribution of substantial gratuities to all persons employed. At the beginning of the present year, after deducting two lines purchased by the State from the Société Nationale, the 94 lines conceded represented a length of 2,134.38 kilometres (1,325 miles); and of that number 76 lines, or sections of lines, representing a length of 1,643.63 kilometres (1,022 miles) are already in operation, while the remaining 18

others are either under construction or will be taken in hand very shortly.

Since the beginning of the present year the concession has been granted to the Society of six more lines or extensions, together 72.4 kilometres (45 miles) long, bringing up the number of lines to 97, and the total length to 2,206.78 kilometres (1,371 miles), of which 1,828.27 kilometres (1,135 $\frac{3}{8}$ miles) are laid to the gauge of one metre (3 ft. 3 $\frac{3}{8}$ in.), 356.05 kilometres (221 miles) to the Dutch vicinal gauge of 1.067 metre (3 ft. 5 $\frac{3}{8}$ in.), with a view to through working, and 22.46 kilometres (14 miles) to the standard gauge of 1.435 metre (4 ft. 8 $\frac{1}{2}$ in.), where such lines effect a junction with standard-gauge railways, so as to be worked by the same rolling stock.

UNIVERSITY OF LONDON AND THE IMPERIAL INSTITUTE.

It having been agreed that the Government should take over a portion of the Imperial Institute for the purpose of affording increased accommodation for the University of London, a Treasury Minute giving effect to the proposals for this purpose has just been issued. From this it appears that the lease under which the buildings are held from the Commissioners for the Exhibition of 1851 will be transferred to the Commissioners of Works as representing the Crown, and the latter Commission will thereupon become responsible for maintenance, rates, custody, and protection of the buildings. The Commissioners for the Exhibition of 1851 have assented to this arrangement.

A portion of the western end of the building will be assigned to the Imperial Institute free of rent, and the eastern end and central portion will form the home of the London University. This arrangement will necessitate certain structural alterations which will be carried out by the Office of Works. The vote of £65,000 to carry out this arrangement was agreed to by the House of Commons, on Monday, 31st July, in Committee of Supply.

In answer to Sir Charles Dilke, Mr. Akers-Douglas explained that the money was asked for to purchase a portion of the Imperial Institute for the housing of the London University. The space which would be given to the University in the building would be far greater than was now enjoyed by that body; and in consideration for the transfer of the lease to the Office of Works, the Government would provide funds sufficient to pay off the existing mortgage of £40,000, and discharge the floating debt of £15,000. In addition to the cost of structural alterations, estimated at £7,000, £3,000 was asked for in the estimate for the maintenance and repair of the buildings and for the purchase of the necessary furniture.

As regards accommodation for the practical examinations of the University in physics and chemistry, it has been agreed that this shall be provided in the new buildings about to be erected for the Royal College of Science, subject to arrangement between the two bodies as to dates of user.

Obituary.

SIR ARTHUR COTTON, K.C.S.I., R.E.—General Sir Arthur Thomas Cotton, who died at Woodcote, Dorking, on Monday night, 24th July, was elected a member of the Society of Arts in 1873, and as far back as 1855 read a paper before the Society on "Public Works for India, especially with reference to Irrigation and Communications," which gave rise to much discussion. In subsequent years he read papers on "Indian Harbours" and "Indian Famines," and he was a constant contributor to the *Journal* of important letters respecting irrigation works in India, &c. He was born in 1803, a younger son of Mr. Henry Calveley Cotton, and cousin to the first Lord Combermere. He was one of a family of eleven brothers, several of whom served with distinction and attained high rank in the navy and army. One of these was General Frederick Cotton, who was Chairman of the Council in 1877. Sir Arthur was educated at Addiscombe, and in 1821 he entered the Madras Engineers, of which he was appointed colonel commandant in 1854. He served through the Burmese War of 1824-26, under Sir Archibald Campbell, and was present at the capture of Rangoon. In 1862 he became major-general, and the same year was made Colonel, Royal Engineers, with rank as colonel-commandant. He was made a lieutenant-general in the army, and placed on the fixed establishment of general officers May, 1867, and was appointed general in 1876, retiring the following year. He was knighted in 1861, for his activity in developing the cotton-growing capabilities of India, and was created a Knight Companion of the Star of India in 1866. Sir Arthur Cotton was devoted to the extension of irrigation works in India. In 1828, he was appointed to the charge of the Cauvery irrigation, and was also employed in the survey and improvement of the Paumben pass. In 1844, he carried out the systematic irrigation of the Godaveri delta. In 1858, he planned works for the Mahanadi delta, and was afterwards employed under the Government of Bengal to report upon water communication between the Ganges and Calcutta. In 1863, he reported on the Ganges Canal works, and later, projected works for the Sone irrigation.

HENRY MAUDSLAY, M.Inst.C.E.—Mr. Maudslay, a member of the Society of nearly fifty years standing, died on Tuesday, 18th July. He was the eldest son of Thomas Henry Maudslay, head of the firm of Maudslay, Sons, and Field (d. 1864), who was also a member of the Society. During the time that Mr. Henry Maudslay was a member of the firm he was created by the King of Portugal a Chevalier of the Order of Christ, in recognition of services rendered to the Portuguese Government. He subsequently spent much time in Palestine, and carried out some important excavations in Jerusalem at his own expense. He also rendered much assistance to, and frequently received

the thanks of, the Palestine Exploration Fund. A large portion of the paving which he discovered in Jerusalem was presented by him to St. Paul's Cathedral, another portion being placed in Freemason's-hall. Mr. Maudslay was a past master of the Ironmongers' Company, a governor of Christ's Hospital, and a life governor of a great many hospitals and institutions. Mr. Maudslay was elected a member of the Society of Arts in 1852. He was a frequent attendant at the evening meetings, and often joined in the discussions.

General Notes.

ECCLESIASTICAL ART EXHIBITION. — The twenty-first annual Ecclesiastical, Educational and Art Exhibition in connection with the Church Congress will be held at the Imperial Institute, October 7th to 14th next. One of the objects of this collection is to bring together representative specimens of Ancient Art, of a corresponding nature to those articles at present in use in our cathedrals, churches, colleges, &c., and thus to enable visitors to compare the old work with the new. Loans are solicited of ancient and modern goldsmiths' and silver-smiths' work, ecclesiastical furniture, embroidery, paintings, drawings, carvings, photographs, books, manuscripts, and antiquities. The clergy and churchwardens of the diocese are particularly appealed to for the loan of communion plate and other objects of archæological interest belonging to their churches. A complete catalogue of the articles exhibited will be included in the "Illustrated Guide to the Congress and Exhibition," which will be published shortly before the Congress. A circular letter, signed by the President of the Society of Antiquaries and the Middlesex Archæological Society, and others, inviting contributions to the exhibition has been issued. The address of the Secretary of the Ecclesiastical Art Exhibition is Maltravers-house, Arundel-street, Strand.

ENAMELS THAT CO-EXPAND WITH METALS.—The great difficulty hitherto experienced with cast or wrought iron objects coated with enamel is the unequal expansion and contraction of the two substances, this causing a splintering of the enamel; but M. Sagliot lately brought before the French Société d'Encouragement pour l'Industrie Nationale the results of his experiments in this connection, that have enabled him to constitute a whole series of enamels having various degrees of expansion. It appears that enamels containing cryolite, fluorspar, and a little rutile, or native titanitic acid, possess very high degrees of dilatation, and that cast or wrought iron, coated with calcareous enamels containing no lead, which are not at all injurious, may be formed by using boric acid.

Journal of the Society of Arts.

No. 2,438. VOL. XLVII.

FRIDAY, AUGUST 11, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS.**

The results of the Examinations held at the end of last March have been published.

Copies for gratuitous distribution to each candidate who attended the examination have been sent to each centre. Additional copies can be obtained, price 6d. each.

The dates for the Examinations in 1900 will be Monday, Tuesday, Wednesday, and Thursday, March 26th, 27th, 28th, and 29th.

SECTIONAL COMMITTEES.

At the last meeting of the Council the following Committees for the Indian, Foreign and Colonial, and Applied Art Sections were appointed:—

INDIAN SECTION COMMITTEE.

Sir John Wolfe Barry, K.C.B., F.R.S. (Chairman of the Council).
 Sir Steuart Colvin Bayley, K.C.S.I., C.I.E. (Chairman of the Committee).
 Sir Frank Forbes Adam, C.I.E.
 Lionel R. Ashburner, C.S.I.
 Jervoise Athelstane Baines, C.S.I.
 Sir Charles Edward Bernard, K.C.S.I.
 Sir M. M. Bhownaggee, K.C.I.E., M.P.
 Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D.
 H. M. Birdwood, C.S.I., M.A., LL.D.
 Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I.
 Sir Charles H. T. Crosthwaite, K.C.S.I.
 His Excellency the Right Hon. Lord Curzon of Kedleston, G.M.S.I., G.M.I.E.
 F. C. Danvers.
 Sir Juland Danvers, K.C.S.I.

Sir Charles A. Elliott, K.C.S.I.
 Major-General Sir Frederic Goldsmid, K.C.S.I., C.B.
 The Lord Harris, G.C.S.I., G.C.I.E.
 Colonel Sir Thomas Hungerford Holdich, R.E., K.C.I.E., C.B.
 Sir William Wilson Hunter, K.C.S.I., C.I.E., LL.D.
 Sir John Jardine, K.C.I.E.
 Sir Seymour King, K.C.I.E., M.P.
 Sir W. Lee-Warner, K.C.S.I., M.A.
 Sir Roper Lethbridge, K.C.I.E.
 Henry Luttman-Johnson.
 Sir Charles James Lyall, K.C.S.I., C.I.E., M.A., LL.D.

Miscellaneous.

THE GOBELINS TAPESTRY MANUFACTORY OF THE FRENCH GOVERNMENT.*

To this time - honoured institution the word "manufactory" is applicable in its strict literal sense, for the *artistes tapissiers* have raised their art to such a pitch that no engine or machine can in this case be substituted for hand work, as it has been nearly everywhere else; and the only pre-occupations of those who weave the precious fabrics are a love of the beautiful and a desire to attain the highest perfection.

In the East, from very remote times, fabrics were woven by a loom with vertical weft; and it is said that the Egyptians were the first to place the loom and weft in a horizontal position, for facilitating the manufacture of ordinary tissues, this latter arrangement having received the name of *métier de basse lisse*, in opposition to that of *haute lisse*, which is found at the Gobelins in its definite form.

According to Pierre du Pont, *maître tapissier* to Henri IV., the manufacture of tapestry began to be known in Europe about the 8th century, when some of the Saracens who had invaded the south of Europe introduced the carpet manufacture into France. Both carpets and tapestry were produced by private enterprise until the time of François I., who brought together the most skilful weavers he could find, and established them at Fontainebleau, under the direction of Salomon de Labaines, the King's weaver. Henri II., while maintaining the establishment at Fontainebleau under the direction of Philibert de Lorme, founded a new one in the Hôpital de la Trinité.

At the commencement of the 17th century, Henri IV. housed the weavers, Lorent and Dubourg, in the Faubourg Saint - Antoine, Paris, whence the manufacture was transferred to the galleries of the Louvre. At the same time the King brought from Flanders a party of weavers, under the direction of Marc de Commans and François de la Planche, who were installed in the Faubourg Saint-Marcel, in one of the houses of the Gobelin family, and near the dye works founded at the end of the 15th century by Jean Gobelin. This latter, a dyer of Rheims, had been induced to settle on the banks of the Bièvre, owing to an old tradition which attributed to the water of this stream valuable qualities for dyeing scarlet; and Jean Gobelin, with his son Philibert, remained at this spot during the end of the 15th and beginning of the 16th century, as is clearly seen from a passage in Rabelais.

The sons of Commans and de la Planche separated

in 1629, Raphaël de la Planche establishing himself in the Faubourg Saint-Germain, while Charles Commans, and his children after him, remained in the house of the Gobelins until about 1654. A few years later, Jean Gluck, who brought from Holland a new process for dyeing scarlet, acquired the factory of the Gobelins (then occupied by a dyer named Chennevix, who had been a partner of Etienne Gobelin), so that in the middle of the 17th century the name of Gobelin was associated with both weavers and dyers.

On the other hand, the above-named Pierre du Pont, who about 1604 had invented the art of making Turkey carpets, was established under the patronage of Henri IV. in the galleries of the Louvre; and, in 1627, an ordinance of Louis XIII. granted him the manufacture of "all kinds of carpets and other works of the East, in gold, silver, silk, and wool" for 18 years. His apprentices, to the number of 100, were lodged in the Maison de la Savonnerie, at Chaillot; and in this ancient soap manufactory the first carpet looms were mounted by Lourdet, partner of Pierre du Pont. Accordingly, about 1662, while carpets were made at the Savonnerie, tapestry was produced at the Louvre and in the Faubourg Saint - Germain, the Hôtel des Gobelins then no longer containing weavers but only dyers; and it is at this period that Colbert bought the Gobelins buildings, to which were removed the old looms of La Planche and Commans, and whither were transferred the other weaveries of Paris. The Manufacture des Gobelins was thus definitely founded; and very soon this nucleus was reinforced by weavers from Maincy.

In 1694, when the war absorbed all the country's resources, the manufactory was closed; but five years afterwards work was resumed under the direction of Mansard, although only in the tapestry department. After that period, notwithstanding all the vicissitudes through which the country has passed during the last two centuries, never has there been cessation of work at the Gobelins; but during the Revolution the very existence of the manufactory was several times in danger. The workshops, which contained nearly 300 weavers under Louis XIV., only occupied 46 in 1797, the national manufactures being regarded as useless establishments, and many *chefs d'œuvre* having been destroyed at that period. The Consular Administration, however, re-established the system of apprenticeship, which had been suppressed, while also appointing a director of dyeing.

In 1825, the manufacture of carpets at the Savonnerie was suppressed; and the *basse lisse* looms of the Gobelins were sent to Beauvais, while carpet looms were put up in the vacant workshops, so that at the present day the weavers of the Gobelins manufactory produce the carpets and tapestries that are ordered entirely in looms arranged vertically. The internal organisation of the Gobelins had been ingeniously arranged by Colbert, the director having under his orders the foremen (*chefs d'atelier*), who

* "La Manufacture Nationale des Gobelins," by Louis Turgan, in *Les Grandes Usines: Etudes Industrielles en France et à l'Étranger.* Paris: E. Bernard et Cie.

were at the same time contractors for the work, and fixing for each piece of work the amount to be given to the contractor, who paid his weavers. In order to ensure permanence in the colours, both wools and silks were dyed at the manufactory and handed over to the contractor, so that, the quality of the work being ensured, the weavers had an interest in producing, and the State knew beforehand the price to be paid for a piece of tapestry.

In 1792 the organisation established by Colbert was suppressed; and the contractors (now become foremen) with the artists (now *employés*) received a fixed remuneration. This system is still in force; and the salaries have been but little increased since, although the weavers are lodged in the manufactory and receive a pension at the age of 60. Since the foundation of the Gobelins, in 1662, there have been twenty-three directors, beginning with the painter Le Brun, followed by the painter Mignard between 1690 and 1695, while M. Gerspach, who was appointed Chef de Bureau des Manufactures Nationales in 1885, was succeeded, in 1892, by M. Guiffrey, the present director, an authority in all matters connected with weaving and tapestry.

During more than two centuries the buildings of the Gobelins manufactory remained just as they were under Louis XIV.; but the formation of the Avenue des Gobelins, the great fire in 1871 (when nearly 300 tapestries of inestimable value were destroyed), and works connected with the Bièvre, have partly modified their general appearance.

Visitors to the manufactory (which is opened gratuitously to the public, without formality of any kind, every Wednesday and Saturday) pass through the museum and three small galleries before entering the Atelier de Berri, which contains three looms, whence they descend into a second workshop, that has often been altered but never entirely re-constructed, where the famous Dutch weaver Jans worked in the 17th century. From this workshop, where there are now eight looms, a bridge gives access to the Atelier de la Savonnerie, where two looms suffice for the weaving of carpets, the others, now unoccupied, being veiled by admirable tapestries; and near to the Atelier de la Savonnerie is a third workshop for tapestry, containing two looms. Inasmuch as the number of weavers is now complete, the school of tapestry is without pupils, and the drawing school has been transferred to a new building.

Pupils are admitted to the elementary drawing school at the age of twelve, the instruction generally lasting two years; and from this obligatory course candidates are recruited for the school of tapestry. The education thus begun is completed at the École Supérieure and the Academy, the antique, the living model, and perspective, being subjects that are ardently pursued. It is chiefly in order to furnish recruits for the *ateliers* that the school of tapestry was established. The teaching is graduated, the pupils being first initiated into the use of the tools, after which they are set to execute bands of flat tints, with ornaments

that become more and more complicated. After a year each pupil receives a premium of 100 francs (£4); and, if he passes the examinations satisfactorily, he is paid a salary of 600 francs (£24). After about two years a good pupil is able to begin work at the *Manufacture*; but it is only with long years of practice that a weaver completely masters the great difficulties of his art.

The Gobelins manufactory now consists of three distinct portions—the dye works, the tapestry *ateliers*, and the carpet workshops.

PREPARING AND DYEING THE WOOL.

The dye works at the Gobelins, now under the immediate management of M. Guignet, are incontestably the most important in the whole world, not on account of the quantity turned out, which scarcely exceeds 6 cwt. of wool or silk yearly, but owing to the perfection and multiplicity of the operations; and these works supply the Beauvais as well as the Gobelins manufactory.

The wool, which for a long time came from the county of Kent, is now obtained from the national domain of Rambouillet, and on arrival at the Gobelins is classified according to its destination, and then, after examination by the foreman, is subjected to a scouring process, depending upon the colours which it is intended to receive. Passed cold through lime water or a carbonate of soda solution, the wools have more or less aptitude for receiving this or that dye, according to their origin and the nature of the scouring liquid. The operation of scouring must be watched with great care, especially as regards the carbonate of soda bath, the temperature of which should not exceed 50° Cent. (122° Fahr.), for fear of disintegrating the wool. The skeins, passed over long poles called *lissoirs*, are then plunged into one of the square coppers which contain the mordant, that must be kept at boiling point, after which the wool is subjected to the colour bath.

For producing, not only the many tints, but also the twenty or thirty shades of each tint, required by the manufactory, the dyers must be veritable artists; and at the Gobelins a point is made of producing colours *de grand teint*, i.e., "fast," or permanent. The light shades are specially difficult to obtain; and a great many fine pieces of tapestry, that date from the commencement of the present century, are gradually losing their effect, owing to the decomposition of certain tints which have completely turned brown, while others have entirely lost their colour. Each tint at the Gobelins has its scale, or series, consisting of a certain number of shades, from the lightest to the most intense; and, although the difference between one shade and another is imperceptible to the ordinary eye, dyers distinguish them, not only when dry, but even when still quite wet.

When the colour is simple, the operation of dyeing is conducted in the following manner:—The bath is charged to the deepest shade of the scale, or series, desired; and the dyer, having placed on his poles the

skeins which he destines for the deepest shade, immerses them in the bath, examines them, takes them out, hangs them on uprights at his right hand, re-plunges them into the bath, again examines them, determines the length of time during which he should allow them to steep, or dry; and, when he considers that the skeins have been dyed to the desired point, he removes them and spreads them out, while, if necessary, he can again immerse them, although this must be avoided as far as possible.

During the work of the dyer the bath gradually becomes weaker, and it is renewed by degrees if required. As the impregnation of the liquid diminishes, the shades become so pale that the last appears white when compared with the first; and it is for these last shades that practised eyes and hands are required. While the wool has to be dyed strongly and deeply, the shade must be as light as desired, so that dyeing which attains this degree of perfection is a veritable art, requiring great intelligence and long experience.

The operations above described are often modified in practice. Instead of first taking the deep shades, a commencement may be made with those in the middle of the series, followed by the lighter shades; and, if they should not meet requirements, the skeins of wool are not lost, but are added to those intended for the deep shades.

The substances contained in all dye-stuffs dirty the baths, so that it is important to purify and renew the latter during the operation, and this with so much the greater care as the shades are lighter. When the colour to be obtained is a compound, like the greens, the browns, &c., the bath should be watched even more carefully, the colour which is most rapidly absorbed being renewed if necessary. All these operations are carried on at the Gobelins, in a laboratory rather than in a workshop.

During the last few years some aniline colours have been tried at the manufactory; but, in presence of manifestly unfavourable results, a return was made to the old products and traditions, indigo being used for the blues, woad for the yellows, madder and cochineal for the reds. The colours are even more brilliant than before, because pure substances and improved methods are employed, while the permanence is as great as ever. There are, however, no secrets at the Gobelins, all the receipts being registered and communicated to anyone who asks for them.

When the wools are dyed, washed, and dried, they are passed on to the storehouses, or are sent to Beauvais with the silks, which are largely employed at that establishment, and which are also dyed at the Gobelins manufactory. The wools keep perfectly well for several years; and when they are to be used they are rolled tightly into balls, and then mounted on spools or spindles (*broches*), which the artist-weaver chooses, just as a painter prepares his pallet. In the general storehouse of the tapestry ateliers there are about 11,000 bobbins of wool, and 7,500 bobbins of silk; but all the series of

colours have not the same number of shades, some of them having eight, and others as many as thirty-six. In the detail storehouse, where the weavers go for their supplies, there are about 34,800 spools of wool, and 6,000 of silk, while another storehouse contains the unclassified wools and silks.

TAPESTRY WEAVING.

In the tapestry department, which has been managed by M. Munier since 1859, forty-five artist-weavers and pupils are engaged on the different pieces, working exclusively, as has already been stated, *en haute lisse*, i.e., vertically, although this method of manufacture is scarcely employed elsewhere than at the Gobelins. Works produced in this manner are generally considered superior, the execution being slower, although at the same time more perfect on account of the position of the loom; but it must be admitted that there is great difficulty in distinguishing products of the *haute* from those of the *basse lisse*. At the Gobelins are chiefly executed large decorative panels, with human figures, of 20 or 30 square metres (mean 269 square feet) area, which do not require such minute work as, for instance, depicting a bouquet of flowers for a chair seat.

Two of the three *ateliers*, containing, one three, and the other two looms, 4 m. by 7·5 m. (13 ft. × 24½ ft.), may be visited by the public; and, excepting two of the looms, which are of iron, they are made of wood, being absolutely identical with those used in the 17th and 18th centuries. Two strong uprights, called *cotrets*, carry two large horizontal rollers, that have received the name of *ensouples*, which are made of oak or deal, and have at each end pivots turning freely in bearings, that may be shifted vertically in the groove of the upright. While both rollers revolve on their axes, it is generally the upper one only that is susceptible of vertical displacement. The iron looms, similar in general arrangement to those of wood, have among other advantages that of greater rigidity.

The *chaîne*, or vertical web, in tapestry consists of woollen or cotton threads perfectly vertical, parallel and equi-distant, stretched on the rollers; and, in a groove extending the whole length of the rollers, there is a small wooden rod, called *verdillon*, for fixing the threads. When it is desired to roll up or unroll a portion of tapestry in course of execution, the rollers are rotated by means of levers inserted in holes made for the purpose; and, as the web is thus wound up on one of the rollers while being unwound from the other, the work is always executed at the same height. A little extra tension is given by an iron set-screw contained in the uprights, and acting on the roller bearings, while the rollers are locked in the position given to them so as to prevent their unrolling.

It is stated above that the threads of the *chaîne*, or web, are stretched vertically and in the same plane; but this is only the case to a certain extent, because they are passed alternately over what is called a

bâton de croisure, which is generally a glass tube one inch in diameter, while a string passed alternately between the threads contributes to maintain their distance apart. The threads are, therefore, in reality, divided into two sheets, those on the weaver's side being the *fils d'arrière*, and those in front of the loom being the *fils d'avant*. Over each of the latter threads are passed strings, designated *lisses*, which have the form of rings, and are carried at the other end by a strong pole, called the *perche des lisses*.

The weaver takes his stand behind the loom, with his back turned to the copy (*modèle*), of which he first takes a general tracing, in order to fix the position of certain points sufficiently far apart, the actual contours being drawn in full lines, and the principal tones being designated by dotted lines. This tracing is placed against the back threads of the web; and, with a small wooden style, previously inked, the artist traces upon the weft, thread by thread, the indications he has taken from the copy, the details being put in as the actual work proceeds. Although it is necessary to take these precautions, which permit of executing the work more correctly, too great reliance must not be placed upon them, as the threads become more or less displaced during the course of the work, and perfectly adventitious causes may modify this or that portion of the whole. The artist thus marks out his work; but he is chiefly guided by his artistic sense and the experience he has acquired.

The artist-weaver, who has at hand a great many spools with wool of various colours and different shades, takes one of these spools, after having determined the shade from his copy; and then he sets the end of the woof thread on the weft thread, to the left of the space where the shade is to be placed. He passes the spool from left to right, between the front and back threads, after separating with his left hand the threads that he desires to cover; and with this same hand he then draws towards him the front threads by means of the *lisses*, or strings in the form of rings, while with the right hand he passes the spool backwards from right to left, thus drawing along the woof thread, which he presses against the previous one with the point of the spool. This stitch, which is called *duite*, is all the mechanism employed; and the two operations which constitute it arrange the woof thread alternately at the front and back of the weft threads, while crossing itself between each of the latter threads.

The *duite*, or stitch, may be made with a single weft thread, or with any number of them that the hand is capable of taking in; and, when finished, it is pressed down with a kind of strong comb the teeth of which, passing between the threads of the weft, close up the woof in such a manner as to conceal the weft threads, although if the stitch should happen to be short it is simply closed up with the point of the spool or the middle finger of the right hand. It is by means of these *duites*, or stitches, that the weaver depicts the design upon the weft, but in lines; and he has in front of him

the wrong side of the fabric, on which side he cuts, sets off, and dissimulates the ends of the threads that begin and finish the stitches. It is the shades that determine the number of weft threads to be comprised in a stitch; and in a horizontal portion of uniform tint the stitches are made as long as possible so as to hasten the progress of the work. In the small details, however, it often happens that a stitch only includes two or three weft threads, the contours of the design to be reproduced, the various circumstances of the colouring, the greater or less extent of the lights and of the half tones determining the length of the stitches and also their number. Transition from lights to browns and from one tone to another is made by colours partaking gradually one of the other and arranged in hatchings. The contours determined, or formed, obliquely to the direction of the weft by the various lengths of the stitches are not, for the most part, either rectilinear or regularly curvilinear, but always *dentellé*, or toothed. This arrangement, however, owing to the fineness of the woof threads, has no disadvantage whatever as regards the general effect of the objects represented, disappearing in the details of light and shade, and also in the hatchings, which are employed to graduate the tints, and also for avoiding the mosaic effect that would result from a simple juxtaposition of colours.

“LA RENTRAITURE.”

This term is applied to all subsidiary work with the needle connected with tapestry, such as sewing together the various portions of a new work, and also the repairs made to worn or faded tapestries, while sometimes the borders are not woven on the same loom as is the tapestry, so that the two have to be united. All these operations, which are executed with great care and skill, are entrusted to a *maître rentrayeur*, having under him several workmen and workwomen.

When the work to be repaired has any break of continuity, such as a hole, the weft must be reconstituted by attaching new threads to the old that remain; and then, instead of passing the thread into the woof with a spool or spindle, the work must be continued by the needle. If however, the missing part is of large size, it is often more convenient to weave it in the loom and then insert it in its place.

All factitious methods for restoring old tapestries are strictly forbidden at the Gobelins Manufactory, for instance, that of scraping the wool and painting it with appropriate colours for restoring the original tone. The Atelier de Rentrature besides doing work to tapestries belonging to the State, also undertakes repairs to those contained in private collections, and entrusted to the Gobelins for that purpose.

CARPET WEAVING.

The carpet *atelier*, managed by M. Jacquelin, after having occupied nearly forty weavers in 1860 now employs only ten, because during the last few years the vacancies caused by decease, pensioning off and

departures have not been filled up; but attempts are now being made to restore to this branch of the manufacture its former importance.

The weaving of carpets differs entirely from that of tapestry, the tissue produced by the artists of the Savonnerie being a pile, the weft of which is wool and the woof of very strong hempen threads. The looms are the same as for tapestry, although of larger dimensions—one has just been put up that is 12 m. (nearly 40 ft.) long—and the artist, placed in front of his loom, works on the right (face) side of the work, having the copy (*modèle*) above him, while the wool employed generally consists of five threads, having different tones but equal value, that harmonise.

For making the stitch the weaver, having chosen his spool, takes with the fingers of his left hand the weft thread on which he has to commence, and draws it slightly towards him, while passing behind it the spool with wool thread which he holds in the right hand; and he then draws towards him, by means of the *lisse*, or string in the form of a ring, the next weft thread placed a little behind the first, surrounding the latter with a slip knot which he draws tight. Between these two passes the woof forms, in front of the weft, a ring the amplitude of which depends upon the height of the pile; and a round iron rod terminating in a blade, inserted in this ring, occupies a horizontal position, and becomes charged in succession with a series of wool rings formed by repeating the stitch, each knot being pressed down and tightened upon the tissue with the thumb and fore finger.

The act of withdrawing the *tranche-fil*, as it is called, from left to right cuts the wool rings; and, when a row of stitches is thus made for a certain length, they are joined together by two very strong hempen threads, passed between the two sheets (*nappes*) of the weft and superposed at the points. This would not suffice, however, to form a strong fabric; but it is necessary to tie together the threads of the weft with another hempen thread forming woof. For placing it in the tissue the weaver brings the hind threads forward, passes the woof between the two rows of threads, presses it down with the comb, and then allows the hind threads to return to their position, taking care to allow this woof sufficient slack to permit its following all the inflections of the weft threads. In this manner the stitches are fixed, as it were, when the weaver presses down with the comb the stitches and the hempen threads, which latter enter into the fabric, becoming quite hidden therein.

The ends of wool thread are then picked apart by means of the needle (*aiguille*), in order that the contours may be well defined, after which the ends of the wool threads, previously cut by the *tranche-fil*, are sheared; and then, by means of scissors with curved—or rather cranked—handles, guided by a small board, the artist again shears the pile with great regularity, when he is able to judge of the effect produced by his work. In the kind of mosaic thus formed, of which the coloured particles are the ends of infinitely small wool threads, the

material is seen in section, instead of lengthwise as in tapestry; and, as the wool threads are perpendicular to the weft, they are flexible—a disadvantage inseparable from velvet pile, which should be borne in mind when choosing subjects for reproduction, because the least pressure may put the lines out of form.

MUSEUM AND WORKS IN HAND.

Temporary exhibitions have been held from time to time in the galleries arranged for that purpose; but it was not until 1885 that the museum was definitely organised, containing tapestries spared by the fire in 1793, 1797, and especially 1871; gifts from the State or individuals, and also works purchased, while all the *genres* and every epoch are represented.

Among the most ancient pieces there are 236 Copt tapestries, that were discovered in Egypt; two ancient Chinese tapestries, one representing a stag and a doe, and the other a ram and a sheep; a cushion cover of the German school, dating from the 14th century; the *Miracle du Landit*, a Flemish tapestry from the *Château du Plessis-Macé*, and the *Idole*, all three of the 14th century; the *Annunciation*, and the *Adoration of the Magi*, both of the 15th century, that were bequeathed by M. Albert Goupil; Louis XI. raising the siege of Salins, remarkably well preserved, though dating from 1501; the *Concert and the Shepherds*, terminated a few years later; the *Wild Boar of Calydon*, the *Ascension of Elijah*, and *Abraham's Sacrifice*, that were woven in Paris at the beginning of the 17th century.

Owing to want of space, some curious fragments of tapestry, not woven, but embroidered, have been hung temporarily over other tapestries; the portrait of Louis XIV. after Rigaud, has been placed on an easel in the first gallery; and a great many hangings are scattered about in the passages, in the ateliers, and in the chapel; *Venus at the Forge of Vulcan*, after Boucher, a *chef d'œuvre* of the 18th century, is now exhibited at the entrance to the *Atelier du Nord*; and the *Entrance of the Turkish Ambassador to the Tuileries* is arranged on one of the vacant looms of the Savonnerie.

The ateliers themselves constitute, especially at the present time, the most magnificent museum of modern tapestry, because the subjects and the copies (*modèles*) are most various, while their execution has attained the highest perfection.

Financial difficulties from the beginning of the 18th century prevented commissions being given to artists specially producing decorative paintings; and a beginning was made by re-copying the works of Le Brun, and afterwards other paintings. Very soon the painters to whom commissions were given, when that was possible, quite ignored the exigencies of weaving; and the tapestry artists gradually accustomed themselves to the new *genre*, multiplying the shades, and producing exact copies of the paintings, after which there was a reaction, the late M. Turgan writing:—

"Some are of opinion that the present method of working with judicious slowness should be maintained, and others that an attempt should be made, as far as possible, to apply the best methods now invented for simplifying hand work, the execution being hastened and the cost diminished. The former think that the productions should consist of paintings that are the most difficult to imitate, in order to maintain the distance which separates the work of the Gobelins from that of commercial establishments; and the latter, on the contrary, opine that all idea of reproducing paintings should be abandoned, but that attention should be exclusively turned to the production of splendid hangings, ornamented with arabesque flowers, and enriched with the precious metals."

During the last few years the intentional imitation of painting by tapestry has been abandoned, at any rate, in principle; and now account is taken of the essential structure of tapestry, the minutely fluted surface of which cannot render either a straight line or a circle, the lights of which have always a little shade, and the shades a little light, special subjects being created that may be executed with a small number of shades. Most of the pieces now being executed are conceived in this spirit, being veritable mural hangings; and the intended tapestry effect is evident at the first glance, "Le Tournoi," after J. P. Laurent, "La Mission de Jeanne d'Arc" and "Le Départ de Jeanne d'Arc," serving as types of this school; but such tendency is less evident in "La Justice Consulaire," of Maignan, "La Renaissance," of Ehrman, and the "Mariage Civil," of Claude.

A replica, or perhaps rather second edition, of the tapestry after Viger Lebrun, "Marie Antoinette et ses Enfants," is now being executed as a present to the Empress of Russia; and there is every indication that the second will be superior to the first copy, which was woven at the beginning of the century. In the same atelier some of the artists are engaged upon Leloir's "Roman au XVIII.^{me} Siecle," and others on Boucher's "Aminthe et Sylvie." In the Atelier de la Chapelle a work of Gustave Moreau, "La Sirène et le Poète," is being reproduced by way of experiment, because of the great difficulty attending the reproduction in wool of such a detailed and elaborate painting.

While the production of the Gobelins manufactory increases every year, the execution remains at least as perfect as ever, if indeed it be not even more perfect; and, at the present time, great activity reigns in this "Dernier refuge d'un des arts somptueux les plus magnifiques."

COAL DUST IN MINES.

The *American Gas Light Journal*, quoting from *Mines and Minerals*, says that by the term dust is meant small particles of solid matter that have surfaces so large in proportion to their contents that they are

easily suspended in moving air. Some dust particles are so small that after they have been raised by a relatively slow current of air, they are slow to fall again when the current motion has ceased. There are other dust particles so large that they are lifted only in swift air currents that move with hurricane velocities. Between these extremes the gradations in size are so great in number that their classification has never been attempted.

Coal dusts, in common with the dusts of other solids, are of various sizes, and are found deposited in situations where the current velocity of the air is too low to support them; for example, on the haulage roads in coal mines the large particles that are only suspendable in rapid air currents, such as are set in motion with the swift moving cars, are always found on the floor, while the lesser particles of constantly decreasing size are found at increasing elevations on the projections of the sides, until the top timbers are reached, where on the upper sides are found the impalpable particles that only fall in air that has ceased to move.

In all situations the deposition of dust particles is subject to the common law. "The contents of dust particles are proportional to the velocity of the air movements that suspend them." The largest particles of dust are only suspendable in rapid air currents, and the minutest particles are the only ones that are suspendable in air that has no true current motion, but only an eddy motion, such as is found in a closed room where minute dust particles are seen dancing in a sunbeam.

The gradation of dust particles with reference to the air movements by which they are suspended is especially important with regard to the inflammability of coal dust when suspended in the air of mines. The following propositions are indisputable, and being so, they furnish the facts by which it can be proved that the dust that is suspendable in nearly still air is more dangerous than that which is only suspendable in air currents moving with relatively high velocities. First, large particles of coal can only burn slowly, as the oxygen required for their combustion can only be supplied by converging streams of air that lie in the radii of spheres whose contents are proportional to the contents of the coal particles; this means that a given sphere of air contains the weight of oxygen required for the perfect combustion of a particle of coal.

Some idea of the volume of air required to burn up one of the large particles of dust that are suspendable in a rapid current of air, may be obtained when it is shown that a sphere of air 1.5 inches in diameter is required to supply the necessary oxygen. Experience and observation have shown, however, that such dust is never all consumed, for when it is examined after an explosion has occurred it is found to be coke that has been separated from the volatile matter of the coal.

For particles of dust to be perfectly consumed in a fraction of a second of time by the oxygen contained

in spheres of air 1.5 inches in diameter, the velocity of the air converging on the particle of dust would have to be such as cannot be attained, because the necessary motive force is never present to do it.

For coal dust in air to cause an explosion, the heat developed by its almost instantaneous combustion must be sufficient to raise to the temperature of flame the air that contains it. Large particles of dust cannot produce an explosion, because the period required for its complete combustion is too long. Very fine dust, such as is suspendable in nearly still air may, however, cause an explosion, for the following reasons: (a) The areas of the surfaces of small particles are much larger in proportion to their contents than those of large particles. (b) The disengagement of volatile matter from dust particles is proportional to their surfaces divided by their contents. (c) The combustion of the volatile matter disengaged by small particles requires shorter periods than does the volatile matter disengaged by large particles, because the air and the gas are more intimately mixed when ignition occurs.

It may now be safely affirmed that large dust, such as is suspendable in swiftly moving currents of air, is not explosive, and that the only dust that can be consumed in a period of time sufficiently short to raise the air in which it is suspended to the temperature of flame is the fine small dust found in nearly still air. This does not, however, solve the problem of dust explosions, for, admitting that it is only the smallest particles of dust that can supply the combustible requirement of a dust explosion, an important query still remains unanswered, namely: How does the force act that makes the air streams advance on a burning particle of coal dust? The answer is, the air streams within an imaginary sphere do not exist, and, therefore, the force by which the air supply is maintained must be sought for elsewhere.

It has been noticed that the dust found in mines after an explosion consists, wherever the fire has been, of particles of coke that can only have been produced at such a temperature as would be generated by the burning of inflammable matter such as the gases given off by coal, when it is heated.

It is evident from this occurrence, that in such cases it is not the fixed carbon but the volatile matter of the dust that is the cause of the rapid ignition that makes coal dust in air explosive. Again, as no propelling force is present in the air to direct converging streams to the burning dust particles, the means for supplying the required oxygen must be sought for in some other way.

When coal is heated above the temperature of water boiling at 212° F., it gives off inflammable gas, and when the temperature is still further raised, the gas is disengaged with increasing rapidity. Consequently, every particle of dust when heated will project into the surrounding air little jets of gas that will mix with the air and make the required explosive mixture that will, when it is a maximum one, consist of nine and a half volumes of air and one volume of

gas, as truly as any other maximum explosive mixture of gas and air. Granting the accuracy of this conclusion many things that are otherwise inexplicable in the behaviour of coal dust when experimented with become intelligible; for example, the charge of dust in air will sometimes be insufficient to disengage sufficient gas to make an explosive mixture; and at other times the charge of dust will be so high as to disengage when heated an excess of gas. At other times the dust particles in a swift current will yield gas too slowly.

To illustrate these conclusions, suppose, after the manner of the experiments of Mr. Henry Hall, the English mine inspector, that dust of different sizes is let fall in a mine shaft in which the air has no current, and that half way down the shaft a large flame is kept burning. Two things would happen first, the velocities of the falling particles would be somewhat proportional to their sizes and no ignition or explosion would occur until the arrival of some particles that were among the smallest, and were present in just such a charge as would disengage sufficient gas to make a sheet of flame that would fill the shaft when ignition began.

The question here arises, in which portion of a coal mine is the air most likely to be dangerously charged with the class of coal dust that would make an explosive mixture under conditions favourable to its ignition? Such a place is a room in a bituminous mine or chamber in an anthracite mine. All rooms cannot, however, be equally subject to the dangers of dusty air; for example, the first room on the incoming side of a panel will receive clean, uncharged air and should a shot blow out at any time no explosion can occur, because the dust normal to the face of the room will have been carried into the room on the return side of it before the shot was fired. The danger of dust charges in the air will, however, increase until the last room on the return side of the panel is reached, for then it is not possible for clean air to enter such a room unless the air has been previously purged.

Dust explosions are generally associated with blown out shots, or air that contains a small percentage of marsh gas. It is also a matter of common experience that coal dust makes a mixture of gas and air explosive that would not otherwise be so, but these experiences do not explain why an ordinary lamp flame will not ignite a dust charge that becomes explosive in the presence of a blown out shot. What supplies the efficacy of a blown out shot is not so much its great heating power as its percussive action, for this quickly diffuses the heat and quickens combustion.

In the same way the effects of an explosion of gas are vastly magnified by the presence of coal dust in the air of a mine, for once the air and gas explode the compression of the air in the neighbourhood of the initial explosion intensifies and quickens the combustion of the dust it contains, until the extent of the fiery blast is many times increased.

Where danger from the presence of coal dust lurks

a mine, the air entering a room in which a shot is to be fired should be cleaned by a water spray ed in the cross cut through which the air enters.

It is possible that very fine coal dust may, without engaging gas, burn with sufficient rapidity to cause an explosion, as such coal is subject to oxidation, but hitherto very little coal dust has been met with that was sufficiently quick in the diffusion of time to justify the conclusion.

COMMERCIAL EDUCATION IN RUSSIA.

Commercial education is continually receiving more attention and encouragement in Russia. Not only the Government, but also commercial institutions, large firms, and even private individuals, are opening new commercial educational establishments, varying from the engineering college (polytechnic) opened by the Government at Warsaw last year, where young men who wish to become civil, mechanical, chemical, or electrical engineers, architects, or surveyors, can obtain a thorough, theoretical, and practical technical education, to the simple evening artisans' class, designed to give apprentices a certain amount of theoretical knowledge of their trade to supplement the practical knowledge gained at their work. Consul-General Murray says that between these two extremes come commercial schools, where boys can get a thorough commercial education as clerks or commercial men, and artisan schools, where the sons of working men can get a preliminary education at certain trades, such as carpentering, locksmiths, &c. It thus only remains for the parents, and the boy himself, to decide what line he will take, and how much time can be given to his education, for which facilities are at hand from the time he first goes to school until he has finished at the engineering college at 22 or 23. The two branches of commercial education which appear to be the most neglected, as compared with Germany, are shorthand, it being extremely difficult to get a clerk who can take down a letter in shorthand, and then print it off on the typewriter, so common an accomplishment elsewhere, and the careful special training of commercial travellers, which is carried to such a pitch of perfection in Germany, has little attention paid to it in Russia.

TOBACCO CULTIVATION IN ITALY.

The province of Lecce has for a long time past been considered as peculiarly indicated from the character of the soil, as well as its climate, for the cultivation of tobacco, and rightly so, as good quality leaves are certainly produced, and the so-called "Lecce" snuff which is sold in small drums, not unlike a diminutive Smyrna fig drum, has long been favourably known to snufftakers. Consul Cocoto in his last report states that under the preceding Go-

vernments the cultivation of tobacco was almost free of restriction, but since Italy has become a first-class power the production and sale alike of salt and tobacco has become a Government monopoly, with the result that the plant is grown only under certain restrictions and with the constant surveillance of the Government department to which the monopoly is attached. The enormous increase of late years in the use of the cigarette has rendered it necessary for the monopoly to provide this article in its various varieties in constantly increasing quantities, and some few years back efforts were made to cultivate the form of the tobacco plant grown mostly in Turkey. With this end in view the department sent a quantity of seedling plants to Lecce for experimental purposes, and as the experiment gave favourable results the plant has been gradually introduced in substitution for other qualities which were formerly grown in the district. It appears that one of the principal conditions of success in the growing of this delicate quality of tobacco is that the land be exclusively manured with ovine matter, and on landowners it was specially enjoined that none but sheep dung should be used by them in the cultivation of the "Oriental" tobacco plants confided to them by the department. The result of the crop has, it appears, been disappointing; cigarettes made from the leaves grown in the province of Lecce have proved defective, the tobacco was not aromatic, and would not keep in some cases, which the department attributed to insufficient manuring, or the total absence of manuring, whilst in the case of other parcels, the smell was altogether offensive, which was attributed to the plants having been manured with ordinary farm manure, and not the special manure indicated by the department. Matters have been brought to a head by the department announcing that unless landowners fulfil the conditions imposed on them when accepting the cultivation of the plant for account of the Government, it will become necessary to discontinue the cultivation of Oriental tobaccos in the province. The President of the Chamber of Commerce recently called a meeting, at the county town of Lecce, of the various landowners interested in the cultivation in question, and, after a long discussion, on the proposal of the Mayor of Lecce, a memorial was unanimously adopted by the meeting, attributing the bad results complained of by the department to the fact that the price which the producer receives from the department when grown rendered it quite impossible for ovine manure to be exclusively used, inasmuch as the manure in question was not obtainable in any quantity, there being no inducement held out to rear sheep in the district. The meeting further deliberated that the extension of land now admitted to tobacco cultivation be increased, the prices paid be increased, the classification of the produce to be less rigorous, particularly as regards the "Oriental" qualities, and that the Government institute an ambulatory professorship to further instruct growers as to the best means of growing the tobacco plant.

This incident is of recent occurrence, and the result is so far unknown. Consul Cocoto says that it is to be hoped that a compromise of some kind will be arrived at, so that the province shall not lose this most important industry.

FOREST AND MINERAL WEALTH OF THE SOUDAN.

The following information, extracted from a report by Sir William Garstin, K.C.M.G., on the Egyptian Soudan, received by the Foreign-office through H.M. Agent and Consul-General at Cairo, is taken from the *Board of Trade Journal*.

A very possible source of future wealth to the Soudan lies in the vast forests which line the banks of the Upper Blue Nile and extend, in an easterly direction, to the Abyssinian frontier. In the Bahr-el-Ghazal province also, particularly in the Bongo country, large forest tracts exist.

The ebony tree (*Dalbergia melanoxylon*) is met with south of Karkauj, on the Blue Nile, and again in the vicinity of the Sobat River. This tree does not, in these latitudes, attain to a very large girth, nine inches being apparently its maximum diameter. It must, however, be very common in these forests, as most of the principal houses in Omdurman are roofed with it. The value of *Acacia arabica*, from which the white and red gum is obtained, is well known; while the other kinds of acacia, such as *Acacia nilotica* (in Arabic "Sant"), is the chief source of the fuel supply.

A bamboo is met with in the ranges of hills to the south of Famaka, and, according to some, "mahogany" is found in the forests round Fazogl and in the Beni Shangul country.

The means of transporting such woods can only be by the river. Unfortunately, neither the ebony nor the acacia will float in water, and, therefore, such transport is debarred in these cases. If a good and serviceable timber tree can be discovered in the Blue Nile forests which can be floated down the river to Egypt, a large source of revenue will undoubtedly have been found. Extensive saw-mills might be erected at Assouan, utilising the power available at the dam now under construction, and an important timber trade might one day arise.

On the White Nile, in the Bongo and Rohl districts, the india-rubber creeper (*Landolphia florida*) is found in great profusion. If the rubber yielded by this creeper be not of quite so good a quality as that obtained from the Assam india-rubber tree (*Ficus elastica*), it is still of sufficient value to be counted as an important asset in the future trade of the Soudan. This plant, which has large laurel-shaped leaves, and a white flower resembling a jasmine, requires several years to mature before yielding rubber in any quantity. The natives obtain what they require by tapping the stem, usually in such a reckless manner that the

creeper dies under the operation. The Assam india-rubber tree should certainly flourish well in most parts of the Soudan, more particularly south of Khartoum. Although this tree takes from twenty to thirty years to arrive at a girth sufficient to permit of regular tapping, its yield is so valuable (about £3 per tree per annum) that its introduction into the country is well worth attempting.

It is very much to be hoped that a scientific examination of the Soudan forests may ere long be carried out under the superintendence of an expert. An Indian forest officer (from Burma for choice) might be deputed for this purpose. It is certain that much valuable information would be obtained from such a report. Such an appointment needs no recommendation—its necessity is obvious. A trained forest officer could, moreover, render good service by advising the Government as to the best method of preserving the valuable fuel supply which at present exists on the banks of both rivers. This supply, although apparently inexhaustible, must speedily diminish, unless cutting and felling of the areas is carried out upon some regular system which will permit of the young trees growing up and replacing those cut down. It is, of course, inevitable at present that the felling should be carried out in a wasteful manner. Fatigue parties are landed from the boats, and are required to cut the largest amount of wood in the shortest possible time. The men have no idea of the value of the trees, and naturally select those which are nearest to the water and easiest cut. Should this practice be continued, it is certain that a few years must see a great diminution in the belt adjacent to the river. On the Blue Nile even the valuable gum-producing acacias are being felled for fuel.

Minerals.—Very little is known regarding the possibilities of mineral wealth in the Soudan. Until the country is more settled, an investigation of the mountainous regions of Kordofan and Darfur on the west, and of the Abyssinian frontier on the east, would be impossible. Iron ore is found in the Bahr-el-Ghazal province, and also in Darfur; while gold mines were at one time worked in the mountains south of Fazogl. Could coal be discovered, it would make a great change in the whole question of the Soudan. In a few years' time it is probable that the Geological Survey Department of Egypt will be able to depute parties to examine the Soudan. For the present nothing can be done.

THE PREPARATION OF VERMOUTH IN FRANCE.

The manufacture of vermouth in France is confined almost exclusively to the city of Marseilles, where all the important manufactories exist. The article is made from ordinary white wine, which is produced extensively in the region of which Marseilles is the principal centre, and which on account of its

undance is very cheap. A pure wholesome white ne may be bought in the South of France at an exceedingly low price. While returns showing the oduction of wine in France are published every ar by the Government, no statistics are kept con- rning either the production, consumption, or ex- tation of vermouth. The two principal points in rope from which vermouth is exported are Mar- lles and Turin. Vermouth, according to the nited States Consul at Havre, is simply an infusion certain plants and bitter aromatic herbs and roots a quantity of wine, the degree of which has been enghened by the addition of one-ninth of its bulk alcohol, in order to bring the wine, which is usually not more than 10° alcoholic strength, up to 15°. ie alcohol used should be pure, clear, and about 85° in strength. The following are the redients of ordinary French vermouth:—Dry nite wine, muscatel wine, wormwood, bitter ange peel, camomile, water germander, Floren- ie iris root, centaury, Peruvian bark, aloes, inamon, nutmeg, alcohol at 85°, and rasp- rry juice. The herbs and other ingredients are metimes allowed to remain in the wine for a period two months, the solution being stirred every fifteen ys. After the expiration of two months the wine drawn off into another barrel and is allowed to ain therein for two weeks, after which it is drawn a second time. In the event of the vermouth being udy, which is often the case, the manufacturer orts to the simple process known as *collage*, which nsists of stirring in some boiled milk in the por- tion of one pint to 26 gallons of vermouth. The uite of a single egg, well beaten, for each 26 gallons, about half a fluid ounce of fish glue, is also used this purpose. The vermouth should be allowed remain in the barrel for about five days after the *lage*, after which time it may be drawn off and ered. If the vermouth thus made is not sufficiently eet, a little sweet wine or syrup may be added. Its ree of sweetness, however, should not exceed 5° to on the Beaumé scale. Newly made vermouth has flavour of herbs, which is occasionally a little too ounced. Age alone causes the disappearance of s. Certain manufacturers, instead of putting the rbs and other ingredients directly into the barrel, st inclose them in a linen sack, which is then pended in the barrel of wine. The sack is hdrawn every five or six days, the liquid ex- sessed from it into the wine, and the sack again pended. It is left in the wine for a month, at the l of which time it is taken out, all the liquid sessed out of it, and the fluid thus expressed returned the barrel. Other manufacturers first make an obolic extract of the ingredients, which extract is erwards mixed with the wine in the proportions en below. To obtain the alcoholic extract referred it is but necessary to reduce the dry ingredients ntioned to powder, and to place the same in about to 12 quarts of alcohol of 85° strength. The ation is allowed to remain standing for a week,

after which 19 quarts of alcohol, and 7·35 quarts of white wine are added, together with the herbs cut into small pieces. The solution is then warmed in a water bath, which should not be heated above 140° Fahrenheit. After half an hour's warming it is removed from the fire, allowed to cool, and to remain standing for eight or nine days, during which time it should be frequently stirred in order that the sediment may be brought as much as possible in contact with the liquid. The solution, when perfectly clear, is placed in a large glass vessel, and forms an extract of vermouth. To make the article of commerce, 1·58 quarts of the extract are mixed with 2·11 quarts of white wine. If, in the simple process of infusion first described, the addition of alcohol to the wine precipitates the tartar contained in the latter, and causes cloudiness, the solution should be allowed to stand a few days until it clears, after which the solid ingredients may be added. The quality of the vermouth manufacture in France depends in a great measure upon the sort of wine used. The wines most employed are those of the valley of the Rhone, certain Spanish wines, and the wines of the extreme South of France. There is a difference between the French and Italian vermouth. A number of French manufacturers make Italian vermouth, however, not for the purpose of deceiving the customer as to its origin, but merely as a type of vermouth, distinct in flavour from the article known as French vermouth. The following are the ingredients which enter into Italian vermouth:—Sweet white wine, wormwood, helenium, calamus odoratus, centaury, holy thistle, water germander, cinnamon, angelica root, gentian, nutmeg, fresh orange sliced, and alcohol at 85°. When the process of infusion, above described, is completed, the manufacturer, or an expert connoisseur identified with his manufactory, samples the vermouth in order to find whether or not it possesses the desired taste. Should the beverage be too bitter, the fault can be remedied by adding a small quantity of wine until, little by little, the proper flavour is reached. If not sufficiently bitter, a small quantity of the solid ingredients may be again infused in the wine. Nor is it necessary that vermouth should possess great alcoholic strength to be good. Some manufacturers make vermouth which contains 17° of alcohol, while others keep their product down to 12°. The average strength is from 14° to 15°.

THE WALNUT IN FRANCE.

In France it cannot be said that the walnut tree is cultivated in the ordinary acceptation of the term. In the north-western part of France it is rarely met with, being found chiefly in the southern and south-eastern part of the country, notably in the Department of Lot, Corrèze, Isère, Drome, and Dordogne. The departments of Drome and Isère produce what is known in commerce as the "Grenoble" walnut. The

nuts which grow in the Department of Lot are given the name of the department itself; those grown in Corrèze are known as "Marbots," while the "Corne" and "Brampton" walnuts come from Dordogne. But even in these regions the acreage planted in trees is very difficult, if not impossible, to determine, for the reason that they are seldom set out in orchards. On the contrary, they are found along the roadsides, or growing in small numbers in the fields. The result is that no official statistics exist, or are published regarding the acreage planted in walnut trees. Nor can the value of the land on which the trees grow be placed at any definite figure, for the reason that no land is purchased or sold especially for the growth of walnuts. When once above ground the French walnut tree grows rapidly. After a growth of two or three years it will produce a few nuts, from which the grower can determine what quality of fruit he can expect from the tree. In fifteen years the tree will give a remunerative crop. It may be said to arrive at maturity in from 50 to 60 years, when, under favourable conditions, an average tree will yield 220 pounds of nuts. A deep, well-drained soil, situated on a hill side, with a basis of lime and granite, appears to be the most suitable for the cultivation of walnuts, and with the exception of occasional trimming, the tree requires but little care. From the first year, trees are trained in the shape of a round bush, the interior of which is freed from excessive growth. Branches which appear to be developing more rapidly than the others are also trimmed or trained, in order that the tree may be well balanced. After being watched for one or two years the trees require little attention, so that little or nothing is expended in keeping them in condition. The nuts are usually gathered towards the middle of October, or sometimes at the end of September, according to the atmospheric conditions which have prevailed during the summer. Those which have fallen to the ground beneath the tree are collected in baskets, while those which still cling to the branches are beaten off with long poles. The nuts are then put in lofts or storehouses where they are allowed to dry for a period of from two to four weeks. Unless the weather is damp two weeks is usually sufficient. Before the nuts are baled for shipment they are usually exposed to sulphur fumes. This has not only the effect of cleansing the shells but acts as a preservative to the kernel. The French walnut tree, which is one of the sturdiest that grows, seldom suffers from pests or other diseases; it lives to a great age, and dies only from decay. In departments where walnuts are plentiful, a salad oil is expressed from the kernels by a crushing process. Those who have tasted this oil once, says the United States Consul at Havre, never desire to taste it again; but it is used freely by peasants who cannot afford to buy oil of a better quality made from olives. Nut oil was also formerly used by artists for the purpose of mixing colours, but of recent years it has been superseded by oil made from linseed.

General Notes.

WEST INDIAN BULLETIN.—Dr. D. Morris, Commissioner of Agriculture for the West Indies, has issued at Barbados the first number of the *West Indian Bulletin*, which is the journal of the Imperial Agricultural Department for the West Indies. This is a double number of 141 pages, and consists chiefly of a report of the First Agricultural Conference in the West Indies, which was held in January of the present year, at Barbados, under the presidency of Dr. Morris.

CALCIUM CARBIDE FACTORIES IN NORWAY.—With its many waterfalls and a plentiful supply of chalkstone in some localities, Norway would appear to be more favourably situated, with regard to the production of calcium carbide, than countries where steam (and not water) has to be used to produce the necessary electric power. H.M. Consul-General at Christiania reports in a despatch, dated 8th of June last, to the Foreign Office, that two calcium carbide factories have started work in Norway. The large of 3,000 horse-power, is situated near Hafslund, the smaller, of 1,500 horse-power, near Borregaard, facing each other on either side of the Sarpfoss waterfall, above Fredrikstad. It is stated that the Hafslund factory is shortly to be increased to 5,000 horse-power. It has been built by the Electricitats Aktiengesellschaft (formerly Schuckert and Co. Nurnberg. Other factories are now in contemplation.

WORKMEN'S COMPENSATION.—A comparative table of the compensation allowed to the family of workman overtaken by a fatal accident in Great Britain, France, Germany, Austria, Italy, and Norway is published in the *Echo Des Mines* of June 22nd. In Italy the compensation consists of a lump sum equal to five times the yearly wage, and in the event of there being no heirs, the indemnity is paid into a common fund, which is employed for meeting the insolvency of employers, subsidising the mutual benefit societies that afford relief to the injured during the first five days following the accident, and also establishments that give medical assistance to the injured, as well as for founding prizes for safety appliances, while no distinction is made between natives and foreigners. In Norway, the sum of 50 crowns (£2 14s. 2d.) is allowed for funeral expenses and annuities are paid to the widow (or widower incapable of working), and also to "ascendants," equal to 20 per cent. of the annual wage, and the same to orphans of both parents up to 15 years of age (only 15 per cent. if they have lost but one parent); but in no case must the total amount of annuities exceed 50 per cent. of the wages, while no annuity is given to foreign representatives not residing on Norwegian soil at the time of the accident. In Germany, foreigners have the same rights as natives in this respect, but if their representatives have left the country the Miners' Provident Fund may pay a lump sum in discharge of liability.

Journal of the Society of Arts.

No. 2,439. VOL. XLVII.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

"OWEN JONES" PRIZE.

This competition was instituted, in 1878, by the Council of the Society of Arts, as trustees of the sum of £400, presented to them by the Owen Jones Memorial Committee, being the balance of subscriptions to that fund, upon condition of their expending the interest thereof in prizes to "Students of the School of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers and Hangings, Damask, Chintzes, &c., regulated by the principles laid down by Owen Jones." The prizes are awarded on the results of the annual competition of the Science and Art Department.

Six prizes were offered for competition in the present year, each prize consisting of a bound copy of Owen Jones's "Principles of Design," and a Bronze Medal.

The following is a list of the successful candidates:—

- Armour, Edith O., School of Art, Battersea.—
Design for printed muslin.
- Kincaid, James, School of Art, Glasgow.—Designs
for a hanging and a carpet rug.
- Long, Thomas W., School of Art, Battersea.—
Designs for printed muslin.
- Marples, George, Royal College of Art, South Ken-
sington.—Design for damask serviettes.
- Simpson, Ernest H., School of Art, Leeds.—Sten-
cilled designs for the decoration of a dining-room.
- Whittaker, Bertrand, School of Art, Macclesfield.—
Design for a damask table cloth.

The next award will be made in 1900, when six prizes will be offered for competition.

Proceedings of the Society.

CANTOR LECTURES.

CYCLE CONSTRUCTION AND DESIGN.

BY ARCHIBALD SHARP, A.M.Inst.C.E.

Lecture I.—Delivered February 20, 1899.

A paper on "The Evolution of the Bicycle" was read in this Hall last Session by Mr. J. K. Starley. It is, therefore, unnecessary for me to say anything about the early forms of the bicycle, but I shall deal at once with the construction and design of the present-day type.

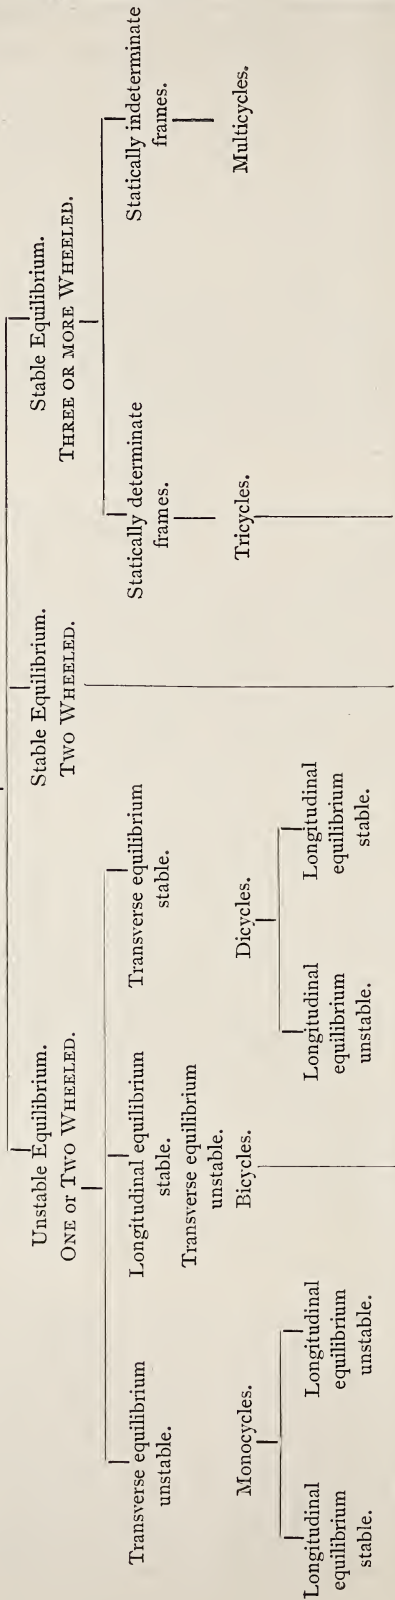

THE FRAME.

The frame of the bicycle is the part on which more than any other the safety and comfort of the rider depends, it may therefore suitably form the subject of the first lecture. The frame may be regarded as a structure, supported at the centres of the wheels, carrying the rider and the driving gear; while, to allow for steering, this structure is divided into two portions by a hinge joint at the steering-head. Cycles may be classified with regard to the arrangement of the steering-wheel, as shown in the accompanying Table (p. 756). Rear-steering bicycles have never been popular. Front-steering bicycles are divided into two classes—front-drivers, of which the "Bantam" bicycle, at present made by the Crypto Works Company, Limited, is the only existing example; and rear-drivers, which include the modern bicycle. Rear-drivers are further subdivided according to the driving gear adopted.

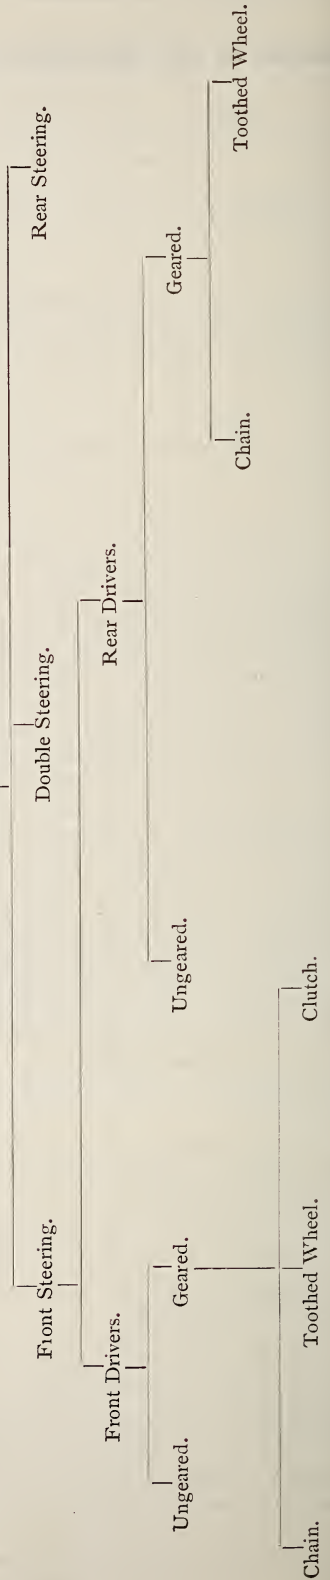

The principal dimensions of the frame on which the rider's comfort depends are (1) the wheel-base, *i.e.*, the distance between the centres of the wheels, (2) the height of the rider above the ground, (3) the position of the rider between the steering and driving wheels, (4) the slope of the steering-head, and its position relative to the centre of the steering-wheel.

Wheel-Base.—In the "Ordinary" bicycle the wheel-base was as short as possible, but it has been found that the longer the wheel-base, the greater comfort in riding over ordinary roads. At present 42 or 44 inches is about the usual wheel-base, while 48 to 50 inches is necessary for a machine with very long cranks. Whatever be the relative merits of long and short cranks, I think it probable that for the average tourist the increased wheel-base necessary for the long crank more than compensates for any

CYCLES.

BICYCLES.

slight addition to the weight of the frame. If the rider is placed exactly midway between the steering and driving wheels, he receives only half the vertical motion communicated to the wheel in passing over a stone. As regards the height of a rider above the ground, the higher the mass-centre, the easier is the steering, and less the liability to side-slip; on the other hand, the wind resistance, the most important factor at speeds over twelve miles an hour, is increased. High frames for tall riders are usually made with the same wheel-base as low frames. But for equal comfort and freedom from pitching, the high frame should be associated with a longer wheel-base. If the wheel-base were made exactly proportional to the height of frame, the angles at the corners would be the same for high or low frames, and the same set of lugs could be used.

The frame of the "Ordinary" bicycle consisted simply of a tubular backbone with rear forks at its lower end, forming practically a tubular beam. The diamond frame of the modern bicycle, on the other hand, constitutes to a great extent a braced girder. A simple beam and braced girder may fulfil exactly the same functions, but the necessary weight of the one may be very much less than that of the other. In the present lecture it is impossible for me to discuss to any extent the nature of the straining actions in beams and girders, but I must attempt to show the essential differences between the two. I have here a wooden lath (Fig. 1), about 30 inches long, which I could

FIG. 1.

easily break by supporting it at its two ends and applying my weight in the middle. By simply adding a vertical strut in the middle, and passing a piece of string between the ends of the lath and over the end of the strut, I form a simple truss which is quite strong enough to carry my weight in the middle. A beam originally straight becomes bent when supporting a transverse load, this bending is only possible if the individual fibres can vary in length. The top fibres are

shortened, the bottom fibres are stretched, while at some intermediate place there is no alteration in the length of fibre. This place is the neutral surface of the beam, and if a cross section be made, the line of intersection of the neutral surface and the section plane is called the neutral axis of the section. The further a fibre is from the neutral surface, the greater evidently is its stretch or compression, and, consequently, the greater also is the intensity of the pull or push on it. The resistance to bending of a fibre in a beam is measured by the pull or push on it multiplied by its distance from the neutral surface. Hence, in a beam, to secure the greatest economy, *the material should be placed as far as possible from the neutral surface.* By simply turning this lath with its long faces vertical, its strength as a beam is enormously increased, while if the material be actually removed from the neighbourhood of the neutral surface and placed further away, as in the hollow rectangular beam, the strength is further increased.

Struts and Ties.—A bar subjected to a pull is called a *tie* or a *stay*, a bar subjected to a push is called a *strut*. In both struts and stays the axis of the stress coincides with that of the bar, and the acting forces are applied at the two ends. In a braced frame the object of the designer is to dispose the individual tubes so that each will be subject to either a pull or a push. The forces acting on a strut or a tie are applied at the ends, while the forces acting on a beam must be applied at three points at least. Hence, in designing a bicycle frame, if it be desired to eliminate as far as possible all bending stresses on the tubes, *none of them should be supported at three points.* I shall apply this principle in criticising some designs of frames that I shall show in the lantern presently.

Diamond Frame.—The diagram (Fig. 2, p. 758) shows the constructional evolution of the diamond frame, although the historical evolution was a much longer and more complicated process. The top figure shows a simple truss made up of two triangles, the second and third show essentially the same triangulated structure, the fourth shows the diamond frame, or, to be more correct, the pentagonal frame with sloping down-tube, in universal use at the present day. It is a maxim found in all text-books of mechanics that the straining action on any plane section of a structure can be estimated by considering all the forces on one side of that section, hence, as the right-hand portions of Nos. 3 and 4 are identical, the

stresses on the top-tube and bottom-tube of No. 4 must be the same as in the corresponding tubes of No. 3. But these latter can only be a push and a pull respectively. It follows,

FIG. 2.

therefore, that in the diamond frame, if it be required that no bending stresses exist on the top and bottom tubes, they must, if produced, intersect at a point vertically above the front-wheel centre (Fig. 3). If these conditions be not attended to, there will be bending stresses on them transmitted by the lugs. I have here a model which illustrates this fact. This model of a diamond frame is made with pin-joints which can be screwed up tight so as to offer a considerable resistance to distortion at

the lugs, or which may be left quite loose so that the open quadrilateral of the frame is free to take up any position under the action of the forces. If the steering-head be too long, the frame collapses in one direction (Fig. 4); if the steering-head be too short, the frame collapses in the other direction (Fig. 5). The small brass models, lent by Mr. Dawson, M.Inst.C.E., and designer of the Amulet bicycle frame, shows the same phenomena. These models are all pin-jointed so that each member can act only as a strut or a tie, but cannot resist bending. The incompletely triangulated frames can therefore all be distorted. But, as regards lateral bending, they are all more nearly on an equal footing.

FIG. 3.

FIG. 4.

FIG. 5.

If a diagonal be inserted in the frame from the top of the steering-head to the crank-bracket, the frame is triangulated, and, assuming there are no bending stresses at the lugs, it is easy to calculate the stress on each tube. The stress-diagram for such a frame, the weight of the rider being assumed 150 lbs., of which 30 lbs. is applied at the crank-bracket, shows that the greatest stress is along the seat-struts, on which the thrust is in

this particular example 117 lbs. If the driving gear and the pedal pressure could be applied in the middle of the frame, a sectional area of less than 1-100th square inch would be amply sufficient to give the necessary strength for the seat-struts, and the total weight of a bicycle frame might be well under 12 lbs. But, as will be seen presently, the lateral stresses due to the pedal pressure and the pull of the chain are very much greater than those due to weight. It is comforting, therefore, to any rider whose machine happens to run away downhill, that the frame has a very large margin of strength for resisting vertical stresses, with the exception perhaps of the steering-post. By sitting far back on the saddle, the stress on the steering-post is diminished. The Raleigh \times frame bicycle has its frame completely triangulated, and it is perceptibly more rigid than the usual type.

Any triangulated structure may be regarded as a whole as a beam, and this point of view is useful sometimes in dealing with bicycle frames. The bending-moment on any section depends on the wheel-base, the position and magnitude of the load, and in no way on the shape of the frame. Similarly, in a bridge-girder of a given span to carry a certain load, the straining action on any vertical section is measured by the bending-moment on that section, and is quite independent of the type of girder, whether plate, lattice, or bowstring. We therefore see that, taking a top-tube of a certain size, the vertical strength of the frame as a whole is proportional to its depth; or, conversely, for a given load the stresses on the tubes are inversely proportional to the depth of the frame.

In the frame of a lady's bicycle, with two straight tubes to the steering-head (Fig. 6),

FIG. 6.

the two tubes being much closer, the stresses on the top and bottom tubes are very much greater than in the corresponding tubes of the diamond frame.

In the Crypto front-driver (Fig. 7), the crank-axle is concentric with the driving-wheel hub, and the rider is more nearly midway between the wheels. The wheel-base is less, con-

sequently the bending-moment on the frame is less.

FIG. 7.

In a tandem bicycle, the weight carried is double, and the wheel-base is greater than in a single, the thrust on the top tubes is about two-and-a-half and three times that on the top-tube of the single machine. The thrusts on the diagonal and on the front down-tube are respectively about three-and-a-half and six-and-a-half times that on the down-tube of the single machine, while the pull on the rear down-tube is about four times the thrust on the down-tube of the single machine.

Driving Pressure—Chain-Struts.—From the fact that the centre of the pedal is a considerable distance from the middle plane of the frame, and from the fact that the transverse dimensions of the frame are reduced as much as possible in order to keep down the tread, the transverse stresses on the frame when pedalling hard are very much greater than those due to mere weight on the saddle. In fact, it is these transverse stresses that practically determine the size of the tubes used in the frame. In the same way, the pull of the chain tends to bend the lower back-forks sideways, and they have to be designed to the best advantage to resist this bending (Fig. 8). Round tubes (*a*) and D tubes (*b*) are most commonly used. In order to keep the tread as narrow as possible, the space between the tyre and the side of the crank must be small, an oval tube with its long axis in the plane of bending (*c*) cannot therefore be used. Twin tubes (*d*) were first used, I believe, in Mr. C. W. Brown's dropped frame, then by Messrs. Humber and Co., and are now used by a great number of makers, the frame of the Centaur cycle being a good example. A careful investigation will reveal the fact that twin tubes are just equivalent to a single tube of weight equal to that of the twin tubes. Since as much

material as possible should be disposed at the greatest distance from the neutral axis, greater strength is obtained by taking an oval tube (*e*) of the same weight as the round tube, but of much greater perimeter; a still better arrangement is to use a rectangular tube (*f*), as in the Referee bicycle. I have suggested a further development in this direction by having a brazed rectangular tube made from two pieces of thin steel plate of high strength (*g*), in which

FIG. 8.

the thickness of the flanges is twice that of the webs. The fastening of the chain-struts to the crank-bracket and the bridge-piece should be as rigid as possible, in order to confine the unavoidable comparative flexibility to the portions at the sides of the wheel. The B.S.A. fittings, with two tubes 1 inch diameter from bracket to bridge-piece, are well designed in this respect.

Down-Tube.—For similar reasons the frame would be much stiffer under the vertical pressure on the pedals if the down-tube were made in duplicate, one tube going to each end of the crank-bracket. This design was fairly common some years ago, and was known as the double diamond frame, the bottom-tube from the crank-bracket to the bottom of the steering-head being also in duplicate.

The diagram (Fig. 9) shows sketches of two machine frames, in each of which a straining action is produced by screwing the central bolt. If the bolt be in compression, the two ends of the frame tend to separate. In the right-hand sketch, which represents diagrammatically one form of testing machine, this tendency is directly resisted by the pull on the two tie bolts. In the left-hand sketch, which represents diagrammatically a punching or rivetting machine, the straining action due to the central bolt has to be transmitted in a round-about way, and bending stresses of considerable magnitude are induced. In the first machine the lines of the frame follow closely the line of the applied stress; in the second machine this is not possible, and the frame is proportionately much heavier. Similarly, in making the crank-bracket of a bicycle stiff under the action of the pedal pressure, the line

FIG. 9.

of thrust of the leg may be taken as between the saddle and the pedal, and the greatest economy of material will be obtained when the lines of the frame follow this as closely as possible.

If we could conceive the back wheel to be taken out, and a horizontal diagonal from one end of the crank-bracket to the opposite end of the hub-spindle be inserted, the rear-frame so obtained would be a perfectly braced structure in three dimensions, and would be as stiff as the width of tread would allow.

Frame of Chainless.—The stresses on the lower back-fork, due to the driving effort on a bevel-gear bicycle, are of quite a different nature. Fig. 10 shows diagrammatically the forces on the gear and lower back-fork when a driving effort is applied. The upper diagram shows the pressures between the toothed-wheels and on the bearings, the lower diagram shows the direction of the pressures on the frame-tube supporting the intermediate

axle, due to the driving effort. These four forces constitute an upward bending action in a vertical plane. The maximum bending-moment is equal to the mutual pressure on the front pair of wheels multiplied by the radius of the large wheel. The twisting-moment on the rotating shaft is the product of the same pressure into the radius of the small bevel-wheel. Hence the straining action on the frame-tube is much more severe than that on the rotating shaft. The greatest twisting-moment a tube of circular section may be safely subjected to is twice the bending-moment it may safely stand; in other words, a circular tube is twice as strong in torsion as in bending. Therefore, it seems more in accordance with the nature of things to have the frame-tube outside the rotating shaft, as is done in

(Fig. 11) answers almost exactly to this description. A frame with diverging tubes is weaker immediately above the crank-bracket, the

FIG. 11.

effective depth of the frame at this point being reduced. The long unsupported head of the straight tube frame is subjected to no stress due

FIG. 10.

the Columbia and Sterling bicycles. In the Acaténe and the Quadrant cross-roller bicycles, the frame-tube is inside the rotating shaft.

Frame of Lady's Bicycle.—The frame, with two straight tubes converging to a point vertically over the centre of the front wheel, gives the best arrangement as regards a vertical load. The down-tube is subjected to bending by the thrust of the top-tube, but if made stout enough to resist the lateral bending due to the pedal pressure, it will be stout enough to bear the thrust of the top-tube. To make the frame a perfectly braced structure, a pair of tubes should be taken to the driving-wheel spindle, the introduction of this pair of tubes would also strengthen the frame laterally against the pull of the chain. The frame of the Amulet bicycle

to the weight of the rider, but if the handles be pulled backwards or pushed forwards, stresses are introduced. The Osmond frame, with a small curved piece joining the top tube

FIG. 12.

to the top of the steering-head, is an improvement in this respect. The Raleigh frame (Fig. 12) has a further advantage, that the tube from the top of the steering-head to the

crank-axle, besides supporting the former, stiffens the latter against lateral bending. The Amulet frame has all these advantages, and the further important one that the extra pair of back-forks, a short distance above the crank-axle, makes it stiff under the pull of the chain. The popular type of frame (Fig. 13),

FIG. 13.

with one straight and one curved tube, is not vertically so rigid as the frames already described, as both tubes may be subjected to bending, being not sufficiently connected together. If great clearance for the dress be desired, as well as strength and rigidity, Burford's web frame, consisting of two tubes united by a central web, is to be recommended.

Vertical strength has been obtained by dropping the frame below the crank-axle, the best known example being Mr. C. W. Brown's frame (Fig. 14).

FIG. 14.

Tandem Frames.—The best arrangement as regards vertical strength is shown by Fig. 15, giving practically a triangulated

FIG. 15.

frame. Sometimes a second top-tube is added, but I cannot see that this increases the vertical strength.

When a tandem is required for a lady and gentleman, the lady may occupy either the front or the back seat; Fig. 16 shows a lady-

front tandem. This frame leaves something to be desired as regards vertical strength. Brown's open-front tandem frame is much better in this respect, while the duplex chain-

FIG. 16.

struts make it stiff laterally. The Mohawk open-back tandem frame is completely triangulated, and strong vertically. It would perhaps be slightly improved in resisting torsional strains by making the diagonal run from the front crank-socket to the top of the steering-head. The Raleigh and Referee tandem frames (Fig. 17) are designed for a

FIG. 17.

lady to occupy the back seat, while the frame being slightly dropped in front allows the front rider greater facilities for dismounting.

There is no difficulty in making tandem and multiplet frames as stiff vertically as required, but the longer the frame the more whippy it becomes unless special precautions be taken to strengthen it against lateral bending and twisting. A multiplet frame may be roughly compared to a thin sheet of steel which is very strong vertically but quite flexible laterally. No arrangement of bracing in the vertical plane can strengthen the frame laterally. The necessity of keeping the tread narrow practically precludes lateral bracing, and the lateral rigidity must be obtained by the resistance of the tubes to bending. If the two riders do not nick together in pedalling, a considerable torsional strain is put on the frame. This can best be resisted by a single tube of large diameter.

Front-Frame.—The front-frame consists of the fork-sides, fork-crown, steering-tube, and handle-bar. The steering-post and fork-sides form practically a beam on which the greatest straining action occurs near the lower end of the steering-tube. Practically

the weakest point of present day bicycles under a vertical load is the bottom of the steering-head. It is very important that this should be sufficiently strong, since the greatest stress at this point will occur when running down-hill at a high speed over an uneven road, under which conditions weakness in the steering-tube might be fatal. The greatest stress on the other portions of the frame probably occurs when a heavy driving effort is being exerted, as when going uphill. Under these conditions, the speed is usually slow, and even though the frame should prove to be weak, no serious accident is likely to occur. If the rear-frame be strong enough laterally to resist the driving effort it will be quite strong enough to resist the vertical stresses when running downhill at a high speed. A braced-front frame is probably the strongest and stiffest structure, but may be objected to on the score of appearance. The Referee triple-head is a very well-known contrivance for adding to the strength of the front-frame.

The crown serves to unite the top of the fork-sides and the bottom of the steering-tube. The most commonly used is the plate-crown, which has for one of its recommendations that its design is such that even with imperfect workmanship in brazing the fork-sides it may stand quite satisfactorily. In the B.S.A. crown (Fig. 18), an inside lug projects from the under

FIG. 18.

surface of the top-plate, and fits into the end of the fork-side, so that the parts will hold together in position without brazing. A triple-plate crown is sometimes used in tandems and multi-plets, the designers evidently thinking that if two plates are good, three plates are much better, but since the crown is subjected to bending and torsion, the stresses can be best resisted by having the material as far apart as possible. No bridge builder would ever dream of putting a third flange in a plate-

girder midway between the top and bottom flanges.

The arched fork-crown (Fig. 19) is much used by American makers, it is neater in

FIG. 19.

external appearance, and is easier to keep clean. From the disposition of the material it must be slightly heavier, other things being equal, than the plate-crown.

Spring Frames.—A spring frame is intended to reduce vibration and give the rider greater comfort when passing over a rough road, as compared with a rigid frame under the same conditions. Most spring frames have specially made springs inserted at various places. The Triumph Cycle Company, Limited, in their "natural spring frames," make the various frame-tubes curved so that they may yield more than a straight-tubed frame carrying the same load. A spring frame has to absorb a certain quantity of energy or work, which it again restores.

The extension of a bar of unit length and section is proportional to the stress applied within certain limits. But the work done in extending a bar of unit length and sectional area is half the product of the greatest stress and the extension produced by that stress. Therefore the work or energy that can be absorbed by a bar of unit volume without permanently altering its shape is proportional to the square of its elastic strength. In steel of a quality like that of a weldless tube, the elastic limit may be about 12 tons per square inch, in a wire spring of tempered steel the elastic limit may be 100 tons per square inch. Taking the elastic limit of the

material in a properly constructed spring at 6 times that of a weldless steel tube, the weight of a natural spring frame would be 36 times that of specially designed springs capable of absorbing the same shock.

This figure requires a slight modification, as the specific extension of tempered steel is somewhat less than that of mild steel, the ratio being, roughly, 5 to 6; making the weight of the natural spring frame 30 times that of the properly constructed special spring frame for the same shock. Thus, the natural spring frame, unless very heavy, cannot absorb as much shock as one with special springs; on the other hand, the complexity of the frame with special springs has hitherto prevented it from becoming popular.

Miscellaneous.

STANDARD TIME IN INDIA.

The suggestions of Mr. Oldham, the superintendent of the Geological Survey of India, respecting a standard time for India, in a paper printed by the Asiatic Society of Bengal, are quoted in *The Times*.

Mr. Oldham describes the present system in that country, by which every place keeps its own time, as a barbarous arrangement, unworthy of a country pretending to civilisation. A traveller going from one town to keep an appointment in another must find out how many minutes there is between the times of the two. To some extent a standard time is used, for the railways adopt Madras mean time all over India, and the telegraph department does the same, but the official telegraph guide contains a table of 44 pages, giving the difference between local and standard times. The adoption of a single standard time for India would cause inconvenience because of the extent of the empire from east to west; in some places the difference would exceed an hour. This difficulty, Mr. Oldham suggests, would be met by adopting the system in use in Europe and North America of hour zones, by which the region is divided into belts running north and south, each 15° of longitude in width. Over each belt the same time is used, while in belts to the east and west a change of an hour forwards or backwards is made. In India the lines could follow the boundaries of the chief administrative divisions, as is done in the United States, Canada, and Russia. After discussing various suggested standards of time, Mr. Oldham recommends the adoption of the hour zone system, using Greenwich as the starting-point. This would give only two different times in India, an eastern time, exactly six hours later than Greenwich time, in use in Bengal, Assam, and Burma, and a western time, exactly five hours later than Greenwich, in use in the rest of India. The traveller in either

group of presidencies or provinces would find the same time in use everywhere, and when he crossed the boundary he would know that the time was an even hour earlier or later according as he was travelling westward or eastward. In practice, in Calcutta all watches would have to be put back six minutes, but on the other hand the railway clocks and those in the rest of the town would not show different times. "I have myself," says Mr. Oldham, "recently had to deal with a mass of time records referring to the earthquake of 1897, and found that a large number had to be rejected because it was impossible to ascertain what standard of time had been used, while in many others it was only after a large mass of calculations had been gone through that the relation of observations from different places to each other could be determined." The steps necessary to initiate the change are stated to be very simple. The first would be to discontinue the 44 pages of variations in the telegraph guide, and when local time was no longer obtainable at the telegraph offices, standard time would come into use. In the local observatories in the presidency towns the time signals should be converted into Greenwich time; and in all public offices standard time should be used. "If this were done, the experience of other countries has shown that the general public would soon come to adopt the standard time, and having once appreciated its advantages, would soon wonder how they had so long endured the old system."

ARTIFICIAL PRODUCTION OF INDIA-RUBBER.

The *Kew Gardens Bulletin* contains an article on Dr. Tilden's Artificial Production of India-rubber, and quotes from his paper on the Spontaneous Conversion of Isoprene into Caoutchouc, read before the Birmingham Philosophical Society.

India-rubber, or caoutchouc, is chemically a hydrocarbon. But what is called its molecular constitution is unknown. All that has been ascertained is that when decomposed by heat (distillation in closed vessels) it is broken up into simpler hydrocarbons, amongst which is isoprene. Isoprene is a hydrocarbon which was discovered by Greville Williams many years ago among the products of the destructive distillation of india-rubber. Later, in 1884*, it was observed by Dr. Tilden among the more volatile compounds obtained by the action of a moderate heat upon oil of turpentine and other terpenes. It is a very volatile liquid, boiling at about 36°. Its molecular formula is C₅H₈, and it forms a tetrabromide, C₅H₄Br₄, but no metallic derivatives like the two homologues of acetylene.

Bouchardat† observed that when isoprene is heated to a temperature near 300°, it gradually polymerises

* "Trans. Chem. Soc.," vol. 45, p. 410.

† "Compt. rend.," vol. 87, p. 654, and vol. 89, pp. 361 and 1117.

into a terpene, which he called diisoprene, but which is now called dipentene. This compound boils at 176° . A quantity of colophene, similar to that which is produced by the action of heat upon turpentine, is formed at the same time. When isoprene is brought into contact with strong acids, aqueous hydrochloric acid for example, a small portion of it is converted into a tough elastic solid, which has been examined by G. Bouchardat and by Dr. Tilden. It appears to be true india-rubber.

Specimens of isoprene were made from several terpenes in the course of Dr. Tilden's work on those compounds, and some of them have been preserved. He was surprised at finding the contents of the bottles containing isoprene from turpentine entirely changed in appearance. In place of a limpid colourless liquid, the bottle contained a dense syrup in which was floating several large masses of a solid of a yellowish colour. Upon examination, this turned out to be india-rubber.

The artificial india-rubber, like natural rubber, appears to consist of two substances, one of which is more soluble in benzene or carbon bisulphide than the other.

A solution of the artificial rubber in benzene leaves on evaporation a residue which agrees in all characters with a similar preparation from Para-rubber.

The artificial rubber unites with sulphur in the same way as ordinary rubber, forming a tough elastic compound.

The constitutional formula of isoprene is now known to be:—

In a recent letter, Professor Tilden states:—"As you may imagine, I have tried everything I can think of as likely to promote this change, but without success. The polymerisation proceeds *very* slowly, occupying, according to my experience, several years, and all attempts to hurry it result in the production not of rubber but of 'colophene,' a thick sticky oil quite useless for all the purposes to which rubber is applied."

VICTORIA AND ALBERT MUSEUM, SOUTH KENSINGTON.

Sir T. D. Gibson Carmichael, Bart., M.P., has lent his very valuable collection of goldsmiths' work and jewellery for exhibition, and the case containing it is situated in the South Court. The most important work of art in this collection is an exquisite gold shrine, probably of Flemish or Burgundian work of the 15th century. It encloses an enamelled group, consisting of a half-length figure of Our Lord crowned with thorns, upheld by an angel with outspread wings. The two doors of the shrine are decorated on the inside with the Virgin and St. John the Evangelist in translucent enamel, and on the outside with representations of St. John the Baptist and St. Catherine of Alexandria. On the top is a group of

the Coronation of the Virgin. The back is engraved in dotted work with the Death and Assumption of the Virgin. The little cross-shaped receptacle at the top was evidently intended to contain a piece of the true cross. When not in use, this relic was taken out and placed in a compartment constructed expressly for it behind the door in the back, on which appears the Vernacle.

Mr. George Salting has also lent some additions to his collection which will be found in the South Court. The most important, on account of the rarity of its shape, is the fine ewer of enamelled earthenware decorated with ruby and mother-of-pearl lustre, at Gubbio, at the beginning of the 16th century. In front is a shield of arms with helmet, crest, and mantling, the whole being surrounded by a wreath. In his case of Limoges enamels is to be seen another recent acquisition—an enamelled plaque representing Our Lord in the Garden of Gethsemane, by Jean Penicaud I., of Limoges. In one of the arcades are two walnut panels of the early part of the 16th century, carved with angels beneath Gothic niches. The angels have a very distinct German character about them, but the panels are stated to come from the district of Bresse, near Lyons. Mr. Salting has also acquired and lent the carpet which was the property of the late Lord Leighton. At the top is a cheetah hunting a deer, and below is a lion devouring his prey, whilst at the bottom is a curious monster, somewhat resembling the Chinese lion, chasing a deer of equally strange form. The whole is surrounded by a conventional floral border.

In the Tapestry Court may be seen a valuable carpet, lent to the Museum for a short time by the Girdlers' Company. In the centre are the arms of the company, and on either side are two panels, one with an eagle and one containing devices, the meaning of which are at present unknown. This carpet is not only of a beautiful and instructive type, but is of considerable value to the student of the history of carpets, as it is known that this carpet was ordered to be made for the company in the early part of the 17th century.

The Museum itself has gradually acquired a representative series of costumes of the Georgian period. A recent addition to the collection of ladies' dresses shows a somewhat unusual combination of weaving, painting, and embroidery. The dress is of damask brocade, with sprays of flowers carefully painted by hand, and small leaves embroidered in blue silk. It dates from near the middle of the 18th century. An interesting coat and waistcoat have lately been presented to the Museum by Mr. Frederick Rathbone. They are of silk with a small diaper pattern in uncut velvet pile. The buttons are of Wedgwood's jasper ware, with classical figures and contemporary portraits in white on a blue ground. The shape of the coat and waistcoat show them to date from the later years of the 18th century. These costumes may be seen in cases in one of the arcades of the South Court.

Obituary.

SIR EDWARD FRANKLAND, K.C.B., F.R.S.—Sir E. Frankland, the distinguished chemist, who died in Norway on Wednesday, 9th inst., was a member of the Society of Arts since 1877, and held a seat on the Council in 1881 and 1882. He presided on several occasions at the evening meetings, and frequently joined in the discussions on Water Supply and River Pollution. He also contributed a paper to the Water Supply Congress held by the Society in May, 1878. Frankland was born at Churchtown, near Lancaster, in 1825, and was educated at Lancaster Grammar School. He afterwards studied chemistry at the Museum of Practical Geology, and in the laboratories of Liebig and Bunsen at Giessen and Marburg. He was appointed Professor of Chemistry in Owens College, Manchester, in 1851, in St. Bartholomew's Hospital in 1857, in the Royal Institution in 1863, in the Royal College of Chemistry in 1865, and in the Normal School of Science (South Kensington) in 1881. When he succeeded Dr. Hofmann in 1865, as Professor at the College of Chemistry, he undertook to continue the monthly analysis of the water supplied to the metropolis, which Hofmann had begun a few months before for the Registrar-General's reports, and Frankland continued these analyses from that date. In 1868, he was appointed a member of the second Royal Commission on the Pollution of Rivers, when the Government supplied him with a fully-equipped laboratory to enable him to carry out the necessary inquiries. In August, 1859, he spent a night on the summit of Mont Blanc in company with Dr. Tyndall, when was commenced his series of experiments on the source of light in luminous flames. About 1866, he commenced his researches on the source of muscular power, in connection with his ascent of the Faulhorn in company with Fick and Wislicenus. He was elected a Fellow of the Royal Society in 1853, and in 1857 he received its royal medal for his "Researches on the Isolation of the Radicals of Organic Compounds." In 1894 the Copley medal was presented to him. He was foreign secretary of the Royal Society at the time of his death. Frankland was a member of several foreign academies. He was elected, in 1866, a corresponding member of the French Academy of Sciences, and subsequently he became a foreign member of the Academies of Berlin, Munich, Upsala, &c. He was president of the Chemical Society in 1871, and the first president of the Society of Chemical Industry in 1877. The University of Oxford gave him the degree of D.C.L. in 1877, and Edinburgh that of LL.D. in 1884. The honour of K.C.B. was bestowed upon him in 1897.

General Notes.

ROYAL ACADEMY.—It has been decided by the President and Council of the Royal Academy that the next winter exhibition shall consist exclusively of the works of Van Dyck.

RUSSIAN CALENDAR.—The Russian Government after many years' discussion, has determined to abandon the old style or Julian calendar, which is twelve days behind the now universal system of the Gregorian cycle, and which has been a source of annoyance to Russians doing business with other countries who were compelled to use both dates, as well as to foreigners trading with Russia. The St. Petersburg Astronomical Society has taken the matter in hand, and with the co-operation of the ministers will appoint a commission to be composed of sixteen persons, nine of whom are to be members of the Astronomical Society who will arrange the details. It is expected that the new style calendar will come into effect in 1901.

MILLAIS MEMORIAL.—It was decided at a meeting held at Marlborough House, under the presidency of H.R.H. the Prince of Wales, that a bronze statue of the late Sir John Everett Millais, Bart., P.R.A., should be erected in front of the Tate Gallery, Millbank, and at a meeting of the Sub-Committee, held on the 18th July, 1899, Sir Edward Poynter reported that Mr. Thomas Brock, R.A., had consented to execute the statue and pedestal, and promised to prepare a sketch for the statue without delay. It was hoped that the statue might have been placed on the main floor of St. Paul's Cathedral, but the Dean was unable to give his consent to this as every available space was already occupied. It is hoped that a mural tablet to Sir John's memory may be erected in the Cathedral. The subscriptions amount in all to £2,100.

IRON IN AMERICA.—The production of pig iron in the United States in the first half of 1899 was 6,289,167 gross tons, against 5,869,703 tons in the first half of 1898, and 5,904,231 tons in the second half. The production of Bessemer pig iron in the first half of 1899 was 3,788,907 gross tons, against 3,703,584 tons in the first half of 1898, and 3,633,800 tons in the second half. The production of basic pig iron in the first half of 1899, all made with coke or mixed anthracite coal and coke as fuel, was 465,657 gross tons, against 337,485 tons in the first half of 1898, and 447,959 tons in the second half. The production of spiegeleisen and ferro-manganese in the first half of 1899 was 104,496 gross tons, against 109,641 tons in the first half of 1898, and 104,128 tons in the second half. The whole number of furnaces in blast in the United States on June 30th, 1899, was 240 against 202 on December 31st, 1898. The number out of blast on June 30th was 175, of which several have since been blown in and others are preparing to blow in.—*Engineer.*

CANTOR LECTURES.

CYCLE CONSTRUCTION AND DESIGN.

By ARCHIBALD SHARP, A.M.Inst.C.E.

Lecture II.—Delivered February 27, 1899.

BALL BEARINGS.

The earliest bearings used in cycle construction were of the plain cylindrical journal type. With the now almost universal adoption of ball bearings for cycles, the general impression amongst cyclists is that the frictional resistance of the latter is very much less than that of the former. As a matter of fact, if the cylindrical journal bearing can be kept efficiently lubricated there is little to choose between it and a ball bearing when each is carrying a fairly heavy load. It is the question of lubrication that separates the two types

will run satisfactorily for a long time without any oil supply. At the present day the plain cylindrical bearing is used for the crank-axle in the Collier two-speed gear, and for the spindles of the intermediate pinions of the Crypto front-driving gear. In both cases provision is made for efficient lubrication, and the rider of either would never suspect from his actual experience that he had such an old-fashioned contrivance on his machine.

Adjustable Bearings.—The adjustment after wear of a cylindrical bearing is a matter for the mechanic; if the bearing surfaces be made conical a simple screw adjustment can be used to take up the wear. A conical bearing was much used for the back hub of the Ordinary bicycle.

Ball Bearings.—Fig. 1 shows a diagrammatic section of a ball bearing with conical adjustment. Two rolls of balls, B, each run between a pair of hardened steel ball paths, one fixed to the spindle, and one to the barrel. One of the cones is screwed up hard against a shoulder on the spindle, while the other is screwed until both rows of balls are lightly pressed between their paths, and no perceptible shake is left. The adjusting cone is locked in position by the lock-nut N.

There are three kinds of motion at the point or surface of contact of two bodies having relative motion, viz., rubbing, rolling, and spinning. In ball-bearings these three motions exist simultaneously, although it is a popular belief that only rolling motion exists. Two adjacent balls rub on each other; but the mutua pressure between the balls is very

FIG. 1.

and makes the ball bearing far superior for cycles. A cylindrical journal bearing must be lubricated continuously if the best results are to be obtained from it, whereas a ball bearing

little. Fig. 2 is intended to show the nature of the rolling and spinning motions. The motion of a ball relative to its path may be most conveniently studied by imparting to the

whole system a rotation about the axes of the bearing sufficient to bring the centre c of the ball to rest. The ball-paths C and D will then be rotating in opposite directions. If the bearing is of a two-point contact type, the pressures f_1 and f_2 on the balls (Fig. 2) must be

FIG. 2.

equal and opposite, and therefore the points of contact a and b of the ball with its paths must be at the ends of a diameter. From a let a tangent av_2 be drawn to the common surfaces in contact; then if pure rolling motion exists at a , the parts of the ball and of the ball-path which actually roll on each other may be considered to be small portions of a pair of cones having a common vertex, v_2 ; the ball B must therefore be rotating about the axis cv_1 . Consider the motion of the ball on the outer path D , a similar argument will show that if the relative motion at b be pure rolling the ball must be rotating about an axis cv_1 . But the ball cannot be rotating at the same instant about two different axes. The probability is that it does rotate about some axis cv , in which case slight spinning motions exist at a and b in addition to the rolling motion.

Two, Three, and Four Point Contacts.—In Fig. 1 each ball has two points of contact with

FIG. 3.

its paths. Fig. 3 shows a three-point, Fig. 4 a four-point contact bearing. The three-point

contact bearing has a considerably greater amount of spinning friction. The instantaneous axis of relative motion must itself pass through

FIG. 4.

the two points of contact of the outer path. But if only a pure rolling motion existed at each of these points the instantaneous axis must lie in the surface of the ball-path. There must, therefore, be a considerable spinning motion at each point, so as to bring the resultant motion to take place round the aforementioned axis.

One or two important points of comparison may be made between the two types of bearing. Fig. 5 shows three sections of a two-point bear-

FIG. 5.

ing. The first section shows the line of contact making an angle of 45 deg. with the axis. The second section shows the inner path of exactly the same dimensions as in the first case, the outer path of exactly the same outline, but with its diameter a little less; the effect is to bring the line of contact nearly perpendicular to the axis. The third section shows the outer ball-path a little larger in diameter than in the first; the effect is to bring the line of contact more nearly parallel to the axis. In the second case there is little or no resistance to end thrust, and the balls may actually jamb between the ball-paths, developing pressure sufficient to break one or other. In the third case the wedging action of the bearing is greatly intensified, and the total pressure on the balls may be three or four times that due to the transverse load on the bearing. In a three-point bearing, the cone being straight-sided, if any deviations be made from the normal size of the cone or cup, no alteration is made in the direction of the line of contact, and no evil effects arise.

Nomenclature and Classification.—The inner ball-path is usually termed a *cone*, the outer ball-path a *cup* or a *disc*. The inner portion of the bearing I shall call the *spindle*, and the outer portion, the *barrel*. In wheel hubs, the barrel rotates, in pedals and crank-brackets, the spindle rotates. From Figure 1 it is easily seen that the adjustment of the bearing can be obtained by moving one of the four ball-paths; we, therefore, have two types of adjustment, *cone-adjusting* and *cup-adjusting* bearings.

FIG. 6.

Figures 6 and 7 show two types of bearing; in Fig. 6 the cups face outwards; in Fig. 7,

FIG. 7.

they face inwards. Some important properties of ball-bearings, which I shall refer to presently, depend on the direction in which the cups face; I have, therefore, called them "outward-cups" and "inward-cups" bearings respectively.

Pressure on Bearings.—It is well known that owing to the slope of the ball-paths, there is a kind of wedging action in ball-bearings, so that the total pressure on the balls is greater than the external load. Figs. 6 and 7 show the direction of the pressures. In a pedal or in a front-wheel hub where the load comes exactly at the middle of the length of the bearing the pressures on the balls will be the same for outward-cups and inward-cups bearings, provided the slope of the paths be the

same in both. The point *f* where the line of contact of the balls cuts the axis, may be called the "point of virtual support" of the bearing, and the distance between these two points for the two ball rows may be called the "virtual length" of the bearing. It will be noticed from the diagram that provided the actual distance between the ball rows be the same in both cases, the outward-cups bearing has a much greater virtual length than the inward-cups bearing. The model illustrates this point very well. I have here what is practically a hub with very large ball-races, at present it is arranged as an inward-cups bearing (Fig. 8), and the two points *f*, for each row of balls coincide at the middle of the bearing, the virtual length is therefore zero, and the bearing as you see, has no lateral stability; it constitutes, in fact, a universal joint. Its lateral stability is increased by either moving the ball-races closer together or further apart.

Mr. Ackermann will now remove the central distance piece, and bring the ball-races as close together as the model permits. The pressure lines from the two rows of balls now cross, as indicated by the dotted lines (Fig. 8);

FIG. 8.

FIG. 9.

and, as you see, the bearing has now a fair amount of lateral stability. The model may

now be arranged as an outward-cups bearing, and keeping the same distance between the ball-races, as in the first experiment, the virtual length is greatly increased ($f_1 f_2$ Fig. 9); and, as you see, the bearing is very stable laterally.

Pressure on Crank-axle Bearings.—In a bearing where the pressure is applied outside the ball-races, as in the case of a crank-axle, the actual pressures on the rows of balls is very much less with outward-cups than with inward-cups. At present, it is almost the universal practice of English makers to have the crank-bracket bearing with inward-cups, but many American makers, and one or two English makers (Messrs. Rudge-Whitworth, Limited, and Messrs. Ryley, Ward, and Bradfield, makers of the "Tribune" cycle) make outward-cups crank-bracket bearings. It is instructive to look at the diagram illustrating the directions of the pressures on the pedal and on the bearings of the crank-bracket.

FIG. 10.

Fig. 10 shows diagrammatically a crank-bracket with the pedal pressure P applied at some distance outside both rows of balls. The pressure on the near row of balls will be confined to two or three balls near the bottom, and the direction of the resultant F_1 will practically coincide with the line of contact of the lowest ball. Now the axle is acted on by three forces, the pedal pressure and the resultant pressures F_1 and F_2 of the two rows of balls. Hence, by the well-known law quoted in all text-books of mechanics, these three forces must intersect at one point, and the direction of the pressure F_2 on the further row of balls is determined. F_2 passes through the point of intersection of F_1 and P , and through the virtual support f_2 . Fig. 11 shows the force diagram drawn out, from which it will be seen that the pressure on each row of balls is very much greater than the pedal pressure P . The diagram is perfectly general, and can be applied to any case. I have here a wooden model, of about twice usual size, of an axle with a pair of loose cones which can be turned with their vertices out-

wards or inwards, and which illustrate experimentally the same facts. The cups are also of wood, and are not fixed in any way, but they are actually supported by a pair of pins projecting from the outer surface, the centre-line of the pin passing through the point of virtual support. One end of a spiral spring is attached to these pins, and the other to an adjustable screw bolt passing through a bracket fixed to the base of the apparatus. The only forces acting on each cup are the pressures of the balls and the pull of the spring; the latter, which is indicated at once in magnitude and direction, is therefore equal and opposite to the resultant pressure of the balls. The pressure corresponding to that exerted on the pedal is applied by a third spiral spring. On tightening up one or other of the springs, the axle with its bearings adjusts itself into its position of equilibrium. It has been tacitly assumed that the pressure on the ball-races is at right-angles to the axle; but if it be attempted to

bring this spring supporting the near cup any nearer the vertical, the cup at once tilts and does not remain concentric with the cone. The spring may be brought nearer the horizontal, causing the other spring also to

FIG. 11.

come nearer the horizontal. In fact, the direction of the resultant pressure F_1 , must be a line passing through the virtual support f_1 , and passing inside the ball-circle. The model is so arranged that the actual support can be

moved to the same plane as the ball-circles; in this case the cup tilts in the opposite direction.

The model is at present arranged as an inward-cups bearings, and for a pedal pressure of 15 lbs., the pressures on the ball-rows are 51 lbs. and 60 lbs. respectively. Mr. Ackermann will change it to an outwards-cup (cone-adjusting) type, and keeping the same distance between the rows of balls, we find that, for a pedal pressure of 15 lbs., the pressures on the ball-rows are 26 lbs. and 35 lbs. respectively.

The wall diagram or the model also shows clearly the effect of bringing the applied pressure nearer the ball-races. In the case of the pressure due to the pull of the chain, the pressure P may be applied very near the ball-race. If it be applied through the point of virtual support f_1 , the pressure on the further row of balls is not zero, as many people imagine, but is actually an end thrust in the direction of the axle. On applying a pedal pressure of 15 lbs., passing through the virtual supports, I find the pressures on the bearings 15 lbs. and 27 lbs. respectively.

In a one-row ball bearing, as in the Quadrant pedal, the lateral stability depends essentially on the geometric conditions I have been explaining. If the pressures were at right angles to the axis, the one-row bearing could have no lateral stability.

I have designed a ball-bearing, with the object of reducing the frictional resistances to a minimum. The main rows of balls run between concentric cylindrical paths, and have therefore no power of resisting end thrust. This is taken up by a third row of balls, or by a row at each end, making in all four rows of balls. The spinning friction in this bearing is therefore reduced to a minimum, and is due only to the end thrust, not to pressure on the axle or hub. If the resistance of a ball-bearing were about 100 times what it actually is at present, this type of bearing might be of practical value. But as the frictional resistance of any decently made ball-bearing is very small, the additional complexity probably outweighs any advantage.

Fig. 12 shows Garrard's bearing for larger and heavier work, in which the same principle is developed more fully. The bearing illustrated is for a shaft 2 in. diameter, and a number of balls, several gross, rotate between slightly conical ball-paths fixed on the shaft and bearing case respectively. Adjustment for wear is provided, and end thrust is taken up by the ball-thrust bearings at the ends.

Dust-proof and Oil-retaining Bearings.
—In comparing the two figures showing out-

ward-cups and inward-cups bearings respectively, it will be noticed that if oil be supplied to the middle, it will be retained in the inward-cups bearing. The inward-cups bearing is therefore oil-retaining. The best cone-adjusting hubs are at present made with down turned lips, so that they are made slightly oil-retaining. Dust-proof washers are often supplied, which completely block up the space between the cup and the cone.

FIG. 12.

[A number of lantern slides illustrative of hubs, bottom brackets, and pedals, by various makers, were shown on the screen.]

Disc-adjusting bearings were first used by Humber and Co. for the bottom brackets, and

FIG. 13.

by the Elswick and the Centaur companies for hubs. Fig. 13 represents a section of the

Humber bottom-bracket bearing. Fig. 14, a view of the Elswick hub, with disc, washer, and locking-ring separate. The washer fits loosely on the disc, and when the latter is properly adjusted, one of the holes in the

on a hollow spindle; the inner spindle fastening the hub to the frame can be withdrawn without disturbing the adjustment of the bearing, and the wheel can then be easily removed from the machine.

FIG. 14.

washer engages with a short pin projecting from the hub; the disc is thus prevented from turning. The locking-ring binds all firmly together. Fig. 15 is a view, partly in section, of the Centaur cup-adjusting pedal.

FIG. 15.

Figs. 16 and 17 are views of outward-cups crank-axle bearings used in the Rudge-Whitworth and Rambler bicycles respectively. The latter is cone-adjusting, the former cup-adjust-

FIG. 16.

ing. In the Rambler bicycle, one of the cranks is forged in one piece with the axle. The other crank is cotteder, and has three claws projecting from its boss to carry the chain-wheel, Fig. 18 (p. 773) is a section of the B.S.A. ball-head, a special feature of which is the spherical seatings for the ball-races.

Fig. 19 (p. 773) is a section of the Quick Detachment hub, in which the cones are formed

Wheels.—Most carriage and vehicle wheels are made with wooden spokes uniting the hub to the rim; the rim is made of segments of wood, and the whole construction is secured by an iron tyre shrunk on the wood rim. An initial compression is thus induced on the spokes, which is balanced by a circumferential tension on the combined rim and tyre. In bicycle wheels the stress conditions are reversed; the spokes are made of thin wire incapable of resisting compression. They are screwed up until a certain tension is obtained,

FIG. 17.

which induces a circumferential compression on the rim. Direct-spokes run radially from the hub centre to the rim. A direct-spoke wheel is quite satisfactory for the purpose of transmitting the load from the axle to the ground. But for driving, the direct-spoke wheel may not be rigid enough tangentially. If a driving effort be applied to the hub of a direct-spoke wheel, the hub rotates and the rim lags behind, until the centre-lines of the spokes all become tangential to a very small

circle. The driving moment applied to the wheel must be equal to the product of the total pull on all the spokes multiplied by the radius of this small circle.

FIG. 18.

In a tangent-spoke wheel the spokes are arranged tangentially to a circle of considerable size as compared with the aforementioned one; and if the initial pull on the spokes be the same for all, one half are pulling at the rim tending to drive it forward, the other half tend to drive it back. The driving effort is transmitted by the pull on one set of spokes being slightly increased, that on the other set slightly decreased. For a given driving moment the stress on the spokes may be very much less than in the direct-spoke wheel.

FIG. 19.

Spread of Spokes.—If the spokes of a tension-wheel all lay in the same plane, the wheel would have very little lateral rigidity; any couple tending to move the spindle would distort the wheel. When the spokes are spread out at the hub, a bending-moment applied at the spindle would have the effect of increasing the pull on one pair of opposite spokes, and diminishing the tension on the other pair.

Rims.—The lateral spreading of the spokes of a wheel should be looked upon as a means of connecting the hub rigidly to the rim, rather

than of giving the rim lateral stability relative to the hub. The rim must be of a form possessing sufficient lateral stability in itself, otherwise it cannot be built up into a good wheel. The lateral components of the pulls of the spokes tend to bend the rim sideways. If the rim be very narrow, as was the case with the solid tyres of the past decade, the liability of the rim to buckle is greater than with the wider rims used for pneumatic tyres.

[Specimens of rims, spokes, hubs, &c., by the Cycle Components Manufacturing Company, the Birmingham Small Arms Company, and the Jointless Rim Company, were exhibited. The rims made by the latter company are each cut from two square pieces of flat sheet steel, which undergo a process of spinning, until the required section is obtained; the two parts or rings are then soldered together. Also specimens of the Westwood, Hollow, Jointless Hollow, and C. C. Hollow.]

Wood Rims.—The question of wood *versus* steel for wheel rims is one that is not clearly understood, even by many engineers; but the mechanical principles involved are very simple. The strength of a rectangular beam subjected to bending is proportional to its width, the square of its depth, and to a coefficient depending on the strength of the material. The width of the rim for a pneumatic tyre must be practically the same whether wood or steel be used. I have here two beams of wood and steel respectively of equal width, length, and weight. It will be noticed that the steel beam is hardly strong enough to support its own weight, whereas the wooden beam is much stronger and stiffer. Roughly, the strength of steel may be taken 10 times that of wood. But the weight of steel is 10 times that of wood, and consequently, if the two beams be of the same weight, the wood beam is about 10 times as deep as the steel beam. So that, due to the increased depth, the strength of the wood beam is 100 times that of the steel beam, but, due to the smaller strength of the material, its strength coefficient is only one-tenth; the final result being that the wooden beam is about 10 times the strength of the steel beam of the same width and weight. Of course, no bicycle rim is exactly rectangular in section, and by curving the section, the strength of a steel rim is increased; so that comparing actual bicycle rims of steel and wood, the difference in strength may not be nearly so great as the above figures (for rectangular sections) show.

Materials.—To deal thoroughly with the subject, "Materials of Cycle Construction,"

would require a separate course of lectures; I can only refer briefly to the strength of some of the more important materials. If a load be applied at the end of a bar, and be gradually increased, the bar will ultimately break. If the bar be of one square inch section, the load on it at the instant of breaking is called the breaking tensile strength of the material. The effect of small loads on a bar is to distort its shape; if the stress applied does not exceed a certain amount, the bar recovers its original shape when the stress is removed. The elastic strength of a material is this limiting stress, and of course in any structure intended to last for a considerable time it should never be exceeded. If the elastic strength be exceeded, the deformation is more or less permanent, and the period of ductility or plasticity is reached. Now, steels of strength varying from 25 to 75 tons per square inch are used by engineers every day. Steel rails have an average strength of about 50 tons per square inch; the steel used in steam boilers, or for large bridges, has a strength of 26 to 30 tons per square inch. The question at once arises—why is the strongest steel not always used? This question can be better answered after having discussed the amount of mechanical work done in loading a bar. In loading a bar up to its elastic limit, the bar stretches slightly, and the applied load moves through a certain distance. The work done is a measure of the resiliency. The chief function of springs is the absorbing or storing up of a certain amount of energy or mechanical work, and restoring it again. When the elastic limit is exceeded, the stretch of the bar is much greater, and the amount of work required to actually break it is considerable. The relation between the stress, the deformation, and the work done on a bar can be best represented by a stress-strain diagram. In Figure 20, the stress on a bar at any instant is represented by the vertical ordinates, and the corresponding elongation by the corresponding abscissæ. Confining our attention to the stress-strain diagram for mild steel, curve A, as the load is gradually increased from zero up to about 30,000 lbs. per square inch, the elastic extension of the bar is proportional to the load. The total elastic extension, however, is so small (about 1-100th of an inch in a bar 10 inches long) that this portion of the stress-strain diagram practically coincides with the vertical axis. On further increasing the load, the elongation takes place at a quicker rate until when the stress indicated by the point *b* is

reached, the material yields suddenly a considerable distance without any increase of applied stress. This goes on until the point *c* is reached, when to produce further elongation, a further increased stress is required. The relation between stress and strain is then indicated by the line *c d e*, *e* indicating the breaking point of the material, giving an elongation of about 25 per cent. of the original length of the bar. The work done in breaking the bar is indicated by the area between the base line of the diagram, the stress-strain curve and its ordinates, and may be said to be a measure of the toughness of a material. In a material like hard tempered steel there would be little or no elongation before fracture; and although its strength

FIG. 20.

might be very great, its stress-strain diagram would be a line lying very close to the vertical axis, the work done in breaking it would be very little, and a slight concussion might be sufficient for fracture. Curve B shows the stress-strain diagram for a solid-drawn steel tube. Curve C that for the helical tube used by the Premier Cycle Company; this has a high tenacity, and a comparatively large amount of work is required to break it, it is therefore a very suitable material for cycle frames. Nickel steel has a very high tenacity, and a fair amount of elongation before fracture. Aluminium-bronze contains a very small proportion of aluminium, and is therefore a heavy alloy. Alloys containing a large per-centage of aluminium, and therefore light, have very low strength. Curve D shows the stress-strain curve for pure aluminium; a glance at the various

urves will show that aluminium is utterly un-
suitable for use in a cycle frame.

Malleable Cast Iron is used by our best
bicycle makers for the lugs of the frame.
Ordinary cast iron is a material utterly un-
suited for use in a cycle frame; but by a pro-
cess of cementation in furnaces extending over
a period of 7 to 14 days, the castings are con-
verted, by the removal of the contained carbon,
into malleable iron, a material having quite
different physical properties. The malleability
can easily be demonstrated by smashing under
a hammer. Makers interested in steel stamp-
ings or sheet steel lugs, sometimes try to throw
discredit on malleable cast iron lugs, but if
properly made they answer their purpose
wonderfully, even if they are a trifle heavier than
sheet steel lugs.

[*Sheet Steel Lugs*, by the Cleveland Machine
crew Company, and by the Gormully and
Jeffery Manufacturing Company, as used in
the "Rambler" bicycle, were exhibited; also
a number of internal liners, for reinforcing the
tubes of the frame.]

Miscellaneous.

BUDAPEST ACETYLENE EXHIBITION AND CONGRESS.

An International Exhibition of Acetylene Appa-
ratus, combined with a Congress lasting five days,
for the reading and discussion of papers dealing with
the new industry, was held at Budapest last May.
The Exhibition seems to have received more "official"
recognition than is given in similar cases in this
country, for it was formally opened by the Hungarian
Minister of Commerce, while a Secretary of State, a
Privy Councillor, and a member of the House of
Magnates took part in the inaugural ceremonies.
According to the catalogue, eighty-six firms exhibited,
including twenty-four from Germany, seventeen from
France, twenty-eight from Austria-Hungary, and the
remainder from England, America, Holland, Italy,
Russia, Sweden, Switzerland, and Roumania. The
Exhibition was also more or less international in character,
for the principal European countries—except England
—were represented on that body. As the result of
their deliberations they distributed twenty-two gold
medals, twenty-nine silver medals, and eighteen
diplomas, of which one gold medal, two silver medals,
and one diploma fell to English exhibitors. Besides
the ordinary gas generators, there were on view a
number of other articles—purifiers and purifying
material, driers, burners and burner fittings, portable
lamps for cycles and carriages, samples of carbide,
and models and diagrams of electric furnaces. With

few exceptions, the apparatus, lamps, &c., were
exhibited in actual work, so that the public should be
in a better position to judge of their practical merits.

The general appearance of the stalls showed that
great advances had been made in the construction of
generators and kindred appliances during the year
which had elapsed since the previous Exhibition held
in Berlin in 1898; "freaks" were less conspicuous,
the use of thin tin plate was far less common, much
heavier metal was employed, and the machines were
built more scientifically and mechanically. Indeed,
according to a German writer, the 1898 Exhibition at
Berlin appears to have been a little "too previous;"
many of the generators were very faulty, the burners
smoked, purification had not been investigated, and
the general result was calculated rather to warn away
possible purchasers than to make them enamoured
of the new method of artificial illumination. But
although progress during the last twelvemonth was
evident from an inspection of the Budapest Exhi-
bition, with the solitary exception of France, it was not
so marked in other countries as it would have been
had the budding industry not been crippled by the
insufficient supply of, and exorbitant prices demanded
for, carbide all the past winter. Many fresh works
have already been constructed, others are still in
course of erection, and before the long evenings come
again, it is hoped that calcium carbide will be pro-
curable without difficulty, and that its price will have
settled down to a level corresponding more fairly to its
actual value as deduced from the energy, &c., consumed
in manufacturing it.

For the first time, so it is stated, the whole of the
Exhibition at Budapest, indoors and out, was lighted
by means of unprotected flames of acetylene made by
the competing firms, some 2,500 burners being em-
ployed, which absorbed about 3 cwt. of carbide per
hour. As pointed out by a critic on the spot, this
arrangement, though perhaps a trifle dangerous in
view of the number of generators shown in actual
operation, was only judicious; for if the authorities
of an acetylene exhibition act as though they were
frightened of their own gas, how shall they persuade
the public to adopt it?

The papers read during the Congress were of two
classes, a series of popular lectures were given on the
properties and use of acetylene by various authorities
in order to disseminate correct information among
the visitors; and a number of technical communica-
tions on points of interest to the carbide manufacturer
and generator maker were delivered by experts from
several countries.—*Engineer.*

ELECTRIC POWER AT NIAGARA.

Professor George Forbes, F.R.S., who read a
paper before the Society on December 14th, 1892, on
the "Utilisation of Niagara," has written the follow-
ing letter from Niagara to the editor of *The Times* on
the recent development of the enterprise:—

"It was with unmixed pleasure that I have been able to pay a long-promised visit to Mr. W. B. Rankine, one of the vice-presidents of the Niagara Falls Company, to see how the commercial developments at Niagara were progressing; and I believe that a concise statement may be of interest to your readers. In June, 1892, and again in December, 1894, when the first works were nearing completion, I gave in *The Times* some account of what was being done, and since then the public has taken much interest in similar electric developments of water-powers.

"It is 4½ years since I was last here, and the first thing to strike one is the great number of enormous new factories which have been established on the company's land. Nearly every one of these consumes a very large amount of power, as is shown by the following statement, which any one can verify, showing the names of the factories and the amounts of power used in each:—

	h.p.
International Paper Company.....	7,200
Pittsburg Reduction Company (aluminium) ..	3,950
Carborundum Company	1,000
Buffalo and Niagara Falls Electric Light Co..	500
Electro - Chemical Company (peroxide-of-sodium)	400
Buffalo and Niagara Falls Electric Railway..	200
Niagara Falls and Suspension-bridge Railway	250
Buffalo and Lockport Electric Railway	350
Oldbury Electro-Chemical Company.....	1,000
Mathieson Alkali Works.....	2,000
Cataract Power and Conduit Co. (Buffalo) ..	3,000
Tonawanda Power Company	500
Union Carbide (of Calcium) Company	10,000
Surface Coating Company (enamelling)	20
Niagara Development Company (workmen's dwellings)	75
Niagara Waterworks	45
Total	34,590

"To these additions are to be made in October, and two new works, the Atchison Graphite Company and the Lead Reduction Company (Litharge), will be supplied, bringing the total up to 45,190 horse-power contracted for, bringing in an income of over £150,000. The operating expenses do not exceed £25,000 per annum.

"This is a most interesting result in three ways—(1) It shows that the original promoters were right in believing that the locality, with cheap railway transport, was favourable; (2) it shows that the general plan of the works, by which any customer could have any kind of electric current he desired, has been appreciated; and (3) it gives an indication of the enormous strides which have been taken of late years in electro-chemical and metallurgical processes.

"Regarding the machinery, the dynamos, which were totally new, not only in size but in their general design, never give the slightest trouble; and the transformers, ranging up to 2,500 horse-power, have answered their purpose perfectly, even with the low

frequency of alternations, which was generally condemned by theorists when I introduced it, but which is recognised now by every one at Niagara as contributing largely to the success of the scheme. The rotary transformers, for converting alternating into continuous current, which are used for nearly half of the power, gave some trouble at first, being the first which had ever been commercially used. But the difficulties have been successfully met. A good deal of the other machinery was of a new character, and bold in design, but has generally worked well. The setting-up and working of the transmission line to Buffalo reminds one of the earlier electric light stations in the United States, but this is bound to be one of the most important applications in the future.

"The general conclusion arrived at, after thoroughly inspecting everything under the best auspices, is that the boldness of the originators of the scheme has been justified, and that the wants of manufacturers which require power in any form can be supplied. It must be remembered, however, that much depended upon the favourable locality, and this warning may be given, that it would be rash to develop a large water-power in this way without demands for power. At the inception of all these schemes there is one thing more important than overcoming the engineering difficulties, and it consists in ensuring the support of those who require large quantities of power, electrical or mechanical."

LAC AND ITS SOLUTIONS.

The British Journal of Photography contains an article on this subject, from which the following extracts are taken. The article is written in reference to the use of lacquer for photographic lenses and camera fittings, and was suggested by a letter from a correspondent asking for particulars in regard to lacquer. "Up to a few years ago," says the correspondent, "we were able to make an exceedingly good lacquer for our brasswork, the colour was peculiar, and was much admired for our class of work. The last few years, however, we have had great trouble with our lacquer; in the first place, the druggists refused to let us have the spirit unless there was something put into it, and we had to get the lacquer made up by the druggists. Now, however, we have got a license from the Excise people, in order to get the spirit ourselves, and yet we cannot get the same class of lacquer we got in former years. . . . Some twelve or fifteen years ago I tried a great number of experiments about lacquer, and used all sorts of colouring materials, but I found that although I could get almost any colour I liked with suitable dyes, these colours were liable to fade. . . . I finally got the very best result by using nothing but seed-lac . . . a beautiful lacquer, just the colour we wanted. . . . I have tried various specimens of seed lac lately, and can get nothing like the old result," &c.

Before solving this riddle, which we think we shall

to readily, we should like to refer a little more in detail to the varieties of lac found in commerce. It is a rather singular fact, in connection with an article of such importance as lac, that the literature on the subject should be so sparse and the facts so variously stated. It is known to be associated with the life history of a little insect. The insect appears in vast numbers on the small twigs and branches of certain trees; the insects die after depositing eggs, and the twigs are found covered with an incrustation variously stated to be dead bodies of the female insects, a secretion exuded by them, or an exudation from the tree caused by punctures made by the insects. This we may leave to be settled by experts. The incrustation is there, and the twigs which they cover are collected. These twigs are termed "stick-lac." Seed-lac is the name given to the incrustations after being removed and triturated in a mortar, with the double object of dissolving the colour out of them (which colour is the basis of the famous lac dye) and reducing the little lumps to small pieces. Seed-lac forms the principal ingredient in many of the older recipes for lacquer at a time when methylated spirit had not been devised. Now, unless the natives have invented factitious seed-lac, it is quite evident that seed-lac at the present time cannot be any different from what it was fifty or a hundred years ago, so that any difficulty in making lacquer must be sought elsewhere.

Incidentally let us describe the production of shellac. The seed-lac is collected and placed in canvas bags, which are heated sometimes before a charcoal fire, and at others over a fire. When heated to melting, the bags are twisted, and the lac drops out. If received into water, it forms "button lac." When smeared, so to speak, over the smooth surface of a portion of the plantain tree, it hardens and flakes off in the form of shell-lac. This shellac is of various degrees of translucency and colour. The finest is known as orange lac, and its quality is gauged by its glass-like transparency and the lightness of tint. The poorer qualities, as before described, are called "ruby," "garnet," &c., according to the depth of colour. "Lump-lac" is simply a melted agglutination of seed-lac. We have thus a complete key to the colour, and an explanation of the preference given to seed-lac. It is unaltered by the hand of man, and so possesses the virtues of gum-lac in the highest degree, and is accompanied by a portion of the original colouring matter, which is nothing but the well-known lac dye, one of the fastest of red dyes—the material used for dyeing the best quality of the soldiers' "red coats." The old lacquer makers preferred to modify and deepen this colour by adding various vegetable colours, notably gamboge, annato, saffron, and very frequently aloes. Many makers added sandarac and other gums to their lacquer to add to its brilliancy, though we are inclined to think that any addition whatever reduces its resistance to mechanical injury.

There is then only the solvent left to consider, and here we do not doubt the key to the mystery is to be

found. Our correspondent is probably unaware that the methylated spirit of to-day is different from that of a dozen years ago. The new kind, as we have often stated, is made by adding a light petroleum oil to ordinary alcohol, the mixture being incorrectly termed "methylated." This name is only truly given to the old kind. The addition to the alcohol in that kind consisting of methyl alcohol, known also as wood spirit, wood naphtha, pyro acetic spirit, &c. If our correspondent will ask the Inland Revenue authorities to revise his license and alter it to a permission to use the old kind of methylated spirit, we think all his difficulties will vanish. With regard to the solvents, there can be no doubt that something beyond a mere solution of the lac is needed, for it is well known that the users of French polish prefer either all wood naphtha, or a least a large proportion of naphtha in the liquid they use. Finally, we append two very old and tried recipes for lacquers of different colours, which we know were in use more than half a century ago:—

Shellac	120 parts.
Sandarac.....	45 "
Mastic.....	30 "
Amber	30 "
Black resin.....	90 "
Dragon's blood	30 "
Turmeric.....	30 "
Gamboge	30 "
Rectified spirit	1000 "
Shake occasionally till dissolved and strain.	
Seed-lac	120 parts.
Gamboge	120 "
Dragon's blood	120 "
Saffron	30 "
Rectified spirit	1000 "
Put in a hot place, stir at intervals, and filter.	

HIGHER EDUCATION OF WOMEN IN GERMANY.

The movement in Germany to open new callings for women, and to make them economically independent, has, during the last few years, met with marked success. In various cities, societies have been formed for the establishment of girls' colleges. H.M. Consul-General at Frankfort says that in Karlsruhe there is already such an institution. Also in Cologne, a society, "Verein Mädchen Gymnasium," is planning the organisation of a college with nine classes for girls, the sixth class of which is to be opened in 1900. In Hanover a girls' college is to be opened, which, as a commencement, is to begin with the upper third class. The school fees are to be 100 marks (£8). The object of the school is to enable pupils to pass the matriculation examination for admittance to the universities. The Senate of the University of Giessen has decided by a large majority to admit women as students, and also to attend different lectures as if they had matriculated. A

necessary condition is the certificate of having passed the examination at a gymnasium, or "real gymnasium," viz., a school of first rank. At the University of Berlin, at the commencement of 1899, the first female was presented with her doctor's diploma. It appears that general regulations regarding the admittance of women to regular study is now imminent in Germany, inasmuch as the various separate societies have pronounced themselves in its favour.

THE MINERAL PRODUCTION OF CANADA IN 1898.

An interesting summary of the mineral production of the Dominion of Canada for 1898 has been issued by the Canadian Geological Survey; and in a recent report, the United States Consul at Toronto states that although the returns are not yet all in, the summary shows that the output for the year 1898 is considerably in excess of that of the previous year. Of the total output of metallic products, valued at £4,323,000, £2,750,000 was gold, £2,000,000 of this representing the yield of the Yukon district. Silver (fine, in ore, &c.) was produced to the value of £516,000. The other metals were copper (fine, in ore, &c.), £430,000; nickel (fine, in ore, &c.), £365,000; lead (fine, in ore, &c.), £240,000; and iron ore, £30,000. The output of non-metallic substances was £3,177,000, of which coal represented more than half, viz., £1,650,000. Building material (including bricks, building stone, lime, sand, gravel, and tiles) was valued at £720,000; petroleum, £196,000; asbestos and asbestic, £97,000; and Portland cement, £196,000. The estimated value of the mineral products not returned is put down at £50,000, thus bringing the total value of the mineral product of the country last year to £7,550,000, or £1,820,000 more than 1896, when the value was £5,730,000. There was an increased output of coal in all the different districts, and a gain of 50 per cent. in the output of copper in the province of Ontario. There has also been an increase in the output of nickel, but a decrease in lead, silver, and asbestos.

Obituary.

ROBERT WILHELM BUNSEN, FOR. MEMB. R.S.—The renowned chemist Bunsen died on the morning of the 16th inst. at the great age of 89. He was born in 1811, and graduated at the University of Göttingen as Ph.D. in 1831. He succeeded Wöhler as Professor of Chemistry in the Polytechnic School at Cassel in 1836, and after several changes he was appointed to the chair of experimental chemistry at Heidelberg in 1852, and he remained there in spite of an invitation to Berlin until his resignation in 1889, after which he lived in retirement at Heidelberg. Bunsen's fame is so wide and his biography has been so often written that it is unnecessary to enumerate here his claims to distinction. It will suffice to

enumerate some of the honours awarded to him in England. He was elected a Foreign Member of the Royal Society in 1858, and in 1860 the Copley Medal was presented to him by that body. The first award of the Davy Medal in 1877 was jointly to Bunsen and Kirchhoff for their researches on the solar spectrum. He was elected an Honorary Corresponding Member of the Society of Arts in 1896, and last year the Albert Medal was awarded to him "in recognition of his numerous and most valuable Applications of Chemistry and Physics to Arts and Manufactures."

COLONEL WILLIAM ROWE LEWIS.—Colonel Lewis, of the Sussex regiment of Artillery, an Commandant of the Sussex Artillery Volunteers, died on the 3rd December, 1898, at the age of 71 and was buried in the picturesque churchyard of Sedlescombe. He commenced life as a Civil Engineer, and was a pupil of Brunel, but he left the profession early in life, and settled at his home at High Beach, near Battle, as a country gentleman. He was a Justice of the Peace, Chairman of the School Board, member of the County Council and of the Highway Board. He was greatly interested in literary and scientific questions, and was a member of several societies. He was elected a member of the Society of Arts in 1884.

WILLIAM SIMPSON, R.I.—Mr. Simpson, the well-known artist and foreign correspondent, died on Thursday, 17th inst., at his home at Willesden. Although he was not a member of the Society of Arts, he was an active member of the committee of the Applied Art Section, and took a great interest in the work of that Section. He was born at Glasgow, October 28, 1823, and was employed by Messrs. Day and Son in London in 1851 as a lithographic artist. On the outbreak of the Russo-Turkish War in 1853, he proceeded to the Crimea to make sketches of the campaign, and his lithotints of the Seat of War, which were published in two folio volumes, and are now highly valued as a fine historical example of book illustration, ranking by the side of the beautiful work of David Roberts in the Holy Land. In 1866, he joined the staff of the *Illustrated London News*, and he remained connected with that paper until his impaired health compelled his retirement. He was at the fall of Sebastopol, at the opening of the Suez Canal, and at the capture of Magdala. He was in China in 1871-2, and visited the Great Wall. He accompanied the Prince of Wales to India in 1875, and in 1877 he visited Mycenæ and the Troad. Mr. Simpson read several papers of interest before the Society as follows:—In 1872, "Symbolism of Oriental Ornament;" in 1878, "Mycenæ, Troy, and Ephesus;" in 1879, "Archeological Vestiges in Afghanistan;" in 1886, "Experiences on the Afghan Frontier;" in 1888, "What Style of Architecture shall we follow;" in 1891, "Lithography, Finished Chapter in the History of Illustrative Art;" and in 1892, "Mud a Material in Persian and Eastern Architecture." He received the Society's silver medal for the paper on "Lithography."

Journal of the Society of Arts.

No. 2,441. VOL. XLVII.

FRIDAY, SEPTEMBER 1, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS, 1900.**

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

Proceedings of the Society.**CANTOR LECTURES.****CYCLE CONSTRUCTION AND DESIGN.**

BY ARCHIBALD SHARP, A.M.Inst.C.E.

LECTURE III.—Delivered March 6, 1899.**CRANKS.**

In modern bicycles, with very few exceptions, the power of the rider is applied to a pair of pedals carried at the ends of a pair of cranks. The length of the crank of the safety rear-driver has been, up till a year or two ago, usually from 6 to 6½ inches; but recently, Mr. Crompton and Herr Blathy have experimented with much longer cranks, up to 9½ inches in length, with correspondingly high gear, and the results obtained have been such, that now long cranks can easily be obtained. It may be said at once that the question of the most suitable length of crank is a physiological one rather than mechanical. The claims advanced by the advocates of long cranks have been stoutly resisted by hard riders, who have been in the habit of using cranks of normal length. The latter contend that the increased sweep of the leg must conduce to stiffness, saddle sore-

ness, and a host of other imaginary evils. Many of them have actually tried the long crank, so that their opinions must be entitled to due consideration. The little personal experience I have had of the long crank has led me to look upon it with great favour. On four separate occasions I have had rides, varying in length from 40 to 70 miles, and on no occasion did I experience the discomfort predicted by the short crankists; on the other hand, I found the long slow sweep of the thigh a more exhilarating motion than that provided by the crank of normal length. It is possible that a hard rider, who travels 10,000 miles per annum, several years in succession, with 6½-inch cranks, gets muscle-bound; and does find a longer crank uncomfortable and inconvenient. His experience, however, may be utterly misleading as a guide for the average rider, who is content with 1,000 miles per annum, or less. The latter would get more quickly accustomed to long cranks than the former. Anyone who is disposed to experiment with long cranks and high gear, may safely do so without fear of being considerably out of pocket if the experiment ends in failure, as far as he is concerned personally. The long crank and high gear machine with its longer wheel base, and high crank bracket, makes an excellent machine for shorter cranks. Looking at the question mechanically, and regarding the legs and feet of the rider as a mechanism which in its working must absorb a certain amount of friction, the total work done by the rider may be divided into two parts, the external work communicated to the pedals, and the internal work absorbed in friction of the joints, muscles, and ligaments. Making reasonable assumptions, I have deduced figures which show a slight advantage in favour of long cranks, but so small, that the only safe deduction from my premises is that there is no reason why the long crank should not at least be as good as a 6½-inch crank. Fig. 1 is intended to show the extreme movement of the leg when pedalling with cranks of various length. The sixteen sketches are arranged in four columns showing cranks of 5, 6½, 8, 9½ inch cranks respectively. The four figures in the top row are drawn with the saddle in the highest possible position consistent with the rider reaching the pedal at its lowest point. An ankle action of 70° is assumed in each case, the length of the thigh from hip-joint to knee-joint is 16 inches, the length of shank from knee-joint to ankle-joint is 16½ inches;

the length of foot from ankle-joint to the centre of the pedal is 6 inches.

The angles swung through by the hip, knee, and ankle, are shown numerically in Table I., p. 781. If the internal work expended in swing-

the numbers so obtained are tabulated, and can be compared with each other.

It will be noticed, from Fig. 1, that while the knee moves from its highest to its lowest point, the crank in most cases moves through

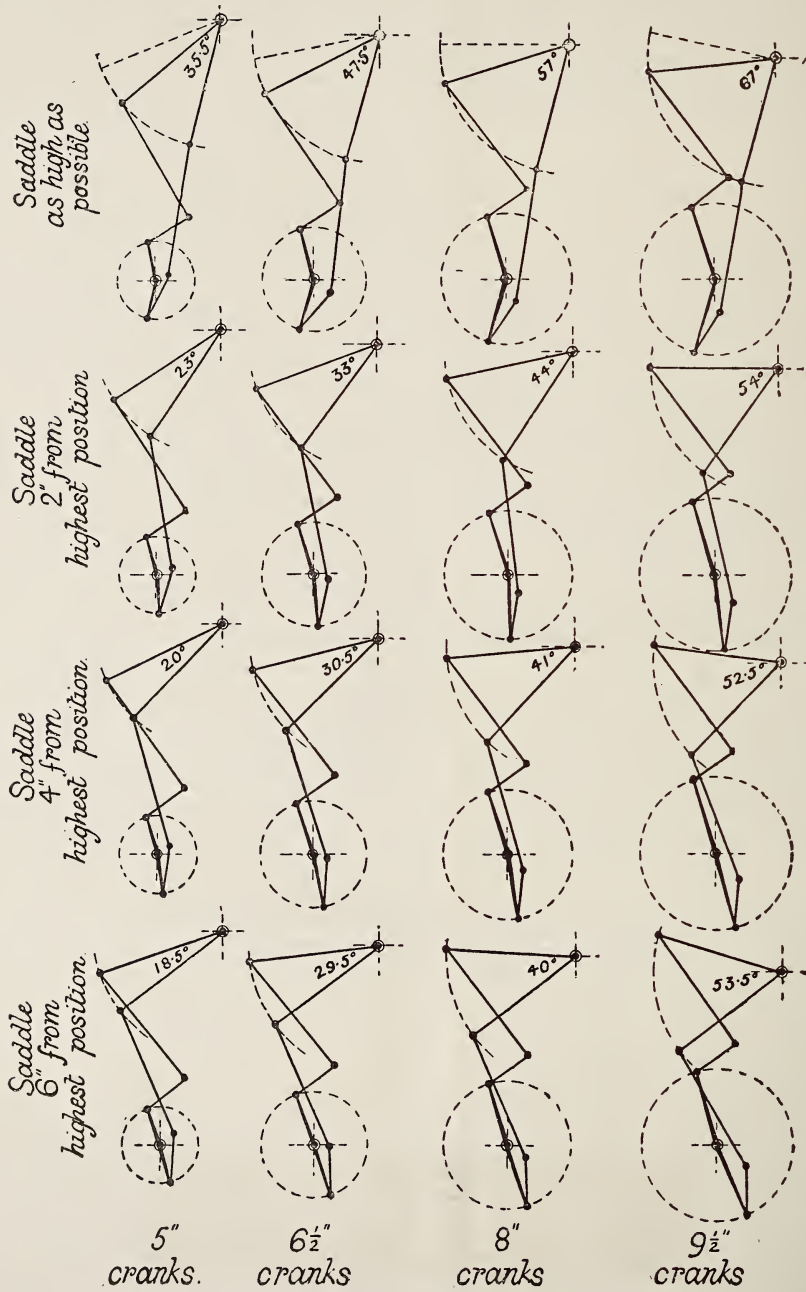

FIG. 1.

ing the ankle, knee, and hip joints through 1° be assumed proportional to 1, 2, and 3, the relative internal work for any case is found by adding together the ankle angle, twice the knee angle, and three times the hip angle;

less than two right angles. If the pressure applied to the pedal were always in the direction of the line joining the knee to the pedal pin; as would be the case with an inanimate arrangement of links and levers, there would be

TABLE I.
LEG AND ANKLE ACTION IN PEDALLING.

Saddle position.		5 in. cranks.	6½ in. cranks.	8 in. cranks.	9½ in. cranks.
Highest possible.	Hip angle degs.	35	47	57	67

	Per-centage loss ... °C	42	43	41	41

a period between the end of the driving action of one crank, and the beginning of the driving action of the other. This period has been called the "dead angle" by M. Bourlet ("Nouveau Traité des Bicycles et Bicyclettes"). It will be noticed that the dead angle is reduced by lowering the saddle, is zero for a 6½-inch crank with the saddle 6 inches below its highest possible position, and is actually negative for the 9½-inch crank with saddle 6 inches below highest position, in other words, the driving arcs for the two cranks overlap. Now I will not contend that the latter is therefore the best of the sixteen cases shown in Fig. 1, but I am inclined to believe from these diagrams, from my own riding experience, and from observations of the practice of racing men, that most cyclists, especially ladies, ride at present with their saddles too high for the best results.

the pedal end of the crank the principal straining action is a twisting-moment, and the best shape to resist this stress is circular. At the other end, the principal straining action is a bending-moment, and the best section to

FIG. 2.

resist this stress is rectangular. The sections a, b, c, d, may be said to be suitable, but the sections e and f are unsuitable, since the greater part of the material lies near the neutral axis of bending. The total weight of a crank, however, is so small, that manufacturing operations are perhaps the most important factor in their design.

CHAINS.

In nearly all modern bicycles the power has to be transmitted from the crank-axle to the hub of the driving-wheel, and the chain is the transmitter usually employed. The Morgan chain as used in the very early tricycles was made up of a series of tubular rollers alternating with links. Fig. 3 shows the block chain as made by Mr. Hans Renold. In the block chain the rivets uniting the pairs of side-plates rest in cylindrical bushes in the blocks of the chain. Messrs. Perry and Co. were the first to use specially hardened bushes of pen-steel, to protect the comparatively soft rivet from rubbing on the block. Fig. 4 shows diagrammatically the construction of the roller chain. In this, instead of a block, a pair of inner side-plates, which are united by a pair of tubular sleeves, are employed. The rivet uniting the outer

FIG. 3.

Fig. 2 shows the shapes of the sections of cranks — rectangular, round, oval, trough-shaped, diamond-shaped, and T-shaped. At

side-plates has this tubular sleeve as its bush. A live roller surrounds the sleeve and comes directly in contact with the teeth of the chain-

wheel. Thus the rubbing of the blocks along the wheel teeth with a block chain is replaced by the rubbing of the roller on the sleeve. The wearing surface, instead of being a narrow one near the end of the block, is distributed round

FIG. 4.

the entire surface of the roller. [Exhibit of chains.] In all roller and block chains of the usual type the rivet rubs on the block or the sleeve, as the chain bends or unbends in passing on or off the chain-wheels; this rubbing being of course accompanied by a certain amount of friction. In the pivot chain made by the Cycle Components Company, an attempt is made to eliminate this friction by the substitution of a knife-edge support for the rivets. The Morse chain (Fig. 5) is somewhat similar in design.

FIG. 5.

[An experiment was made on an apparatus lent by the Cycle Components Manufacturing Company, showing that the knife-edge friction was much less than that of a rivet in a cylindrical bush.]

Strength of Chain.—The side-plates of a chain are subjected to a tensile stress, the rivets and tubular sleeves to bending and shearing stresses. The side-plates should therefore be made quite straight, so as to resist the pull as directly as possible; similarly the rivet and sleeve should be made capable of resisting bending stresses. In the old roller chain 1 inch pitch, each half of the sleeve was made in one piece with the inner side-plate; consequently, if the rivet pressed uniformly on the sleeve, the line of pull of the inner side-

FIG. 6.

plate would not coincide with the middle of the side-plate. (Fig. 6.) In another form of 1 inch pitch roller chain, the side-plates were

cranked with the object of making all links exactly alike instead of alternately in pairs. Fig. 7 shows $\frac{1}{2}$ -inch pitch roller chain, as

FIG. 7.

made by the Garrard Manufacturing Company, and of which there are specimens on the table. In the best modern chains the side-plates are made quite straight with their axis of symmetry coinciding with the axis of the pull.

Stretch of Chains.—It is found that chains gradually elongate under the severe stresses to which they are subjected in ordinary working. The word "stretch" does not quite express what happens. Possibly there is little or no actual stretch of the side-plates, but the bearing pressure of the rivets and sleeves on the side-plates is so great that deformation gradually takes place, which in the aggregate is

manifested as an elongation of the chain. In the roller chain of $\frac{1}{2}$ -inch pitch the dimensions of the rivets and sleeves are possibly nearly as small as they can be made with a fair amount of durability. The roller chain of $\frac{3}{4}$ -inch pitch has much greater margin of strength in this direction.

Chain Wheel.—The teeth of chain-wheels perform quite different functions from those of spur and bevel gearing. If the pitch of the chain-wheels be exactly equal all that is necessary is that pockets for the blocks or rollers should be cut out below the pitch-polygon of the wheels. The portions of the teeth projecting above the pitch-polygon act nearly as guides for the chain so that the blocks or rollers enter the pockets properly. The function of the teeth is therefore analogous to that of a funnel used for pouring liquids into a narrow necked bottle. Fig. 8 shows the principles underlying the design of the proper shape to be given to the teeth of the chain-wheel; *a, b, c, d*, are centres of consecutive rollers in contact with the chain-wheel, they therefore form the corners of the pitch-polygon. As the motion of

the wheel continues in the direction of the arrow, the roller *a* will soon leave the wheel. The relative motion of chain and wheel will be the same if we consider the wheel fixed, and unwind the chain in the direction opposite to

FIG. 8.

the arrow. It will thus be seen that the centre of the roller *a* will move along the circular arc *aa*₁, having the point *b* as its centre. The links *ab* and *bc* being then in line, the further motion of the roller *a* is along the circular arc, *a*₁*a*₂, having the point *c* as a centre. Similar consideration will show that when the tooth gets near the on-coming chain the path of the roller *b* will be the curve formed by the series of circular arcs, *b*, *b*₁, *b*₂, having the centres *b* and *a* respectively. If a pair of curves be drawn parallel to those curves, the fullest possible tooth outline will thus be determined, as shown by the shaded outline. With such a tooth outline, the rollers will rub along the whole length of the tooth.

of the chain to mount the wheel. If the centres of the tooth-outlines be taken slightly inside the pitch-polygon the chain will enter and leave the wheel more freely, but if this be overdone the chain will tend to mount the wheel. Fig. 9 shows the tooth outline adopted by the Garrard Manufacturing Company for the teeth of wheels for their ½-inch pitch roller chain.

Variation of Speed.—The number of revolutions in a given time of the crank-axle and the back hub are inversely proportional to the numbers of teeth on their respective chain-wheels. But since the pitch surfaces of the chain-wheels are not circular but are polygons, the speed-ratio does not remain constant. In a roller chain-wheel with six teeth the variation of the speed is 7·8 per cent. With 12 and 24 teeth on the back hub the variation is 1·8 and 0·4 per cent. respectively.

Noise of Working.—Each link of the chain as it comes into contact with the chain-wheel strikes it with an appreciable speed. If the chain-wheel revolves in the direction opposite to the arrow (Fig. 8), the motion of the rivet *a*, relative to the chain-wheel as it strikes the latter is one of rotation about the centre *b*. Thus for a given speed of rotation, the shorter the links the less is the speed of striking, and the less is the noise of working. For a given pitch and speed of rotation the speed of striking is therefore independent of the number of teeth in the chain-wheel. This probably accounts for the smoothness of action of the ½-inch pitch roller chain.

Friction.—The frictional resistance of chain

FIG. 9.

The design of the teeth of wheels for block chains can be made in exactly the same way, the radius of the end of the block being taken instead of that of the roller. But as there is no necessity for the blocks rubbing along the whole length of the tooth, the points of the tooth can be reduced; if the centres for the tooth-outlines be taken a little closer together than the corners *b* and *a* of the pitch-polygon, the blocks will not rub along the teeth when the pitches of the chain and wheel are exactly equal. The outlines of the teeth at the pitch-polygon are still exactly perpendicular to the sides of the polygon, and there is no tendency

of the chain to mount the wheel. Reference had already been made to the rubbing of the rivets on the blocks or sleeves. The amount of this rubbing is quite definite, and during one revolution of each chain-wheel the rubbing of the rivets is equal to one rivet making a complete revolution in its block or sleeve. Then there is the *rubbing of the blocks along the teeth*. If the pitch of the chain and wheels be exactly equal this may be zero. With a new chain the pitch of the driver wheel is a little greater than that of the chain and the acting tooth is near the bottom (Fig. 10), and as the driver rotates, the block *a*₁ *a*₂ ultimately leaves the chain-

wheel and in so doing rubs along the tooth, *A*. When the chain has stretched so that its pitch

As the end, *a*, of the block leaves the seating of the chain-wheel (Fig. 10) the end *a*₂,

FIG 10.

is slightly greater than that of both chain-wheels the acting teeth are at the top (Fig. 11)

turns in contact with the tooth, *A*. During a complete revolution of the wheel the total

FIG. 11.

and the amount of rubbing of the blocks on the teeth is much less. Fig. 12 shows the block

friction due to this action is the same as if the end of the block turned through half a revolution in contact with the wheel. When the chain has stretched so that its pitch is slightly greater than that of the chain the acting tooth is at the top and there is no friction due to this cause. (Fig. 11.)

FIG 12.

end, *b*₂, just coming into contact with the tooth, *B*, and Fig. 13 shows it bedded on the seating.

Some experiments on the friction of chains have been made by Professor Carpenter who has found the frictional loss, in some cases, to be less than half of 1 per cent.

Gear-case.—The possible sources of frictional loss being so numerous, if the best results are to be obtained, the chain and wheels should be protected from mud, grit, and dust, and if possible should be surrounded by an oil-bath gear-case. A naked chain may absorb 4.7 per cent. of the rider's power, although it may not be very appreciable to him in ordinary riding.

FIG. 13.

Chain Adjustment.—Provision has to be made for adjusting the chain as it stretches. Fig. 14 shows the well-known eye-bolt and nut adjustment for the back-hub, as made by the

The blocks also rub along the seating of the chain-wheels if there be any difference in the pitches.

Cycle Components Manufacturing Company, Limited. Eccentric adjustment for the spindle

frame-tube, and neat gear-cases enclose both pairs of bevel wheels.

FIG. 14.

of the driving-wheel is being largely used. Fig. 15 shows the volute cam chain adjustment

FIG. 15.

made by the Birmingham Small Arms Company, Limited. In this a pair of volute cams are placed on the ends of, and turn with the spindle, and bear against fixed stops. The nuts at the ends of the spindle being loosened the spindle is turned, when the volute cams force it backwards, tightening the chain. The spindle is then locked in position by its end nuts.

In the Columbia chainless bicycle, the intermediate shaft rotates inside the frame-tube, and the front pair of bevel wheels are enclosed in the crank-bracket chamber, an outside bearing being screwed on the end of the crank-bracket chamber. The intermediate axle is inserted in position from the rear, hence the necessity for the short bridge-piece to carry the driving-wheel spindle.

The Sterling chainless gear differs from the Columbia mainly in the fact that the large bevel wheel is near the middle of the crank-axle, and therefore engages with the opposite side of the small pinion. The large crank-axle wheel being in this case on the opposite side of the intermediate shaft, as compared with the arrangement adopted in the Acatene and Columbia machines, necessitates the intermediate spindle being prolonged beyond the centre of the driving-wheel. With this arrangement both gear-cases can be incorporated with the frame of the machine. It has the further advantage that as the angle between the wheels of each pair is reduced, the relative

FIG. 16.

Bevel Gears.—Fig. 16 shows the Acatene bevel gear for bicycles. In this gear the intermediate shaft rotates on the outside of the

motion of the teeth on each other is less, and the friction of the gear is considerably reduced, as can be shown as follows.

In Fig. 17 two bevel wheels are shown in gear, rotating in the direction of the arrows A and B. The speeds of rotation (number of revolutions) are inversely proportionate to the

FIG. 17.

diameters, and can be represented in magnitude and direction by vectors a and b , in the directions of the shafts and of lengths proportionate to the speeds. The directions of the arrows a and b must be such that the rotations A and B appear either both clockwise or both counter-clockwise. Now the friction of the toothed wheels depends (other conditions remaining unaltered) upon the relative speed of the wheels. This can easily be found by supposing the whole mechanism, including the wheels and the frame, to be given a rotation equal and opposite to a . This is indicated by the vector a_1 . The wheel 1 will thus be brought to rest, and the wheel 2 will roll round it, its instantaneous axis of rotation being $v.p$. The rotation of the wheel 2 is now the resultant of a_1 , and the original rotation b , and is indicated in magnitude and direction by R_1 . If the speed-ratio and angle between the shafts be kept the same, but the wheel 1 be brought to the other side of 2, the resultant relation would be R_2 . Thus the ratio of the frictions of the Sterling and Columbia bevel gears is the ratio of R_1 to R_2 .

Cross-roller Gear.—The Quadrant cross-roller gear, of which there is a specimen on the table, may be described as a roller crown gear, consisting of a pair of discs from which pins project at right angles, each pin being surrounded by a roller. Fig. 18 shows a well-known case of two equal wheels with parallel shafts rotating in the same direction, and with their centres apart a distance equal to the sum of the radii of the pins or rollers. Similarly, Fig. 19 shows a cross-roller gear in which the kinematic action is exactly the same. It will be noticed on comparing these two figures that the same pair of roller wheels may be used in each case; so that the angle between the

shafts makes no difference in the condition of correct working, provided of course that the rollers are long enough to mesh with each other. This practically means that the adaptability and flexibility of the cross-roller gear

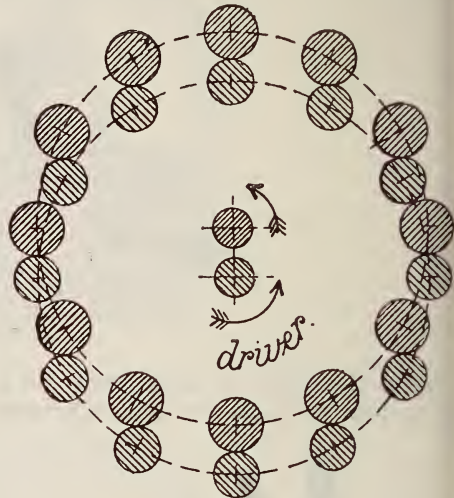

FIG 18.

exceeds that of any other mechanism used for cycle driving. This is a property of great practical importance, in so far that distortion to the frame either through careless workmanship or accident does not affect to any appreciable extent the easy running.

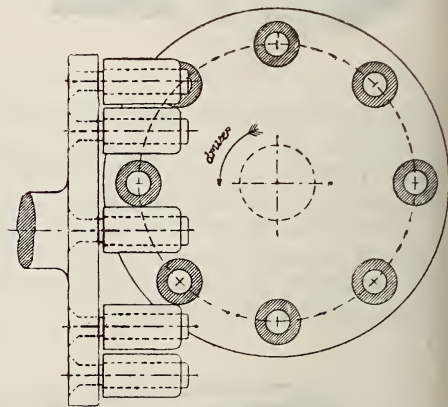

FIG 19.

As regards the frictional resistance, the only appreciable item is the rubbing of the rollers on their pins, and as they are always enclosed in neat gear-cases with a liberal supply of oil, under ordinary touring conditions, the cross-roller bicycle should compare favourably with the best chain-driven bicycle, and should be superior to a naked chain of whatever type. Fig. 20 shows a horizontal section of the gear.

FIG. 20.

A bevel roller gear, Fig. 21, was made a short time ago by the Wilkinson Sword Company, in which one wheel of each pair carried a series of rollers which geared with a solid toothed wheel. A pair of wheels each with circular teeth or

fastened to the hub, and a concentric toothed wheel fixed to the fork of the bicycle. When the speed ratio of the hub and axle is $2\frac{1}{2}$, the hub toothed-wheel is smaller than the fork toothed-wheel.

FIG. 21.

rollers will not gear together with exactly constant speed ratio. I have investigated the subject of designing wheels with circular teeth or rollers in which the variation of the speed ratio should be reduced to the smallest possible amount.* A bevel roller gear with 24 and 18 rollers respectively has a speed variation of 0.9 per cent.

Front-driving Gear.—Fig. 22 shows a view

FIG. 22.

of the Crypto epicyclic gear for front-driving bicycles. When the speed ratio is $1\frac{1}{2}$, a disc prolongation of the crank axle carries four small pinions which gear with a toothed wheel

Two-speed Gears.—The question of two-speed gears and free pedals depends largely on statistics. If a rider and machine weigh 200 lbs., and if the greatest comfortable pedal pressure be 75 lbs. and be exerted vertically downwards, a gradient of 1 in 10 can be climbed with a gear of 30 inch. Such gradients are rare, and therefore it may be said that under no conceivable circumstances can a gear lower than 30 inch be recommended. At the other extreme when running down a slight slope, or going along the level with the wind at one's back, the machine will run by itself, and if free pedals are provided, the feet may remain at rest. If the gradient be steeper, either back pedalling or the application of a brake is necessary. The resistances to be overcome in propelling a bicycle are due to (1) friction of the mechanism, (2) rolling resistance of the tyres on the ground, (3) vibration and jolting due to rough roads, (4) air resistance, (5) gravity when ascending hills (when descending hills gravity, of course, accelerates the motion). The best gear for a bicycle is that which will allow the rider to move his pedals at the speed most convenient for him developing his power, and at the same time proportion the speed of the machine to that of the pedals, so that the work done by the rider shall be just equal to that required to overcome the resistances. But

* "Proc. Inst. Civ. Eng.," vol. 121, pp. 237-279.

since four out of the five resistances enumerated vary considerably from moment to moment it follows that in the ideal bicycle the gear should also vary. A two-speed gear is not a mechanism transmitting more power to the driving wheel of a bicycle than the rider delivers to the pedals, it is simply the means of giving closer approximation to the ideal best gear under widely varying conditions than is possible with a single-speed machine. If the per-centage of time during which any particular gear is the ideal best could be tabulated it might be possible to arrive at a definite conclusion as to the best arrangement of a two-speed mechanism. In a two-speed gear the question of the ratio of the high and low speed is of importance. If the diagram shown were a fair representation of the requirements; two gears of 60 and 75 would be about the best. In the present form of the "Collier" two-speed gear the gear ratio is 20-17, giving a difference of 18 per cent. for the high above the low; this I find suits my own personal convenience for speeds of 12-14 miles an hour over the fairly level roads lying to the west of London. At lower speeds or in more hilly districts, a 25 per cent. difference is very suitable; while I think a difference of more than 33 per cent. cannot be advisable under any circumstances.

no appreciable change in the action of pedalling. In the Beaumont two-speed gear two chains are used.

An epicyclic gear in the back hub forms the basis of a great number of two-speed gears *e.g.*, the Reilly and Haigh, the Planet. In the Planet two-speed gear, made by Mr. Telford C. Field, Planet Works, Southampton the high is 58 per cent. above the low gear.

An internal gear, consisting of a spur pinion working inside an annular wheel, is the basis of the Collier two-speed gear, and of the Brown-Lipe gear fitted to Rambler bicycles. The former is applied at the crank-bracket and the internal gear is in operation at high speed. The chain-wheel turns on a ball-bearing at the end of the bracket, and the crank-axle is carried on a hollow axle, the centres of the axles being a short distance apart. At low speed the crank-axle, hollow axle, and chain-wheel are all locked together and rotate as one solid piece. Change from high to low speed can be effected at two points in a complete revolution of the pedals, from low to high at only one point.

Fig. 23 shows the Brown-Lipe two-speed gear at high gear, Fig. 24 at low gear; the former is 25 per cent. above the latter. The hub chain-wheel, 1, runs on a ball-bearing on an eccentric, 10, which turns on a portion, *e*,

FIG. 23.

The mechanisms of the two-speed gears in practical use at present are of three types. In one type the change of speed is effected by altering the number of teeth on the axle or hub chain-wheel. In the Protean gear (which gives four speeds) the number of teeth on the crank-axle chain-wheel is either 18, 19, 20, or 21, and can be altered while riding. The ratio of the highest and lowest gears is therefore 21 : 18; *i.e.*, the highest is 16.6 per cent. above the lowest gear. The chain-wheel is circular when 19 teeth are in operation, and slightly oval at the other speeds; but there is

of the spindle set eccentrically with the axis 8, of the hub, A B. Thus, the chain-wheel may be brought co-axial with the hub (Fig 24) or eccentric therewith (Fig. 23). In the latter position the annular wheel, 4, on the hub is driven at a lower speed than the chain-wheel by the internal pinion, 3. In the former position the narrow toothed-wheel, 2, fits into the corresponding toothed-wheel, 4, on the hub. In changing from one speed to the other, the eccentric, 10, has to be moved axially along the spindle, *e*, and in an intermediate position the chain-wheel is quite free

from the hub. The complex motion of the eccentric sleeve, 10, is obtained by means of a slotted cam in which a pin engages; the rota-

Free Pedals.—The greatest activity of cycle designers at present is manifested in free pedal devices, which have for their object the freeing

FIG. 24.

tion of the eccentric is effected by a rack operated by the rider, and engaging with the toothed-pinion, 5. It will be noticed that the

of the pedals from the driving wheel of the cycle when there is no necessity for the application of driving effort, *e.g.*, when running down

FIG. 25.

chain line is not exactly the same at high and low speeds, the axial deviation of the hub chain-wheel being about 1-8th of an inch, *i.e.*,

hill, or along the level after attaining a fair speed. The hub chain-wheel drives the hub by an automatic clutch, which is released as

FIG. 26.

one-sixteenth of an inch on each side from the straight.

soon as the forward driving effort ceases. Fig. 25 shows the roller clutch made by the

Cycle Components Manufacturing Company, Limited. Each roller tends to move towards the narrow end of the cavity in which it is placed, so long as a forward driving effort is exerted, and therefore the chain-wheel is immediately jammed tight on the central portion permanently fixed to the hub. If the hub tends to move faster than the chain-wheel each roller tends to move towards the wide end of its cavity, and the connection is broken. In order to ensure that the clutch shall come into operation immediately, a forward driving effort is exerted, each roller is pressed by a block and spiral spring towards the narrow end of its cavity. Fig. 26 shows the ratchet clutch as used in the Beaumont free-wheel device. There are three loose pawls passed outwards of weak springs, and eight notches in the chain-ring. One of the pawls catches one of the notches when a driving effort is exerted, but if the hub tends to over-run the chain-wheel, the arrangement of the pawls and notches allows this to take place.

The Juhel gear is a free-pedal device, combined with a pedal backing brake, the whole of the mechanism being contained at the back of the hub.

Miscellaneous.

PROGRESS OF SANITATION.

On Tuesday, 29th ult., the newly-elected President of the Sanitary Institute (Sir William Preece, K.C.B., F.R.S.) delivered his inaugural address at the Hartley Institute, Southampton. After expressing the pleasure he felt in being once more in Southampton, where he had spent fifteen of the busiest and happiest years of his life, he said that the greatest sanitary engineer the world had ever known was Moses. The Book of Leviticus was a treatise on hygiene. For 3,400 years the world stood still, and only one race followed the doctrines and teachings of that great master. The Christian threw his tenets to the wind—the Mahomedan, to his great benefit, had continued to practice some of his principles to the present day. The Jew remained faithful, and was the healthiest and longest-lived type of humanity. The doctrines of Moses could be summed up as the objects of sanitation to-day:—

(1) Pure air, (2) pure water, (3) pure food, (4) pure soil, (5) pure dwellings, (6) pure bodies. There were three very important principles underlying all the practical applications on sanitary engineering:— (1) Energy, or the ability to do work; (2) chemistry, or the power to transform matter; (3) life. The sun being the centre and spring of all energy, it was the function of the engineer to apply this principle of energy to the comfort, happiness, and health of man.

Pure Air.—The supply of pure air to those who breathed it was the object of ventilation. Moses did not legislate for ventilation, for dwellings in Egypt as in the East generally, were open to the heavens. The Israelites dwelt in tents, but he showed how to prevent the pollution of air by the decomposition of refuse, for he ordered it to be carried out without the camp into a clean place and there be burnt. We were only now learning to follow Moses's lead, for refuse destructors were quite a modern and up-to-date "invention." We were even utilising their heat for the generation of steam for electric-lighting generating stations, and we were thereby economising waste, the highest function of the engineer. After pointing out that the air became vitiated by artificial light, such as candles, oil, and gas, and that one ordinary gas lamp acted as five persons in this respect, he said the British Legislature had taken care that lunatic asylums, hospitals, workhouses, and gaols should be well provided with proper air space per person, whereas churches, chapels, theatres, meeting-halls, assembly-rooms, railway carriages, and other places where healthy, honest, and well-to-do people congregated were totally neglected and remained sinks of discomfort.

Pure Water.—Referring to the question of water supply, he asked, Should there not be a duplicate supply, one for domestic and the other for public purposes? This was already done at Richmond and St. Helens. Sea-water was used at Great Yarmouth and Bournemouth for watering the streets.

Pure Food and Pure Soil.—It was in the regulation of the food supply of the Israelites that Moses displayed his profound knowledge of the hygienic requirements of the Eastern nations, and it was by adhering to these regulations to the present day that the Jews lived such healthy lives. Legislation as affecting adulteration of food, the importation of meat, the sale of drugs, fruit, fish, &c., was probably simple, but the enforcement of the regulations, the control of supervising powers, and the appointment of inspectors was weak. Referring to the disposal of sewage, the President said that one of the best examples of water carriage discharging into the sea was at Portsmouth, where Sir Frederick Bramwell, taking advantage of the direction and velocity of the tidal currents of the Solent, had disposed of the crude sewage so as to avoid any possible nuisance or interference with the enjoyment of those who frequented Southsea beach. Sir J. Bazalgette did the same at Torquay, while Brighton and Margate were excellent examples of similar good sea disposal.

Pure Dwellings.—Speaking of pure dwellings, the President said that people suffered not alone from ignorance, but from carelessness and filth. The lower the social scale and the greater the weakness of education, the more callous and indifferent human beings became to cleanliness and comfort; improvidence, the curse of drink, crime, and vice were to be ameliorated only by education and example.

No. 2,442. VOL. XLVII.

FRIDAY, SEPTEMBER 8, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS, 1900.**

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

Proceedings of the Society.**CANTOR LECTURES.****CYCLE CONSTRUCTION AND DESIGN.**

BY ARCHIBALD SHARP, A.M.Inst.C.E.

Lecture IV.—Delivered March 13, 1899.

Rolling Resistance.—When a wheel rolls over a smooth horizontal surface there is a resistance to its motion, termed rolling friction. Professor Osborne Reynolds has investigated the nature of rolling resistance, and he finds that it is due to actual sliding of the surfaces in contact. No material in nature is absolutely rigid, so that the roller has an area of contact, the extent of which varies with the material and the curvature of the surfaces in contact. When an iron roller rests on a flat thick sheet of india-rubber, the roller sinks into the rubber, and lines originally drawn parallel to each other on the india-rubber are distorted. The vertical compression of the layers of rubber below the centre of the wheel causes them to bulge laterally, while the vertical extension of the layers in front and behind the centre of the wheel causes them to get thin laterally. This creates a tendency to a creeping motion of the roller along the

rubber. This action is such that the distance actually travelled by a roller in one revolution is different from its geometrical circumference, the difference in some cases amounting to 2 per cent.

When rolling takes place at any appreciable speed, there is another factor that must be considered. A tyre of a circular wheel rolling on a flat surface gets flattened out, the pressure in front of the geometrical centre of the wheel opposes, and the pressure behind assists, the rolling of the wheel. If the rolling takes place slowly, it is possible that these two pressures may be equal; but in all reversible mechanical actions taking place quickly it is found that there is a loss of energy, which varies with the quickness of the action. In unloading a spring quickly the load corresponding to a given deformation is less than when loading it, more work is required to load the spring than is given out by the removal of the load. The same kind of action takes place between two bodies in impulsive collision, like a pair of billiard balls. The time of contact of a pair of billiard balls may be divided into two portions, during which their centres are approaching and receding from each other. The pressure at any period during approach is less than the corresponding pressure during recess; the ratio of the two pressures being called the *index of elasticity*. In the case of a tyre rolling over a smooth surface, where e is the index of elasticity, and x the vertical distortion, the energy lost is proportional to $(1-e)x$. Comparing three tyres of rubber, air, and steel respectively, rolling on a perfectly hard surface, $(1-e)$ will be possibly smallest for air and largest for rubber; while the displacement x will be the smallest for steel. The rolling resistance of the steel tyre will be the least, that of the rubber tyre the greatest. If absolutely smooth, hard steel tracks could be had for cycling, it is possible that the best results would be attained by having hard steel tyres, as in railway vehicles.

Tyres on Roads.—In moving over an ordinary country road, the nature of the resistances is quite different. The road surface is seldom quite hard and elastic; if a hard metal tyre be driven over a soft road it sinks into it, and leaves a groove of quite appreciable depth. A hard steel tyre sinks further than a narrow solid rubber tyre, and this again further than a pneumatic tyre; the resistances to motion are proportionate. In running over an obstacle, the resistance experienced depends largely on the nature of the tyre. Let a wheel be sup-

posed to move over an undulating road so that it rises without sudden jerk to a height h , the speed being so great that when the wheel is at its highest point it is clear of the obstacle and of the ground. In this case the energy due to the fall from the height h is entirely wasted in shock, there being no means of obtaining a forward impulse from the work done during the descent. If the wheel strikes the object suddenly, and then rises to the height h clear of the ground and the obstacle, the energy lost will be greater than in the former case. If the motion over the obstacle be so slow that the wheel remains in contact with it, the energy of descent of the wheel may be utilised in propelling it forward, and if the reactions on the wheel as it goes on and off the obstacle are equal, there would be no loss of energy. With a hard unyielding tyre this is not even approximately true, except at very low speeds. With a tyre that can adapt itself *instantaneously* to the inequalities of the road, the reactions during rolling on and off are equal, and there is no loss of energy. The pneumatic tyre is a much closer approximation to such an ideal tyre than is an iron or a rubber tyre.

Other things being equal, the loss of energy in moving over a stone or a rough road will be proportional to the weight of the machine which partakes of the vertical motion. In a rigid frame bicycle with iron tyres, as in the old boneshaker, practically the whole weight of the machine had to be lifted, with a rubber tyre the vertical motion of the whole machine was much less, while with the pneumatic tyre the vertical motion may be confined to a fraction of an ounce weight of the part of the outer cover in contact with the obstacle.

The tyre resistance of a bicycle is always much greater than that of the mechanism, and at low speeds is the largest factor in the total. At a speed of 10 miles an hour the air resistance is about equal to the tyre resistance, while at higher speed the resistance of the air is by far the most important. The resistance of the pneumatic tyre is approximately constant at all speeds, so that the power required to overcome it is proportional to the speed. The air resistance, on the other hand, is nearly proportional to the square of the speed, and the power required is proportional to the cube of the speed.

PNEUMATIC TYRES.

When a pneumatic tyre rests on the ground, and supports a vertical load, a

part of the tyre is flattened, and this flattening goes on until the air pressure on the flat portion is exactly equal to the weight supported by the wheel. Thus, the harder the tyre is pumped the less is the area of contact with the ground. Probably the only appreciable resistance of a pneumatic tyre is that due to bending and unbending the cover. The amount of this bending is least when the air pressure is greatest, consequently on a smooth track the tyres should be pumped hard.

The air-tube has merely to form an air-tight vessel to retain the air under pressure.

The outer cover has a variety of functions to perform; firstly, it must be sufficiently strong transversely and longitudinally to resist the air pressure; secondly, in a driving-wheel, or in a wheel to which a brake is applied, it must be strong enough to transmit the tangential effort from the rim of the wheel to the ground; thirdly, the tread must be thick enough to stand the wear and tear of riding on a rough road, and to protect the air-tube from puncture; fourthly, though offering great resistance to elongation it should be as flexible as possible, offering little resistance to flexure as it comes into and leaves contact with the ground.

As regards the stress on the fabric, this is proportional to the air pressure, proportional to the thickness of the tyre, and inversely proportional to the thickness of the fabric. Further, the stress on a transverse section is half that on a longitudinal section, so that if the air pressure be excessive the tyre bursts by tearing longitudinally.

The first pneumatic tyres were made with canvas having the fibres running transversely and circumferentially. In this case no driving effort could be transmitted from the rim to the ground until the fabric was distorted through a considerable angle. In the tangential fabric now almost universally used, the fibres are arranged spirally, sloping 45° to the mean circumferential line. When a driving effort is being exerted, the portion of the tyre near the ground is subjected to a shearing stress as before; but this is equivalent to a tensile stress and a compressive stress in directions inclined 45° ; consequently the spiral fabric is much better able to transmit the driving effort from the rim to the ground. This construction is undoubtedly the best for driving-wheel tyres and for wheels to which a brake is applied; but the front wheel, if no brake be applied, would perhaps better have a tyre with the fibres arranged transversely and circumferentially. The tyre with spiral fibres has

another curious property:—On inflation, the diameter of the tube forming the tyre tends to increase, while the diameter of the tyre, as a whole, tends to decrease, so that the act of inflation tends to tighten the tyre on the rim. This follows from the fact that the tensile strength in the transverse direction is twice that in the circumferential direction, so that the fabric tends to lengthen transversely, and to shorten circumferentially. In the single-tube tyre on the table the diameter at present, when fully inflated, is $26\frac{1}{2}$ inches, on deflation the diameter increases to 28 inches.

As regards flexibility, a woven fabric in which the fibres intermesh with each other is much stiffer than the Palmer or Flexifoot fabrics. In these, the fabric is made up of two layers, in each layer the fibres lie side by side, and are embedded in a thin sheet of india-rubber, the fibres of one layer are arranged at right angles to those of the other. This arrangement gives greater strength and greater flexibility than a woven fabric of the same weight.

Classification of Pneumatic Tyres.—Pneumatic tyres may be divided into three classes, as follows:—

Class 1 has complete tubular outer covers. Tyres of this class can be inflated when detached from the rim of the wheel; in fact, the rim is not an integral portion of the tyre as in the two following classes. The original Dun-

and rim form one continuous tubular ring, subjected to internal air pressure, and to trans-

FIG. 2.

verse tension. The Clincher, Welch-Bartlett (Fig. 3), Palmer, Fleuss (Fig. 4, p. 794), Trench (Fig. 5, p. 794), and Gormully and Jeffery tyres are examples of this class. The outer covers in this class have slightly extensible edges, so that they can be drawn over the edges of the rims.

The Welch-Bartlett Tyre.

FIG. 3.

lop tyre belongs to this class, so do all single-tube tyres, and the Woodstock tyre (Fig. 1) is an example of a detachable tyre belonging to this class. In the Gormully and Jeffery tyre (Fig. 2) there is a slight action of this kind caused by the interlocking of the flap.

Class 2 consists of tyres in which the transverse tension on the outer cover is transmitted to the edge of the rim, so that the outer cover

Class 3 consists of tyres in which the transverse tension on the outer cover is transmitted to the edges of the latter, and there resisted by the longitudinal tension of inextensible wires. The Dunlop-Welch tyre (Fig. 6, p. 794) is the best known example of this class; the Warwick tyre also belongs to this class. The Warwick tyre has one coil of wire embedded in each edge of the outer cover, while the present pattern of the Dunlop-Welch has a triple coil.

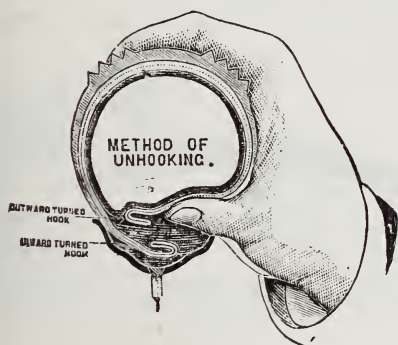

FIG. 1.

The triple coil is made from a thinner wire, the edge of the tyre is therefore rendered more flexible, and a greater facility of attachment

FIG. 4.

and detachment is secured. Fig. 7 illustrates the mode of detachment, one part of the wired edge of the outer cover being depressed into the central channel of the rim, the opposite part projects beyond the edge of the rim, and can easily be pulled over. The pressure between the wire and the rim is at right angles to the surface of the latter, while it is also at right angles to the direction of the stress in the preceding class.

FIG. 5.

Single-tube tyres, of which the Hartford is a representative specimen, have the fabric, the outer layer of rubber, and the inner air-tube all vulcanised together. The alleged difficulty of repair has prevented this class of tyre from being extensively used in this country, although in America they form by far the greatest number in use, the sales in the United States during the year 1897 being said to be a million and a half. As to resiliency, it is claimed that a single-tube tyre can be made more resilient than one with separate air-tube and outer cover. This is a matter that can only be satisfactorily dealt with by experiment.

Side-slipping.—Newton enunciated the first law of motion thus:—"Every body continues in its state of rest or of uniform motion in a straight line, except in so far as it may be compelled by applied forces to change that state." Applying this to the case of a bicycle running on a horizontal surface, it continues moving in a straight line until the frictional resistances bring it to rest. In driving at a uniform rate the driving force just balances

The New Dunlop-Welch Road Racing Tyre.

FIG. 6.

the forces of resistance. When a body moves in a circular path, some force must be acting on it tending to deviate it from a straight line. Thus, when a stone attached to the end of a piece of string is whirled by hand, there is a continual pull by the string at the stone directed towards the centre of the circle in which it is moving, and, conversely, the stone pulls at the end of the string with an equal and opposite force. The latter is called centrifugal

FIG. 7.

force, the former centripetal force. When a bicycle is running in a curved path, there must be a force acting on it directed towards the centre of the circle. The centrifugal force (to use the popular term) is proportional to the weight of the bicycle to the square of its speed, and inversely proportional to the radius of curvature of the path at the instant. If the motion takes place on an horizontal plane, the centrifugal force is resisted by the side

friction of the tyres on the ground. If there were no side friction, bicycle riding would be impossible. A surface of smooth ice approximates to one with no side friction, and it would be a difficult matter to ride on such a surface with the ordinary type of tyre. While moving round a curve the rider automatically leans towards the inside, so that the resultant of the centrifugal force and the weight of the machine and rider passes through the line joining the points of contact of the wheels with the ground. The chance of side-slipping will be reduced to a minimum if the surface of the ground in a lateral direction is at right angles to the slope of the machine. Thus, the banking of racing tracks must be made proportional to the square of the speed, and inversely proportional to the radius of the track. Thus, comparing two tracks for mean speeds of 20 and 40 miles an hour, the slope of the latter at any particular radius should be four times that of the former. A study of the slope of these curves for tracks of small radii will reveal the fact that at high speeds a vertical wall is safer to ride on than a horizontal floor. I do not know whether the feat has been performed by acrobatic trick riders, but should not be surprised if someone worked the idea into his display.

The side-slipping of a bicycle depends on the co-efficient of friction between the wheels and the ground, and the angle of inclination of the bicycle to the vertical. If the co-efficient of friction is great, the chance of slipping is small; if the co-efficient of friction is small, as with smooth tyres on muddy or greasy roads, the chance of side-slipping is greatly increased. It follows from what has already been said that no sharp turns should be made on greasy roads at high or even moderate speeds. To make such turns the bicycle must be inclined to the vertical, the slope increasing with the square of the speed and with the curvature of the path; when the angle of slope from the vertical exceeds the friction, a side-slip ensues.

In ordinary riding the lateral, unavoidable swing of a "safety" is greater than that of an "ordinary," in which the mass-centre of the rider is very much higher; hence side-slipping is much more frequently met with in safeties; in fact, side-slipping was practically unknown to users of the "ordinary." A pneumatic tyre has a much larger surface of contact with the ground than the old solid tyre of much smaller thickness, a fact which is a disadvantage as regards side-slipping on greasy surfaces. On wet or muddy roads a smooth pneumatic tyre

may actually float on a thin film of liquid, whereas the narrow solid tyre would penetrate the film and have actual solid contact with the ground. The non-slipping covers now almost entirely used on roadster bicycles have small projections in the form of continuous or interrupted ridges which are pressed through the thin layer of mud into actual contact with the solid ground.

Influence of Speed on Side-slipping.—The pedals, cranks, and legs of the rider, moving up and down, constitute a couple tending to displace the machine laterally, as shown by the simple experiment of suspending a bicycle with its wheel free from the ground, and turning the cranks quickly. A lateral wobble due to the momentum of the unbalanced weight is set up; in actual riding, the motion of the foot of the tyre is resisted by the side friction, but in conditions favourable to side-slipping it is possible that the action of fast pedalling may often provide the proverbial last straw. A good ankle action, in so far that it reduces the vertical motion of the legs, is favourable to non-slipping. Similarly, free pedals may be in many cases advantageous in this respect. Other things being equal, the long crank with high gear will be better than the short crank in this respect, as the reversals of the vertical motion take place more slowly, and consequently the transverse couple tending to cause side-slip is smaller.

It is a widespread opinion that the actual driving pressure applied to the pedal causes a tendency to side-slip, but provided the body is not shifted laterally I cannot possibly see how the act of pressing on the pedal affects the question one way or the other. The question of side-slip depends entirely on the condition of things at the portion of the tyre in contact with the ground, and any action in any other part of the machine has absolutely no influence on side-slipping, unless it does influence the dynamical conditions at the foot of the tyre. Nearly every new invention in the cycling world is claimed to be a preventative of side-slip, but provided the frames of the machines are all equally rigid under the driving effort, the nature of the driving gear has absolutely no influence on side-slip.

Back-pedalling.—When the machine is running a-head, and pressure is applied to the ascending pedal, the motion is retarded. In this case, although the actual motion is forwards, the effort applied is one that tends to drive the machine backwards; hence the term, "back-pedalling." The other method of re-

tarding the speed is by application of a brake. In order to understand clearly the mechanical and physiological principles underlying these two modes of applying retarding force, it will be necessary to make a short digression on mechanical work. We are all perfectly familiar with the idea of *force* and *effort*, and I will not stop to define the terms. A force acting on a body may accelerate motion, may retard motion, or the body may be at rest under the action of the force.

Mechanical work is defined as the product of force into the distance through which it acts, measured in the direction of the force. If there is no motion there is no work done. If a rope or chain had a heavy weight hung at its end, there is no mechanical work done if there is no motion of the weight up or down. But if the weight be lifted mechanical work is done, and energy must be supplied either by an animal or a motor of some description. If the weight be allowed to descend it will do mechanical work, which may be used to overcome the resistance of a machine. If the up or down motion takes place at uniform speed the *stress* on the rope is exactly the same as if the weight remained at rest. In raising the weight work is said to be done *against* gravity, while during the descent of the weight work is said to be done *by* gravity. Similarly, when a man supports a weight, but does not allow it to ascend or descend, he performs no mechanical work against gravity, if he lifts the weight he does work against gravity, while if he lowers the weight gravity does work upon him. According to this definition Atlas, in supporting the world on his shoulders does no work against gravity. The muscular fatigue will be different in the three cases. If the weight is heavy the man may become fatigued very quickly, but this fatigue is independent of work done against gravity. If he raises a moderate weight (for example his own body) through a considerable distance he will soon find his muscles fatigued, while he may lower the same weight through a much greater distance without experiencing fatigue. To come back to the bicycle, when a rider exerts a driving effort on the *falling* pedal, he does work in overcoming the resistances. When he exerts a driving effort on the rising pedal, work is done on him, and although the effort or stress on his legs and muscles may be exactly the same (as was the case in the ascending and descending weight at the end of a rope), the symptoms of fatigue are different. When driving ahead the rider may be said to

perform positive work, when back-peddalling negative work. Possibly 99 cyclists out of 100 think that when back-peddalling they are working as hard, and fatiguing themselves quite as much as when driving forward, but I think this is not the case.

Personally, I have back-peddalled down the longest hills I can find, and have not experienced the slightest symptom of fatigue on reaching the bottom. Mental anxiety as to one's personal safety on a dangerous descent must not be confused with muscular fatigue. Another experiment bearing out my contentions as to the essential difference in the physiological effects between positive and negative work is the following:—In the building where my office is situated there is a lift giving a total vertical rise of 84 feet, I have been taken to the top by the lift, run down the stairs to the bottom, again been taken up the lift, and so on for twelve times, giving a total height of about 1,000 feet that I have descended. At the beginning and end of the experiment my pulse was 88 and 112 beats per minute respectively, respiration was 16 per minute both at the beginning and end of the experiment, and at the end of the experiment I did not feel in the slightest degree fatigued. The average time of each descent was 54 seconds, the average time of ascent in the lift 42 seconds. Needless to say if I had attempted to run up the stairs 12 times in succession I should have performed quite a different piece of work. In running downstairs, although the muscles are exerting effort they are doing negative work, as in back-peddalling; whereas in running upstairs they are doing positive work, as in driving ahead.

Conservation of Energy.—One of the doctrines, the truth of which has been most firmly established by experimental research, is that of the "Conservation of energy," which asserts that energy cannot be created or destroyed, although it may be transformed from one kind to another. In pure mechanism, kinetic energy is continually being converted into potential energy, and *vice versa*. A bicycle at rest at the top of a hill possesses no kinetic energy, but possesses potential energy in relation to a level at the bottom of the hill. If the machine be allowed to run freely down hill, when it reaches the bottom its original store of potential energy is converted into kinetic energy due to its speed; this may be again converted into potential energy if the machine be allowed to run up-hill. If the frictional resistance of the mechanism, tyres and air could be entirely

eliminated, it would attain exactly its original height. If a bicycle be allowed to descend a hill at a uniform speed, being kept in check by the application of the brake, the potential energy it loses during its descent is dissipated in the form of heat at the brake-block and the surface on which it rubs.

An electric motor on a tram-car being driven up-hill requires a considerable support of energy from the accumulators or from the power-house. When running down-hill the same motor may be arranged as to act as a dynamo supplying energy to the accumulator or to the power-house. In this case the action of the motor is reversible.

A locomotive will run on a down gradient without any expenditure of steam; if steam be supplied to the cylinders the speed will be increased. If the gradient is steep the speed may become excessive, unless retarding force is applied; this may be done by the brakes, or by reversing the valve-gear of the engine so that the mechanism acts as if the engine were to be driven up-hill. In the latter case, not only is there no steam used, but air is drawn into the cylinder during what would be the exhaust stroke if the engine were actually moving up-hill; this air is compressed to boiler pressure during what would usually be the expansion portion of the stroke, and is forced into the boiler during what would usually be the admission period of the stroke. This action may be inefficient, but, without any special attention to it on the part of the engine designers, there it exists.

Similarly, in the case of the compressed air-motor lifting a weight, if the weight be allowed to descend against the resistance of the motor, either by adjustment of the valve gear, or by slightly overloading, the motor acts as an air-compressor, and stores up energy in the compressed air reservoir.

Thus, nearly all inanimate motors are, to a certain extent, reversible, and extending the term *back-peddalling* to their action when the driving effort applied is opposite to the direction of the actual motion, we see that when back-peddalling they act as energy storers.

Animal Motor Mechanism.—The question arises—What becomes of the energy absorbed by back-peddalling? Is it all dissipated in the muscles in some form that cannot be utilised again in driving up-hill, or is some proportion of the energy stored up in a directly utilisable form? Since in the animal mechanism the muscles are probably quite as efficient as any mechanical motors, it does not seem an un-

reasonable speculation that the muscle cells are also, to a certain extent, reversible engines, and that when they perform negative work, as in back-peddalling, there is actually energy stored up in them in a utilisable form. I have already referred to back-peddalling down long hills, without fatigue. I will go further, and say that having finished back-peddalling down the steep side of Harrow-hill, I seem to be actually fresher than at the top. A simple experiment, which can be performed by all, would seem to bear out this contention. I can raise and lower myself by bending my legs, fifty times in one minute. The trunk of my body and arms are raised a height slightly over two feet, my thighs probably a distance of about 15 inches, and the lower part of the leg a less distance. My weight is over 11 stone, so that in each upward movement, I perform say $120 \text{ lbs.} \times 2 \text{ ft.} = 240 \text{ ft.-lbs.}$ of mechanical work against gravity; this repeated fifty times gives 12,000 ft.-lbs. of work per minute. During the descents I perform 12,000 ft.-lbs. of negative work against gravity, or rather gravity performs 12,000 ft.-lbs. of work against the resistance of my muscles. I think it can hardly be asserted that in the operations described I perform 24,000 ft.-lbs. of work per minute, but the probability is that of the 12,000 ft.-lbs. of negative work, a certain proportion, say 25 per cent., is actually stored up in the muscle cells in a form which can be utilised as positive work in the next lift. Thus the total energy to be supplied by the blood to the muscles would correspond to 9,000 ft.-lbs. of work per minute, the remaining 75 per cent. of the negative work being dissipated in some form which cannot be directly utilised.

Numerous mechanical devices have been proposed for storing up the energy of a machine and rider due to the descent of a hill; but from the foregoing arguments, it seems to me not unlikely that in the muscles of our legs we already possess that mechanism. The storage capacity of the muscles may be small, I should not think it greater than that due to lifting one's self to a height of 40-60 feet, but it is large enough, I believe, to afford a rider considerable assistance in conserving his energy at the end of a long run when he is fatigued. Personally, I have always preferred to back-pedal down a hill rather than coast when it is necessary to keep down the speed by the application of the brake. If the down-hill slope, however, be so slight that the application of a brake is not necessary, coasting either with foot-rests or with free pedals is the most

economical; since if no driving or back-peddalling effort be applied to the pedals, a certain amount of work must be expended in moving the legs, this work being dissipated in some form or other. In other words, while during coasting the leg muscles are passively resting, during back-peddalling, I believe, they are actively recuperating.

If there is any appreciable energy storage capacity in the muscles, a racing cyclist, to get the best result out of himself, before commencing a short race say of $\frac{1}{4}$ mile, should be taken on a multicycle or motor cycle, on which he could back-pedal over a distance of about four times that to be raced. A fraction of a second may conceivably be taken off the quarter-mile record by this means. On long-distance grinds, instead of passively resting for 5, 10, or 20 minutes, he should indulge in back-peddalling when he feels fatigued.

It will be gathered from this discussion that the form of free-pedal device that I regard as most satisfactory is one that allows of back-peddalling when the rider wishes. Many two-speed gears allow of back-peddalling in one position of the mechanism, and of free pedals in an intermediate position. The Rambler two-speed gear, which I described last week, is perhaps the best of this type; others on the market at present are the Beaumont and the Bevis two-speed gears.

Brakes.—The variety of brakes at present on the market is tremendous, the most common is the ordinary hand-brake, applied, as the name indicates, by the hand of the rider. In most of the free-pedal machines a brake can be applied when a slight backward motion of the pedals is made. This class has been very excellently named by Mr. Bidlake *pedal-backing brakes*, as distinguished from back-peddalling brakes, which are applied during the ordinary action of back-peddalling, and which supply an auxiliary retarding force in addition to that given by the back-peddalling itself. Pedal-backing brakes may be subdivided into two classes:—In one class a roller clutch is employed, acting in the reverse direction to the free-pedal clutch. When the pedals are moved backwards a slight distance the brake clutch comes into action, and throws the brake mechanism into operation. In the Juhel gear (Fig. 8) the brake clutch is concentric with the free-pedal clutch. In the Wilkinson Sword Company's free pedal machine the brake clutch is on the crank-axle, while in Renouf's free-pedal gear the brake clutch is contained in the hub. With all these arrangements there is

usually an adjustment which enables the rider to apply the brake immediately the pedal backing motion is started, or allows any de

FIG. 8.

sired interval to elapse from the beginning of the pedal-backing to the application of the brake.

In the other type of pedal-backing brake the brake is applied by a pawl hit by the crank during the pedal-backing; this pawl moves easily out of the way during the forward driving of the pedal. Thus the brake is applied only in one definite position of the crank, and a considerable backing-pedal movement may sometimes have to be made. The one on the table made by the Cycle Components Company and supplied with the Ariel free-pedal machine is an example of this class. The application of the pedal-backing brake at one point of the revolution of the crank-axle or at *any* point is a subject that is exciting a considerable amount of discussion in cycling circles at present.

Retarding Force.—The retarding force required to neutralise a gradient, *i.e.*, to prevent the speed increasing, is found by multiplying the total weight of machine and rider by the gradient, expressed in the usual way as a fraction or ratio of the vertical rise to length of road. Thus on the gradient of 1 in 12, a retarding force of $\frac{1}{12} W$ is required. To bring the machine to rest from a speed V miles per hour on the level, within a distance of D feet,

requires a retarding force = $\frac{V^2}{30 D} W$. To

pull up on a down gradient requires a retarding force—

$$\left(g + \frac{V^2}{30 D} \right) W.$$

Speeds from 20 to 30 miles per hour are met with when coasting down a steep hill, and when the traffic and the nature of the road permit, the expert cyclist enjoys the sensations of the quick rush through the air. At these high speeds a very powerful brake is necessary for safety.

Tyre, Rim, and Hub Brakes.—Most bicycle brakes have been applied to the tyre, but many of the common tyre brakes are utterly insufficient to keep the machine under control on a steep hill. Within the last few years rim brakes have become more popular, the Linley front-wheel and the Bowden back-wheel being two of the most successful. The possibility of the brake damaging the tyre has, in my opinion, been over-estimated. The rim brake is cleaner than the tyre brake, and is generally regarded as the more powerful. However, by far the most powerful brake I have tried is a rim brake used by the Gormully and Jeffery Manufacturing Company on the Rambler bicycles. To produce a certain retarding force on the machine, the force required at the brake block is inversely proportional to the speed of the part on which it rubs. From this point of view a tyre brake is slightly better than a rim brake, the latter is much better than a hub brake, and a hub brake is, in turn, much better than a crank-axle brake.

Front v. Back-wheel Brakes.—When a retarding force, R , is applied to a bicycle, either by a brake or back-peddalling, the vertical load on the front wheel is increased, that on the

back wheel decreased by an amount $\frac{h R}{b}$, h

being the height of the mass-centre of machine and rider above the ground, and b being the length of wheel-base. If w_1 and w_2 be the vertical loads on the front and back wheels respectively when the bicycle is running at uniform speed, the vertical loads during the application of the retarding force R , are respectively

$$\left(w_1 + \frac{h}{b} R \right) \text{ and } \left(w_2 - \frac{h}{b} R \right).$$

The greatest possible retarding force R' will be when the wheel to which it is applied is just on the point of skidding, and will be u times the vertical load on that wheel, u being the co-efficient of friction of the tyre on the ground. Thus for a front-wheel brake—

$$R' = u \left(w_1 + \frac{h}{b} R' \right) \text{ or } R' = \frac{u b w_1}{b - u h}$$

For a back-wheel brake—

$$R' = u \left(w_2 - \frac{h}{b} R' \right) \text{ or } R' = \frac{u b w_2}{b + u h}$$

In a single bicycle, as an example, w may be taken $\frac{1}{3} W$, $w_2 = \frac{2}{3} W$, $u = \frac{2}{3}$, $h = 36"$, $b = 44"$; then for a front-wheel brake the greatest possible retarding force is $R' = .49 W$; for a back-wheel brake, $R' = .29 W$. If the road is not absolutely dry, u may be less, say $\frac{1}{3}$, in which case, for a front-wheel brake, $R' = .15 W$, for a back-wheel brake, $R' = .18 W$. Thus, when it is a question of pulling up in the shortest possible space, the front wheel is the best place for the brake. But under usual touring conditions this emergency seldom occurs, and it may be said that an effective brake can be applied either to the front or to the back wheel.

The straining action put on the front-fork and steering-tube is sometimes urged as an objection to the front-wheel brake. But when running at uniform speed, the stress on the front-fork is such that the front wheel tends to get further away from the back wheel. The stress introduced by the application of the brake, tends to bring the front-wheel near the back-wheel, in other words, it is a stress of opposite algebraic sign. Up to a certain point, therefore, the application of the front-wheel brake *diminishes* the stress on the front-fork and steering-tube. This can easily be verified by a simple experiment. Riding at uniform speed on level ground with the steering head a trifle loose, the upward reaction on the front wheel keeps the steering-tube pressed up against the near side of the top row of balls; on applying the brake gradually, the steering-tube can be made to shake between the top row of balls, while a further application of the brake presses the steering-tube steadily against the front side of the row of balls. I have put a Rambler bicycle, with the powerful brake above referred to, to most severe tests by putting on the full power of the brake, but could detect no sign of injury to it.

SADDLES.

Time will not permit of much being said about saddles, which is perhaps no great loss, as the question of a suitable saddle is essentially a personal one; what may give great comfort to one may give absolute misery to another rider. As regards the amount of spring to be given to a saddle, this should be sufficient to allow the leg motion to take place with freedom and comfort. Any greater yield of the saddle beyond that necessary for this purpose may be a direct loss of energy: the mechanical principles involved being somewhat of the same nature as those discussed

with reference to the tyres. I will confine myself to a reference to the Esmond saddle, in which there is little or no resistance to the saddle swaying sideways as the legs move up and down. There should be less loss of energy in this saddle than in those constructed with stiff springs which are continually extending and contracting.

Miscellaneous.

THE OCCURRENCE OF DIAMONDS IN NEW SOUTH WALES.*

There can be no doubt that, sooner or later, as our diamantiferous areas become more thoroughly exploited and developed, and with the advent of more favourable seasons, the diamond-mining industry in this colony is destined to become one of magnitude and importance.

The occurrence of diamonds in New South Wales was recorded by Stutchbury (on the Turon River), and by Hargraves (at Reedy Creek, near Bathurst), as early as 1851. In 1859, the Rev. W. B. Clarke reported their occurrence at Burrendong and at Pyramid Creek, while a year later he also stated them to have been found at Calabash and at Suttor's Bar, Macquarie River. Since then diamonds, in single specimens, have been recorded in many widely separated portions of New South Wales; they have likewise been found in Victoria—chiefly Gippsland—while the late Dr. J. J. Bleasdale reported their discovery at the Echunga diggings in South Australia.

In 1867 they were found to occur at the Cudjgegong River (Mudgee), at which place, during that year, between 3,000 and 4,000 diamonds were won from the claims of the Australian Diamond Mining Co., Messrs. Scott and Allen, and Messrs. Cooney and party. In 1872-73 a somewhat extensive rush took place to Bingera, where a large number of mineral leases were applied for, and it was anticipated that diamond-washing would become a permanent and paying industry. Unfortunately, however, the stones being small, and the Sydney jewellers declining to buy, there was no outlet, and the work was suddenly abandoned. In 1881 the Bingera field was visited and examined by Mr. Geological-Surveyor E. F. Pittmann (now Government Geologist), and the result of his investigations was furnished in a report by him published in the Annual Report for that year. Following this report, renewed interest and attention seems to have been paid to that locality, and since 1883 mining of a more or less desultory and spasmodic character has been conducted there—the scarcity of water experienced in the district, having greatly retarded operations both in that and later years. In

1883-84 diamonds were found in the Tingha Division near the Big River, Auburn Vale, and here also the industry has since been prosecuted in a small way.

Owing to the great difficulty experienced by miners in finding a ready market for their diamonds advantage was taken in 1886 of the exhibit of New South Wales diamonds of the Colonial and India Exhibition (a collection of which had been purchased by the Government, in 1885, for that purpose) to obtain, through the Agent-General, some information concerning the prospect of a market in London for the products of our mines. The exhibit referred to having been carefully examined by Messrs. Thoma Davies, F.G.S., and R. Etheridge, jun. (several of the gems having been cut and polished by Messrs. Ford and Wright, of London) a lengthy and interesting report was furnished by them. The following conclusions, among others, were specially emphasised:—1. That the diamonds of New South Wales in their physical characteristics are more nearly allied to those of Brazil than any other country. 2. They have been largely sold in London as such. 3. As regards colour, they differ practically but little from those of other fields. 4. The general absence of "cleavage" and "macles" is a point in their favour. And 5. That the greater hardness of the New South Wales gems would probably raise the cost of cutting, but this would be compensated for by their extra "brilliancy." Indeed, as a matter of fact, in brilliancy and refractive power the New South Wales gems surpass the African, and one of those cut in London, by the firm above alluded to, was stated to have been as fine a brilliant as it was possible to obtain in any part of the world.

The principal diamantiferous deposits in this colony occur in outliers of Tertiary river drifts and cements representing old river accumulations, of more than one geological age, lying at various distances from present river channels, and once forming portions of widespread and continuous deposits resting on the bedrock of the country. They also occur in the more recent drifts derived from them.

There has been a great diversity of opinion as to their origin and true matrix, and several theories have been advanced, but the question still remains in abeyance. The late Mr. Norman Taylor believed them to have been chemically formed in the older Tertiary drifts; and, in support of this view, adduced what at first sight might appear very cogent reasons. The late Mr. C. S. Wilkinson held the same view at one time; but after an extended examination of the diamantiferous deposits in the Northern District, he suggested that if the Tertiary drifts be not the original matrix of the diamond, possibly its source may be in the metamorphosed Carboniferous or Devonian beds, where they have been intruded by granite or porphyry. Professor David came to the conclusion that the Cope's Creek diamonds were probably derived from the toumaline granite. It is, however, now believed that their source will ultimately be traced to volcanic "pipes" analogous to

* A Report by D. C. McLachlan, Under-Secretary for Mines and Agriculture, Sydney, N.S.W.

those found in the celebrated Kimberley Field of South Africa. Whether or not this solution will prove correct, time alone can determine—certainly up to the present there is no evidence of any such “pipe” having yet been found. But, as pointed out few years ago by the present Government Geologist, Mr. E. F. Pittman, even presuming the existence of such “pipes,” the probabilities are, unfortunately for the prospector, that their ancient surface outcrops lie effectually concealed beneath the basalt flows, which to such a considerable extent cover the diamantiferous areas.

In 1894, in consequence of statements which had been made to the effect that such a volcanic “pipe” had been discovered at Bingera, Mr. Geologist-Surveyor Stonier was instructed to make an inspection and report. Mr. Stonier spent several months in examining the field, but found no evidence to warrant the statements made. Again, so recently as June, 1897, in compliance with a petition from the residents of Bingera for a specific report upon a volcanic “pipe” alleged to have been discovered in the Australian Diamond Company’s Mine, Mr. Geologist-Surveyor J. B. Jaquet was deputed to inspect and report upon the so-called “pipe.” Samples of the rock, stated to be volcanic breccia, had previously been forwarded to the Department by Mr. Wingate, the manager of the mine, and, upon examination, the Government Geologist had pronounced them to be of sedimentary origin. The result of Mr. Jaquet’s examination locally, was to completely bear out the opinion which had been expressed by the Government Geologist. The so-called breccia proved to be Carboniferous claystone, which is the prevailing rock underlying the diamantiferous river drifts of Bingera.

The diamonds found in this colony generally average from 5 to 6 to the carat, although gems of 2-2½ carats are occasionally found, and one of 3½ carats has been recorded. The number obtained per load varies very greatly; the Round Mount Co. (Cope’s Creek, Inverell) in 1886 washed 722 loads for 2,685 carats—from 6 loads obtaining the exceptional yield of 1,080 diamonds, weighing 296 carats, which probably establishes a record so far as our fields are concerned.

Very great difficulty is experienced in procuring accurate and reliable information as to the quantity and value of the gems which, up to the present, have been won, especially as regards the earlier years of the industry.

It is a significant fact that, in spite of the severe drought, with its attendant drawbacks, the output for last year—16,493 carats—is, in quantity though not in value, the largest recorded since the opening of the industry. The Boggy Camp Diamond and Tin Field yielded 14,920 carats of diamonds during the year, valued at £5,625, the gems being associated with tin in considerable quantities. This field has been considerably developed during the year, but work was greatly hampered through the scarcity of water. There are indications that this field will now be

thoroughly tested, as capital has been attracted to it. The next diamond field of importance is situated about six miles from Bingera. This field has been practically idle during the year, owing to the water difficulty, the only work being done by Captain Rogers in the “Monte Cristo” Mine, from which 1,573 carats were won. As soon as rain falls, work will be started by several large companies, and it is expected to prove highly successful.

Considerable interest has lately been centred in these fields, and as some indication of the progress of the Northern District, generally, a local “Mining Exchange” has recently been opened at Inverell—the only one established in any part of the colony outside the capital, with the exception of Broken-hill. Indeed at the present moment there are not wanting signs of a large and progressive development of the field.

ACETYLENE GAS GENERATORS.

At the Congress in connection with the Acetylene Exhibition held at Budapest last May Dr. Ludwig read a paper on gas generators, which is thus reported in the *Engineer*. He gave an account of the progress that had been made in the construction of gas generators during the past year. After a brief but courteous acknowledgment of the huge debt which generator manufacturers, in Germany, as in this country, owe to Professor Lewes, for his careful experiments on the theory and practice of acetylene production, he began by dealing with carbide-to-water apparatus. Ludwig remarked that the mechanism employed to feed the carbide as required into the water had been greatly simplified, and in most recent forms was fairly trustworthy; but as it was usually driven by the rise and fall of the holder-bell, this method of procedure had the defect of throwing considerable and undesirable work on the gasholder, which work, moreover, was apt to vary as the general store of carbide decreased in weight. Carbide-to-water generators were therefore more suited for hand charging, and as such were indicated primarily for installations where a man would be in constant attendance. It will be within the recollection of most readers that Professor Lewes has stated that the output of gas per unit weight of carbide in apparatus of this type rarely exceeds 84 per cent. of the proper amount—a loss which he ascribed partly to imperfect decomposition of the carbide and partly to dissolution of the acetylene in the large excess of water. Unfortunately he has not given any estimate of the relative magnitude of these defects; but it seems clear that, by proper construction of the generator, imperfect decomposition should be capable of almost complete elimination, for the usual source of this trouble depends on the fact that some of the smaller fragments of carbide fall through the false bottom—when one is fitted—and become coated with a resistant layer of lime sludge. Ludwig did not mention this latter objection, possibly because he considered it had already been overcome in the goods

of the best makers; but referring to the loss of acetylene due to dissolution, he stated that a carbide-to-water generator would work with one gallon of water per 2 lb. of carbide—a volume which could only absorb 2 per cent. of the acetylene, assuming the theoretical yield to be 5 ft. per pound. On the large scale the lime sludge might be drawn off, the solid matter allowed to settle, and the liquid returned to the generator, thus decreasing the waste of gas; in smaller apparatus it would be more convenient and cheaper to bear with the loss. Another trouble met with in these generators was the foaming that occurred with certain brands of carbide; and he suggested that this was caused by the use of a material containing aluminium. Aluminium carbide evolves methane on treatment with water; and methane in lime water, he said, always foamed. Experiments with oils, salts, &c., instituted to discover a means of avoiding the difficulty, gave negative results.

Among water-to-carbide generators, improvements had been even more pronounced. When the total charge of carbide contained in the apparatus was distributed among a large number of small compartments, and the water was admitted in such fashion that it could only reach one portion at a time; and when the quantity of water admitted each time some entered the decomposing chamber was more than sufficient wholly to decompose each portion of the carbide, then water-to carbide machines worked quite as well as those of the opposite construction. The system of permitting water to fall either in drops or as a stream on a mass of carbide was being abandoned; for apparatus of this design were specially liable to excessive heating accompanied by the inevitable decomposition of part of the acetylene, while they also had the defect of leaving some of the carbide unattacked. This incomplete reaction was not merely wasteful but was actually likely to prove dangerous if the residues were dealt with carelessly. However, generators of this type, in which the carbide was subdivided into small portions like those previously described, were still being manufactured, and it remained to be seen how they would compete with their rivals. In short, Ludwig's remarks only bear out those made by other observers, viz., that to obtain satisfactory generation, to avoid excessive heating and consequent polymerisation, water must always be in excess at the time and place of actual chemical reaction between the two substances.

Ludwig considered that portable lamps had been improved, but were still far from perfect; that methods of purification were satisfactory, and that if they were employed burner troubles would no longer exist. Purification with liquids ensured greater regularity of action than when the same reagents were used as solids, but the former method involved more loss of pressure. When the gas was to be dried again after purification lime was better than carbide, but precautions must be taken to prevent dust passing into the pipes. In connection with this latter opinion, it may be remarked that a highly purified acetylene has

practically little odour, whereas an evil-smelling gas is—remarkable though it sounds—advantageous in view of the fact that leaks are more safely detected by the nose than by a disastrous explosion. If the pure but damp acetylene be dried by carbide the gas is scented again, and it would seem the proportion of impurities thus introduced might be sufficient to make it smell without causing it to be objectionable in other respects. This is a matter, perhaps, on which further experience is desirable before a final judgment can be delivered.

General Notes.

SWINEY LECTURES.—A course of twelve lectures on the "Pleistocene Mammalia," will be delivered by R. H. Traquair, M.D., LL.D., F.R.S., in the Lecture Theatre of the Museum of Practical Geology, Jermyn-street, S.W., on Mondays, Wednesdays, and Fridays, at 5 p.m., beginning Monday, 2nd October, and ending Friday, 27th October. The Swiney Lectures on Geology are under the direction of the Trustees of the British Museum. Admission to the course is free.

EXPERIMENTAL FLAX CULTURE IN MEXICO.—According to a recent bulletin of the Bureau of the American Republics, it is probable that the growing of flax, for the production of linen, will become one of the industries of Mexico. Experiments were recently made at the National Agricultural School on the outskirts of the City of Mexico, where a plot of ground was sown in flax seed. At the end of sixty-one days, the shoots from these had in some instances reached a height of 41 inches, and gave every indication of taking kindly to the soil and climate, which seems to be well adapted to the cultivation of this plant. The Mexican authorities have become interested in the new venture, and propose to give it every encouragement. The only drawback to this cultivation in the great valley of Mexico, is the lack of water, which, however, can be usually overcome by irrigation. Experiments in flax culture are also being conducted in the State of Flaxcala.

PRODUCTION OF SESAME OIL IN SYRIA.—In the preparation of sesame oil in Syria, the grain is soaked in water for twenty-four hours, and then placed in an oblong pot, coated with cement, on which two men work a wooden hammer of 20 pounds weight. Efforts are made not to mash the kernels. The skins are separated in a tub of water, salted to a degree sufficient to float an egg. The bran sinks, while the kernels remain on the surface. The sesame seeds are now broiled in an oven, and sent to the mill to be ground. From the millstone the oil drops into a jar. It is thick, of a dark yellow colour, and sweet. The product is used extensively by the poorer classes in place of cheese, syrup, honey, &c., and is popular on account of its saccharine properties. Confectionery is made by mixing sesame oil with syrup and other elements. Sesame is widely cultivated in Syria.

Journal of the Society of Arts.

No. 2,443. VOL. XLVII.

FRIDAY, SEPTEMBER 15, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****PRIZES FOR DESIGNS FOR FURNITURE.**

The Council of the Society of Arts hold a sum of £400, the balance of the subscriptions to the Owen Jones Memorial Fund, presented to them by the Memorial Committee, on condition of their spending the interest thereof in Prizes to "Students of the Schools of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers, and Hangings, Damasks, Chintzes, &c., regulated by the principles laid down by Owen Jones."

The prizes will be awarded on the results of the Science and Art Department. Competing designs must be marked "In competition for the Owen Jones Prizes."

No candidate who has gained one of the above prizes can again take part in the competition.

The next award will be made in 1900, when six prizes are offered for competition, each prize to consist of a bound copy of Owen Jones's "Principles of Design," and the Society's Bronze Medal.

EXAMINATIONS, 1900.

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

Miscellaneous.**ARGOLS.**

BY R. HEDGER WALLACE.

Argol is a good illustration of what constitutes an agricultural by-product, it being a substance usually found in abundance in the viticultural districts of France, Germany, Italy, and Spain. Argol is simply the mercantile term for crude tartar, and is a by-product of vinous fermentation. It exists in the juice of the grape, and is soluble therein; but during the fermentation of the juice as it passes into wine, alcohol is developed, which, remaining in the fermenting liquor, causes the precipitation of the argol. Some wines, if bottled when not fully ripe, develop more alcohol on keeping, and a further precipitation of argol therefore takes place, recognisable as a crust in the bottom: hence the meaning of the term "crusted port." This substance forms a crystalline deposit or crust on the inside—bottom and sides—of wooden casks, vats, or tubs in which vinous fermentation takes place. It is, however, only deposited during such fermentation, never afterwards. When the wine is drawn off, this deposit is scraped from the inside, and the crust becomes hard, brilliant, and brittle, and is readily reduced to powder. The crystals are white or slightly coloured, according to the character of the wine in which they are deposited. That which is found in barrels having contained white wine is of a dark cream colour, while that extracted from red wine barrels has a pinkish tinge. The argol deposited by white wine contains fewer impurities than the other, but when refined both are identical. The quantity found also varies according to the quality of the wine. The white wine gives less than the red, the strong more than the light wine. Locality, apparently, also affects production. It is said that the meridional provinces in Italy yield more argols than any other part of that country; and wine-growers in the Pfalz, the area lying west of the River Rhine, state that wine made from grapes grown upon the northern slopes of the ridges and hills yield more argol than wine made from fruit grown on the southern or sunny slopes. In France, the wine producing the largest quantities of argol are those of the extreme south, and the trade in it is consequently limited almost entirely to the regions about Marseilles, Bordeaux, and Lyons. It is well known that, in many instances, it becomes necessary for the viticulturist or wine merchant to clarify the product of the vineyard by treating it either with gypsum or the white of eggs. Wine clarified by gypsum is richer in argol than that which it has not been found necessary to treat in this manner, while clarets cleared by the albumen of eggs are said to produce an argol which yields an exceptionally superior quality of cream of tartar. The most important argol-producing localities in Europe, let us add, are the districts adjacent to Messina, Naples, Palermo, Bordeaux, Lyons, Marseilles,

Lisbon, Barcelona, and Tarragona, all of which are viticultural centres.

Though we recognise argol, or crude tartar, to be a collateral product of wine, yet the fact that it is formed only by wine which has reposed in wooden casks proves it to be a product as recent in origin as are wine casks themselves. Ancient Greeks and Romans knew not the value of casks, for they kept the fermented juice of their grapes in great earthen vessels, very much like those employed to-day in certain parts of Spain. Any one who has travelled in the Iberian peninsula will recall the fact that wine there is often kept in goatskins, stone cisterns, and other strange vessels made of hides and clay. In these receivers argols, or crude tartar, have never been known to form, yet the wines of Spain are rich in the article. In recent years, however, the Castilian viticulturist has almost exclusively employed for storage wooden casks, for the purpose of collecting this valuable sediment, and adjunct to the income from wine-making.

The value of tartar as a medicine is said to have been first discovered by Paracelsus, the celebrated Swiss astrologer, alchemist, and professor of medicine at Basle, who was born at the end of the 15th century. He stated that it was composed of oil, water, and salt, an analysis which is as inaccurate as the same scientist's analysis of the human body, which, according to him, was made up principally of sulphur and mercury. The real composition of argol was, however, determined in 1770 by the celebrated Pomeranian chemist, Scheele, the discoverer of chlorine, who found its active principles to be composed chiefly of bitartrate of potash along with a small portion of tartrate of lime. Argol, then, may be regarded as crude potassium bitartrate, and from it is produced cream of tartar, tartaric acid, tartar emetic, potassium carbonate, blackflux, pearl ash, baking powders, and mordants for fixing colours in dyeing.

An ordinary French wine barrel yields from one to two pounds of argol, or wine lees, which the viticulturist sells to the tartar manufacturer, who either disposes of it in its crude form or refines it into cream of tartar. In some instances, however, these wine dregs, instead of being used in the manufacture of cream of tartar, are employed by brandy merchants to impart a fruity flavour to newly distilled spirits, very much in the same manner as burnt sugar and prune juice are employed in the United States to colour and sweeten whiskey. This much can certainly be said for such a use of wine dregs as noted above, that it is a perfectly innocuous and wholesome essence of the product of the vineyard, and in fact it is based on the theory common to the viticultural districts of France, namely, that the solidified lees of old wine improves the quality of the new. So strong is the feeling as to the valuable quality of the lees, that it is frequently the case that dealers in argols find it difficult to purchase this product except where barrels are broken to pieces as being no longer suitable for storage purposes.

A special collective consular report on the production of argols in Europe has lately been issued by the United States Department of State, and from this volume we note some of the processes of preparation and the preparations made from argol in France, Germany, Italy, and Spain. The process of preparing tartar for commercial purposes in France is not only very simple, but inexpensive. The crude product is generally taken from barrels in which wine has lain for three or four years, that being the average period the liquid is left in the cask previous to bottling. Of course the longer the wine remains in the barrel the better and more abundant will be the lees. About 30 per cent. of these settlings is crude tartar. The wine being drawn off, the sediment is removed in a crust, usually detaching itself in irregular cakes of about four inches square in extent, and half an inch in thickness. These cakes are allowed to dry, after which they are triturated, either by hand or machinery, until they resemble very fine gravel or sand. In this form it is sold to the manufacturer, who boils it in water for two or three hours until it is entirely dissolved. The solution thus made is then drawn off into shallow metal or earthenware receivers, upon the bottom and sides of which the tartar forms as it cools a mass of crystals. The liquid that remains is boiled and cooled over and over again, until evaporation is complete, and nothing but crystals are left. Purified tartar becomes cream of tartar, or bitartrate of potash, forming a white odourless crystal of an acid taste. There are two varieties of cream of tartar made in France, the *crème de tartre de Montpellier*, sold in irregular cake-like crusts, and the *crème de tartre de Marseille*, in smaller cakes. The Montpellier tartar is made by boiling crude tartar in water with animal charcoal and clay; these substances form a white scum, which is taken off and allowed to crystallise, the crystals being subsequently washed in cold water and dried. The pure tartaric acid is then isolated from its acid potash by what is known as "Scheele's process." The processes by which various tartrates and other combinations of tartar are derived from argols are technical and chemical, and much too intricate to be mentioned here.

Argol was extensively used in former years by dyers as a mordant, that is to say, as an intermediate substance, which having a strong affinity for both organic fibres and colouring matter, becomes a bond of union between the two, making thereby a fast colour. The reactions or combinations formed, when used as a mordant, were tartrate of alumina and tartrate of tin. In Germany, argol in former years was much used when woollen goods were dyed, but since the introduction of aniline colours it has lost its value as an article of commerce in this industry. Still, however, the principal market for argols from white moselle is the chemical and cloth factories of Germany, and quite a quantity of tartaric acid is converted into dioxy-tartaric acid, and used in the manufacture of a yellow colouring matter for wool, known as tartrazine. The chief countries which import

argol or tartar are England and the United States, but the shipments to the latter country are exceptionally large, it taking more than double the quantity shipped to all the other countries combined, owing to the fact that it is there used on a very large scale in the manufacture of baking powder, a purpose for which it is not so universally employed elsewhere. The extent to which tartar is used in combination with food products would, it is stated, be perhaps "most easily ascertained from the export books of the numerous baking powder firms of the United States, unless the relative prevalence of dyspepsia in various countries should be deemed a sufficient answer." Such an inquiry, however, does not come within the scope of this article.

Before proceeding to note some interesting facts regarding the production of argols in Germany, Italy, and Spain, we would state that in some countries only the crust of crude tartar attached to the sides of the cask is termed argol, while the sediment adhering to the bottom is designated lees. In this article, however, we use the term argol to include any natural product obtained in the process of wine making which contains tartar. Turning to Germany, we find that there, besides argol (called *weinstein* in German) from wine, there are also what may be termed "husk wine argols" and "mud argols." What is known as "husk wine argols" is obtained from the skins and pulp of the grape remaining after the husk brandy has been extracted, and is produced in the following manner. The husks, &c., which are found in the boiling vats are emptied into a wine press, and all the liquid remaining is pressed out. This is again boiled and drawn off into barrels and cooled with ice-water. In from eight to ten days the argol contained in the liquid crystallises out, and after the water has been withdrawn it is taken from the sides and ends of the barrels. An inferior quality of argol is obtained by not boiling the liquid pressed out, and simply allowing the argols, by what may be termed a natural process, to precipitate out. This is what is known as "mud argols." Some distillers, after having pressed the grapes and secured the brandy, do not boil a second time, as noted above, but allow the extract to run direct into casks or barrels in which birchwood twigs have been placed, and to these, on precipitation, the argols adhere. In casks made of chestnut wood it is said no argol (wine stone) will be formed. In whatever way the crude argol be obtained it is disposed of to the "Weinsteinfabriken," where it is converted into various preparations of tartaric acid, such as cream of tartar, seignette salt, tartar emetic, potassium carbonate, black flux, and pearl ash. The by-products of the *Weinsteinfabriken* are disposed of to manufacturers of fertilising materials.

As was to be expected, a large quantity of argol is produced in Italy. The collections from vats, &c., in that country, are taken to local markets and sold to "tartarari" or tartar men. When a considerable quantity is received, these "tartarari" dispose of their bulks to still larger dealers in more important

centres, and these to large wholesale houses. According to the process of making employed, the article is placed upon the market in five varieties, as follows:—*Feccia asciutta* (dry lees), the name for the lees left behind in the vat after the wine is drawn off for the first time. Then *tartaro crudo* (crude tartar), that is the sediment coating the interior of vats which have been used for a long time. Next comes *cremore di vinaccia* (cream of wine dregs), and it is obtained in the process of obtaining alcohol from the grape skins; the water used in distilling the alcohol is poured into receptacles filled with birch-broom, on which the *cremore di vinaccia* crystallises out. The remainder of the fluid, which does not crystallise on the birch, forms a dense acid sediment, which, after being pressed and dried, is put on the market under the name of *limo di cremore* (deposit of cream). The last form, known as *cremore di seccia*, is obtained when the fresh dregs of wine are boiled in water, and the fluid poured into vats in which the argol crystallises out in the usual manner, as the *tartaro crudo*.

The processes for extracting argols in Spain are three in number, and are very simple. In making wine, the grapes are gathered in large baskets and placed in a vat, which is generally located in a specially constructed outhouse. They are here trodden upon by barefooted peasants, and the juice passes through holes in the bottom of the vat into a tank. When all the juice has been extracted, it is customary to open the bottom of the vat, and to let the grape skins fall down into the juice, and remain there fermenting for six or eight days, in order that the wine may become more highly coloured. At the end of the fermenting period the juice is drawn off and put in barrels, and the grape skins are put into presses, which extract the juice that remains, and this is also put into the same kind of barrels. What remains in the presses are then taken to factories, where alcohol is obtained from it. After this process is concluded vine shoots are placed in the hot liquid residue left, and as the liquid cools argol gathers about the shoots, from which it is, in due course, scraped. It is then dried and whitened by various methods, all of which are considered secret. The argol so produced by this process is, however, of the lowest quality, and is the least valuable.

The juice that was taken from the vat and put in barrels is generally kept from 15 to 20 days, when it is carefully taken out and the lees are sold to wine brokers, who at once extract what wine still remains and then dry the rest and sell it to the tartar factories, in which it is prepared for the market. This kind of argol is ranked as tartar of the second class.

The best tartar is obtained from wine that is withdrawn from the vat and kept in one set of barrels for five years or more, and in the inside of which it crystallises out. When this is finally taken out, it is dried and sold to the factories. The drier the nature of the wine, the more argol it produces. The principal market for tartar in Spain is Barcelona, and there is apparently a large home demand, it

being principally used as a diuretic, refrigerant laxative, and cathartic, and in bread-making.

What has been said as to extracting argols from wine applies also to the extracting of argols from pomace or crushed apples, and it is often so extracted in districts where cider is made. The production of argol or tartar, it must be borne in mind, does not constitute an actual industry in itself, but is only an accessory to wine and cider-making, and may be therefore regarded as a supplementary agricultural industry. Further, it is apparent that the only process for extracting it is a natural one, and it is so simple that it can be undertaken by anyone. Next to the United States, England is the heaviest importer of crude tartar. As we have no vineyards, with one solitary experimental exception, in this country, the production of argols should be taken up by our wine-producing colonies. It is not a high-priced product, but it is a source of profit, as all waste products are when utilised.

LUXEMBURG KID GLOVE MANUFACTURE.

Whereas what is called "chamois" leather is really a sheep's skin split into halves, kid gloves are actually made from the skin of a kid, except that lamb skins are also used, especially for the stronger qualities. The younger the kid, the thinner, finer, and softer will naturally be its skin; and such skins are used for the best-quality gloves, being lighter to manipulate although requiring more care, while the workmanship is the same for all qualities.

Kid skins are obtained from Germany, Austria, Sweden, Brazil, Madagascar, and lately from Cyprus, but more especially from France and Bavaria. Russia and Arabia supply a great many lamb skins, which are larger, thicker and stronger than kid skins, being, consequently, more difficult to work; but they have the advantage of being less liable to tear in the process of manufacture. There is, however, no apparent difference between lamb skins and kid skins; and none but an expert can distinguish between gloves made from the two. As a rule it is the natural outside of the skin which also comes outside in the glove; but in what are called *Suède* gloves, just the reverse is the case. This trade appellation originated through Swedish kid gloves having always been made with the inside of the skin kept outside in the glove. It will be remembered that dark and even black gloves are white inside; and, to preserve this whiteness, special treatment is required, as will be referred to more particularly below. It will perhaps come as a surprise to many to learn that each glove is composed of 15 to 19 pieces, irrespective of the fastening, and also that it passes through from 100 to 160 hands before being packed, each pair separately in tissue paper, and then a dozen pairs together, in a band of yellow paper, ready for delivery.

June is the season for taking in the stock of skins, which are, for the most part, yielded by year-old

kids; and the skins are generally kept in stock for about a year before being worked up. For storing, the skins are packed with naphthaline, in order to kill an insect known as the "Acosti," which would otherwise attack the skins, and render them practically worthless. The larger skins are picked out for making the long gloves known as "mousquetaires," of which only a single pair can be obtained from one skin; but for ordinary gloves, taking one size with another, it may be stated that about two pairs can be got out of a single skin with careful planning. The glove manufacture comprises three distinct processes, viz., dressing, dyeing, and the actual glove-making.

DRESSING.

As many skins as can be dressed in a day are brought out of the storehouse, and first soaked in clean water for two days, the water being changed on the second day; but the thicker lamb skins are soaked for three days. The object of this soaking is to restore the original suppleness of the skins, because it is rarely possible to dress them directly they are removed from the animals. The skins are then immersed, first in a weak and afterwards in a strong, solution of lime and sodium sulphide, contained in pits excavated in the ground and lined with cement. This soaking is continued for two days in the weak, and from seven to ten in the strong solution, each of these baths serving for about 12,000 skins before being renewed. The solution does not attack the skin itself, but it kills the roots of the hair, so that what does not fall off of itself in the pits is easily removed by scraping.

The wool of lamb skins is more difficult to loosen than the hair of kid skins, so that different treatment is required in their case. Instead of their being immersed in a solution, the inside, or flesh side, of the skin is spread over by a bass broom with a paste of the same composition as the solution, but naturally more concentrated, and having the consistency of treacle. After being thus plastered, the lamb skins are folded with the wool inside, stacked, and held down by boards, weighted with stones, in the *Mégisserie* department, where they are left from nine to fourteen days. As the paste would attack the hands, the men wear india-rubber gloves. Whichever be the treatment, however, all the skins are rinsed in clean water—the lamb skins in a running stream—before being given out for the subsequent operations.

The hairing is performed by hand on what resembles a gymnasium horse, one end of which, however, rests on the floor, while the other is supported so as to present an angle of about 40°. The man takes his stand at the raised end, having in front of him a board pivoted near the floor, by means of which board, through pressing against it with his knee, he can clip one corner of the skin, thus holding it fast, so as to be able to scrape off the hair with a blunt and curved knife having two handles, which he works over the skin downwards along the slope, changing the position of the skin as required. The

hair, both that left in the pits and that removed on the horse, is kept in separate parcels, as white, black, and mixed. After being washed mechanically, the hair is dried, first by centrifugal force, and afterwards by heat, when it is sold for making hair-cloth or mattresses; but the wool from lamb skins is used for making felt.

After the skin has been deprived of all its hair, it is trimmed on the same horse, by the head, paws, and tail parts being cut off. For fleshing, the skin is turned inside upwards, being fastened by one corner in the same manner as before, and all the fleshy particles adhering to it are scraped off by an appropriate knife. For graining, the skin is again reversed, and pressed out—still upon the horse—in all directions by a special tool in the nature of a scraper, for squeezing out all the adipose matter contained in the pores. When it has been ascertained by inspection that these several operations have been well performed, the skins, a thousand together, are churned with water for about 20 minutes in a cubical box, about 10 feet diagonally between the opposite corners, to which pivots are fixed for turning on a horizontal axis.

The thousand skins are then soaked in a bran bath, heated to 25° Cent. (77° Fahr.), for three hours, after which they are placed in a barrel-churn revolving on a horizontal axis, with internal wooden projections, and containing a solution of alum and sodium chloride. After the churn has been turned for half an hour, 100 lb. of flour and the yolks of about 300 eggs from China are introduced, when the operation is continued for an hour. On the skins being taken out of the churn, each one is folded with the grain (or what was the hair side) inwards, and dried on the first floor of the drying room, at a temperature of about 40° Cent. (104° Fahr.); but in warm weather the skins are dried in the sun on the roof of the drying-shed. When the skins are perfectly dry, they are dipped in water, and then hammered mechanically by what are termed "fullering stocks," to take off the stiffness, after which they are opened, and drawn out in all directions on a semi-circular *pâtisson*, or "staking knife" as it is called. Two skins are then tied together by one corner of each, and hung over a pole to dry; and, when dry, a few are crumpled up together and stamped upon by men with bare feet. The skins are then pulled out from corner to corner, and stretched over a staking knife, sharper than that mentioned above, being scraped at the same time. In the case of the larger and tougher lamb skins, this operation of drawing out requires far more force than with the smaller and thinner kid skins, so that the men engaged in it often suffer in their hands and knees, while also becoming hump-backed. Here, accordingly, is a case in which a mechanical appliance that would perform the operation as well as hand work should be warmly welcomed; but it must be added that no such appliance yet tried has performed the operation in less time and without tearing the skins. The skins are finally piled in

bundles of 36, folded all together, and then stored for a period of from six months to two years, in order to be seasoned and rendered fit for the next process, viz. :—

DYEING.

The tints most in vogue for gloves, viz., black, white, and tan colour, are almost entirely due to a combination of blue, red, and yellow. The dye substances for producing these latter are Campeachy wood (*Lignum campechianum*), producing hæmatein, for blue; Fernamboko wood (*Cassipouira Brasiliensis*), producing brazilin, for red; and Fustet wood (*Rhus cotinus*), producing fustic, for yellow. The black dye is formed by combining all three of these substances, in certain proportions, with sulphate of iron, and that for tan gloves by mixing campeachy with fernamboko, while gloves of a white tint are cut from undyed skins, the smoothest being chosen for such gloves. For those to be dyed light shades, however, skins must be selected perfectly free from blemish on the grain side; and, whichever dyeing process be adopted, the skins are previously stamped by men with bare feet in a solution of egg-yolk and water. No mordant is required for dyeing light shades; but the skins are dipped in the dye, both sides being thus coloured equally or nearly so, while skins to be dyed dark tints, instead of being dipped, are (as referred to at the beginning of this article) painted, as it were, on the outside with urine, of which the ammonium carbonate acts as a mordant. It may here be mentioned that although a great many substitutes for urine have been proposed, it has never been found possible to secure their adoption by the men.

The number of skins required to execute an order for gloves of a certain colour, tint, or shade, except very light shades, are given out to one or more dyers, according to the importance of the order; and the dyer takes each one separately out of the water-tub under his bench and places it wet, the inside downwards, on a zinc slab, which is formed like a double desk, with a ridge in the middle, for favouring the off-flow of liquid. The skin is then pressed close to the slab by pushing over it a kind of wooden scraper from the centre line to the outside, in order to prevent the mordant, and afterwards the dye, from penetrating to the inside, which must be kept white. The mordant is first applied by an ordinary scrubbing-brush, being swilled off with water; and the required dye is then laid on with a brush in the same manner, the number of coats, that follow one another immediately, depending upon the depth of shade required.

As each skin is dyed it is hung over a pole, the first skin being placed with the inside undermost, and the others on the top of it in alternate order, so that the coloured sides of two skins always come together. When a few skins are thus collected, they are removed by a boy to similar poles in the cage of a lift, by which they are taken up to the drying-room for dyed skins, where they are hung up separately from hooks by two of their corners, being left

from three to four hours, according to their weight and the colour they have received, in a temperature of 38° Cent. (100° Fahr.). The skins are next softened by being placed in contact with damp sawdust for one night, and then drawn out by hand on a *pâlisson*, or "staking knife," like that already described, which operation takes out all creases, while at the same time lightening the shade.

GLOVE-MAKING.

For gloves other than long "mousquetaires," each skin is sheared by hand into a certain number of blanks, about 6 inches long by 4 inches wide, slightly more or less according to size, as marked out by an expert glover. The blanks are drawn out longitudinally to about double their original length, and until they cover the pattern of the size for which they are intended. It will be remembered that, while kid gloves have a seam along the outer side of the little finger, there is none on that of the forefinger. Accordingly, the blanks forming the back and front all in one piece are piled up, 12 deep, alternately with the coloured sides together, just as was the case with the dyed skins.

Formerly each glove blank was sheared out to the required shape separately by hand; but now, for each size of glove, there is a sharp cutting die, made of carefully-tempered steel, about two inches high, and having inside it a metal plate moving therein with easy friction, and kept normally up to the top of the die by springs. Underneath a fly-press with three-threaded screw there is a slide, which is drawn out; and on to this are placed, first the die, then the packet of glove blanks, then a piece of cardboard, and finally a hard-wood block. The slide is then pushed back to its place underneath the press-head, which is now brought down upon the packet, compressing the springs above-named, and cutting the blanks to shape. The pressure is then taken off and the slide again drawn out, the cut blanks, pushed upwards to the top of the die by the springs, being simply removed. This operation cuts the forms of the fingers and the back and front of one glove, as well as the hole for the thumb; and at the same operation are stamped out (in the hole for the thumb) the thumb gusset and the strengthening piece for the inside of the opening at the wrist, and also (from the material left at the end of the little finger) one of the finger gussets, all these pieces being left just adhering, to be severed only at the last moment, in order to prevent their being lost or misapplied.

In addition to the above, two different stampings are required; and they are effected in the same manner, out of pieces trimmed off from the blanks, one for the thumb-pieces, and the other for the *fourchettes à carabin*, or finger sides, the two adjacent being in one piece, and the remaining gussets, also twelve deep. From the waste pieces trimmed off the glove blanks are sheared by hand the long and narrow strips that are used for binding or strengthening the edges of the wrist, and also the opening of the

glove where the hand is inserted; and the waste pieces from these, together with those from the stampings, are sold for making glue.

The marking and pricking for the various braidings, more or less elaborate, that generally adorn the backs of gloves (in some cases superseded by pinching the skin so as to form a rib, and stitching it), are now formed by hand punching, as also the button-holes, or the holes to receive the patent fastenings, as the case may be, and the pinking sometimes given to the wrist edges of ladies' gloves.

All the multifarious parts that enter into the composition of the glove have now to be "assembled" (as the French would call it) or put together like the parts of a child's "puzzle;" and this is generally effected by placing together the edges of the pieces to be united, and passing them between two small rollers on vertical axes, one of the rollers being rotated by gear from the sewing-machine, the work being guided by hand. As the glove is drawn forward, the sewing-machine needle, working horizontally and at right angles to the roller axes, produces the seam, leaving visible the white edges of the skin, which in black gloves are rubbed over with dye material.

The principal kid glove manufactory in Luxemburg (which country exports about 50,000 pairs yearly), is that which was started twenty years ago in the suburb of Grund, on the banks of the Alzette, by M. Albert Reinhard, who, beginning as a workman, and still by preference continuing to do his share in the work (that requires great experience) of selecting skins for the various classes of glove, now employs 1,400 hands, and sends out daily about 2,000 pairs of gloves, of which two-thirds find their way to England, and the remainder to the United States of America.

REPORT OF SCREW GAUGE COMMITTEE OF THE BRITISH ASSOCIATION, 1899.*

In the year 1882, a committee of this section was appointed to determine a gauge for the various small screws used in telegraphic and electrical apparatus, in clockwork, and for other analogous purposes. This committee reported to the section in the succeeding years, 1883, 1884, and proposed that a certain system of screw threads, since known as the British Association screw-threads, should be recommended for adoption by users of small screws in this country. The system is identical, except in one small point, with that used in Switzerland and associated with the

* Report of a committee consisting of Sir W. H. Preece (Chairman), Lord Kelvin, Sir F. J. Bramwell, Sir H. Trueman Wood, Major-General Webber, Colonel Watkin, Messrs. Conrad W. Cooke, R. E. Crompton, A. Stroh, A. Le Neve Foster, C. J. Hewitt, G. K. B. Elphinstone, T. Buckney, E. Rigg, C. V. Bovs, and W. A. Price (Secretary), appointed to consider means by which practical effect can be given to the introduction of the screw gauge, proposed by the Association in 1881. See *Journal*, vol. 32, p. 115, vol. 33, p. 1016.

name of Professor M. Thury. The series consists of 26 threads, numbered 0-25, having diameters from 6 mm. down to $\cdot 25$ mm., and is so closely graduated that only in exceptional cases can any size be required intermediate between two of the set. The form of the thread has proved to be well adapted for practical purposes, and screws made on this system have come into extensive use among English manufacturers of small mechanical apparatus. It has been adopted by several Government Departments, who have imposed its use upon their contractors.

In the year 1895 representations were made to the section, and some correspondents of the technical papers urged, that the value of this system was prejudiced by the fact that purchasers of British Association screws and screwing-tools could not rely on obtaining from manufacturers goods which were interchangeable with one another. This raised at once a question which had not been closely considered by the 1882 committee—viz., the mode of determining whether any given screw of a particular number is or is not a fair representation of the form laid down by the British Association specification. The present committee were appointed at the Ipswich meeting to deal with this point, and with some additional members have sat at intervals up to the present time.

In 1896 an interim report was presented to the section at the Liverpool meeting, in which the problem of the mode of gauging small screws was discussed at length. The principal conclusion reached at that time was that as no means exists of examining a nut or female screw, the efforts of the committee should be directed to obtaining accurate plug or male screws for use as gauges, and combs or chasers.

During the three years that have elapsed since this report was made, the committee have been in communication with different firms, and principally with the Pratt and Whitney Company, of Hartford, U.S.A., a firm enjoying the very highest reputation for work of the kind the committee desired to secure. Finding that this firm were prepared to undertake the production of gauges and tools for the British Association screw-threads on the same lines as they have adopted with the American and Whitworth threads, the committee have been satisfied to leave the matter in the hands of the company till they should ascertain whether they could produce the desired result, and have given them all the information, specification, &c., that were possible. Within the last two months, the Pratt and Whitney Company have submitted to the committee specimens in hard steel of male and female gauge pieces of threads Nos. 3, 7, and 13. The three male screws of these sets have been photographed by Colonel Watkin on a large scale, and have been measured by Mr. H. J. Chaney, Superintendent of the Standards Department of the Board of Trade.

The committee believe these gauges to be sufficiently accurate for practical requirements. The materials of which they are made—hardened steel—

should enable them to stand much use without injury. Their finish and general workmanship are exceedingly good.

The committee, through their secretary, have expressed to the Pratt and Whitney Company their satisfaction with these gauges, and have been informed, in reply, that a higher degree of accuracy may be expected in the future. They are still in correspondence respecting the specifications of limits of error and other details concerning their production on the commercial scale. The manufacture and sale of these gauges by the Pratt and Whitney Company appear to realise the object set before themselves by the committee—viz., to assist the extension of the use of the British Association system of screw-threads by making generally available accurate means for their verification.

While recognising the excellence of the form of the British Association screw-thread for mechanical purposes, the committee feel strongly that the difficulty of producing the form to the degree of accuracy desirable for the best class of work, and especially for gauge pieces, is a serious drawback to its value. Colonel Watkin's photographs show very clearly that the best appliances in the most experienced hands that the committee could find have failed to produce even single specimens of first-rate accuracy. The letters addressed to the secretary of the committee by Mr. George M. Bond, manager of the standards and gauge department of the Pratt and Whitney Company, as well as the high reputation of his firm, leave no room for doubt that very great care has been taken to secure accuracy in these specimens. A considerable number of gauges made by English firms of good standing have been examined by the committee, and have in every case shown errors of the same character as, though usually to a much greater degree than, the specimens submitted by the American firm.

From several sources, and especially in Mr. Bond's letters, it has been urged on the committee that although the difficulties of constructing these gauges of a very high degree of accuracy are practically insuperable, screw-threads of a flat-ended form can be produced with great exactness. A photograph taken by Colonel Watkin of a fine screw taken from an instrument made by Messrs. Brown and Sharpe shows that this is certainly the case.

The American, or flat-ended, form of thread appears to be rapidly establishing itself in France and Germany, judging from the reports we have received of the French and Zurich Conferences, and we understand that it is entirely employed by the French Admiralty, and by several of the French railway companies. These reports refer, it is true, to screws of larger sizes than are included in the range of the British Association and Professor Thury's systems. The conclusions of the recent Conference at Zurich, which adopted the flat-ended thread, were expressly limited to screws of more than 6 mm. diameter, the extreme upper limit of our system. But so far as the easy production of accurate form is concerned, argu-

ments which apply to large screws apply with greater force to small screws; while a form which is suitable for all screws above 6 mm. cannot be wholly unsuitable for screws below that limit. The committee, moreover, were informed by one of their number that he has used screws of the American form in sizes corresponding with some of the smaller numbers of the British Association series, and has found them perfectly satisfactory.

Current conceptions of the possible and desirable limits of accuracy in mechanical construction are rapidly advancing, and while we recognise the value of the work of the committee of 1882, in establishing a generally accepted thread, we are dissatisfied with a standard form for a piece so important as a screw which is open to the serious objection referred to above.

We recommend that this committee shall be re-appointed for the purpose of considering whether the British Association form of thread for small screws should be modified.

POST OFFICE.

The forty-fifth annual report of the Postmaster-General for the year ended March 31st, 1899, has lately been published, from which it appears that the estimated number of postal packets delivered in the United Kingdom during the year was 3,496,513,000, made up of—Letters, 2,186,800,000; post-cards, 382,200,000; book packets and circulars, 701,500,000; newspapers, 154,100,000; and parcels (actual number), 71,913,000.

The number of letters registered in the United Kingdom was 15,240,669, an increase of 7·2 per cent. over the number in the previous year.

London received no less than 28 per cent. of the total number of letters, but the increase during the year was greater in the provinces than in London, London showing an increase of 4·5 per cent. on the previous year, while the increase in England and Wales (excluding London) was 10·8, in Scotland 7·4, and in Ireland 10·3 per cent.

Post-cards have increased in number by 6 per cent. on the year. The rapid growth of correspondence by post-card is indicated by the fact that the total given above is more than double the total recorded twelve years ago.

The number of newspapers shows an advance of some three millions on the total given in the last report. The returns from the different parts of the kingdom vary somewhat, it being estimated that the number of newspapers delivered in the rural districts of all parts of the United Kingdom increased. In Ireland the increase was nearly 10 per cent.

Two causes have combined to cause a decrease in the number of book packets delivered. The book-post has been limited during the whole of the year to packets not exceeding 2 ozs. in weight, and there

have been fewer "heavy postings" of prospectuses and circulars at the chief office.

The total number of parcels delivered during the year, viz., 71,913,000, was 6 per cent. higher than the number for the previous year, and more than double the number delivered 12 years ago. The average postage on inland parcels fell just short of 5d. Of the total number 61,777,000 were rail-borne, and 10,136,000 road-borne. The railway companies received £705,732 as their share (55 per cent.) of the postage on the rail-borne parcels; the postage retained by the Post-office amounted to £792,367. Inland parcels, to the number of 761,801, were registered during the year.

The number of express services reached a total of 641,227, an increase of 16 per cent. on the total of the year 1897-98. 684,500 articles were delivered by express messengers in London, including 282,420 ordinary letters delivered by special messenger in advance of the postman.

Another change made in the service during the year has been the introduction of a delivery of express letters in London on Sunday. The new service was introduced on the 12th February last, and while it is found to add very slightly to Sunday work, it is undoubtedly a boon in cases of special need.

The international express service was extended during the year to France, Algeria, and Corsica for parcels, and to British Guiana and to St. Lucia for both letters and parcels.

The number of undelivered packets dealt with in the year was very considerable, viz., letters, 8,553,936; post-cards, 1,387,084; book packets, 11,301,606; newspapers, 553,622; and parcels, 188,837.

The total value of property in letters opened in the returned letter offices was £720,610.

As many as 44,360 letters were posted without address during the year, and 2,421 of these contained property to the value of £7,076, one letter having in it an uncrossed cheque for £500 payable to bearer. Other articles posted without address were 9,225 post-cards, 102,820 book packets, and 130,635 newspapers. The number of parcels found in the post without address was 14,066.

IRON AND STEEL INDUSTRIES IN 1899.

Owing to the very exceptional pressure that has been put on ironmakers during the present year, there has been a general idea that the make of iron must have been much larger than usual, and larger than would merely be represented by the additional number of furnaces in blast compared with the first six months of last year. On the other hand, owing to the comparative difficulty in procuring adequate supplies of iron ore and fuel, it has seemed to be probable that the blast furnaces have not been worked so regularly or to the same extent of their capacity as the demands of buyers would have rendered otherwise expedient.

indeed, some writers on the subject have gone the length of conjecturing that the increase of demand is not, for that and other reasons, been met by a corresponding increase of supply. All doubts on the subject have now been set at rest by the official statistics collected and published by the British Iron Trade Association, which show that the total make of pig iron in Great Britain for the first six months of 1899 has amounted to 4,782,868 tons, against 4,432,893 tons for the corresponding six months of 1898. This is an increase at the rate of about 700,000 tons a year, and if it is maintained, as is pretty certain to be during the second half of the year, will make the output of 1899 over 9,500,000 tons, which is, of course, a record. Indeed, in no previous year has the pig iron output come up to 6,000,000 tons, so that the year 1899 will apparently not only signalise the largest production of pig-iron on record, but it will also be notable for one of the largest advances in the history of the trade.

It will be remembered that the production of South Wales was last year seriously affected by the strike of miners, which made it practically impossible to procure local supplies of fuel. It is not, therefore, surprising to find that the largest amount of increase as taken place in that district, where the total make for the first six months of 1899 has been 467,960 tons, against only 245,085 tons in the corresponding six months of 1898. In several of the other districts, however, there has been a reduced production of iron, and as that has taken place in the face of an almost unprecedented demand, and of an advance of nearly 50 per cent. in prices it may be assumed that in the districts where this has happened influences were at work which prevented the ironmakers from producing so much as they could otherwise have done. These districts include Cleveland, Lancashire, and Northamptonshire, but in one of them, except Lancashire, has the reduction been very material. The imports of iron ore from Spain and other countries have been the largest on record, and exceed by about 600,000 tons those of any corresponding six months in the history of the trade. This is regarded as a good augury for the future, and the fact should go far to relieve the apprehensions that were generally entertained, and were in some quarters still felt, lest a scarcity of ores may compel a restriction of pig-iron output on a considerable scale. And this satisfaction is emphasised by the knowledge that new sources of supply are every now and again coming into view, one of the latest being a large deposit in Algeria, while several comparatively new fields are being tapped in Spain. Moreover, the home deposits of ore are being proved to be more abundant than was anticipated, several new sources of supply having been opened out in West Cumberland, Northamptonshire, and elsewhere. Finally, there is the iron ore field, which has recently been proved in Kent, and whence it is probable supplies will ultimately be drawn. About twenty-five more furnaces have been in blast during 1899

than were worked in the previous year, and twenty-five more are being rebuilt, or new furnaces in course of construction, so that there is every prospect of a further increase of output if raw materials are sufficiently cheap and abundant.

Stocks of pig-iron all over the country are, however, exceptionally low. At the end of June there were 688,190 tons in public stores, and about 250,000 tons additional in the hands of makers. This is less than six weeks' make, so that the iron in reserve is not over abundant. There is not the same pressure of demand that there was a few months ago. Makers appear to have plenty of orders on hand, and the Continental demand is still very strong. Nevertheless, stocks in some cases are increasing, and especially on the West Coast. If, therefore, there was at any time a danger of a pig-iron famine, which the best informed authorities do not admit, that possibility is daily becoming more remote. Much will, however, depend on the iron trade situation in the United States. Should the Americans make large demands upon British blast furnaces, which is regarded as possible, prices may still run up to a figure that would lead to difficulty.

The statistics of the steel industry show that in the first six months of the present year the production of steel was:—

	Acid (tons).	Basic (tons).	Total (tons).
Open hearth ...	1,443,398	137,291	1,581,319
Bessemer ...	748,919	257,003	1,005,922
Total ...	2,192,317	394,924	2,587,241

Here, again, there is a record output, taking the two descriptions of steel together. The make of open-hearth steel has exceeded by 276,000 tons the make of the corresponding six months of 1898, which was the next largest make in the history of the British steel trade, or, indeed, of the open-hearth steel trade of any country. The make of basic steel is also a record. The largest advance has taken place in Scotland, where the output of open-hearth steel in the first six months of 1899 was 517,107 tons, against 392,350 tons in the first six months of 1898. In all districts alike there has been an increased output in 1899. The make of this description is now at the rate of over 3,000,000 tons per annum, and there is every likelihood that the total make of both descriptions for the year 1899 will considerably exceed 5,000,000 tons. This large increase has been mainly due to the enormous requirements of the ship-building trade, the ascertained make of steel ship plates for the first six months of the year 1899 having been over 700,000 tons, or at the rate of 1,400,000 tons a year. In many cases provision is being made for adding to the many sources of production. This, however, is to a considerable extent being done, not so much by an absolute increase of furnaces as by increasing the dimensions of the newer plant, and thereby securing a much larger output for a given number of furnaces. In other words, 40 and 50 ton furnaces are now to a large extent taking the places of furnaces of much smaller capacity. The total

number of furnaces now available for smelting steel by the open-hearth process is about 400, and a number of new furnaces are being erected.

The statistics of both the open hearth and the Bessemer steel industry for 1899 show quite clearly that there has been no real scarcity of pig-iron. Otherwise the steel output could not have advanced as it has done. At the same time, the increased cost of pig-iron and of fuel, have, to a large extent, upset the calculations of steel manufacturers, many of whom found themselves with low-priced contracts on hand, which they were, in some cases where they had not fully covered their pig supplies, obliged to work off at a loss. Most of these old contracts, however, have now been got rid of, and, at present prices, it is probable that steel makers are doing as well as they have ever done. The outlook of the trade is regarded as exceedingly favourable, and there are not a few who believe that it will become even more so, but this, again, will largely depend on what our American friends may do in the way of placing contracts on this side of the Atlantic.—*The Economist*.

PROCESS OF DRY CLEANING.

The following article is from the *Dyers' Bulletin*, quoted in the *Journal of the Society of Dyers and Colourists* :—

There are a number of methods of dry cleaning, according to whether the industry is to be carried on in a small way or on a large scale. For the latter, a well-equipped workroom is ordinarily furnished with five cylindrical vessels, higher than they are wide, and of a size to just allow of the handling in them of the goods to be cleaned. They may be made of zinc, but copper kettles are to be preferred, or the large stoneware pots used in chemical works; each of them must be provided with a well-fitting lid. The articles to be cleaned are first sorted. These articles comprise :—(1) White silk tissues and ribbons, and such in which besides other colours white predominates; (2) woollen and half-woollen light coloured goods; (3) velvets and all other coloured silk goods; (4) woollen and half-woollen goods of medium shades; (5) dark-coloured articles.

Less available for dry cleaning are half-silks, all cotton and linen goods; and white cotton or linen articles, and such as cannot properly be placed into a washing machine, ladies' hats, satin shoes, &c., must be turned over to wet washing or cleaning by hand. Of the goods suitable for dry cleaning the light coloured are separated from the darker ones, and thrown in separate heaps. Then each piece, the light coloured first, is spread upon a table whose top is covered with zinc, and the coarsest stains or dirt washed out by means of the tampon saturated with benzin, which is placed handy in a cup. The dark pieces are treated last, because the benzin in the cup becomes gradually dark by the tampon being re-

peatedly dipped into it. The remaining benzin poured into a large receiver, with lid, and afterwards added to the dirty benzin from the washing machine &c., for distillation. After filling each of the five vessels to three-fourths of its capacity, the goods classified as indicated, are washed in the same order one after the other, in the first vessel and then thrown into the second, which is then covered with its lid. Then a fresh lot is washed by hand in vessel No. 1, the first treated lot transferred from vessel No. 2 into No. 3, and the second lot from No. 1 into No. 2, while a third lot is being washed in the first vessel the first treated pieces are from No. 3 thrown into No. 4, the following set from No. 2 into No. 3, and the third from No. 1 into No. 2.

The shifting of goods from one vessel to the other takes place because the benzin in the first vessel where the goods are washed out, becomes dark with every succeeding lot, while the first lot, that the white goods, are only brought into contact with clean benzin. The first lot is now again washed in vessel No. 5, then again spread upon a table and examined, and if still dirty spots are found, the material is by means of a clean tampon, or brush treated with benzin from the last vessel, and laid down in it for a while. For the preparatory treatment, as well as this supplementary cleaning, strong brushes may be used instead of tampons, and naturally, softer brushes for thin goods; gauze, grenadine, &c., are not brushed at all. Silks must be brushed pretty hard throughout; as long as the brushes are well saturated with benzin, no damage to the goods or destruction of the gloss need be apprehended; other thin materials are brushed in the direction of the warp, hooks and eyes, &c., must be removed.

When done, the goods are for draining thrown into a zinc or copper cylindrical vessel with lid and perforated false bottom, and an outlet at its lower part, and finally the benzin still remaining in the goods is pressed out by a clothes wringer, or whizzed out by hydro-extractors, for hand-power in smaller concerns, or for steam, &c., power in large establishments. There are hand-power extractors which perfectly meet the requirements of medium-sized cleaning works where only a few hands are employed. The cleaned goods are finally dried in a well-ventilated drying room or drying box, with outlets for the benzin vapours, at a temperature of 70 to 75° C., provided no stains have remained upon the goods, after the washing in benzin, which must be individually removed as indicated heretofore.

In large establishments, where much and rapid work is to be done, the foregoing described washing machines, driven by steam or other high power, are employed instead of the above-mentioned five washing vessels. The machine, or rather the outer drum, is filled with the cleaning liquid to about one-fourth of its capacity, so that the liquid rises to about 10 or 12 c.m. (3 to 4 inches) within the inner or slat drum. Then the goods to be cleared are entered, as they

have been separated in several lots, each lot separately in small articles, such as cravats, ribbon, and very thin and fine tissues which are liable to fall through the meshes of the inner drum, tied in a muslin bag), the rollers of both drums are closed and fastened, and the machine put into motion, and run for eight minutes or one hour with varying velocities, according to the nature and condition of the goods, as before stated. When the goods are rinsed in the rinsing tub in clean benzine, hydro-extracted and dried in the drying room at 70° to 75° C., and can in one to two hours be removed from the drying room perfectly free from the penetrating odour of the benzine. Smaller concerns, which have no properly constructed drying room, but only drying boxes, give the dried goods an airing, to remove this odour, on the loft, which, however, requires a considerably longer time.

But with the benzine treatment, drying and deodorizing, the cleaning proper is not yet ended. If the removal of stains has not taken place before the general scouring, the goods must be carefully examined for stains which the chemical treatment has not removed. If such is the case, the goods are placed upon a marble slab, or even a table which is covered with good oil-cloth or only with clean muslin or similar material, and the stains wiped out with a rush and water and soap. The most tenacious stains are those from oil-paints and resins. These are touched up by means of a tampon with oil of turpentine, a piece of filter paper or thick blotting paper placed under, and another piece put upon them, and a hot smoothing iron passed over it, finally the article is washed in warm soap-water, and after sufficient draining, ironed dry. Very woolly goods, having a strong nap or pile, which have become flat by ironing, are passed over a steam table or steam ironer, whose perforated top-plate is covered with a strong felt cloth, flannel blanket, or similar material. On turning the steam on, the goods being passed over the top of the apparatus left side down, it penetrates them from below and immediately raises the pile to its original position, making the goods look like new, provided the cleaning itself has been properly and effectually carried out.

GERMAN LACE AND EMBROIDERY TRADE.

The German lace and embroidery trade was less last year than in the previous year, but Great Britain still takes the largest part of the exports. It amounted to 11,043 cwt., or 44·8 per cent. of the entire export. New technical schools for this industry have been opened in Saxony, it being considered a necessity to educate capable machine embroiderers, if the trade is to maintain its present high standard.

The Saxon weavers were very dissatisfied with the business of the past year. Good trade was, however, done in chenille curtains and table-covers for Great Britain. The Saxon manufacturers of lace and woven

stuffs complain that the Nottingham firms will not do direct business with them, and refuse to sell even an inch of net except through the medium of the agents. It seems necessary to point out to these firms that such a procedure is liable to injure their trade with Germany.

The import of net, which is principally used in the lace embroidery industry, was only 9,336 cwts., or a diminution of 7·1 per cent. The reason for this was the diminished sales of such articles, and the manufacture of German net. Several factories have been started in Saxony for this purpose, but it remains to be seen whether these new undertakings will permanently injure the British trade. In order still more to foster the home industry, it has been suggested to raise the duty on foreign net. By far the greater part of the imports last year, 8,942 cwts., or 95·7 per cent., came from Great Britain.

The German "posament" or lace industry, which employs many thousand hands in the Erz-Gebirge, showed last year a great improvement on the previous year. The export of German lace, buttons, &c., showed a considerable increase. Of the entire export of 111,191 cwts., with a value of £2,256,618, 38,126 cwts., or 34 per cent., went to England. It is thought in the trade that a still further increase in the exports will take place.

The "English curtain" industry, which, as is well known, has its principal seat in Saxony, and especially in Falkenstein, has found new centres in other Saxon towns, in Zwickau, Dresden, and Zittau. An English factory has been started at Uhingen, near Stuttgart, in Wurtemberg. In Falkenstein, about 140 curtain looms are working, all of which have been sent from Nottingham. Efforts have been made to make the machines in Germany, but Mr. Consul Schwabach is assured by competent persons that these cannot compare with the British machines. It is true that quite lately the firm of E. H. Lange has succeeded in making looms which are said to be easy to work, and which produce well-made goods. If, however, the British makers keep up to their present high standard, and endeavour still more to perfect their machines, they need fear no permanent competition in this direction.

In regard to the "improvement" trade in Madeira embroidery, the following fact is of interest. In October, 1897, the Minister for Trade and Commerce asked the opinion of the Berlin Trade Union on the question, if it were advisable to permit the free transit of goods to and from Madeira for the purpose of "improvement." The Minister was advised to allow this trade to continue duty free, as it could not be said to injure German trade, but was, on the contrary, of decided benefit to the German industry. The Finance Minister conceded the free traffic in this article until further notice. Efforts were again made to introduce a duty on this article, and competent persons were again consulted, but with the same result, and the "improvement" traffic still continues duty free.—*Textile Mercury*.

Notes on Books.

MUSICAL PITCH: Letters, Articles, and Comments in the Press on the Proposal to Adopt the Low Pitch throughout the Pianoforte Trade. London (Waterlow and Sons): 1899. Folio.

This pamphlet contains a reprint of the chief articles and letters which have appeared in the English Press on the controversy respecting the general adoption of the New Philharmonic Pitch, from the beginning of the controversy on the 4th of July until August 31st, the first communication being Messrs. John Broadwood and Sons' letter to *The Times*, in favour of the New Philharmonic Pitch ($A = 439$ double vibrations at 68° Fahrenheit), derived from the Diapason Normal $A = 435$ at 59° Fahrenheit. A list is given of the pianoforte manufacturers who have signed the agreement in favour of the general adoption of the Low Pitch, which is as follows:—"The vexed question of a suitable pitch for pianofortes should be settled, and believing the time has arrived when it can be done, we, the undersigned, after due deliberation, have decided to adopt the Paris Diapason Normal, but with the allowance for a higher temperature in orchestral performances, accepted since 1896 by the Philharmonic Society, viz., $A = 439$ ($C = 522$) at 68° Fahrenheit. From the 1st of September, 1899, we intend to adopt this pitch as a standard for pianofortes, both for retail and wholesale purposes, and with regard to the late Philharmonic Pitch, $A = 454$ ($C = 540$), when required as an exception, and not, as has been for many years in this country, the rule." It will be remembered that the Society of Arts' pitch ($C = 528$ vibrations), which was adopted in 1860, was given up by the Council of the Society in 1886, in favour of the French pitch ($A = 435$, or $C = 517.3$). The reasons for this action are given in a report of the Society's Committee, and printed in the *Journal* Feb. 12, 1886 (vol. xxxiv. p. 265).

PRACTICAL ELECTRICITY AND MAGNETISM. By John Henderson, B.Sc. Longmans, Green and Co. 1898.

This is the second of the series of laboratory manuals edited by Mr. Henderson and Mr. Joyce, the first being a treatise on elementary physics, by the same author. It is intended for fairly advanced students, and is meant to be used as a companion in practical laboratory work. The work consists of six chapters, the first five of which deal respectively with the Measurements of Resistance, Current, Electromotive Force, Quantity, and Capacity, while the last is devoted to Magnetism. The construction and use of the instruments used, galvanometers, resistances, standard cells, &c., are carefully described, and full practical directions are given to the student. At the end of each chapter are references to important papers dealing with the subject-matter of the chapter.

General Notes.

METROPOLITAN ASYLUMS BOARD.—According to the report of the Board for 1898, the total expenditure was £719,128, showing an increase of £53,735 over that of the preceding year. The expenditure is roughly summarised as follows:—(I.) For imbeciles, £140,135; (II.) for infectious sick, £319,069; (III.) for ambulance services, including medical department, £30,739; (IV.) for boys under training, £18,857; (V.) for children, £4,530; (VI.) for general expenses, including repayment of loans, £205,798.

SANITARY INSTITUTE.—The 28th course of lectures and demonstrations for sanitary officers will be delivered on Mondays, Wednesdays, and Fridays, from September 15th to November 29th, 1899. The course will comprise the following lectures:—Part I.—Six lectures on elementary physics and chemistry in relation to water, soil, air, and ventilation; two lectures on elementary statistics, meteorology, and local physical conditions. Part II.—Eighteen lectures on public health statutes; the practical duties of a sanitary inspector, *e.g.*, drawing up notices as to sanitary defects, drain-testing, disinfection, methods of inspection, note-taking, and reporting; municipal hygiene or hygiene of communities; building construction in its sanitary relations; measurement and drawing plans to scale. (Inspections and demonstrations will be arranged in connection with the lectures.) Part III.—Seven lectures on meat and food inspection, including taking of samples of water, food, and drugs for analysis. (Practical demonstrations of meat inspection will be given.)

SCHOOL BOARD FOR LONDON.—The number of pupils admitted to the Evening Continuation Schools, conducted by the School Board for London, last session, rose from 57,586 to about 109,000, showing an increase of about 51,414 compared with the numbers in the preceding session. The 18th Session commenced on Monday, 11th September. As many as 348 schools for general instruction were opened, and, in addition, there were twelve special schools for commercial work, and eight special science and art schools. Lectures in literature will be given in 21 schools, gymnastics will be taught at 58 centres, and ambulance and home nursing will be taught by doctors in upwards of 100 schools. There will also be facilities for women and girls to learn practical cookery, dress-cutting and making, and laundry-work, and for men and boys to receive instruction in wood-work. Some form of physical exercises will be taught in all schools. Students are prepared for the examinations of the Science and Art Department, Civil Service, Society of Arts, &c., and prizes and certificates are awarded. Applications for prospectus should be made to the Clerk of the Sub-Committee on Evening Continuation Schools, School Board for London, Victoria-embankment, W.C.

Journal of the Society of Arts.

No. 2,444. VOL. XLVII.

FRIDAY, SEPTEMBER 22, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS, 1900.**

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

THE SOCIETY OF ARTS.

(1754-1899.)

The Society of Arts is one of the three oldest of the learned and scientific societies in the country, for when it was founded in 1754 only the Royal Society and the Society of Antiquaries were in existence. As it had a large field to itself, it was comprehensive in the scope of its work. For a long time it alone filled the place which is now occupied by the many societies which have since been founded for the promotion of special branches of science, industry, and art. It was—as indeed it still is—at once scientific, technical, industrial, commercial, and artistic. Before the foundation of the Royal Academy it held exhibitions of pictures, and assisted in the education of art students by prizes and examinations. Until the Royal Agricultural Society was established, it was the principal institution in the country for the promotion of agriculture and the application to agriculture of scientific principles. It anticipated the Institution of Civil Engineers, and the other engineering institutions, in the encouragement of civil and mechanical engineering. It encouraged chemical research, and the application of chemistry to industry, before the Chemical

Society and the other chemical institutions which in later years have dealt with various branches of that great science. And it promoted arts and industries in the Colonies more than a century before the Royal Colonial Institute or the Imperial Institute.

During the first half century of its existence the objects of the Society were principally attained by the award of premiums for useful discoveries and inventions. In this way it distributed £28,434 between the years 1754 and 1783. There was probably at the time no better way of discovering meritorious inventions, and bringing them to public notice, though it was liable to the obvious imperfection that the prizes could be awarded only in accordance with the best knowledge of the time, whereas the objects to be rewarded were, or ought to have been, in advance of such knowledge.

In the department of Fine Arts, it had a share in assisting the education, and encouraging the youthful efforts of many of the most eminent artists from the time of Reynolds to our own days. On its prize lists are found the names of Richard Cosway, Joseph Nollekens, George Romney, Sir Thomas Lawrence, P.R.A., Sir William Ross, William Mulready, Thomas Bewick, Aloys Senefelder (the inventor of lithography), John Flaxman, W. Wyon (the medallist), Sir Edwin Landseer, Sir Charles Eastlake, P.R.A., W. P. Frith, J. C. Hook, Sir J. E. Millais, P.R.A. One of the first, if not the first public exhibition of pictures in London was that held in 1760 at the Society's rooms in the Strand, near Beaufort-buildings, an exhibition which really led to the foundation of the Royal Academy in 1768.

The improvement of Agriculture was one of the very earliest objects of the Society, and the first volumes of its Transactions are devoted in large measure to this subject. Indeed, so important a branch was it of the Society's operations that the publication which practically served as the Society's Transactions for the first few years of its existence was known as "Dossie's Memoirs of Agriculture." It would take too long to record even a selection of the improvements it effected, or tried to effect. Some of the more important may be merely mentioned. The want of timber for shipbuilding and other purposes was one of the great needs of the country at the time of the Society's foundation. The country was to a large extent deforested, and some organisation was required to prevent the spread of the evil. An earnest effort was made by the

Society to attract public attention to the need for renewing the stock of timber. Between the years 1775 and 1781, twenty-two gold medals and a few smaller prizes were presented to landed proprietors in various parts of the country. About three-quarters of a million trees were planted under these awards. The attempt was entirely successful, thousands of acres were planted, and, as a practical result, the supply of timber was renewed. Many of the woods throughout the country owe their present existence to the initiative of the Society of Arts.

The encouragement of the Arts and Industries of the Colonies was another of the first objects to which the Society devoted itself. The Colonies of the country, it is to be remembered, were then all situated in North America (now the United States) and the West Indies. Prizes were given for new colonial industries, for the introduction of machinery into the Colonies, for the importation into this country of colonial products. Contemporary records show how greatly the Society's efforts were appreciated in the West Indies and in the American colonies. Many valuable plants were introduced abroad, and many valuable products brought home through the agency of the Society.

A special division of the Society was devoted to mechanics and manufactures, and another to minerals and chemistry. By means of the two committees which dealt with these divisions, large sums were distributed in prizes and donations to meritorious inventors. The range of work of these two committees was so wide that it is difficult to give even a summarised account of what they did in the first sixty or seventy years of the Society's life; but it may safely be said that there was hardly a single branch of industry at the time which was not helped forward by their efforts. The manufacture of iron, textile manufactures, chemical manufactures, and, in later times, all the various applications of science to manufacturing purposes received a share of the Society's attention. Perhaps some of the prizes were ill-bestowed, and many deserving inventions were refused awards. Looking back through the old records of the Society it is not difficult to discover occasional instances in which rewards were refused to inventions in which present knowledge can perceive the promise of future discovery. But on the whole the premiums were judiciously bestowed, and were of much value in stimulating and rewarding invention. But for the unwise prejudice which prevented the recog-

nition of any patented object, the premiums would have been more useful still.

As time went on it was found that the award of prizes for meritorious inventions was not the most advantageous way of attracting public attention to them. The opinion of a committee on a new and untried invention is very liable to error. The more novel the invention, the more varied from previous ideas, the less likely is it to commend itself. This was even truer at the beginning of the century than now, when the great and startling developments of science have rendered public opinion less intolerant of novelty.

It was found that the best test of merit was practice, and the best service that could be rendered to an inventor was to give him the opportunity of publicity. In the industrial, as in the material, world, the rule of the survival of the fittest holds good. Hence the practice was instituted of holding meetings, at which new scientific discoveries and their applications were described and discussed. This idea seems to have been mainly due to Mr. William Aikin, the distinguished chemist, who was secretary to the Society in the early part of the century; and he introduced the practice of delivering lectures on various branches of industry and improvements connected with them. In 1842 the practice was reduced to a system, and from that time to the present day one of the most useful portions of the Society's work has been the holding of such meetings for the reading of papers and the delivery of lectures.

The recorded reports of these meetings for many years past form a continuous chronicle of the progress of the applications of science and of art to practical purposes, and there have been few of the prominent technical scientific discoveries of recent years whose introduction to public use has not been assisted by the Society of Arts. The long series of "Cantor Lectures" delivered before the Society form almost a full industrial cyclopædia. In their delivery, their special educational value was very great, and their published reports form a useful contribution to the industrial history of the country.

While referring to the Society's meetings special reference should be made to those of the Indian Section, the value of which in promoting a knowledge in this country of subjects relating to the Empire of India has long been and is still constantly recognised by the Government of India and by the India Office. If the work of the Foreign and Colonial (originally the

African) Section has been less important, that is only because its special field of labour has for some years been occupied by the Colonial Institute, and more recently still by the Imperial Institute, a body whose very existence is a high testimony to the work of the Society of Arts, founded as it was by H.R.H. the President of the Society on lines similar to the older body, and to carry out, under more influential auspices and on a larger scale, precisely the same work.

As special institutions came to be established to deal with various branches of science and industry, the Society gradually abandoned some of its older fields of work, but it has still remained the one unspecialised Society, always ready to afford an arena for the discussion of any prominent subject coming within its rather wide scope. There are now some fifty scientific societies meeting in London, dealing with different branches of science. It is not too much to say that the greater number of them deal with subjects at one time or other included in the Society of Arts programme. Many of them originated more or less directly from the Society of Arts. Some originated at meetings held at the Society of Arts' rooms, others were promoted by the more active members of the Society at the time. It may, however, be said that, as each relieved the Society of some of its work, it left behind more than sufficient new material to occupy the energies of an institution dealing not with special departments of science, but with the practical application of all departments.

For it may be said that the only way in which the Society has differentiated itself from other institutions of a similar nature is that it devotes itself principally to the application of science and of art to practical purposes. Its value in this direction was recognised by the Prince Consort, who found it a most useful instrument for carrying out his own ideas, and impressed upon it much of the character it now bears.

Apart from its regular work, holding meetings for the advancement of knowledge and the dissemination of useful information, the Society has devoted itself to a vast number of definite public objects, to the promotion of which its organisation has been in various ways applied. Some of them may at least be mentioned. Perhaps the most important service ever rendered by the Society was the establishment of International Exhibitions. The first Exhibition of 1851, as is well known, was originated, and its organisation carried on till it could be

handed over to a Royal Commission, by the Society. In the same way the Exhibition of 1862 was started, and to a large extent carried out by the efforts of the Society.

Another great branch of the Society's work is that dealing with education. Through its efforts was originated the system of carrying out local examinations from a common centre, which soon after received such full development through the agency of the Science and Art Department. The Society's examinations, founded in 1856, though its example has been followed by other agencies, amongst whom must be specially mentioned the Local Examinations of the Universities, still continue to be the only examinations of an important character dealing with commercial education.

It was the Society of Arts that first drew public attention to the need for technical education, and, by the holding of conferences and discussions on the subject, aroused the public feeling which led to the appointment of the Royal Commission of 1881, with all the vast developments of that branch of education which have followed the report of that Commission. Among the many institutions whose establishment was fostered by the Society may certainly be mentioned the City and Guilds Institute for the promotion of technical education, which at its origin was greatly assisted by the Society, and has of late years developed into a most important educational agency, the system of technical examinations founded and carried on by the Society on a small scale for some years, in spite of opposition and indifference.

The great improvement in decorative art which has marked the last half of the present century in this country may be said to have had its birth in the Society of Arts. Chiefly owing to the strenuous efforts of the late Sir Henry Cole, the Society originated a campaign against the ugliness and ignorance in artistic matters which was certainly prevalent in England about the end of the first half of the century. Its efforts were for a long time met with ridicule, but public opinion was gradually converted, and the value of beautiful and artistic surroundings in daily life, instead of being a matter to be sneered and laughed at, is now regarded as a matter of course.

It would perhaps be too much to say that the attention which matters of public health now receive was entirely or even in the main due to the efforts of the Society, but it did a most valuable public service in popularising a know-

ledge of the subject, and disseminating accurate information on sanitary matters by means of the conferences it held on sanitary subjects from the years 1876 to 1879.

Many other public objects have been initiated or promoted by the Society. It took an active part in the improvement of the Patent-law, since the first improvements in 1852 down to the last Patent Act of 1883. It was the action of the Society that first secured protection for copyright in works of art. Its Food Committee was one of the earliest agencies to draw attention to the necessity of providing means by which meat and other foreign food products could be successfully imported. One of its committees for a long time urged on the Post Office the necessity for a Parcel Post (suggested in 1858), and worked up public opinion until it was granted. Another for a long time urged the necessity of cheaper telegraphic communication, and suggested to successive Postmasters-General the desirability of shilling telegrams, long before they were granted.

The Royal College of Music was founded as the National Training School for Music by the exertions of the Society. As far back as 1839, the Society dealt with the question of uniform musical pitch, and established a pitch of its own which was only recently formally abandoned in favour of the better-known French *diapason normal*.

The introduction of moderate-priced scientific apparatus was initiated by the Society of Arts' Microscope in 1855. Thousands of these instruments were sold for three guineas, at a time when it was believed that no microscope of any practical value could be produced for four or five times that amount.

The idea of marking, by distinctive tablets, houses associated with the names of distinguished men, originated with this Society, and has in London been carried successfully into effect. Such historical houses are fast vanishing, and the attempt to rescue them from forgetfulness has been very popular and, it is hoped, useful.

The whole of the work of the Society of Arts has been carried out without any Government aid, or indeed without any endowment. It is practically dependent entirely upon the annual subscriptions of its members. Its present income is about £10,000 a year, and this is expended annually. It has in past years received a certain amount of money by way of legacies, and it possesses trust funds amounting in all to £14,000. Most of these trusts are chargeable with the award of various

prizes. It has about £17,000 of its own, unaffected by trusts of any kind, mainly accumulated during the past twenty-five years out of surplus revenue.

The buildings in the Adelphi, which it has occupied since 1775, are not freehold. The original lease expired in 1867. It was renewed for a period of thirty years, which expired in 1897, and the lease was further renewed for a period of seven years, ending in 1904. The accommodation is now hardly sufficient for the needs of the Society. It is especially deficient as regards the requirements of a library, and the want of convenient library accommodation has for many years past been a serious drawback. There is every reason to believe that with ampler premises the operations of the Society might be extended, a greatly increased number of members attained, and consequently larger funds provided, which might be expended in objects of public usefulness. The Society's meeting-room has been largely used by other societies, to whom it has been readily lent, and for public meetings for objects cognate to the work and purposes of the Society.

ELECTRICAL MACHINERY ON BOARD SHIP.*

Everybody is familiar with the great advance in comfort on board ship following the substitution of electric lights for candle and oil lights, and it is only natural that ever since the first application of electricity, endeavours should have been made to extend its use on board ship.

The first part of the electrical system to be developed was the generating plant, as it was very soon apparent that belt-driving, otherwise universally resorted to, was not reliable enough. As a first improvement, Mr. J. S. Raworth constructed rope pulleys for an endless rope, which could be stretched while running by means of a movable guide pulley. This rope gear, although it avoided the danger due to the belt slipping off the pulleys, shared with the belt-driving the serious disadvantage of occupying too much space.

About the same time, Brotherhood engines, running at a high speed, were first used coupled direct to dynamos; but their construction at that time was not very well understood, and the ships' engineers greatly preferred double-acting engines of simple construction. To meet their views, and to economise space, Mr. Haworth constructed a friction driving gear, which has been extensively used, and merits, therefore, a short description. The dynamo is bolted to a cradle which can rock the dynamo in the direction of the armature spindle, and this carries a pulley of com-

* Abstract of paper by Alexander Siemens, M.Inst.C.E., read before the British Association meeting at Dover.

pressed paper, which is driven by the fly-wheel of the steam-engine, against which it is pressed by adjustable springs. The cradle supporting the dynamo is placed between the steam-engine and the fly-wheel, so that the whole arrangement is very compact.

After this gear had been in use for some time, Mr. Charles Hall, the electrical engineer of the P. and O. Company, suggested driving the dynamo direct by a Tangye engine at the comparatively low speed of 180 to 200 revolutions per minute.

This type of generating plant has practically been adopted for all modern ships, and it may be observed in passing that direct driving is nowadays recognised, even in places where there is no want of space, as superior to belt driving for all purposes.

In view of the contention that English practice is lagging behind that of other countries, it is as well to remember that at the Chicago Exhibition the two or three direct-driven sets were almost ridiculed by the American engineers, who confidently predicted that the Old Country would soon drop this practice, and adopt the American method of belt driving.

As a plant typical of the American practice of that time, the power plant of the Brooklyn Tramways can be mentioned, where Corliss compound engines drove a fly-wheel, from which a belt, five feet wide, drives two dynamos on the first floor of the building.

It is needless to say that direct driving is now as much in use in the United States as it is here, and, in fact, everywhere. There can, therefore, be little doubt that the type of generating plant adopted on board ship has reached a stage in its development which, no doubt, will be improved, but will not be materially altered.

When electricity was introduced on board Her Majesty's ships some inconvenience was caused by the magnetic field of the dynamos affecting the ships' compasses in cases where iron bulkheads happened to be near the dynamos, and extended to the neighbourhood of the compasses. In order to guard against eventualities of that kind it is now usual to employ iron-clad dynamos on the men-of-war. For the same purpose, the distribution of the electricity is in most cases effected by the double wire system, the flow and return being laid side by side to all points of utilisation. These conductors form the most valuable part of the electric system, through being easily adapted to the scanty accommodation on board, readily repaired, without danger arising from their being damaged, when they are properly fitted up, and easily tested to ascertain that they are in working condition.

Such qualities contributed not a little to the speedy introduction of the electric light, but they are still more appreciated for the distribution of power. The larger the ships are the more it becomes necessary to supplement manual labour by mechanical power, and it is a trite saying that modern ships are nothing but machine shops.

Until lately it was usual to drive all this auxiliary machinery by small steam-engines or by hydraulic

power, and this necessitated a network of piping all over the ship, which is difficult to arrange neatly, and which gives endless trouble through leakage. In addition, there are waste products from all the auxiliary steam-engines, and their disposal requires additional pipes and complications. All this inconvenience is avoided by employing electric motors, and for certain purposes, where the load on the motor does not vary much, they have been generally introduced.

That their use has not been more extended is due to the difficulties which arise from variations in the load on the auxiliary machinery. Taking the case of a winch, it frequently happens that the strain on a cable increases sufficiently to stop the movement of the winch altogether, and this would cause the current through the electric motor to rise to a dangerous extent. It is impracticable to protect the motor by a fuse, as the interruption of the circuit through the blowing of the fuses would allow the strain being taken off the winch, and in most nautical operations it is necessary to keep the strain on.

There are two methods in use to overcome this difficulty, one is to employ shunt-wound motors, running continuously, and operating the winches, &c., through friction clutches; and the second is to employ special cut-outs in connection with series-wound motors. By these cut-outs the current through the motors is not interrupted altogether, but if the winch or other machinery is stopped so that the current becomes excessive, the main circuit is interrupted, and a bye-pass only left, in which sufficient resistance is inserted to allow only the maximum safe current to pass.

As an example of the first method, a steering gear and rudder indicator may be mentioned, which are constructed on similar lines, the indicator being, so to speak, a working model of the steering gear. A shunt-wound electric motor replaces the usual steam-engine, and turns the main shaft of the steering gear backward and forward by means of clutches, which are actuated by currents sent from the bridge. The current through the magnets actuating the clutches is interrupted automatically by the movement of the rudder-head, and a new impulse is wanted from the bridge before the steering gear will move again.

For the convenience of the quartermaster, the contact-making apparatus on the bridge is designed in the usual shape of a small steering wheel, so that it does not differ externally from the wheel used with steam-steering apparatus. On the rudder-head a similar contact apparatus is fixed, which controls the solenoid clutches of the rudder indicator on the bridge, which is, as stated above, a working model of the steering gear, and shows the quartermaster the exact position of the rudderhead.

Such an indicator has been in use on the s.s. *Faraday* for some time, and has given complete satisfaction, so that it is contemplated to substitute the corresponding electric-steering gear for the present steam-steering gear as soon as room can be found for larger generating plant.

Here, again, appears an obstacle to the introduction of electric motors on board, and it can only be overcome by designing the engine-rooms for the accommodation of powerful electric generating plant.

There is every indication that this requirement is now being fully recognised, and that in future it will be possible to utilise electric motors in connection with all auxiliary machinery, and the absence of all pipework outside the engine-room and boiler space will greatly increase the safety and convenience of working ships.

Sometimes it has been suggested that the main engines of a transatlantic liner should also be worked by electricity, either on the plan adopted by Mr. Heilmann, for locomotives, or by means of accumulators. Although this may seem feasible at first sight, our present knowledge is not sufficiently advanced to make a practical test of either suggestion. Marine engines are the lightest per horse-power that are constructed; it would, therefore, not be possible to put smaller engines on board to generate electricity than those now used to drive the propellers direct. It is, therefore, self-evident that the Heilmann system cannot be economically applied for the main engines of ships.

Equally impossible would it be to use accumulators for driving electric motors connected to the propeller shafts, as their weight would greatly exceed the capacity of the ship. This is easily shown by the consideration that a 6,000 tons ship, propelled by 8,000 indicated horse-power, will take about 150 hours to cross the ocean, equal to 1,200,000 horse-power hours. Fairly efficient accumulators give about 10 watt hours per 1 lb. of their weight, so that a horse-power hour can be obtained for 75 lbs. of accumulators. The ship in question would, therefore, have to load about 40,000 tons of accumulators for the trip across the Atlantic.

No doubt there are further discoveries in store which will enable future electricians to attack the problem of propelling large ships electrically for long distances; for the present, it has only been proved to be an advantage to drive electrically the auxiliary machinery on board ship.

INTERNATIONAL ASSOCIATION FOR TESTING MATERIALS.*

Prior to the year 1800 little was known of the properties of the materials of construction. Galileo had shown in 1638 that the strength of a rectangular beam varied with the square of its depth, Hooke in 1678 had announced the law that the stretch of a spring was proportional to the stress upon it, various authors had discussed the forms of beams of uniform strength, and Euler in 1744 had enunciated his formula for the resistance of columns under compression. Theory was far in advance of practice, for experiments had

been so few and so imperfect that the elastic limit was scarcely recognised.

During the years from 1800 to 1850 great progress was made in the theory of elasticity, and a slow growth took place in knowledge of the properties of materials under stress. The methods of testing were, however, imperfect, and progress was slow, and, with the exception of the classic researches of Hodgkinson, the work of this period was mostly of value as a preparation for that of the future.

In 1882, through the influence of John Bauschinger, a number of German experimenters met at Munich and discussed the question as to how uniformity in the methods of testing materials could be promoted. As a result of this meeting, formal conferences were held at Dresden in 1884, at Berlin in 1886, at Munich in 1888, and at Vienna in 1893, delegates from other European countries being often present. The reports of the proceedings of these conferences, published in Bauschinger's "Mittheilungen," attracted wide attention, and the great value and importance of the discussions became universally recognised in engineering circles. In short, the movement assumed an international character.

In 1890, as a result of the International Congress of Engineering held at Paris in the preceding year, the French Government appointed a commission to formulate standard methods for testing the materials of construction. Its report, published in 1894, in four large volumes, is one of the most valuable contributions to the subject, but from the first it was recognised that ultimate conclusions could not be determined by a commission of one nationality, and accordingly, since 1895, the French Government has given hearty support to the work of the International Association.

In 1895, as a result of the four preceding conferences, the fifth conference met at Zurich, all European countries, except Turkey, being represented. At this congress the International Association for Testing Materials was formally organised, its object being, as stated in its statutes, "the development and unification of standard methods of testing for the determination of the properties of the materials of construction and of other materials, and also the perfection of apparatus for that purpose."

In 1897 the second congress of the International Association was held at Stockholm, there being present 61 members, representing 18 countries. The congress continued in session for three days; reports of committees were presented, papers read and discussed, and plans outlined for the future work. It was resolved that the next congress should be held in Paris in the summer of 1900, and the Council was authorised to appoint technical committees to make reports at that time on special problems relating to the objects of the Association.

At a meeting of the International Council held early in 1898 appointments were made of chairmen of 21 committees on technical problems, and the number of members on each committee from each country

* An address by Professor Merriman quoted in *The Iron and Coal Trades Review*.

was assigned. It was also recommended, in order to expedite the appointment and work of these committees, that the members in each country should meet and form a national section of the International Association.

The membership of the International Association numbered 493 in 1895, 953 in 1896, 1,169 in 1897, 1,488 in 1898, and is now probably about 2,000. Germany takes the lead in regard to numbers of members, it having 387 in 1898, while Russia had 315, Austria 158, England 83, Switzerland 83, United States 68, Sweden 68, France 66, Holland 48, Norway 42, Denmark 39, Spain 36, Italy 35, and 60 from nine other countries.

The subscriptions of 6s. per year transmitted to the International Council are used by it in issuing its publications, and in assisting its committees in defraying a part of the expenses of their special investigations. The detailed proceedings of the congresses have been printed in the journal *Baumaterialienkunde*, published in the French and German languages, at Stuttgart, which has been furnished to members at 10s. per year. It will be seen, therefore, that a member who desires to be fully informed regarding the work of the Association must necessarily subscribe to this journal.

The technical questions proposed for discussion at the Paris congress of 1900 are 19 in number. The organisation of the international committees which are to consider these topics is now complete. Probably the most important of these subjects is that of standard international specifications for testing and inspecting iron and steel; this committee originally consisted of about 40 members.

Of the nineteen problems to be considered by the nineteen international committees, six are on iron and steel, one on stone and slate, eight on cements and mortars, one on tile pipe, one on paints, one on lubricants, and one on the dry rot of wood. The fact that there are eight committees on cements and mortars and only six on iron and steel may seem abnormal, but it should be remembered that in the testing of hydraulic cement, the personal equation of the observer enters to a far greater degree than in the case of metals, and that its rapidly increasing use demands the immediate perfection of methods which will render comparable the work of different laboratories.

While the main object of the Association is to establish rules for testing, it is recognised that this cannot be done until a thorough knowledge is obtained of the properties of materials under varying conditions. Accordingly, the work of some of the committees is to collect and digest the information now on record, or to make scientific investigations that will render present knowledge more complete and definite. Thus, there is a committee on the properties of steel at abnormally low temperatures, one on the relation of the chemical composition of stone to its weathering qualities, one to digest the work of previous conferences and conventions on the adhesion of hydraulic

cement, one on the causes of the abnormal behaviour of cements as to time of setting, and one on the protection of wood against dry rot. Some of these subjects have already been discussed at the congresses of Zurich and Stockholm, and accordingly the reports to be presented to the Paris congress should contain positive additions to present knowledge.

There are advantages and disadvantages in doing technical work by committees. One advantage accrues through the harmonisation of the different views held by individuals, whereby non-essentials are rejected and only fundamental methods are retained. One of the disadvantages is that this process of harmonising views takes time, causing reports to be long delayed, particularly with international committees. Some technical societies appoint committees with great reluctance, fearing that their reports may be regarded as official action. In the case of an international organisation, no such fear is felt, and the report of a committee is to be considered from the same point of view as the paper of an individual member. Through the formation of the national sections, the work of the international committees can certainly be made more valuable and effective than ever before, for each national sub-committee, after having eliminated disagreements of its individual members, can work as a body to impress its views upon the other national sub-committees. In many cases an international agreement may be found difficult to make, but if made after such full discussion it will be sure to be authoritative and valuable.

The subject of the chemical analysis of iron and steel has been discussed in previous conferences and congresses, and at the Stockholm meeting of 1897 it was formally resolved to establish an international sidero-chemical laboratory at Zurich. It is, however, to be doubted whether the establishment of chemical and physical laboratories falls properly within the scope of the objects of the Association. If sufficient funds could be raised so that men of different nationalities might meet at such a laboratory to actually make analyses and tests, each criticising the others, while at the same time learning from them, then undoubtedly effective work would be done in harmonising differences and perfecting standard methods. It is to be hoped, if the establishment of the sidero-chemical laboratory at Zurich proves to be successful, that it may tend to further this method of research. It is, however, the opinion of many members that results as good, if not better, would be secured by arranging systematic schemes of investigation, and distributing the actual work of analysis or testing among the laboratories of different countries.

THE VIENNA EXPORT ACADEMY.

Since October, 1898, there has existed in Vienna a commercial school of an entirely original organisation. This is primarily shown from the fact that the institution is directed by a high official of the Austrian

Ministry of Commerce. This direction is not merely nominal, but is evidenced, apart from daily influence on the life of the pupils, by weekly conferences, under the chairmanship of the director himself, at which reports are received from the teachers of the studies of the past week, and those to be taken up in the coming ones. Every topic, even in its smallest details, is in direct relation to the object of the institution. This object is the promotion of the Austrian export trade. No serious patron of the academy wishes that the young men, immediately after finishing their studies, should become Austrian exporters. On the contrary—and this is the second original phase of the scheme—it is desired that the graduates, on leaving the academy, should act as clerks in exporting and manufacturing firms, there to learn the practice of some special branch of business, whereupon, under further support of the Ministry of Commerce, the graduates are to be placed with larger foreign firms; and, finally, by joint protection of the Austrian Government, the Chambers of Commerce, and the particular foreign consulate concerned, they will be aided to establish themselves abroad. According to a recent report of the United States Consul at Vienna, the academy has a preparatory course of one year, and a regular course of two years. Further, there are special courses of greater or less duration. The tuition fee is 150 florins (£12 10s.) a year. The pupils are given the opportunity to occasionally visit, under the supervision of thoroughly informed teachers as guides, the prominent industrial establishments of all typical export articles, as well as certain commercial cities and ports of special importance. Thus, for instance, an excursion to Hamburg is planned, while trips to mills, sugar refineries, breweries, and furniture factories are undertaken. The Imperial Royal Commercial Museum, of which the export academy has been made an integral part, has placed at the disposition of the academy its library, its valuable trade collections, and the requisite geographical maps and apparatus. The academy has a yearly subvention from the Ministry of Commerce of 20,000 florins (£1,666), and a like sum was to be raised by popular subscription. First of all, graduates of the higher commercial schools are entered as regular students in the academy. Further, pupils are admitted who have passed the grammar schools and possess such knowledge of commercial branches and of the French and English languages as can be acquired in a commercial school of two classes. All desiring to be admitted as regular students must pass a preliminary examination. In exceptional cases pupils who have completed their studies in an unusually excellent manner in a commercial school, and can produce testimony of already having done praiseworthy work of a practical kind, may be admitted as regular students by the faculty without preliminary examination. This rule of exception has already been applied in many instances, and gives the academy some of its most promising pupils. Two groups of students can be plainly distinguished—those with and

those without practical experience. In no class of the academy are more than thirty students admitted and only twenty in the preparatory course. The actual number of pupils at present is near the maximum allowed. Attendance at the classes and lectures of the export academy is compulsory and subject to strict supervision. An absence of eight days without proper justification is followed by striking off the student's name from the roll. This is another distinguishing feature of the school, wherein it differs from all other Austrian and German high schools, and recalls the Paris "Ecole des Hautes Etudes" as well as French schools in general. At Christmas and Easter in each year, oral examinations are held in all the branches of study. During the first year, the annual examination takes place in the first half of July. The regular students have to undergo a severe final examination at the close of the second year before a board of examiners, presided over by a representative of the Ministry of Commerce. The names of students who do not pass one oral examination without good excuse are struck off the roll. In some cases the board of examiners may permit the repetition of a year's course or of the severe final examination. Only those students are admitted to the second year who have favourably passed the annual examination in all branches of the first year's course. There are thirty-four hours weekly in the preparatory course, and in the first year thirty-four or thirty-five obligatory hours every week, besides some that are not obligatory. The preparatory course has for its purpose to advance graduates of gymnasia about as far in one year as an ordinary commercial school does in two or three years. Of the two yearly courses of the academy only the first has so far been opened, and the students have in all the examinations up to the present given brilliant evidence of the excellent curriculum. In this course great stress is laid on the study of the French and English languages, with practice in correspondence (six hours each, weekly). Four hours a week are devoted to domestic and foreign law, so far as it concerns commerce. Three hours are given to practical exercises in the office work of export import, and factory businesses. Instruction in this important branch is entrusted to the assistant-director of the academy. In view of the burden entailed by the large number of school hours, home time is demanded only for languages and office lessons. Instruction in economics, with special regard to tariffs, in the usages of export trade, in commercial geography, and on knowledge of the world's ware according to kind and production, is imparted in so-called seminaries—that is, institutions which afford immediate practice of what has been learned from the teacher's lecture, and, so far as possible, actual inspection of the modes of production and of sample. Consul-General Hurst is of opinion that this experiment of "giving the pupil the most important fact in the school, instead of letting him learn by heart what he is sure to speedily forget, and to have him

practice it on the spot until indelibly engraved on his memory, is one of the most daring as well as important innovations, and deserves to be imitated." Besides all this, lectures on selected subjects of actual interest are given by professors of the export academy, by manufacturers in the various industries, and by Government officials, and are attended voluntarily by the students, who display deep interest in them. In this manner they become acquainted with special questions of the day that are engrossing public interest, in a manner that is unbiassed by party standpoint.

KEW GARDENS.

The following historical notice of the Royal Botanic Gardens, Kew, from the "Colonial-office List" for the present year, is quoted from the *Kew Bulletin*:—

"Kew as a scientific establishment dates from 1759, when a Botanic, or, as it was then called, a Physic, Garden was established by the Princess Augusta of Saxe-Gotha, Dowager Princess of Wales.

"It was energetically maintained by her son, George III., with the scientific assistance of Sir Joseph Banks, who was virtually for the greater part of his life director. Under his advice, collectors were sent to all parts of the world. The first New Holland plants were introduced during Cook's voyages, 1768 to 1780. At Sir Joseph Banks's instance the system of inter-colonial exchange was commenced, which has been maintained ever since. The most memorable undertaking of this kind was the voyage of the 'Bounty' (1787) for the purpose of introducing the bread-fruit tree from the South Seas into the West Indies. Nelson, the Kew collector, was amongst those sent adrift by the mutineers, and eventually died of the exposure. Another Kew gardener, James Hooper, who had been attached to Lord Amherst's Embassy to China, remained in Java, and was from 1817 to 1830 Hortulanus of the celebrated Dutch Colonial Botanic Garden at Buitenzorg, which he helped to create.

"Both George III. and Sir Joseph Banks died in 1820, and the colonial and other work of Kew languished, though it was not absolutely abandoned, during the reign of George IV. and William IV. In 1838 the abolition of the whole establishment was contemplated by the Government. Public opposition led to the appointment of a Treasury Committee, the report of which was presented to Parliament in 1840. The following paragraphs briefly defined the functions of the reorganised establishment:—'A national garden ought to be the centre round which all minor establishments of the same nature should be arranged From a garden of this kind, Government would be able to obtain authentic and official information on points connected with the founding of new colonies; it would afford the plants there required without its being necessary, as now, to apply

to the officers of private establishments for advice and assistance.'

"These recommendations having been adopted by the Government, Sir W. J. Hooker, F.R.S., was appointed director in 1841 to carry them out. A close connection between Kew and the Colonial-office immediately sprang up. A scheme for a complete series of colonial floras was sanctioned in 1856, and has been steadily prosecuted. Kew serves, to a large extent, as an advanced horticultural school. Special attention is given to the preparation of gardeners for colonial service. Some sixty men, trained at Kew, are now in official employment in different parts of the empire.

"Relations with the botanical institutions of the self-governing colonies are maintained by semi-official correspondence. With those of colonies more directly under the control of the Colonial-office, the connection is closer.

"Colonial botanical institutions fall roughly into three classes. Those of the first-class are usually, like Kew, administered by a scientific director (Sir W. T. Thiselton-Dyer); those of the second-class by a skilled superintendent; the third-class consists of botanic stations. These last are small and inexpensive gardens, devised in 1885, in order to afford practical instruction in the cultivation of tropical crops, and were intended to develop the agricultural resources, at first, of the smaller West Indian Islands, and subsequently (1887) of British possessions in tropical Africa. Each is in charge of a curator, who is a gardener trained at Kew.

"The most important colonial botanical institutions in intimate relation with Kew, are the Gardens at Ceylon, Straits Settlements, and Jamaica.

"In 1898, in accordance with the recommendations of the West India Commission, a Special Department of Agriculture was created for Barbados, the Leeward and the Windward Islands, and was placed under the charge of a Commissioner (Dr. D. Morris, C.M.G., M.A.), with headquarters at Barbados."

THE SOUTH-EASTERN COAL-FIELD.*

The discovery of the South-Eastern coal-field is of great practical value, as it will probably result in the same development in Kent of industries and manufactures which has taken place where the coal has been worked, under the same conditions, under the cretaceous and jurassic rocks in France and Belgium. It is of equally great theoretical value, as it proved the truth of Godwin-Austen's view, published in 1858, that the coal measures lie buried underneath the newer rocks in South-Eastern England.

The first boring to be noticed was at Ropersole, a spot near the highway between Dover and Canterbury—eight miles from Dover, at 400 ft. O.D.—the

* Abstract of paper read by Prof. Boyd Dawkins, F.R.S., at the Dover meeting of the British Association.

surface being composed of upper chalk, with a thin stratum of clay-with-flints. It was begun at the close of 1897, and had at the present time pierced the strata to a depth of 1,773 ft. 7 in. In the author's opinion the coal measures of Ropersole were a portion of the same series as those at Dover. Here, as at Dover, the question of seams of coal resolved itself probably into a question of sinking deeper. Here only two unimportant seams have been met with in a thickness of 197 ft. There 12 seams were penetrated in a thickness of 1,054 ft. 6 in., the thickest 4 ft. seam being at the bottom. The Ropersole boring established the fact that the Dover coal measures extended northwards for a distance of eight miles and beyond in the direction of Canterbury. The coal measures set in in Kent at a sufficient distance to the north-east of Brabourne to allow of the presence of the carboniferous limestone and millstone grit. These probably dip at the same high angle as the Devonian below.

Their south-western boundary could only be accurately defined by further borings, such as those which were now being carried on at Ottinge, about two and a half miles to the north-east of the scarp of the Downs, and six miles to the south-west of Ropersole. Their range to the north and the east still remained to be proved. They were, however, continued under the Channel, as had been proved by the boring at Calais in 1850 as well as those carried out in 1898 at Strouannes, near Wissant. In this district they were clearly shown by other borings to be faulted into the Devonian and other pre-coal-measure rocks. The thickness and value of this south-eastern coalfield could only be estimated by the exposed coalfields of northern France and Belgium, and of Somerset. That of Liège was 7,600 ft. thick and contained 85 seams, presenting an aggregate thickness of 212 ft. of workable coal. That of Mons was 9,400 ft., with 110 seams yielding 250 ft. of coal. In Somerset the coalfield was 8,400 ft. thick, the seams were 55 in number, and yielded 120 ft. of available coal.

It was obvious from these figures that the possibilities of the south-eastern coalfield were very great, although it still remained to be proved how far these great thicknesses of rock had been denuded in Kent before the deposition of the triassic and jurassic rocks.

To sum up, the results of these borings were likely to bring about the same economic revolution in Kent as was brought about in France by the extension of the coalfield of Valenciennes and Mons, about ninety-five miles to the west of its original outcrop at the surface, and to within some thirty miles of Calais. The coalfield had been proved at Dover. Its range for eight miles to the north had been also proved at Ropersole. Its southern boundary, as yet ill-defined, was marked by the Pembroke-Mendip anticline, ranging under the southern scarp of the chalk downs. Its range in other directions was unknown, and awaited further investigation. To the south of this anticline the palæozoic floor was probably composed of pre-coal-measure rocks. If, however, the coal

measures did occur, they were buried under such great thicknesses of superincumbent rock—largely sands and loams full of water—that it would be difficult to work them.

They knew now by experiment, not only where to seek, but also where it was advisable not to seek, for the coal measures. The difficult problem of the buried coal measures in South-Eastern England, now being worked out by private enterprise, was likely to add greatly to the resources of this country, as it had already added to the wealth of geological knowledge.

In the discussion that followed the reading of the paper, Professor Dawkins said further that there was good blazing coal, as well as steam coal and anthracite, found in South Wales, exactly corresponding to that of Dover; that he had found no lignite in the Dover coal measures, but some in the secondary rocks, the oolites, above; that no temperature observations were possible in the borings; and, finally, in respect of the depths of the coal measures, that he was of the opinion that the seams reached at Dover formed only the upper part of the measures, so thick at Westphalia, where they were 7,200 ft. thick, and reached 7,600 ft. at Liège.

THE PRODUCTION OF RUBBER IN THE AMAZONS.

The principal rubber-bearing areas in the State of Para are the islands of the River Amazon near the city, the principal, Marago, having an area of 2,500 square miles; the banks of the river Tocantins; the banks of the rivers Zingu, Jary, and Tapajos. The upper and lower districts of the Amazon produce the same kind of rubber, but that coming from the upper river obtains a slightly higher price, being dryer by the time it reaches the port of shipment.

The collecting season for rubber in the Lower Amazons begins when the waters have subsided—about July—and ends in January or February. Collecting is not undertaken, as a rule, in the wet season, because the quantity of water that accumulates in the forest impedes the movements of the collectors, and the rain water that runs on the trunks of trees prevents the clay cups from adhering to the bark. The sap is also weaker in this season. The United States Consul at Para, in a recent report, says that the collectors employed are principally Brazilians, immigrants from the States bordering on Para, such as Ceara, Maravham, and Piauhy, also Portuguese and half-castes. The pure South American Indian is of very little use as a labourer. He has but few wants, lives by fishing and hunting, and is less dependent on labour than more civilised people. There are many thousands of collectors in the rubber field, yet the number does not supply the demand.

The last few years have shown a steady and rapid increase in the exports of rubber, and while labour has also gradually increased, it has failed to keep pace with the fast-growing demand. Among other

articles used in the india-rubber industry is a clay funnel, in shape very much like an ordinary toilet water-jug without a bottom or handle. It is made of the clay that is found in most parts of the Amazon region. The fuel used in the funnel consists generally of the nuts of the following palms:—Native name—"Urucuri," "Tucuma," "Inaga;" botanical name—*Attalea*, *Astrocaryum*, and *Maximiliana regia*. It was at one time imagined that the excellence of Para rubber was greatly due to the kind of fuel used in curing it. The palms that furnish the fuel were accordingly transplanted to Africa, with a view to the production of Para rubber there. The experiment, however, has not met with success. The reason these nuts are selected in Brazil is because they emit a continuous dense smoke, and are more portable than other fuel obtainable. However, when none of the palms named are accessible, bark and twigs are used as fuel.

Everyone engaged in the forest carries a knife. One of its uses is to cut down fuel for the preparation of rubber. The blade is about 26 inches long, and about 2 inches broad. Owing to the damp climate, the blades are electro-plated, thus preventing their becoming rusty before they are marketed. The handles are made of wood, and are carved or inlaid with brass. The rubber collector's axe is a very small affair. It is required to chip a smooth surface on the bark preparatory to attaching a cup to the tree. The handling of the axe requires great skill, in order not to injure the bark. A smooth surface is made in order to prevent impurities from mixing with the sap. The cups are of clay or tin. The former are attached to the bark by means of a little clay. Their weight, however, makes them inconvenient to carry when the trees to be tapped are separated by long intervals; the collector then prefers to carry tin cups, which are much lighter than the others. They easily penetrate into the bark by means of their sharp edges, and hold to the tree without the use of clay. The use of the tin cup, however, is to some extent injurious to the tree.

Part of the collector's outfit consists of a light gourd, large enough to carry the contents of from 500 to 700 cups. A clay bowl is next required in order to receive the contents of the gourd. It is of sufficient size to contain the product of several days' work before it is cured. The calabash tree provides calabashes which are employed to ladle the milk from the clay bowl into the mould. A broad-bladed wooden paddle is used as a mould, and is made locally. This completes the outfit for the rubber collector. All these articles are made locally, with the exception of the knives. The axes and the tin cups are manufactured in the towns and villages of the Amazon region. The collector has to use his knife to cut his way through the undergrowth, and also to cut down a sapling occasionally to bridge a rivulet. At times he is knee-deep in ooze or up to his waist in water. On arrival at a rubber tree, he chips away the rough parts of the bark, makes a more or

less smooth surface, attaches a cup and makes a small gash above for the sap to fall into the cup, and repeats this process in a line round the tree until he has attached six or seven cups. Then he proceeds to the next tree and does the same. He continues this process until he has tapped from 75 to 150 trees, which can be done in a day, if they are not too far apart. On the following days, the gashes in the trees are made a trifle lower down than the first ones. Some collectors tap the trees in the morning, and return to collect the sap in the evening, whereas others tap in the evening, and collect in the morning. An expert gathers 7 pounds daily in the Lower Amazon; in the Upper Amazon three times this amount is collected. When the accumulated rubber is sufficient—usually in three or four days—a collector lights a fire in the hut he has erected, places the funnel over the fire, pours a thin coat of milk over the paddle, and holds it over the smoke to coagulate. The process is repeated until a large cake has been formed. To release the paddle from the cake, it is necessary to make a slit on one side. The paddle mould makes a cake of uniform and even shape, and is in general use in the State of Para. In other parts, a spit is placed on two upright forked sticks, and given a rotary motion. By this means, the rubber is cured with greater ease. Paddle-smoked rubber is decidedly preferred, as it is dried and seemingly more carefully cured.

Many attempts have been made to introduce improved curing apparatus. Up to the present, however, the efforts have not been successful, because the common method, although very primitive, possesses the advantage of being simple and inexpensive. The process of curing rubber is found to be very injurious to the eyes. Many cases of total blindness result from it. There are three grades of Para rubber, viz., fine, medium, and coarse. If rubber is not uniform, and contains impurities, it is classified as medium. The coarse quality, or "Sernamby," consists of scraps that have not been cured. Insufficient labour is the most serious difficulty in the rubber industry. Consul Kennedy says that it would scarcely seem advisable to invest money in rubber estates unless the owner can first see his way clear to obtain sufficient labour with which to collect the rubber.

ARTIFICIAL TEXTILE FIBRES.

The following abstract of Mr. W. M. Gardner's opening lecture of the winter session in connection with the chemistry and dyeing department at the Bradford Technical College is taken from the *Textile Mercury*:—

After describing the peculiarities of the three natural fibres, wool, cotton, and silk, Mr. Gardner said that if the structures of the three were contrasted it would be seen that wool and cotton possessed a highly-organised or cellular structure, whereas silk, being merely a

solidified liquid, had no special interior formation, thus resembling a thread of glass. It was therefore obvious that as regarded structure the silk fibre offered a much more promising field to the chemist who attempted its artificial reproduction than did the highly-organised wool or cotton. Given the requisite liquid it would not be an insoluble problem to produce from it a fibre resembling silk in every respect. On the other hand, it was hopeless to expect that an artificial fibre possessing the same internal structure as wool or cotton would ever be produced. No chemist had hitherto succeeded in reproducing the simplest body which exhibited a cellular structure. As regarded the chemical structure of the fibres they found that cotton was the simplest in composition. Most of the artificial fibres were produced from cellulose as a basis, and thus were chemically more closely connected with cotton than with wool or silk, but one or two were obtained from gelatine, and thus approximated to silk. In appearance, however, they all, without exception, resembled silk rather than wool or cotton. The first attempts to produce a valuable fibre artificially consisted in dissolving waste solvent, and then saturating cotton yarn or thread in this solution, thereby greatly increasing the lustre. Mr. Gardner proceeded to mention a number of commercially valuable products formed by various reagents on cellulose, and similar to some of the artificial fibres in composition. Collodion silks constituted the ordinary "artificial silks" of commerce at the present time. The name, "lusto-cellulose," had been proposed for these products, but had not been generally adopted. It was proposed in 1894 to manufacture this product in England, and Bradford would in all probability have been fixed upon but for the fact that the heavy tax on alcohol in England rendered any manufacture in which it was largely used expensive. The works were, therefore, established near Zurich, but the company had an office in Bradford. The manufacture of art silk by the processes he had described might be considered as consisting in the solution of the cellulose, followed by its regeneration in the form of a fine thread, the increased lustre of the new fibre being due to its smooth external surface. Dealing with the action of reagents on cellulose, the lecturer said that the action of alkalis was not less interesting than the action of acids, since by the aid of alkalis several most important fibres, mercerised cotton, and several forms of viscose silk were obtained, as well as many other useful substances. The applications of the ordinary mercerising process were (1) to increase the affinity for dyes, (2) to produce crepon on cotton, (3) to produce crepons on wool, cotton, or silk-cotton unions. Now, it was possible to contract either the wool or the cotton in a mixed fabric. The most important outcome of the mercerising process, however, was the observation that by mechanically preventing the shrinkage which naturally occurred during the process, a greatly increased lustre was imparted to the cotton. By this simple modification of a fifty-year-old process, the textile industries had been

enriched with what was practically a new fibre, which approached silk in lustre, but which was infinitely cheaper. He did not propose to embark upon the stormy seas associated with a discussion of the patent rights in connection with this process. Only during the last five years had it reached importance, but its enormous development, due largely to the skill and enterprise of the Bradford dyers, had been such that several thousand pieces of cotton cloth were lusted per day in that district, in addition to enormous quantities of hank and warp yarn. The magnitude of the trade was emphasised by the fact that, possibly for the first time on record, the value of the cotton material exported to the United States from the consular district of Bradford had, for the four months ended August 31st, exceeded that of the dress stuffs, and was four or five times as great as the value normally exported during the same period. This was mainly due to goods lusted by mercerisation.

General Notes.

CHAMPAGNE PRODUCTION.—The Rheims Chamber of Commerce has just published the official statistics of the output of champagne, from which it appears that the amount for the year 1898-99 was over 106,000,000 bottles. This is less than the total for 1896-99—over 111,000,000 bottles, but the total for 1893-94 was under 87,000,000 bottles.

FRENCH INDUSTRIAL PRIZES.—Among the prizes offered by the Société d'Encouragement pour l'Industrie Nationale, open to all the world except members of the Society's Administrative Council, and that will be awarded next year, are the following:—Two thousand francs (£80) for a publication useful to the chemical or metallurgical industry, a treatise or metallurgical chemistry summarising the works that have appeared on the subject during the last twenty years being invited; two prizes of 500 francs (£20) each for scientific chemical researches the results of which are useful to industry, the authors not being required to have realised the practical applications which they may foresee as resulting from their observations; 200 francs (£80) for the scientific study of an industrial process the theory of which is still imperfectly known, the methods that permit of obtaining a given result being often known long before the nature of the phenomena is suspected, and yet the knowledge of which has great interest as regards reducing the number of empirical trials necessary for realising fresh improvements; and 3,000 francs (£120) for the production of permanent magnets, the qualities expected from which are power and stability. The models, papers, descriptions, &c., must be sent in before 31st December to the Secretary of the Société d'Encouragement, 44, Rue de Rennes, Paris.

BY PROF. HENRY R. PROCTER.

Lecture I.—Delivered April 17, 1899.

The manufacture of leather is a typical instance of a trade of great antiquity, which has attained a high degree of development by purely empirical methods, but of which the science is still very young. In such cases, the first aim which the technologist must set before him is to explain and understand the underlying reasons of the processes to which experience has led; and not till this is fairly accomplished can we expect to rival the brilliant success which science has scored in newer, and, in many cases, simpler trades.

For this backwardness the chemist is not wholly to blame. The earliest glimpse which we have of prehistoric man shows him as a hunter, whose first impulse in the colder climates must have been to clothe himself in skins. Skin, however, is not to be worn without preparation. Left moist, it goes quickly to decay; and, dried, it becomes hard and horny, and impossible even as the most primitive kind of clothing. The emollient effect of fat must have been felt on his own hands by the first man who handled raw meat, and the suggestion to rub it into the moist skin to keep it soft must early have occurred to him. This, combined with stretching and suppling with the hands, is sufficient to convert it into a sort of leather, and the method is in use to this day by savage races in every continent of the world. Even in England the furrier employs methods on his finest furs which differ from it in detail, but not in principle. Later on, the preservative effect of smoke would be surely noticed in houses without chimneys; the action of alum would be observed in some cases where it had been accidentally or experimentally substituted

for salt, in lands where it effloresces as a natural product; and the effect of vegetable tans may perhaps have been discovered in some primitive attempt at dyeing by the aid of barks or seeds. Certain it is, that even in the earliest historical times, the art of leather manufacture had reached an advanced stage; and specimens of dyed and gilded moroccos from the time of the Pharaohs still exist, not perhaps inferior in appearance to the leathers of the present, for which few would venture to claim a similar durability.

The difficulty of the chemist, however, does not arise alone from the immense amount of empirical knowledge accumulated in this oldest of trades, where almost every conceivable device has been tried; but yet more from the fact that the science involved belongs in almost every case to the most obscure and difficult branches of chemistry and physics. The structure of animal skin is very complicated, and the chemical constitution of its components is yet unknown. The molecular weight of its principal, and probably its simplest constituent, gelatine, is on the least computation near 2,000, and may be much more; and of the vegetable tannins it cannot be asserted that the structure of any single one is clearly understood. Add to this that the physics involved in the swelling and osmotic absorption of colloids, and you have a series of problems calculated to tax the knowledge of the best chemists who exist; and, it is needless to say, quite beyond the scope of the simple physics and inorganic chemistry of the earlier part of the century. The result is, that while the mechanical treatment of very difficult materials is extraordinarily perfect, the chemistry and physics of the subject are mostly yet to make, and few more promising fields, both as to scientific interest and practical result lie open to the technical investigator.

The raw material of the trade is extremely varied, ranging from the thinnest kid-skin to the stoutest ox-hide, and the purposes to which leather is applied are innumerable. With such a range of material and requirements, the modes of treatment are necessarily numerous, and it would be impossible in the course of four lectures to explain them in any detail. Fortunately a similarity of structure of the material, and of principle in its manufacture, runs through the whole group, and having once mastered this, it becomes possible to grasp the reasons for variation in the details, even when that variation is so great that at first sight

the processes seem to have but little in common.

Naturally, the principal material of the trade is derived from the skins of domestic animals killed for our food by the butchers; ox and cow hides, and calf, sheep, and lamb skins. These are mostly delivered at the tanneries as they are taken from the animals, in a more or less fresh condition. But in addition to these, we draw supplies in enormous quantities from distant countries, which, of course, have to undergo some form of curing to render their transmission possible. Near the sea, and in civilised lands, salt is the material usually employed, and it answers its purpose on the whole effectively and well. The preparation of such hides is seen at its best in the great slaughtering and packing establishments of Chicago and St. Louis. The hides are removed systematically from the animals without cuts or damage, and with little adhering flesh, and are spread out in cellars, in piles of perhaps 20 feet square and 5 or 6 feet high, salt being plentifully sprinkled on each hide. After lying in this way for about a fortnight, the salt is shaken off, and the hides are tied up in bundles for delivery. Similar methods are adopted in the great saladeros of South America, such as "Liebig's" at Fray Bentos. Further inland, on the pampas, where the cattle are reared, the cost of salt is too high, and the weight of wet salted hides too heavy for transport on the backs of mules, and simple drying is resorted to. This should be done under protection from the sun, which in some cases is hot enough to convert the interior of the hide into glue after evaporation is checked by surface drying; but, unfortunately, this precaution is not always adhered to. Damage to dried hides also often takes place by putrefaction in the interior after surface-drying, and unfortunately such injuries cannot be detected until the hides have been softened and limed, when the damaged part dissolves, and the hide blisters or breaks into holes. To avoid these injuries, salting and drying are often combined, and such hides are known as "drysalted."

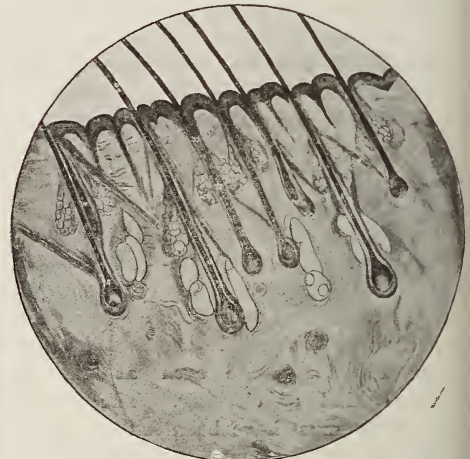

A somewhat interesting process of this sort is applied to many of the hides of the small cattle of India, known in the trade as "East India Kips." Salt is scarce and dear, and in several districts a natural salt earth is used for curing. This is made into a paste with water, and rubbed repeatedly into the flesh side of the kips with a soft brick while they are being dried. These cures are called "plaster cures,"

since the earth is white and more or less calcareous, and when dried has almost the appearance of whitewash, and of course adds considerably to the weight of the hides. It is rather singular that these earths contain scarcely a trace of sodium chloride, but principally sodium sulphate with a little carbonate and some ferric oxide. The latter, being insoluble, has no injurious effect on the hides if dried quickly, and kept dry, but if exposed to moist air for a lengthened period, a portion is converted into hydric ferrous carbonate, which dissolves and produces stains, and these are a serious disadvantage to the tanner.

Goat skins, and sometimes sheep and calf skins, are preserved by drying, while sheep skins, after being deprived of their wool, are frequently treated by a process known as pickling, which will be more conveniently considered in a later part of the course.

All the skins of which I have spoken, though they are characterised by differences of thickness and texture, are anatomically so similar, that their structure may be considered together.

FIG. I.

SECTION OF CALF SKIN, SHOWING HAIRS AND SEBACEOUS AND SUDORIFEROUS GLANDS.

The skin is much more than a mere covering for the animal: it is a complex organ of secretion and sensation. In all mammalia it has two principal layers which are not only very distinct in their structure, but in the chemical character of the materials of which they are composed. This difference of structure corresponds to a difference of origin which dates back to the first few hours of the development of the germinal cell, which as it multiplies by division, rapidly forms an upper, a lower, and a middle layer. From the upper of these is

developed the epidermis or outer skin with its appendages, hair, horns, nails, hoofs, and the like; the middle layer furnishes all the bony and fibrous structure of the body, of which the true or inner skin forms a part; while the lower layer supplies the epithelial lining of the internal organs, which in structure closely resembles the epidermis.

Although the various structures which have been named as arising from the epidermis are very different in their outward appearance, they are all constituted of simple animal cells, differing only in shape and size, and secreting cell walls of keratin or horny matter, a substance, or perhaps a class of substances, which is nearly allied chemically to the coagulated albumen of a hard-boiled egg.

FIG. 2.

HAIR BULB, SHOWING PAPILLA, AND INNER AND OUTER ROOT-SHEATHS.

As the epidermis is unprovided with blood-vessels, its growing cells can only derive their nourishment from the lymph of the true skin on which they rest, and hence only in the innermost layer can active growth take place. They multiply, as is usual with cells, by increase of size, and division both of the cell

and its enclosed nucleus so as to form two complete cells. As the lower layer increases, it pushes away the older and outer cells from their source of nourishment; these flatten, dry up, and die, and form the outer surface of the skin, whence they are removed by friction or washing, or where they are protected by the hair, separate in small flakes of scurf, which in moderate amount is a perfectly healthy and normal product.

The original development of the young hair from the epidermis layer is somewhat interesting. A knot of minute capillary blood vessels forms on the surface of the true skin. The epidermis cells, stimulated by the liberal nourishment which this provides, increase rapidly, and press down into the true skin, and partially surround the knob, which sinks deeper and deeper, and at last remains embedded in the bulb of the growing hair as its source of nourishment, and connected with the corium by a mere stalk. As this process goes on, the epidermis cells seated on the top, sides, and neck of this knob, which is called the hair papilla, become differentiated in character from those of the surface layer, and produce respectively the pith and cuticle of the hair, and the lining or "hair-sheath" of the tube of epidermis through which it grows. Near the neck

FIG. 3.

STEM OF HAIR, WITH SEBACEOUS GLAND AND ERECTOR MUSCLE.

of this hair-sheath a somewhat similar process goes on, resulting in the development of two or more small glands, or grape-like masses of cells, which take on the duty of producing within them a peculiar oil, which is discharged by ducts just below the neck of the sheath, and serves the purpose of lubricating the hair and

giving it its natural gloss. The replacement of old hair is very similar to what has been just described, the young hair originating below the old sheath, into which it usually grows. In a very similar way to the hairs, other glands, not unlike the oil or sebaceous glands just mentioned are produced, which secrete perspiration, and so serve the important ends of moistening the skin, and thus cooling the body, and of removing certain waste products from the blood. It is worth noting that these glands, of which the activity is readily effected by sensations, and especially by the emotion of fear, are apparently unprovided with nerves! Probably the effect is an indirect one and dependent on the surface circulation in the true skin, which is controlled by the sympathetic system. Perhaps it is also worth pointing out that warts and corns and such abnormal growths of epidermis tissue have much in common with the phenomena of the growth of hairs. Like them, they originate in an increased supply of blood to a particular spot, and warts at least are easily cured by touching them with nitric acid until the underlying knot of blood vessels is killed, when the wart immediately ceases to grow.

The structure of the true skin or *corium* is quite different from that of the epidermis which has just been described. In place of the layers of cells, with their keratin walls, we have bundles of fibres composed of a substance which scarcely differs from gelatine, and these fibres are not in themselves living cells, but are produced by narrow nucleated cells which lie among them. Instead of depending for nourishment on the liquids of the underlying layer, the true skin is abundantly supplied with blood vessels, and, unlike the epidermis, it is capable of feeling, and is indeed the organ of the sense of touch, the nerves of which terminate in its small projections or papillæ. Interspersed among the white gelatinous fibres are some yellow "elastic fibres" of quite different material, which form a sort of elastic skeleton to the skin, but are of little direct importance in the manufacture of leather.

The structure of the white gelatinous fibres is peculiar. It is generally stated that they consist of bundles of finer fibrils, tied as it were at intervals by yellow "elastic fibres," and cemented together by some gelatinous substance; but perhaps it would be more accurate to say that they are so constituted as to be readily split up into these finer fibrils by the action of solvents, since it is by no means clear

that the so-called cementing substance is in any way chemically different from the fibres themselves. Both acid and alkaline solutions possess the power of swelling and splitting up the coarser fibres or fibre-bundles, at the same time dissolving a portion of their substance, and this dissolved substance continues of the same character even if the action is so long continued that it may be presumed that all soluble matter of a different character to the fibres themselves has been dissolved and removed. Towards the outer surface of the skin on which the epidermis rests and in which the hair roots are embedded, the fibre-bundles are naturally divided into these finer fibrils which are closely felted together into a compact layer which is often called the "grain." This word "grain" is used by the leather manufacturer in a variety of senses which is apt to become confusing. It is not only applied to the compact layer of tissue, of which I have just spoken, but to a thin film which covers it and separates it from the epidermis, and which is known to anatomists as the "hyaline" or glassy layer, and which remains as a sort of glaze on the finished leather. The word is also used not merely to express this material surface, but sometimes to describe the little projecting marking upon it formed either by the papillæ and hair pores, or artificially in the process of leather manufacture, and from these perhaps the word was originally derived, since in old times such markings were in some cases formed by pressing seeds into the surface of the leather. Thus a sheepskin embossed to imitate alligator or pigskin is said to have an "alligator" or "pigskin" grain, and so well is this done that even experts are sometimes deceived by it. It is, however, always easy by study of the arrangement of the hair pores with a lens to decide to what animal the skin belonged. The bristles of the pig and the fine wool of the sheep leave very different traces behind them. This may be readily seen in the photo-micrographs of various grains given in Figs. 4, 5, 6, and 7 (p. 831), for which I am indebted to Mr. A. Seymour-Jones.

While towards the surface of the skin, the fibre-bundles are as it were teased out and more closely felted together, they become a looser network in the middle portion, and again form a compacter structure towards the inner surface, though without any separation into the finer fibrils. The skin is attached to the animal by a looser network of connective tissue composed of the same white fibres as the skin itself,

and both this tissue, and the looser parts of the true skin are often full of fat. This fat does not exist as mere free globules of fatty matter, but is contained in cells (Fig. 8, p. 833) by which it has been secreted, and these cells are usually

FIG. 4.

COW HIDE—GRAIN SURFACE, MAGNIFIED.

so full of oily matter that the protoplasm and nucleus of the cell are pressed closely against the cell-wall. This fact is not without its importance to the tanner, since it explains the impossibility of removing the fat till the cell-

FIG. 5.

WELSH SHEEP—GRAIN SURFACE, MAGNIFIED.

walls have been broken down by the solvent action of milk of lime, or the liquefying ferments of bacteria. The structure of the true skin may be roughly likened to that of a piece of broadcloth, which is composed of woollen

yarns, each containing a large number of separate wool-fibres, these on the outer surface are more or less separated from the yarn by milling, and felted together among themselves to a close surface in which no separate threads

FIG. 6.

EAST INDIA SHEEP—GRAIN SURFACE, MAGNIFIED.

are visible. The analogy would be still closer if the cloth were sized, so as to cement the fibres together into a coherent mass.

Turning to the chemical constitution of the skin and epidermis, we find the same broad

FIG. 7.

EAST INDIA GOAT—GRAIN SURFACE, MAGNIFIED.

differences which have been marked out by their anatomical structure. The keratins, of which the cell-walls of the epidermis are formed, are closely related to coagulated albumin, of which the most familiar instance is the white of

a hard-boiled egg, and like it are insoluble even in boiling water; if, by heating at a high temperature under pressure they are at length dissolved, they form a viscid solution which does not set to a jelly on cooling. They are almost equally insoluble in acids, but are comparatively readily soluble in alkaline solutions, though there are great differences in this respect between the soft parts such as the growing layer of the epidermis, and the harder structures, such as hoofs, horns, and hair. Alkaline sulphides, such as those of sodium and calcium, have a quite peculiar effect on the keratins, dissolving and breaking up even the harder tissues with great rapidity, while their effect on the true skin is comparatively slight; and they are therefore becoming of great technical importance in freeing the skin from hair and epidermis before tanning. As regards the actual chemical constitution of keratins, or even of albumins, little is known, and it may suffice here merely to state that like most other animal products they are compounds of carbon, oxygen, hydrogen, and nitrogen, with, in addition, a trace of sulphur and of inorganic ash.

Unlike the keratins, the white fibres of the true skin, which constitute perhaps 95 per cent. of its solids, are swollen even by cold water, and readily dissolve by the aid of moderate heat, forming a solution which is merely viscid while hot, but which sets to a firm jelly on cooling. In fact the only product of the treatment of white skin-fibres with hot water is gelatin, and the true skin is one of the most important commercial sources of gelatin and glue; the other being the gelatinous tissue of bones, which only differ from skin in anatomical structure, and in being loaded with mineral matter, principally calcium phosphate. When the latter is dissolved out by treatment with dilute acid (usually hydrochloric) a semi-transparent elastic mass remains, which is dissolved on boiling with water, precisely in the same way as skin. Whether bones or skin-cuttings are employed, the commercial process for making gelatin consists firstly in a most careful purification of the material from mineral and objectionable animal matters, and then a cautious digestion to dissolve the gelatin. The clear solution is then rapidly cooled in troughs or moulds till it has set to a firm jelly, when it is cut into thin slices by a machine which forces it through a sort of grating of steel blades. The slices are laid on netting, and rapidly dried in a current of warm air, and are then ready for use. Occasionally, instead of

cooling and cutting in the way I have described, the gelatine solution is concentrated by evaporation in vacuo, generally in a Yaryan apparatus, and run on to glass plates, where it stiffens, and the drying is completed on the nets. The manufacture of glue (Fig. 9, p. 833) only differs from that of gelatine in the lessened care used in purification, and in the thicker sheets in which it is dried, and in fact, very common glues are used in some branches of confectionery work. The idea that glue is made from horns and hoofs is a popular error, since it has just been stated that these tissues are only soluble in water by the aid of extreme heat and long digestion, and that the solution, when obtained, has no power of setting to a jelly on cooling. It has probably arisen from the common use of the porous bone which fills the interior of cows' horns, and which has of course a similar shape. Gelatine is most readily dissolved by soaking for a short time in cold water, which it absorbs, and swells up into a jelly, which on heating to 35° or 40° C. at once melts into solution. For culinary purposes it is best to throw away the cold water in which it has been soaked, especially if the gelatine is not of first-rate quality; as practically none of the gelatine is dissolved, while many of the impurities are soluble and so got rid of. The swollen gelatine may then be melted simply by pouring hot water upon it. Where good setting power is desired, it is necessary to avoid the use of much heat, or of frequent meltings, as gelatine easily passes into soluble modifications which have no setting power.

If dried skin is soaked in cold water, it swells much in the same way as gelatine, but it is not nearly so easily liquified by the application of heat, but must be cooked for a considerable time before it passes into solution. The white fibre is therefore not absolutely identical with gelatine, but probably differs slightly in its degree of hydration, as ordinary gelatine strongly dried at a high temperature becomes much less soluble in water.

If the white fibres of skin, or ordinary dried gelatine be treated with very dilute acid or alkaline solutions, they absorb a much larger volume of the solution than they would do of pure water, but very little of the fibre or gelatine is dissolved. With somewhat stronger solutions the fibre is less swollen, but more dissolved, and moderately strong acids and alkalis dissolve it freely, apparently without decomposition. Very strong acids and alkalis on the other hand break it down into simpler products, first into peptones, and later into

amido-acids, ammonia, and probably other products. These points are of importance, both as regards the theory and practice of leather manufacture, and it will be necessary to recur to them at a later stage.

FIG. 8.

FAT CELLS.

a, fat globule; *m*, cell wall; *p*, protoplasm; *n*, nucleus, *f*, fibre bundle of corium.

We are now in a position to consider the treatment of the raw hide or skin preparatory to tanning, and though the details of the process will differ with the kind of skin, and the purpose for which the leather is intended, the principles are so far identical in all classes of leather, that it will be convenient, at least at first, to take a broad general view, rather than to deal in detail with individual cases. In primitive times, we may presume that skins were first dressed with their hair or fur, but this is now exceptional, and when it is done, belongs rather to the province of the furrier than the leather manufacturer. We have, therefore, before tanning, to cleanse, and in some cases to soak and soften the skins, and to treat them in such a way as to dissolve the epidermis and loosen the hair, and then both hair and epidermis must be mechanically removed, since neither of them are desired in the finished leather. It is also frequently necessary to adopt special means to remove the lime and other chemicals which have been used in these preliminary operations, but which would prove injurious during tanning, and to bring the fibrous tissue of the hide itself into a suitable condition to produce the kind of leather required.

Where the skins or hides have come direct from the butcher, the first step is generally to cleanse them from blood and dirt by washing in fresh cold water, which is best accomplished by soaking for a few hours in a pit or pool, and then washing for a short time in a "washwheel," which is a sort of perforated rotating drum, into which a stream of water is introduced by a pipe passing through the axle.

Raw material which has been preserved by salting or drying demands different, and more radical treatment. That which has been merely salted is the least difficult, and even this needs much more thorough soaking and washing than the fresh goods, and several changes of water. It is not that very long is required to remove the soluble salt, which dissolves at once in the water, and rapidly diffuses out of the skin if the surrounding water is frequently changed; but that the fibrous structure of the skin has been very thoroughly dehydrated by the action of the salt, and only takes up water with considerable difficulty, and not only time, but the complete removal of the salt is required before this swelling can properly take place. For ox and cow hides, three or four days' soaking in as many changes of water is needed, and this should be supplemented by 10 or 20 minutes in the washwheel. Dried goods, such as the dried "flint" hides of Texas and South and Central

FIG. 9.

GLUE BOILING.

America, or the kips of India are much more difficult to deal with, and the more so, the greater the heat to which they have been exposed in drying. It is well known that highly dried gelatine takes up water again with great difficulty, and in some experiments made by Director Eitner, the head of the Vienna Imperial

Research Institute for Leather Industries, upon calfskin, it was found that while skin dried at low temperatures softened rapidly and completely in water, samples which had been exposed to a temperature of 60° C. could not be softened sufficiently to tan even with the aid of vigorous mechanical kneading. In former times it was customary to soften dried goods of the heavier sort in soak-pits in which the water was never changed, as the putrefactive bacteria and their products have a powerful solvent influence on hide, and greatly facilitate the softening, but at the cost of a very serious loss of valuable hide substance. This method has been almost abandoned in England owing not only to its wastefulness, but to the nuisance involved; but in India the native tanners still live round ponds into which all their refuse is run, and in which they soften their hides. Twenty-four hours of such treatment at Indian temperatures is said to make the most refractory hide "as soft as a rag." The method now adopted in England for this class of goods is to place each pack or parcel in a fresh water, which is not changed till the goods are softened. This for dried kips cured with the salt earth mentioned in an earlier part of the lecture requires about a week, while so-called "arsenic-cured," which are mostly merely dried, take considerably longer. Of course, in this length of time in warm weather the soak-water becomes distinctly putrid, and the process may be considerably improved both in the interests of the tanner and the public. More frequent change of water is, however, of doubtful advantage, since putrefaction once started in the hides it will hardly be checked by mere change of water, because abundance of bacteria will remain in the skin itself; and, apart from the cost, a large volume of water slightly charged with putrefying products may be a greater nuisance and more difficult to deal with than a smaller volume containing the same amount of products, and the cost of the water must also in many cases be taken into account. Recourse must, therefore, be had either to chemicals to quicken the softening, or to antiseptics to prevent the putrefaction, or to both. For the first of these purposes, caustic soda, used at the rate of about 1 lb. per 100 gallons of water, is probably the most effective, not only producing a much more rapid and effective softening than water alone, but, as has been shown by Eitner, actually dissolving less hide substance in the time required, and so yielding a better leather, and a greater gain to the tanner. Sulphide of

sodium may be used for the same purpose, but is not quite so effective. Borax has also been used, serving at the same time as an antiseptic, but since less than a 1 per cent. solution has little effect, it is probably too costly. Another promising method is the use of a very weak solution of sulphurous acid, which, when made on the spot, is cheap enough, and is at the same time a powerful disinfectant as regards putrefaction bacteria. The thickest hides, if soaked for 42 hours in a sulphurous acid solution maintained at a strength of 1 part per 1,000, and then for 24 hours in pure water, will be fully swollen without any mechanical assistance. Such hides will, however, lime very quickly, probably owing to their sterilised condition, but there is no difficulty in unhairing them by the use of a little sulphide of sodium. The use of carbolic acid and other disinfectants of the aromatic class is not very satisfactory, especially in alkaline solutions, as they are much less effective when combined with alkalis. In any case they would probably prevent the satisfactory treatment of the sewage by bacteriological filters, which seems much the most promising means of abating the nuisance of tanners' effluents.

Where the soaking is done in water only, it is usual to assist the softening by mechanical means. In this country a fulling mill or "fuller stocks" is generally used, in which two heavy hammers are alternately raised by cams, and allowed to fall on the wet hides; while in America, a modified form known as a "hide-mill" is preferred, in which the hammers are moved in pendulum fashion by cranks. Considerable care has to be taken that the hides are not submitted to these machines till they are soft enough not to be injured by the violent bending, and many tanners are now satisfied with "drumming" in a machine like a large churn, or in the washwheel already described; while where caustic soda or sulphurous acid is used for softening, no mechanical treatment at all is necessary, and this is a distinct gain not only in saving of labour, but in avoiding loss of weight in the hide, from which a good deal of partially dissolved hide substance may be worked out. Where goods are stocked, the process generally takes place after they have been soaked a few days, and they are then returned to the soak-pit until fully soft. Some sole-leather tanners now omit the stocking during soaking, and instead, drum the goods after they are partially swollen in the limes.

The lighter skins, such as calf and goat, are rarely softened by stocking, but are worked

over with a blunt unhairing knife on the flesh side, and before stocks were introduced, the same method was made to suffice for the heavier classes also.

Miscellaneous.

CHEMICAL AND BACTERIOLOGICAL EXAMINATION OF WATER AND SEWAGE.*

It is desirable that results of analysis should be expressed in parts per 100,000, except in the case of dissolved gases, when these should be stated as cubic centimetres of gas at 0° C. and 760 mm. in one litre of water. This method of recording results is in accordance with that suggested by the Committee appointed in 1887 to confer with the Committee of the American Association for the Advancement of Science, with a view to forming a uniform system of recording the results of water analysis.† The Committee suggest that in the case of all nitrogen compounds the results be expressed as parts of nitrogen over 100,000, including the ammonia expelled on boiling with alkaline permanganate, which should be termed albuminoid nitrogen. The nitrogen will, therefore, be returned as:—(1) Ammoniacal nitrogen from free and saline ammonia; (2) nitrous nitrogen from nitrites; (3) nitric nitrogen from nitrates; (4) organic nitrogen (either by Kjeldal or by combustion, but the process used should be stated); (5) albuminoid nitrogen. The total nitrogen of all kinds will be the sum of the first four determinations. The Committee are of opinion that the per-centage of nitrogen oxidised—that is, the ratio of 2 and 3 to 1 and 4—gives sometimes a useful measure of the stage of purification of a particular sample. The purification effected by a process will be measured by the amount of oxidised nitrogen as compared with the total amount of nitrogen existing in the crude sewage. In raw sewage and in effluents containing suspended matter it is also desirable to determine how much of the organic nitrogen is present in the suspended matter. In sampling, the Committee suggest that the bottles should be filled nearly completely with the liquid, only a small air bubble being allowed to remain in the neck of the bottle. The time at which a sample is drawn, as well as the time at which its analysis is begun, should be noted. An effluent should be drawn to correspond as nearly as possible with the original sewage, and both it and the sewage should be taken in quantities proportional to

the rate of flow when that varies (e.g., in the emptying of a filter-bed). In order to avoid the multiplication of analyses, the attendant at a sewage works (or any other person who draws the samples) might be provided with sets of 12 or 24 stoppered $\frac{1}{4}$ Winchester bottles, one of which should be filled every hour or every two hours, and on the label of each bottle the rate of flow at the time should be written. When the bottles reach the laboratory quantities should be taken from each, proportional to these rates of flow, and mixed together, by which means a fair average sample for the 24 hours would be obtained. The Committee at present are unable to suggest a method of reporting bacterial results, including incubator tests, which is likely to be acceptable to all workers.

Dr. Samuel Rideal, the secretary, in sending this report to *The Times*, writes:—"The Committee are anxious that all official reports in this country shall be reported in a similar manner, as it will then enable such reports to be compared with one another without calculation. It will be noticed that the report urges the adoption of the system of recording the results adopted originally by the Rivers Pollution Commission, and which was confirmed by the committee of the American Association for the Advancement of Science in 1887, and I believe it is no breach of confidence for me to add that the Royal Commission at present sitting will also conform to these suggestions. A further advantage of the 'parts per 100,000' over 'grains per gallon' is that continental results are always recorded in this manner. The Committee hope next year to supplement this report by further recommendations to cover those other points not embodied in the present report, and, as secretary of the Committee, I shall be glad to receive the views of other workers to lay before the Committee."

JAPANESE AND CHINESE PAPER.

The results of the inquiries of the commission of industrial experts, which was appointed by the German Government to visit and report upon the markets of East Asia, show, according to a German trade review, that the various markets present excellent prospects for the paper trade, and the paper industry generally. The Korean hand-made papers, thus far very little known in foreign countries, are of much interest. They are of yellowish colour, silk-like gloss, and extraordinary strength. In purity they are behind the better grades of Chinese papers. These papers are made in sheets about 29 $\frac{1}{2}$ by 51 inches. Oiled papers of this kind are used in place of window glass, and very impure but extremely strong board is also made of the same raw material, as well as blotting and wrapping papers. The Japanese hand-made papers are divided into two classes. The so-called "hansi" (half paper) is loaded with about 20 per cent. of rice starch; the "minogami" consists entirely of fibre. The Hanshi papers are the stronger and coarser, and are made in

* Interim Report of a Committee appointed by the British Association to establish a uniform system of recording the results of the chemical and bacteriological examination of water and sewage, consisting of Professor W. Ramsay (Chairman), Dr. Rideal (Secretary), Sir William Crookes, Professor Frank Clowes, Professor Percy F. Frankland, and Professor R. Boyce.

† British Association Report, 1887.

smaller sizes (about $9\frac{3}{4}$ by 13 inches), while the Minogami papers are thinner and better and of larger (11 by 16 inches). A quire of paper is called "jo" in Japanese, and has from 20 to 48 sheets; a ream is called "shime," and has from 480 to 2,400 sheets. The prices of hand-made paper have recently risen about 15 per cent., because the growers of bast demand and obtain higher prices for their product. Printing paper is used in Japan not only for printing purposes, but also for writing. The most popular sizes of printing paper are 25 by 27 inches and 31 by 43 inches flat. The consumption of paper has increased extraordinarily in Japan, and, although the home production is large, there is a good market for imported paper. Rice straw is an important factor in the manufacture of Japanese machine-made paper; only when there is a poor rice crop is wood fibre imported to any appreciable extent. Several Japanese paper mills, as well as the Fuji paper mill (the largest in Japan), produce their own wood pulp and wood fibre; the Ixono mill is said to be the only fibre mill which sells its products. Wood fibre is imported for the most part from Sweden, and fetches, according to quality, from £16 to £24 per ton. In Skiroishi and in Atami, families make a paper textile in which the warp threads consists of silk or cotton yarn, while the woof thread are twisted from narrow strips of hand-made paper. How much the production of hand-made paper increases, is demonstrated by the fact that in 1887 the total value of the production amounted to £940,000, while in 1895 it had risen to £1,820,000. The production of machine-made paper in Japan was in 1896 approximately as follows:—Fuji, 12,000,000 lbs.; Oji, 12,000,000; Kobe, 7,000,000; Senji, 6,000,000; Yakaichi, 3,000,000; Abe, 2,000,000; Yukosha, 800,000; Shimozato, 800,000; Ixono, 200,000; or a total of 43,800,000 lbs. The Muramatsu paper mills, near Shizuoka, produce excellent hand-made paper, and especially noteworthy are the napkin tissue papers, unrivalled in silky gloss and beauty, which are also painted or printed with pictures, as well as the unsurpassed Japanese crape tissue paper. Among the most curious things to be seen in Japan, are the jackets and trousers of strong hand-made paper with which the Japanese soldiers were supplied during the war between Japan and China. The seams and button holes were sewn with cotton thread. Chinese hand-made papers are made mostly of rice straw and are coloured or stained on one side by hand, for instance, crimson for visiting cards (which are thin large octavo sheets), pale red for bills, yellow sprinkled with gold or green for wrapping goods, orange for wedding finery, &c. Large quantities are consumed in the principal place of its manufacture for decorating various places of worship which are visited by Chinese from all over the country, and considerable quantities are also sent to the adjoining provinces. There is no doubt that cheap imported machine-made printing papers, stained or unstained, could successfully compete with these

home-made and hand-made papers, and the East Asiatic countries would certainly appear to present an attractive and lucrative field for the European exporter of paper.

MINERAL PRODUCTION OF CHILE.

The province of Autofogasta is composed of the three departments of Tocopilla, Autofogasta, and Taltal, and each of these has its part of the same name, from which almost all the products are shipped, the other ports being minor ones. The department of Autofogasta, which is the principal one, is wonderfully rich in gold, silver, copper, salt, and anhydrite, also in lead. The production of Bolivia is nearly all exported through the port of Autofogasta, as the Autofogasta and Bolivia Railway is the only one that extends into the heart of that country, having a length of some 600 miles. Silver, copper, antimony, bismuth, tin, mercury, and sulphur are received from Bolivia. The gold mines of Autofogasta exist in three districts—San Cristobal, Santa Maria, and at the mouth of the River Loa. The gold is found in well-defined fissures, quartz lodes in quartz trachyte, and, with the exception of one mine—the Bolaco in San Cristobal—very little work has been done, chiefly owing to the lack of water which has to be taken in carts 36 miles. The United States Consul at Autofogasta says that the production of San Cristobal has averaged, for the last two years, 200 kilogrammes (440 lbs.) of fine gold annually. The per-centage has averaged 10 ozs. to the ton. The production from Santa Maria and the Loa is small. There are several silver districts in the department of Autofogasta, the most important being Caracoles, Sierra Gorda, El Inca, Paine, Laukir, Atahualpa, Aralar, Sierra de Plomo, Piquios, and Cerro de Pascua. These are distributed all over the department, and, with the exception of Sierra Gorda, the cost of transport by carts to the different stations on the railway is very heavy. The production of silver, which reached 250,000 kilogrammes (550,000 lbs.) fine in 1873, from Caracoles alone, has been reduced in subsequent years to 25,000 kilogrammes (55,000 lbs.) in the whole department. The first three districts named are the only ones at work at present. The ores are chiefly chlorides or limestone. The production of copper is gradually increasing, owing to the higher prices quoted for bar. The chief districts are Chuquicamata, Sierra Gorda, Lomas Bayas, El Desesperado, Naguayan, El Cobre, and Blanco Eucalada. The ores are chiefly green carbonates, oxychlorides (atacamite), and silicates, there being little sulphuret. None of the mines have any depth. The products of most of them suffer from the high railway rates. The production can now be estimated at 12,000 tons annually of 15 per cent. copper, or 1,800 tons fine. It is expected that this will soon be doubled. Half is shipped direct, and half used for making copper matte with a per-centage of silver, by

mixing with silver ores. There are extensive nitrate of soda fields in the department, which have been worked since the year 1870. The first discovered, at Salar, six miles in the interior of Autofogasta, have been worked out. Others found further in, and belonging to the same company, employ from 800 to 1,000 men, and produce from 30,000 to 35,000 tons a year. There are other fields in Aguas Blancas, 60 miles south-east of the port of Autofogasta, where work is to be resumed shortly. These are of vast importance, and as soon as a railway is constructed the production is expected to increase very considerably. There are extensive fields of borate of lime about 160 miles from the coast, at Ascotan, Carcote, O'lagüe, Tilopozo, and Carvagal. The only ores that can be worked at present are those of Ascotan and Carcote owing to poor railway facilities. The production is about 7,000 tons a year. There are some large deposits of sulphate of iron near Sierra Gorda which have been worked on a small scale for treating copper ores. An entire hill of very pure salt, some 20 miles in length, exists at about 150 miles from the coast. The railway is too far removed to make it available for commerce. Small deposits of an hydrite are found in different parts near Caracoles. There are some good lead mines with a small per-centage of silver in Sierra del Plomo, Cerro del Árbol, Sierra Gorda, and other districts, but they are not worked at present owing to defective means of communication. The department of Tocopilla produces gold, very little silver, copper, nitrate of soda, and borate of lime. The amount of gold won does not amount to much and is all sold in Autofagasta. As regards copper, near the port of Tocopilla there are several mines which yield sulphurets and which have been worked to a depth of 200 fathoms. In Cobija and other ports south of Tocopilla there are also very rich mines. The present production of the whole department is about 9,000 tons a year of 15 per cent. ore. All this is sold to the Lotta Company, in the south of Chile. The fields of nitrate in Toco, 50 miles inland, are extensive. They belong to different owners, and produce 100,000 tons a year. The department of Taltal produces gold, silver, nitrate of soda, and copper, all in large quantities. The famous gold mines of Guanaco produced, ten or fifteen years ago, enough to keep four large establishments going. Now the production has decreased, owing to the small amount of work carried on. It is calculated that about half a ton of pure gold is still produced. The ores are all milled in the port of Taltal. There are some very rich silver districts, amongst which may be mentioned Cachinol (including the famous Arturo Prat mine), Sierra Esmeralda, Griton, Cifunchos, and Argolla. With the exception of the first-named, there is very little work done; still, the production is not less than 25 tons of bar silver. The nitrate fields are very extensive, and have, like the others in the province, their railway. The yearly production is about 90,000 tons. There are several copper mines,

the production of which amounts to about 4,000 tons a year of 18 per cent. ore.

INFLUENCE OF BACTERIA ON THE DECAY OF CEMENT.

The Analyst quotes from a paper by A. Stutzer and R. Hartleb on this subject in the *Zeitschrift angew. Chem.* In 1896, Stutzer observed that the cement mortar which had been in use for eight or nine years as lining to a water-supply reservoir was converted into a brownish mud, containing less lime and more iron oxide, &c., than the original cement. This disintegration he ascribed, and still believes to be primarily due, to the solvent action of the carbon dioxide in the water, which dissolved the lime of the cement in the form of bicarbonate. But on extracting further samples of the mud from the same reservoir lately with sterilised water, the present authors found that it was highly charged with nitrifying organisms; so much so, that when introduced into a 0.1 per cent. solution of ammonium sulphate, the ammonia reaction practically disappeared in fourteen days, and nitrite reactions were given powerfully. A similar experiment with asparagine only gave a nitrite reaction after six weeks, but here it was necessary for ammonia first to be formed before nitrification could set in. A further test with a 0.1 per cent. solution of sodium nitrite showed that nitrites were formed but slowly. It would appear possible, therefore, in the case of waters containing any appreciable proportion of oxidisable nitrogenous matter, that this production of nitrous acid by the agency of micro-organisms may play some part in the destruction of cement. The parallel action that is noticed in sea-water, unless the cement is fortified by the addition of extra active silica, is due rather to the soluble sulphates than to carbon dioxide, which is not present in such large quantities as in fresh water; it has not been feasible to determine whether bacteria assist in this disintegration likewise.

With reference to this matter, G. Barth, in the same journal, quotes another instance of cement decomposition occurring in three years where the water contained no unusual amount of carbon dioxide, and he seems to consider the previous explanation plausible.

GLASS AND PORCELAIN INDUSTRIES OF BOHEMIA.

The northern portion of Bohemia, though without a large city, supports a population of about 375 to the square mile, making it the most densely populated part of Austria-Hungary. It is rich in mineral wealth, having the iron of the Erzgebirge and the rich coalfields of the Eger River Valley in close proximity, and has the best material for the manufacture of porcelain, pottery, terra-cotta ware, and

the world-renowned Bohemian glass-ware. The Eger river, one of the tributaries of the Elbe, waters the western, and the Elbe, the northern part of this section. The coal beds of the Eger valley are among the richest of the Continent, and find their shipping point mostly at Aussig on the Elbe. Rich kaolin and terra-cotta beds yield the material for the porcelain and pottery manufactured and hand-painted in many of the villages. For this latter, which is largely a home industry at very low wages, some of the colours (as ultramarine, chrome green, and alizarin) are also of home manufacture. The United States Consular-Agent at Haida says that this porcelain and pottery industry is carried on in the villages and towns all the way from the environs of Karlsbad to Tetschen-Badenbach. Tetschen has also a large factory of buttons, made of "vegetable ivory." In the northern quarter of the region described, all the materials exist for the production of the clearest crystal glass. The people have had experience of over 200 years in converting the crude material into the best glass, and shaping it into the choicest utensils and ornaments, by cutting, polishing, engraving, painting, and gilding. All this has given Bohemian glass a world-wide renown. The refining is largely a home industry at very low wages; the wives, daughters, and sisters of the male workers. Some of them, real artists, carry the ware in large baskets on their backs up and down the mountains between the factories and their own homes. The wages range; for women's work, consisting mostly of washing, packing, and carrying the glass, from 5s. 2d. to 8s. 4d. a week. Men receive the following:—Glass cutters, 10s. 4d. to 14s. 6d., engravers, 16s. 8d., to 25s., painters and gilders, generally including those who are employed in burning and burnishing, 21s. to 33s. 4d., the best painters, capable of doing good portrait work, may earn 42s. to 50s. a week. All this labour is counted at eleven working hours a day, and workers supply their own food, and often the fuel for burning in the paint. Haida, forming with Arnsdorf one town of 6,000 inhabitants, is the centre of this industry, and it is estimated that within a six-mile radius of Haida, 10,000 people are engaged in this industry of glass refining.

LEATHER INDUSTRY IN GERMANY.

According to Consul-General Sir Charles Oppenheimer, a result of the study by German experts of American progress is the establishment of a German leather industry. Germans claim to have themselves invented the manufacture of leather with the use of chrome salts, and Dr. Heinzerling, of Frankfurt-on-the-Main, is named as the inventor of this process, which, in the year 1884, was finished by Schu'z in America for technical use. This leather appeared first in the latter eighties on the American market. It is said especially to possess greater resisting power

against dampness than ordinary chevreau leather. Six to seven years ago German factories commenced to manufacture chevreau from chrome. A firm bought several patents, and sent experts to America to study the process on the spot. This factory is furnished with new American tannery machinery, which is capable of turning out daily 500 dozen goat-skins, and they contemplate raising the output to 1,000 dozen per day. The factory has succeeded in working off hides from various sources, with like success. Another German firm is said to have been successful in manufacturing calf, cow, and strap leather with chrome salts, according to a new process invented by Dr. Heinzerling. This success has caused great rejoicing in Germany, and German papers conclude from this that the technical and commercial methods of the Americans ought to be studied by proper skilled experts in order to be able to beat the work of the Americans. As to the branches of trade which, in this connection, are next to be taken in hand, are mentioned the shoe, bicycle, and iron industries.

General Notes.

CONGRESS OF HYGIENE AND DEMOGRAPHY.—The following letter has been received from the Science and Art Department:—

"27th September, 1899.

"SIR,—I am directed to state that the Department of Science and Art has received, through the Foreign Office, a copy of a note from the French Minister at this Court, stating that the Tenth International Congress of Hygiene and Demography will be held in Paris from the 9th to the 17th of August, 1900, and that the French Government are desirous that Her Majesty's Government should be represented by one or more delegates. It is pointed out that the President of the Congress, Dr. Brouardel, Dean of the Faculty of Medicine of Paris, would be glad if a special committee were formed in England, with which the Organising Committee could communicate respecting the participation of other countries, the preparation of the prospectus, and kindred questions. I am to request that you will be so good as to cause this information to be published in the *Journal of the Society of Arts*.

"I am, &c.,

"W. DE W. ABNEY."

LUXEMBURG KID GLOVE MANUFACTURE.—In the article on this subject, published on p. 806 of the *Journal* for 15th September, it is stated that Luxembourg exports about 50,000 pairs of gloves yearly; but M. Reinhard calls attention to the fact that the figure is 50,000 *dozen* pairs, a number which he alone has exported in a single year.

Journal of the Society of Arts.

No. 2,446. VOL. XLVII.

FRIDAY, OCTOBER 6, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS, 1900.**

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

Proceedings of the Society.**CANTOR LECTURES.****THE MANUFACTURE OF LEATHER.**

By PROF. HENRY R. PROCTER.

LECTURE II.—Delivered April 24, 1899.

In the last lecture we left the hide or skin softened, and thoroughly washed from salt and dirt. It still requires both chemical and mechanical treatment before it is ready for actual conversion into leather. The hair must be loosened, so that it can be removed. The inner or flesh side must be freed from loose underlying tissue and fragments of flesh left on by the butcher, and the hide cleansed as far as possible from fat and the remains of epidermis tissues such as hair roots and glands. It is also necessary, either at this stage, or at the very beginning of tanning, that the gelatinous fibres of the skin should be swollen by some agent, either acid or alkaline, which has the power of splitting the fibre-bundles into their finer fibrils, so as to increase their bulk, and the surface they present to the action of the tanning substance. If, as is most usually the case, lime has been used in this preliminary treatment, it is necessary to secure its removal, especially if vegetable tans are to be used, and, where soft and flexible leathers are

required, to bring the fibres back from their swollen state to a soft and flaccid one, since if tanned in a swollen condition the leather would be hard and in extreme cases even brittle.

The agents which are practically used to loosen the hair are putrefactive fermentation, lime and other alkalies, and alkaline sulphides. The putrefactive method may fitly be first considered as no doubt it was the first in historical sequence. If hides or skins are allowed to remain for a few days in warm weather in a damp condition without the use of antiseptics, putrefaction sets in, beginning perhaps first in the lymph and liquid contents of the skin, but spreading rapidly to the soft and growing layer of the epidermis, which it liquifies and destroys. As this layer surrounds the roots of the hair, the latter is loosened, or, as the tanners say, "slips." To the primeval huntsman this accident must frequently have occurred, and where he has set his soul on a fur jacket must have been very annoying, but it probably gave the idea of the earliest method of removing the hair where its removal was needed. In much later times the common method was to lay the hides in pile or to fold them up in a warm and damp place, sometimes after a previous washing and light salting to lessen the danger of putrefaction spreading to the true skin itself until the hair was loosened. The method is still largely in use for special purposes, but in a somewhat modified form. Instead of laying the hides together, where they cannot be examined and where the action is apt to be irregular from uneven heating of the skin, or from other causes, they are now hung up in a room which can be moistened by water sprinklers and warmed by steam, and which is generally so arranged as to be protected from sudden changes of temperature and with but little ventilation. The process is called "staling" or "sweating," and one of its most important applications is to the unwooling of sheepskins; as in this case the value of the wool is generally much greater than that of the pelt, and wool is injured by lime and most of the other chemical means of loosening the hair. After the previously washed skins have been hung in this way for about a week, the wool is so thoroughly loosened that the "woolpuller" spreading the skin on a sloping "beam" in front of him can push it off with his hands, separating into different baskets the various qualities which are found on different parts of the animal.

Another case in which a similar putrefactive method is frequently employed is in the manufacture of sole-leather, and especially that made in the United States from dry hides. In this case the aim is to avoid solution or washing out of any of the constituents of the skin, and so to obtain a heavier yield of a firmer and more solid leather. When the process is properly conducted the effect is almost entirely confined to the soft growing cells of the epidermis, and putrid ferments have no effect in swelling or splitting up the fibre-bundles. It is, therefore, necessary in the case of sheepskins to lime them, much like skins from which the hair has not been removed, so as to fit them for tanning, while in the case of heavy hides for sole-leather the necessary swelling is effected by the use of acid at the beginning of the tanning process, before which they sometimes also receive a light liming. It is probable that the failure of English attempts to produce a satisfactory sole-leather by the sweating process has often been due to ignorance of this essential condition to success.

There is but little to be said in scientific explanation of these methods. The bacteriological process is of course a very mixed one, and no special care is or perhaps can be taken to secure the right organisms, beyond choosing conditions of temperature and moisture which favour a rapid and satisfactory action. It is stated, however, by von Schroeder that the bacteria which are most active in loosening the hair have little effect on the skin itself. There is no doubt that a considerable part of the solvent effect on the epidermis is not due alone to the direct action of the bacteria, nor even of the solvent ferments which they produce, but to the ammonia which is freely given off during the process, and acts like other alkalis in loosening and dissolving the epidermis. A piece of fresh skin hung in a beaker over a little liquid ammonia has the hair loosened as much in a few hours as it would be in some days of putrefaction. The greatest danger of the method is the spreading of the putrefaction from the epidermis layer into the surface of the true skin, and it rarely happens that some damage is not done to the delicate hyaline layer which should form a sort of glaze to the finished leather. Such damage shows itself by a whitish and dull appearance of the surface, and in coloured leathers by irregular dyeing.

Liming is a far more important means of loosening the hair than putrefaction and one in far more general use. Lime in common with

other alkalis has not only a solvent effect on the epidermis, but swells the fibres of the true skin, and splits them up into their constituent fibrils, and as both these effects are essential to the production of a good leather, we have in lime an agent admirably adapted for our purpose. Not the least of its virtues is its limited solubility in water, not much exceeding 1½ parts per 1,000, which renders its action mild and gradual, and the employment of an excess innocuous, since only the dissolved portion acts on the skin. In practice a milk of lime is always used, so that as the lime is consumed by the skin the solid portion passes into the solution and keeps it of uniform strength. If caustic soda or potash were substituted for lime, the very weak solution which alone could be safely used without skilled chemical control would become very rapidly exhausted, and its strength would have to be constantly renewed by additions, which in milk of lime take place automatically. In practice the hides or skins are generally drawn into a pit filled with well mixed milk of lime, and allowed to sink in it in a position as flat and straight as possible, and so that a small quantity of the undissolved lime settles between them. After lying, say 24 hours, the hides are drawn out with hooks (tongs are frequently used for skins), the lime is well stirred or plunged up, and the goods are returned to it, and this process is repeated daily till the hair or wool is sufficiently loosened, which usually requires from a week to ten days. The more frequently the goods are handled and fresh lime and liquor brought into contact with them, the more rapidly will they unhair and the less excess of lime will be required. Sole-leather tanners, who are often negligent in this respect, frequently use as much as 10 or 12 per cent. on the raw weight of the skin, but it is probable that not more than 2 or 3 per cent. is actually consumed. The lime pit is generally used repeatedly on successive parcels of hides or skins, and in making a new lime liquor, a considerable excess of lime must be used, about double of what is needed to strengthen it for a new "pack." Von Schroeder found that 6 grammes of CaO per litre was a suitable strength, but in practice much more is generally added. The chemistry of the liming process is by no means so simple as might at first sight appear. Its effects are not due to the chemical action of the lime alone, but also to that of the enzyme products of bacteria, without which so weak an alkaline solution would have little solvent action on the

epidermis structures. Sound sterilised hides in a sterilised lime will not unhair in any reasonable time by the action of the lime alone, but if previous to liming they have undergone slight putrefaction, or been submitted to the action of the ferments of a putrid soak, or if a small quantity of such ferments is introduced into the lime liquor itself, unhairing will take place in a normal way.

The effect of this combined action of bacteria and lime is to break down the epidermis matter of the skin, first into soluble forms identical with peptones or nearly so, and then into simpler and simpler products as time goes on, till we arrive at amines and amido-acids, often of the fatty series, and finally at ammonia, carbonic acid, and water. An old lime contains, in addition to the full quantity of caustic lime which it will dissolve, a large amount of dissolved lime which is no longer caustic, but combined with weak organic acids, together with ammonia, peptonised hide substance, and a large number of living bacteria and their products, some of which are the solvent ferments or enzymes of which I have spoken. It therefore happens that, contrary to the usual belief of tanners, an old lime is much stronger than a fresh one in its solvent effect on hide, although it swells it less, since the enzymes have an effect like that of a puer liquor, directly opposed to swelling; and ammonia swells much less than lime, though its solvent effect is greater. The effect of such old limes is, therefore, to dissolve and loosen the fibrous tissue of the skin, giving poor weights and spongy leather, and where the limes are very stale there is a great danger of injury to the grain by the direct action of bacteria. Absolutely new limes, on the other hand, swell the fibre well with very little loss of hide substance, but if the hides have not undergone any previous putrefactive action, they loosen the hair very slowly.

Between these two extremes the tanner has it in his hands to produce considerable variation in the effect of liming. Thus for sole-leather, where solidity and thickness are points of prime importance, only new or nearly new limes should be employed, since the object is to swell with as little solution and loss of hide substance as possible; while for dressing leathers which require softness, somewhat older limes may be usefully employed, though in no case should this be carried so far as to endanger active putrefaction and damage to the grain. It is generally advantageous to work the limes in series, beginning in an old

lime when the solvent action is most useful and least injurious, and finishing in a fresh one which plumps better and is less dangerous.

The temperature of the lime is a matter of some importance. Contrary to the usual rule the solubility of lime diminishes with increased temperature, but at the same time its solvent action increases still more rapidly, and its power of swelling diminishes, so that a warm lime unhairs much more quickly than a cold one, but with less swelling and more solvent action on the skin, so that loose and light-weighting leather generally results. In the case of sole-leather especially the use of warm limes is a fatal mistake, but on the other hand, at very low temperatures the action is almost arrested, and to obtain uniform results it is best to maintain them at a temperature of about 60° Fahr. There is, however, one way in which heat may be satisfactorily employed to assist liming, which is often called the "Buffalo method," because of the place where it originated. If hides after a comparatively short liming are placed for some hours in warm water, the removal of the hair is much facilitated, and less hide-substance is dissolved than in the longer liming which is otherwise necessary. In the States the method is often employed for sole-leather, the liming being in extreme cases reduced to 10 hours and the hides being left in water heated to 100-110° Fahr. overnight. But little lime is used, but it is frequently strengthened with a small quantity of sodium sulphide, say 4 oz. per hide. In such extreme cases the hide contains but little lime, and its fibre is scarcely swollen, so that recourse must be had to swelling with acid before tanning, as in the case of sweated hides. It is however obvious that any result between this and that of ordinary liming may be obtained by the appropriate use of warm water.

An indirect method of liming has been very recently patented by Messrs. Pullman, of Godalming, which possesses much scientific interest, and promises to be of considerable commercial importance. From the difficult solubility of lime, and the consequently weak solutions which must be employed, the ordinary process of liming is a slow one. Caustic soda, on the other hand, can be used in much stronger solution than caustic lime without injury to the hide, and from its great powers of diffusion penetrates very rapidly. By treating a hide which has been saturated with caustic soda with a neutral soluble salt of calcium, a double decomposition takes place, and caustic lime is formed actually in the

interior of the fibre of the hide. Both solutions may be used in any convenient way, as for instance, in pits or paddles, but for rapid work a drum is the most convenient, as a comparatively small volume of liquid is sufficient to treat a considerable quantity of hides. Through the kindness of Messrs. Pullman I had the opportunity lately of watching the treatment of a lot of 15 salted hides throughout the process. As my time was limited, the goods were drummed with the soda solution for only about three hours, and with the lime salt for less than an hour, at the end of which time the goods were fully plumped and ready for un-hairing, though perhaps the hair was rather tight, as preferably they should have had at

way. Another very important point is, that as soda soaps are soluble and easily emulsify grease, the latter is much more completely removed than by the ordinary method.

The most curious point about the invention is that if the skins are free from putrefaction and kept in a sterilised condition before treatment, no immediate loosening of the hair takes place, though they may be fully limed, and it is thus possible to properly prepare them for tanning with the hair on. A short soaking before liming in an old soak liquor, or an addition of sodium sulphide to the caustic solution, will cause the hair to loosen at once, thus proving the importance of the bacterial action in the limes to which I have already alluded.

FIG. 10.

SOLE-LEATHER LIMEYARD. PENKETH TANNING CO., LTD.

least an hour longer in the soda solution. Apart from this they had the appearance of being fully limed; and though I was not able to follow the tanning process further, I see no reason why they should not turn out good leather. Messrs. Pullman assure me that the method is not more costly than the ordinary one, and if it proves on further experience to turn out an equally satisfactory product, it will have the great advantages that no lime slab, and only a very moderate quantity of waste liquor is produced, that the time is very much lessened, as well as the plant required for treating a given quantity of hides, and that the amount of liming effect produced can be regulated much more accurately than in the ordinary

Of late years the alkaline sulphhydrates, either alone or in conjunction with lime, have come very much into use as unhairing agents. It has long been known that these compounds had a very curious effect on the hair and harder keratin tissues, breaking them up, and dissolving them in a way very different to the caustic alkalis, which act slowly in the cold on the harder structures, though they gradually loosen and dissolve the soft and growing cells. Hair, for instance, moistened with a strong solution of calcium or sodium sulphhydrate, is rapidly reduced to a pulp, its inner contents being so far liquified that under the microscope it has the appearance of strings of sausages, and in a few hours can be washed off or swept

off the skin with a broom. On the other hand, the effect of these compounds on the gelatinous fibres of the true skin is much less powerful than that of the caustic alkalies, neither dissolving nor swelling them to any great extent; so that a hide unhaired with sulphhydrates is left in a much less altered condition than with lime, and with less solution of the cementing substance of the fibre bundles, so that if suitably tanned or tawed, it gives a more solid and less porous leather. The chemistry of the reaction on the hair has not yet been studied, but the sulphhydrates disappear (as such) from the solution.

Red arsenic has always been objectionable, both from its expense and its poisonous character, and of recent years the restrictions on its use imposed by the German and Austrian Governments have been so severe as to render the discovery of an effective substitute of great importance. The effective agent in the mixture of realgar and lime is the calcium sulphhydrate formed, and many years ago it was shown by Boettger that it could be equally well produced direct by passing hydrogen sulphide into milk of lime, but unfortunately the compound is very unstable, and its manufacture on the spot is too troublesome and costly for general

FIG. 11.

UNHAIRING. PENKETH TANNING CO., LTD.

The first application of this principle seems to have originated in the East, where a mixture of lime and realgar (a red sulphide of arsenic) has long been used as a somewhat dangerous means of removing superfluous hair from the face. It is very possible that its use was introduced into Spain by the Moors, to whom many of the mediæval improvements in arts and manufactures are due. The mixture is still largely used in the manufacture of glove kid, and some of the finer sorts of leather, either alone, or as an addition to the ordinary limepit, where it enables the skin to be thoroughly cleansed from the epidermis structures, without so much loosening its texture as lime alone would do.

adoption. Gas lime and calcium sulphide residues of the Leblanc soda process have both in their time been tried as sources of calcium sulphhydrate, but with only partial success, and it was not until the introduction of crystallised sodium sulphide by a German firm of chemical manufacturers that any great progress was made. The material crystallises with nearly 70 per cent. of water (10 eq.), and is somewhat deliquescent, but keeps well. As it is not a sulphhydrate but a sulphide, its solution in water may be regarded as a mixture of equivalent parts of sodium sulphhydrate and sodium hydrate, and it is not improbable that it really dissociates in this way:—

Its action on the skin supports this view, as it swells the gelatinous fibres much more than calcium sulphhydrate, as would be expected from a mixture containing caustic soda. When sodium sulphide is mixed with slaked lime, a mutual decomposition occurs—

and calcium sulphhydrate is formed, together with an equivalent quantity of sodium hydrate. The formation of caustic soda is probably the reason why the mixture has not proved an entirely satisfactory substitute for that with red arsenic, in which no caustic soda is formed, but it has come into extensive and important use in unhairing a great variety of leathers which were formerly treated with lime alone, and it is especially available for the heavier dressing leathers where toughness and solidity are important.

Sulphide of sodium and the sulphhydrates may be practically employed for unhairing in several ways. With a paste of calcium sulphhydrate, or a strong solution of sodium sulphide thickened with lime, skins and hides may be unhaired in a few hours, either by applying it direct to the hair side, when the hair is of course destroyed; or by painting it on the flesh, when it penetrates the skin and destroys the roots of the hair or wool. The latter method is frequently used for sheepskins, where the wool is valuable, as a substitute for "staling." For sole-leather the mixture is frequently applied direct to the hair, which is of comparatively little value, but it is difficult to ensure its penetration to the roots, and if a spot is left untouched, the hair must be shaved off. To obviate this the hides are now frequently brushed or paddled for a short time in a strong unthickened solution of sodium sulphide, and then laid in pile till the hair is destroyed, when it can be removed by drumming in the wash-wheel with water. Where these rapid methods are adopted, the fibre is practically unswollen, and before tanning the hides must be swollen with acid.

A much more common and important method of use is to add a small portion of sulphide of sodium to the limes, perhaps four ounces per hide, when the unhairing will be more rapid, and the solution of the cementing substance of the fibres less than with lime alone.

The discovery of a thoroughly satisfactory substitute for realgar is still a desideratum. Calcium sulphide is insoluble in water, and at ordinary temperatures will not take up the water necessary to convert it into a mixture of sulphhydrate and hydrate. The sulphhydrate is

too unstable for commercial use, and its solution is not sufficiently concentrated for cheap carriage. Barium sulphide is soluble in water like the sodium compound, but is more expensive, and so far as it has been experimented with, somewhat less convenient. Some of the polysulphides of calcium are pretty soluble, and cheap, and though they have no unhairing powers alone, they apparently form calcium sulphhydrate on mixture with lime. A mixture, probably of calcium sulphhydrate and polysulphides, is being pretty extensively used in Austria in place of realgar, under the name of "calcin." Polysulphides seem to have great power of reducing the swollen condition of hide fibre, and hence may prove useful as "bates" or liquors for diminishing swelling. The "tank waste" or calcium sulphide residues of the Leblanc process become soluble by the action of air and carbonic acid, forming a complex mixture of polysulphides and thio-sulphates, and good results in unhairing were obtained some years ago by Mr. J. Muir, of Beith, by first lightly liming, and then treating the hides with this solution, which in conjunction with the lime, rapidly loosened the hair.

So far we have confined our attention solely to the chemical treatment of the hide or skin prior to unhairing. The actual mechanical removal of the hair generally takes place on a sloping beam or iron or wood with a convex surface, over which the workman leans, and pushes the hair off with a blunt two-handled knife. Various machines have been devised to accomplish this labour, but they have not as yet come very largely into use, mainly because the hand work is rapid and not difficult, and judgment can be used in working off the hair on any spot where it is tighter than usual, while machines in many cases leave spots which have afterwards to be removed by hand on the beam. Sometimes goods are unhaired in the wash-wheel or by fulling in the "stocks."

After unhairing the skins or hides are usually "fleshed." This operation is done on the same beam on which the goods are unhaired, but a sharp two-edged knife is employed, with which adhering fat, flesh, and loose tissue left on by the butcher is removed, partly by cutting, partly by scraping. In England this is still most frequently accomplished by hand, but in America, on the cheaper classes of upper-leather, machines are almost invariably used, and the fleshing usually takes place in the hair and before liming. There are reasons why this method cannot perhaps be generally adopted in England which time will not allow

me to explain here, but I believe by suitable changes in the after treatment of the leather it could be much more often employed than it is. Even in the United States the fleshing of sole-leather is usually done by hand. The machines used mostly depend for their essential action on a cylinder with spiral blades under which the hide or skin is drawn.

Whenever the hides have been treated with lime it is necessary that this should be removed before tanning, as it forms insoluble compounds with the tannins, which oxidise and darken on exposure to the air and spoil the colour of the leather. Where soft and pliable leathers are

On the other hand, while the removal of the lime is always desired, the solution of the fibre substance is demanded in very different degrees for different classes of leather, and in many cases would be better avoided altogether. The reduction of the swelling is mainly an osmotic effect, and is by no means directly connected with the solution of the fibre, but may to a considerable extent be brought about by the mere removal of the alkaline condition caused by lime. I hope in the next lecture to consider a little more closely the chemistry and physics of these phenomena of swelling and shrinking, in connection with the theory of the tanning pro-

FIG. 12.

FLESHING.

to be manufactured it is also necessary to reduce the swollen condition of the fibre produced by lime, and in some cases also to dissolve a further portion of the cementing substance of the fibres, so as to give the leather more stretch and softness. Hitherto these results have mostly been obtained by various fermentation processes, often of a disgusting character, but there now seems a possibility of superseding them by cleaner and more reliable methods. In considering the chemistry of the subject, we must remember that, as in the case of liming, more than one effect at the same time has been attained by the older processes, and that no method will supersede the old one if it only provides for one of these effects.

cess, but, for the moment, it may suffice us to remember that the presence of the lime increases the capacity of the fibre to absorb water, and so causes it to swell up.

We have, therefore, to consider in the first place the best means for the removal of the lime, since in many cases, this alone will suffice, as, for instance, in the production of harness leather, where a firm texture and reasonable softness are all that is required. Naturally the neutralisation of lime with an acid is the first idea which would occur to the chemist in this connection, but there are certain difficulties which must be provided for before it can be successfully carried out. Mere washing of the lime out with water is generally im-

practicable, since it is combined with the fibre, physically or chemically, in such a way that it will not diffuse into water in any reasonable length of time. If the lime can be exactly neutralised with acid, the neutral salt can be easily washed out, if it is soluble, but if the acid is employed in the least excess, it is greedily absorbed by the fibre, which again swells, and it becomes as great an evil as the lime, which it has expelled. It is, therefore, necessary to exactly adjust the quantity of acid to the lime in the skins, and rather to leave a trace of lime unremoved, than to use acid in excess. For dressing leather, the operation is best performed in a vat with a paddle to keep the skins in motion in water at a temperature of about blood heat, and sulphuric acid is as good as any other, as the calcium sulphate formed is more soluble than the lime itself. By experience the required quantity of acid may be exactly known, but if not, it is necessary to proceed tentatively, adding the acid little by little, and judging principally by the feel of the skin. Test paper in the liquid is of little service, as the acid will be completely absorbed by the skin long after all the lime is neutralised; but the skin itself may be tested by applying a solution of phenolphthalein to a cut surface, which will turn pink so long as lime is present. For sole-leather, the hides are best suspended in cold water, in which they are kept in gentle motion, and a sufficient quantity of acid is added at once to remove the lime completely from the surface, but not to neutralise the whole of that present, since a trace of lime left in the interior of the hide is not prejudicial. In this case the hide as a whole will remain plump, but the individual fibres will become reduced, so that it will lose its firmness, and become soft and easily compressed. It must be specially noted that as the skin is capable of taking up acids from very dilute solutions, the effect, if time is allowed, will depend on the total quantities of acid present, and not on its concentration, so that a large volume of a dilute solution may act more powerfully than a small volume of a stronger one.

Another method which in many cases is very useful both for sole and dressing leather, is to employ an acid so feeble that it is incapable of swelling the hide, while it still can neutralise the lime. For this purpose one of the most useful acids is boric, but several organic acids have been suggested for the purpose, principally sulphonic derivatives of the aromatic series. Much more might be profitably said

on this subject if time allowed. Salts of ammonia may be usefully employed to remove lime with liberation of ammonia, which has much less swelling power, and is more easily removed by washing. The addition of ammonium chloride to the bath used in delimiting dressing leather with sulphuric acid, adds considerably to the safety of the operation, as it is unnecessary to absolutely neutralise the whole of the lime, and if sulphuric acid is accidentally added in excess, the chlorides present tend to control its bad effects on the skin.

I must, however, now pass on to the fermentative methods which are still most commonly in use. The simplest of these is what is called the "bran drench," which is sometimes used alone, as in the manufacture of calf kid, but more commonly to supplement the action of the dung bates. Principally through the investigations of Mr. J. T. Wood, we are now able to explain this very completely. Hot water is poured upon bran, and the mixture is set with a few pailsful of a fermenting drench liquor, and the skins are placed in the liquid, which is generally maintained at a temperature of about 70° Fahr. Fermentation soon sets in, and gas is evolved, which floats the skins up to the surface, and at the same time lactic and acetic acids are formed, which act upon the lime. The skins are put down into the liquor again, but soon rise a second time, and when this has taken place two or three times, which may occur in 12 to 16 hours, the action is generally sufficient. Mr. Wood has isolated the principal bacteria concerned in this fermentation, which he has named *Bacterium furfuris* α and β . He finds that either of these organisms alone will produce the required effect, but that they act more satisfactorily together, and are generally both present in the drench. These organisms are in themselves incapable of fermenting the starch, which is the source of their nutriment, but which must first be converted into glucose by a zymase, cerealine, which is naturally present in the bran. The fermentation has the peculiarity that, in addition to the lactic and acetic acids, and carbon dioxide, considerable quantities of hydrogen are evolved, so that the gas can be actually inflamed. The bacteria of the drench are incapable of acting directly on the skins, and a quite similar effect is produced by the action of a very dilute solution of lactic and acetic acids, which is now sometimes substituted, with considerable gain in safety, as false ferments sometimes get the

upper hand in the ordinary drench with disastrous effect. The most dangerous of these is one which produces a sudden change from the lactic to a butyric fermentation, by which the skins are extremely swollen and rapidly dissolved. It will be noted that the bran drench, though a bacterial process, results in a simple "pulling down" and neutralising of the skins with weak acids, and they should come from it in a soft, white, and slightly plump condition. If, as is often the case, it follows the processes of puering or bating, the ferments of these processes to some extent thrive in the drench, and its effects may to a certain extent resemble that of dung bates; but in presence of glucose, the fermentation is always of an acid character, while the liquefying bacteria of the dung bate require an alkaline medium. Wood states, however, that the specific drench ferments almost certainly have originated from the dung.

Bating (abating) is a treatment in fermenting infusions of pigeon or hen dung, which is applied principally to the heavier sorts of shoe leather, such as thin ox and cow hides, calfskins, and so forth. Puering (probably from the French *puer* to stink) is a similar treatment with the excrement of dogs, and is used especially on the lighter kinds of skin, such as glove leathers and morocco, and is generally followed by a bran drench to cleanse the skins and complete the removal of the lime. In principle the two are extremely similar, and may be discussed together, though there are considerable differences both in their effect and mode of application.

In earlier years, before bacteriological effects received so much attention as they now do, attempts were made to account for the action of these processes on purely chemical grounds, but it is now recognised that the effect of the traces of ammonia salts and phosphates which are present in the solutions, are of no importance as compared to those of the products of bacteriological action, and the researches of Mr. Wood, who has done so much to clear up the theory of the bran drench, have shed much light on the present subject also. He has shown that the presence of living bacteria is unnecessary, and that in the dog puer at least, the really active agents are the enzymes or soluble unorganised ferments which bacteria have formed, and organic salts of amines or compound ammonias which have resulted from their action on the organic matter present. Each of these classes of substances has a

reducing action on skin when used alone, but the proper puering action only takes place when both are present. He has separated the amines from a puer liquor by distillation with soda, and combined them with hydrochloric acid, and has precipitated the soluble ferments with strong alcohol. On dissolving these in water at the rate of $\frac{1}{2}$ per cent. of each, a liquid was obtained which had precisely the same effect on skin as the original puer without any danger of injury to the skin from false ferments. He has found that similar compounds can be obtained by fermentation of a nutrient gelatine solution with other bacteria than those obtained from puer, and that the solution can be concentrated in vacuo, and kept till it is required for use; so that we may now look forward very hopefully to the complete disuse of the dangerous and disgusting processes which have long been a trouble and a disgrace to the tanner, though apparently there are practical difficulties in the manufacture of concentrated solutions on a commercial scale which have not yet been wholly overcome.

It is fair to note that Messrs. Popp and Becker, of Frankfort, have been working independently of Mr. Wood on similar lines, and both they and he have succeeded in producing artificial bacterial bating preparations identical in principle, and perfectly successful in practical use. I have recently had the opportunity of discussing the question with one of the leading technical chemists of the industry, who has tested both preparations very thoroughly, and on a large scale, in an important German leather works, and his results leave little doubt that the older processes will soon become obsolete.

In the present practice, for light skins such as kid and sheep, a liquor is made by dissolving dog dung in water at a temperature of about 90° Fahr. to a turbid solution, in which the skins are kept in gentle motion. In a short time, ranging from an hour upwards, according to circumstances, the previous plump and limy skin becomes so flaccid that the common statement that it can be drawn through a wedding ring is hardly an exaggeration, and when it is tanned, instead of producing a plump and somewhat hard leather, the product is soft, and can be stretched in any direction without springing back. The effect may be well seen in the leather of a kid glove. It is clear that something beyond mere removal of the lime has taken place, and that something, so far as we at present understand it, consists in a solution of the cementing substance of the

fibres, and in some osmotic effect which causes the swollen fibre to give up its water.

The effect of the pigeon or hen bate is less in degree than that of the puer, but so similar in character that it is hardly necessary to go into detail about it. The process generally takes place without artificial heat, and lasts four or five days, though it may be much quickened by working at the same temperature as the puer, say 90° Fahr. It is best to exhaust the material with warm water, and allow it to ferment for about a week in a separate tank, using only the clear liquor wherewith to treat the skins, as injurious bacteria are apt to be contained in the sediment, which settle into folds of the skin, and destroy its grain surface. What difference there is in the action of the bate from that of the puer may very possibly be due, in Mr. Wood's opinion, to the greater amount of urates present.

Miscellaneous.

MANUFACTURE OF MEZCAL.

Mezcal is a strong spirit prepared in Mexico from the stem of the Maguey, or *Agave Americana*. When carefully manufactured it is free from fusel oil, has a bland taste, and a slightly aperient medicinal effect. The agaves grow best on a stony, volcanic soil. After the young plants have been put out they require no attention, except occasional cutting back of the shrubby vegetation. At the end of six or seven years they are cut down, the leaves are removed, and the stem is split. A single stem makes a load for a donkey. At the hacienda the stems are steamed for twenty hours, sliced, and ground with water in a stone edge-runner mill; the pulp thus produced is fermented for six days, strained, and washed; the residue is eaten by cattle for the waste sugar it contains. The liquor is distilled, and the spirit rectified once; it matures in one year if kept at a temperature of 65° Fahr. The chief valuable constituent of the stem is a high per-centage of uncrystallisable grape-sugar, from which the alcohol is derived by fermentation. The leaves yield a large proportion of strong fibre, which can be easily separated in a machine of simple construction, and commands a ready local sale at about 2½d. per pound, for the manufacture of ropes and sacking. The cultivation of the agave is very well suited to the dry *tierra caliente* of Mexico, as it requires little labour, and is unaffected by drought; every part of the plant is useful, even the waste cellular tissue of the leaves being a good cattle food. The profits of the industry are said to be considerable.

FORMOSAN CAMPHOR INDUSTRY.

The camphor trade, that is to say, the manufacture of camphor, for some time past in the hands of German merchants only, has ceased to be of interest to any but Chinese and Japanese, the latter having in every way more facilities for handling this article in the interior. Although from time to time reports are received of robbery with violence perpetrated by banditti up-country, most places where camphor is now manufactured can be considered as more or less quiet.

The British Consul at Tamsui, quoted in the *Board of Trade Journal*, states that since it has been decided by the Formosa Government to institute a camphor monopoly, production has materially increased, owing to the high prices ruling in Hong-Kong during the last few months.

The monopoly was to come into force on 1st July, 1899, and from that date the Government alone was to be allowed to purchase camphor from the producers. As they will only buy a certain quantity per annum, they will have absolute control of the working of camphor, together with all matters respecting the cutting down of trees, &c.

Permits will be issued to producers, and anyone having the proper concession-papers and who has taken out a license in due form, will be allowed to produce camphor.

The Government will itself undertake the sale of the raw camphor, after production, in its unrefined state, and will dispose of it to purchasers at certain points to be determined upon by the Government. These places will probably be Daitotei (Twatutia), Shinchiku (Tekcham), Tokoham, and the towns on the west coast where camphor has usually hitherto been deposited awaiting transport.

The Government has already fixed the price of camphor for the period from July 1st, 1899, to the end of the financial year at 30 yen (say £3) per 100 catties (say 133½ lb.). The Consul is of opinion that this price would seem to be too low, and that it will very probably be raised for the following reasons. If the Government buys at 30 yen at the places of production, *i.e.*, as it comes out of the stills, this would give the manufacturer only 2 or 3 yen profit, not taking account of possible and probable losses occasioned by typhoons or other causes, whilst if the Government proposes to make its purchases at Daitotei (Twatutia), Shinchiku (Tekcham), and the other places mentioned, 30 yen would be quite insufficient to give a profit after deducting expenses for cost of transport from the stills and loss in weight. This last item alone would amount to at least 10 per cent.

The present monthly export to Hong-Kong may be calculated at from 2,000 to 2,500 boxes from Tamsui, and say from 100 to 200 boxes from Kelung to Japan. Owing to the enhanced prices ruling in Hong-Kong, in anticipation of the monopoly, the total export from the island has increased by about 600 boxes a month.

TEXTILE INDUSTRIES OF SAXONY.

Work in textiles represents the major part of Saxony's industries; hundreds of persons are directly employed in their production, and they furnish occupation to the makers of machines and others. According to the census of 1895, Saxony employs 27½ per cent. of all the textile workers in the German empire, and upwards of 32·7 per cent. of all the persons employed in Saxon industries are in textiles. Many work at home on what is known as the house industries. In 1885, there were 113,341 hands in the mills; in 1890, 146,484; in 1895, 165,459. The horse-power used in the mills was, in 1886, 33,352; in 1890, 52,299; in 1895, 81,292. Almost every branch of textiles is carried on in the kingdom, but the most important is the production of middle-grade woollen and cotton goods. One great speciality is vigogne, a yarn made from a mixture of wool and cotton, or from cotton alone. The total number of spindles, including those employed in the manufacture of thread is—cotton 850,000, vigogne 600,000, carded yarns 350,000, worsted 700,000. A large quantity of Saxon yarn is sent abroad. The kingdom produces, annually, worsted yarns worth £4,760,000, and vigogne yarns worth nearly £2,000,000. The Greiz Gera district has 11,500 power-loom producing annually cloth worth upwards of £2,800,000. Fancy woollen cloths are produced on the hand-loom of Glauchau and Meerane. The annual output is valued at about £3,400,000. Flannels for women's and children's clothing are made in great quantities and varieties. Of these, £2,500,000 worth are sent to Asia, Africa, and South America. Cotton, linen, and half-linen goods go mostly to South America. The annual product is about £3,800,000. Calicoes, lace curtains, embroideries, shawls, upholstery goods, &c., are made in Saxony. The weaving industry employs about 94,500 persons. Forty thousand are employed in knitting, producing goods worth £4,760,000, divided as follows:—Hosiery, £2,900,000; gloves, £1,200,000; and underwear, £660,000. Embroideries are among the most important textile products of Saxony. In Plauen and its neighbourhood there are 2,500 of the so-called flat-stitch embroidery machines, representing about £350,000, producing annually goods worth from £1,800,000 to £2,000,000. Besides these there are 3,000 hand machines for flat-stitch work. Saxon laces and embroideries amount to nearly £3,000,000 per annum, and are produced by 16,000 persons, 10,000 of whom are employed in mills, and 6,000 in their own houses. Annaberg and its adjacent city, Buchholz, have 14,000 hands employed in trimmings and passementeries. The total product is valued at £1,200,000 annually. England, Germany, and the United States are the largest buyers. Bleaching, dyeing, printing, and finishing, adjuncts of the textile trades, have reached a very high degree of excellence in Saxony. Dyeing employs 10,000 persons. Chemnitz, the seat of the famous diamond black works of Louis

Hermsdorf, employs 2,600. There are upwards of 19,000 persons engaged in bleaching, printing, and finishing.

DIAMOND PRODUCTION OF THE TRANSVAAL.

According to the United States Consul at Pretoria, the output of diamonds in the Pretoria district during 1898 amounted to 11,025 carats, valued at £8,867. In December, 1897, the output was 166 carats, valued at £146, and for the same month in 1898 the output was 3,100 carats, with a value of £2,389. The largest stone found in 1898 was 38½ carats. Although the diamond industry is not developing with abnormal rapidity there is every cause for satisfaction, the first stone having been discovered at Reitfontein only in August, 1897. The average value of stones found in the Pretoria district is 16s. per carat, the average value of Kimberley diamonds 26s. per carat, and those found at Jagersfontein, in the Orange Free State, 34s. per carat. The diamonds in the Pretoria district are found in pipes, as on Schuller's mine and on Montrose. A similar formation has been found on Rooodeplaats on the Pienaars river, and another is also reported at Kameelfontein and Buffelsduff. On the De Kroon farm, about 26 miles west of Pretoria, diamonds have been found, but according to the State geologist, not in a blue ground formation. At Byrnestpoort an alluvial deposit is being worked, also one on the adjoining portion of the Elandsfontein farm. The area of diamondiferous ground is very extensive though its thickness is not considerable. The total quantity of diamonds found in 1898 in the Transvaal was 22,843 carats, valued at £43,730. At the alluvial diggings 12,283 carats, valued at £35,228, were found; while from the pipes 10,560 carats, valued at £8,502, were obtained. The difference between alluvial and pipe diamonds consists in the fact that river stones are of a far better quality and are generally larger.

THE COCOA PALM AND ITS PRODUCTS IN THE PHILIPPINE ISLANDS.

There are several species of cocoa palms growing in the Archipelago, but the ordinary cocoanut tree (*Cocos nucifera*) is the most important. The Indians make use of it in a good many ways, but only the principal ones need be enumerated. The kernel of the nut they use for food, while the liquid the shell contains makes a refreshing drink. If allowed to stand for some time, this liquid forms a very agreeable milky juice, that is relished not only by the natives, but by Europeans as well. After this juice has coagulated, it is mixed with sugar and made into bonbons, known as cocoa sugar, and also into various other delicacies. According to a recent report of the United States Department of Agriculture, by

tapping the central bud that crowns the coconut, a kind of wine, called *tuba*, of an agreeable pungent taste, is produced. This *tuba*, when allowed to ferment, produces vinegar, and when distilled, a kind of brandy, that is highly relished by the natives. From the husk of the coconut the Tagals make ropes and cords, and a material for calking their boats. From the woody shell they carve spoons, cups, beads for rosaries, and many other articles. The leaves they use to cover the roofs of their houses. Roofs made in this manner are thick and tight, but they have the disadvantage of burning readily, so that in the towns and villages where the houses are thus covered, conflagrations spread with great rapidity. The veins and smaller ribs of the leaves are used to make brooms, the midribs serve as fuel, and the ashes are utilised in making soap. The trunk of the palm is made to serve as a pillar to support the houses that its leaves overshadow. Oil barrels, *tuba* casks, and water-pipes are fashioned from hollow sections of the trunk. From the roots the natives extract a red dyeing material, that they chew in place of the areca palm nuts or *bonga* when the latter cannot be procured. Large quantities of coconut oil are manufactured in the Philippines. This oil is much prized by the natives. The men and women both use it to anoint the thick growth of hair that adorns their heads, and it thus finds a ready sale at remunerative prices. It is also used in the lamps that take the place of gas-burners in the streets, and in those used by the natives and Chinese in their houses. Manila exports annually about 150,000 pesos (£25,000) worth of coconuts to China and British India, and about 30,000 pesos (£5,000) worth of coconut oil to China.

General Notes.

RECENT APPLICATIONS OF ELECTRO-METALLURGY.—In a paper on this subject, read before the British Association by Mr. Cowper-Coles, an electrolytic process for the manufacture of reflectors was described, suitable for making parabolic reflectors for search-lights. The process consists in using a glass convex mould, on which is chemically deposited a coating of metallic silver. The mould thus prepared is immersed in an electrolyte of copper sulphate, the mould being rotated in a horizontal position, the number of revolutions being about fifteen per minute. The copper adheres firmly to the silver, and together they form the reflector, which is subsequently separated from the glass mould by placing the whole in cold or lukewarm water, and then gradually raising the temperature of the water to 120° Fahr., when the metal reflector will leave the glass mould, due to the unequal expansion of the two. The concave surface of the reflector obtained is an exact reproduction of the surface of the mould; it has the same brilliant polish, and requires no further treat-

ment to answer all the purposes of a reflector, with the exception that it must be coated with a film of some suitable metal to prevent it tarnishing. Palladium is found to answer this purpose best, as a bright coating can be deposited rapidly to any desired thickness. Palladium resists tarnishing and the heat of the arc to a wonderful degree.

ARMoured GLASS.—Glass plates cast with wire gauze, or rather mesh, enclosed in its substance, submitted to tests at the Chemnitz Technical Institute and the Vienna Technological Museum, were found to possess great consistency as well as resistance to pressure, shock, and the effects of heat, the resistance being 25·5 kilogrammes per square centimetre (361 lbs. per square inch), and the consistency 255·12 kilogrammes per square centimetre (3,610 lbs. per square inch) of the transverse sectional area. While plates of ordinary glass frequently broke under the sudden application of pressure, the strengthened glass was only cracked; and the cracks caused by rapid changes of temperature permitted neither damp nor flame to pass. It has already been proposed to use the strengthened glass for protecting water-gauge tubes; and the above-named qualities would seem to indicate its use for the glasses of safety lamps.

GERMAN SUGAR PRODUCTION, 1898-99.—According to a statement published in the *Reichsanzeiger*, of August 12th, the quantity of refined and manufactured sugar produced in Germany during the campaign year 1898-99 (August 1st, 1898, to July 31st, 1899) was 1,186,686 tons, as compared with 1,207,350 tons during the campaign 1897-98. The quantity of raw sugar produced was 1,515,526 tons in 1898-99, against 1,664,268 in the preceding sugar campaign. The quantity of raw beets used in sugar manufacture is stated to have been 12,144,291 tons in 1898-99, and 13,697,891 tons in 1897-98.

POLISH GEESE MARKETS.—It is not generally known that a regular "goose market" is held at Warsaw during the month of October, through which some 3,000,000 geese pass, some for consumption at Warsaw, but most for export to Germany. One-third of the geese come from the Government of Vilna, and many more have come long distances, which would ruin their feet, to prevent which they are "shod," as it is called, before setting out on their journey to Warsaw, that is, they are driven first through tar poured on the ground, and then through sand. After the operation has been repeated several times, their feet become covered with a hard crust which protects them during their long march on hard ground. Formerly, almost all the geese were brought to Warsaw alive, but latterly, thanks to quicker means of transport, comparatively few, as it is found cheaper to have them on the market ready killed. Enormous numbers of geese are also sent direct from various points in the country, by road or rail, to Germany; for instance, from one small station 300 railway-wagon loads are sent yearly.

BY PROF. HENRY R. PROCTER.

LECTURE III.—Delivered May 1, 1899.

In the preceding lectures we have discussed the character of the hides and skins from which leather is made, and their treatment preparatory to tanning. We must now pause to ask ourselves the precise meaning of the word "leather," and the nature of the change which takes place in its production from the raw skin.

While skin is easily putrescible, leather is one of the most imperishable of animal products; and while dried skin is hard and horny, and almost impermeable to air, leather is flexible and porous. The essential points, then, are the resistance to decay, and the soft and porous character of the material, though the latter qualities are present in a greater or less degree, according to the process of manufacture and the purpose for which the leather is intended. We have seen that the moist and raw skin consists, practically, of gelatinous fibres, distended with water, soft, and more or less sticky; and it is obvious that when such a material dries, the fibres will adhere together and contract into a rigid and horny mass, impervious to air, and translucent to light because of its solid and comparatively homogeneous character.

Our first aim, then, in attempting its conversion into leather must be to prevent the adhesion of the fibres which, individually, from their tenuity, are flexible enough. We may accomplish this in a variety of ways. Most simply, we may replace the water between the fibres by some liquid in which they are insoluble, and which will absorb and withdraw the water with which they are swollen, thus allowing them to shrink and harden without adhesion, and without producing any chemical change in the fibres themselves. We may render this result

permanent by producing chemical changes in the fibres which render them insoluble in water, and prevent their swelling; or we may simply coat their surfaces with an insoluble and, consequently, non-adhesive layer. The merit of having first clearly seen and expressed these essential principles in leather production belongs to the now venerable Professor Knapp, who, in 1858, in a paper of 30 pages, entitled "Natur und Wesen der Gerberei und des Leders," published a mass of practical experiment and clear explanation, which has been a mine for tanning inventors ever since. In it, for instance, the latest process of chrome tanning was not only anticipated, but clearly described, so that if its value had been understood it could have been worked 40 years ago as well as to-day.

Knapp showed that a piece of raw skin prepared for tanning, if suspended in absolute alcohol frequently renewed so as to maintain its strength, was converted into white leather, not distinguishable in feel or appearance from ordinary alumed leather, such as is used for capping druggists' bottles. We have here a leather in which no chemical change has taken place, and which on thorough soaking in water returns to the condition of raw pelt. The change is a purely physical one, and the principles involved are so important to a clear understanding of our subject, that it is necessary to consider it in some detail. We have to deal here with the nature of jellies, and the causes which lead to the swelling of colloidal bodies by absorption of liquids, and the converse—a question which has hardly received the attention from physicists which its inherent interest and its cardinal importance to biologists deserves. It enters into the explanation of every stage of the tanning process, from the soaking of the raw skin to its final conversion into leather. The jelly state has been well defined in a recent paper by Pauli (Pascheles) as "one in which a solid body has taken up a liquid without itself losing the solid state, while the absorbed substance still acts in many ways as a liquid." A jelly is in fact a typical case of "solid solution;" and as, in solutions in general, we may consider either of the two bodies concerned as the solvent or the dissolved substance, the whole question resolves itself into one of mutual solubility. There are many liquids, as for instance ether and water, which, when shaken together, do not mix, but have a limited mutual solubility. In the case named, the water dissolves a little ether, and the ether dissolves a portion of

water, but the two solutions separate from each other as soon as the shaking is discontinued. Their strengths are such that the solution-pressures of ether and water in both solutions are in equilibrium with each other; so that there is no tendency for either ether or water to pass out of the water-ether into the ether-water solution or *vice versa*. If now we introduce a third substance, say potassium carbonate, which is soluble in water but not in ether, into the water-ether layer, it will dissolve with, and satisfy the attraction of a portion of the water molecules, the outward solution-pressure of the water in that layer will be diminished, water will diffuse into it from the ether-water layer to restore the equilibrium, and the ether will become more concentrated and smaller in volume.

If a sheet of dry gelatine be suspended in water, it will absorb water and swell till equilibrium is reached, the attraction of water for the gelatine molecules at that dilution being equal to the attraction of water molecules for each other (and for the very small quantity of gelatine molecules which become dissolved in the outside solution). If we add a third substance, say alcohol, which has a strong solution-attraction for water (as evidenced by the contraction of volume, and the heat evolved when they are mixed), but is scarcely soluble in gelatine or gelatine jelly, the outward pressure of the external water is of course diminished, water passes out of the jelly to restore the equilibrium, and the jelly contracts. The close analogy of the two cases is obvious. If we concentrate our alcohol outside, we may almost completely dehydrate the jelly, and if we add sufficient excess of alcohol to a warm aqueous gelatine solution, we may quantitatively separate the gelatine as a firm elastic mass. The action of the alcohol in converting the raw pelt into leather is now clear—it first takes the place of the water in the spaces which separate the fibres, and then dehydrates and hardens the latter, so that in drying no adhesion takes place, or one so slight only, that it is easily overcome by a little mechanical stretching.

If gelatine or well washed pelt be immersed in a solution of common salt, it becomes somewhat more swollen than in water. The salt lowers the solution-pressure of the water, but as the presence of gelatine does not affect its solubility, the concentration of the salt solution contained in the swollen gelatine is precisely the same as that outside, and there is no tendency for water to pass outwards. On

the other hand, as the affinity of the water is partially satisfied by the salt, a larger volume is required to bring it into equilibrium with the gelatine, which therefore swells. Some salts, however, as for instance ammonium sulphate in strong solution, dehydrate the gelatine almost like alcohol, though, according to Hofmeister, all salt solutions have some special concentration at which they produce a maximum swelling greater than that of pure water. Doubtless these peculiarities correspond to differences of solubility of the salt in the gelatine which for the present we cannot explain, but must be content to regard as properties of the materials.

If gelatine or raw skin be placed in a dilute solution of any acid it becomes swollen, and generally to a much larger extent than in salt solutions, and the equilibrium reached is of a more complex character. A part of the acid in the swollen jelly appears to be simply dissolved in the water absorbed, while another part is more closely united to the gelatine, and the latter part no longer obeys the simple laws of equilibrium of solutions, but acts as if it formed a weak chemical compound with the gelatine. Thus in very dilute solutions, practically the whole of the acid is taken up by the gelatine, and the external liquid may become quite neutral to the ordinary indicators. If we calculate the amount of acid fixed by the gelatine in excess of that corresponding to the volume of external solution absorbed, we shall find that it rises to a maximum with increasing concentration up to a certain point, and then slowly diminishes. A maximum swelling corresponds to the maximum of "acid fixed," and as concentration increases the swelling diminishes much more rapidly and considerably than the "acid fixed." The maximum of swelling and "acid fixed" corresponds to different concentrations with different acids, and the amount of acid fixed also varies, following no regular molecular proportion. The explanation of these facts is partly given by researches which I have now in progress, and is, I believe, to be found in considerations of chemical and physical equilibrium such as I have tried to apply in the simpler cases of alcohol and salt solutions, but it is, at any rate, too complex to discuss in detail in the present lectures.

We have seen that both acid and common salt solutions produce swelling of the hide fibre, but when we experiment with both together we meet with an astonishing phenomenon—instead of getting a swelling, which is the sum

of the two effects, we get an intense dehydration and contraction, equal to that produced by strong alcohol—the addition of salt to a dilute acid solution, such as will produce a maximum swelling, will precipitate gelatine from its solution, and dry up swollen jelly to a firm and almost hard condition: the water in the jelly being reduced from perhaps 40 times the weight of the air-dry gelatine used to about its own weight. A quite similar, and probably equally powerful effect is produced on actual skin. We may get some hint of the causes at work if we reflect that even with hydrochloric acid alone, as we increase its quantity we easily pass the concentration of maximum swelling, and begin to get contraction, though the experiment cannot be carried very far on account of the direct solvent effect of strong acids on gelatine jelly. I am inclined to think that both the swelling and the subsequent contraction are due to the necessity of an equilibrium between the Cl ions of the hydrochloric acid in the outside solution and those of the much less ionised hydrochloric acid “fixed” by the gelatine, the much lower ionisation of the acid fixed being proved by the fact that it no longer changes the colour of methyl orange. Now, if this be the true explanation, it is easy to see that if the solution outside be saturated with the highly ionised sodium chloride, which is not in any degree “fixed” by the gelatine, though it freely diffuses through the water in the jelly, the acid gelatine must contract and become more concentrated in order to establish an equilibrium with the abundant chlorine ions outside. At the same time the proportion of acid “fixed” by the gelatine becomes increased by the same cause.

Similar effects are produced by sulphates in presence of sulphuric acid, and indeed by any acid in presence of large quantities of common salt. The latter is indeed to be expected, since the law of mass action teaches that under such circumstances the acid fixed by the gelatine must be mainly hydrochloric.

I now pass on from these theoretical considerations to an important technical application. Sheepskins, unwooled and prepared for tanning, are preserved for exportation by what is known as “pickling” with solutions of sulphuric acid and salt, in this condition they are brought from New Zealand and Australia, and are shipped largely to the United States. The pelts, after liming, puering, and drenching, are first paddled in a very dilute solution of sulphuric acid to which a portion of salt is added to control the swelling, and are then

brought into a strong brine, in which they become white and flat, and can now be packed wet in casks, and preserved for months without change. If the skins in this condition are dried out, they are found to be converted into a white leather, which, after stretching and softening by “staking” (drawing over a blunt steel blade fixed on a post), are indistinguishable in appearance from ordinary alumed leather, and indeed have been sold for such.

We have seen that the joint action of acid and salt dehydrates gelatine as alcohol does, and we now see that it is also capable of converting the raw skin into leather. The principle is, in fact, used in preparing lambskins for use instead of furs in Eastern Europe. The raw skins are covered with a mixture of rye meal and brine, and allowed to lie in tubs till the meal ferments, when the lactic acid formed brings about the effect which I have described. It was formerly supposed that the function of the brine in the pickling process was to remove the acid, but it is shown by analysis that unless great excess of acid has been used no trace of acid diffuses into the strong brine, but that any present in it is taken up by the skins. The effect of excess of acid is gradually to rot the skins, as they will take up much more acid than is necessary for their preservation, and, indeed, I have effectively pickled skin with 1-10th of the acid generally used. So far as I can judge from laboratory experiments, the process may be simplified and improved by introducing the skins at once into saturated brine in a paddle vat, and gradually adding a calculated quantity of acid which is all taken up by the skins. If pickled skins are placed in water the salt diffuses out, while the acid is retained, and causes them to swell up enormously; and it is therefore necessary to begin the tanning process in sumach liquors, which contain a large percentage of salt. If no more than the really requisite quantity of acid is used it is possible to tan the skins even in unsalted liquors, and a very little salt to begin with is all that is required. Instead of using salted liquors, the acid may be neutralised with chalk or borax before tanning.

We have now some facts before us which will help us to understand the function of salt in the ordinary process of making alumed and chrome leathers. It will be shown, when we come to consider the tanning effect of salts of the alumina group, that the compound really fixed upon the skin is a very basic salt of the metal, or more probably even the oxide itself.

Now these metals in the trivalent state are very weak bases; so much so that the hydrochloric acid may be split off from ferric chloride even by dialysis through parchment paper, leaving at last only a solution of colloid ferric oxide. We should, therefore, expect that the well-known attraction of hide fibre for acids would be sufficient to decompose these salts, and that the fibre would become swollen with the acid, while some proportion of the base would also be fixed. The facts justify our conclusion. With normal ferric chloride the fibre is so swollen that only rotten leather results, and though with alumina salts the swelling is not so considerable, only a hard and useless leather can be made with alum or alumina sulphate alone, while the quantity of base fixed is not very large. When, however, we add salt to the mixture, the swelling is prevented, and the acid is taken up and fixed in larger quantity, and at the same time a much larger quantity of the base is absorbed, so that we have a leather which we may consider as being partially really tanned by alumina, and partially by "pickling." If we make our alumina salt basic in the first place by "neutralising" with an alkali, the salt is no longer essential; and in the case of chrome at least, it is practicable, after tanning in a solution of a basic salt, to remove practically the whole of the acid from the fibre by treatment with a weak alkali, with improvement to the quality and permanence of the leather.

No complete explanation can yet be offered of the tanning effect of the trivalent salts of the iron and alumina group, though the subject has been investigated by Knapp, Reimer, and others. Mills and Sawers (*Jour. Soc. Ch. Ind.*, 1895, p. 252) analysed the products formed by acting on gelatine jelly with some chromium and aluminium salts, and give empirical formulæ, but their composition is so varied that it is hard to resist the conclusion that they are rather results of physical equilibrium than true chemical compounds. Not merely the amount of the absorbed chromium and aluminium, but the basicity of the absorbed salt varies under different conditions, and there is nothing to contradict the suggestion that the oxide or hydrate rather than any particular basic salt is the essential tanning substance. This view is also supported by the fact so much utilised in photography, that chromic acid and the bichromates render gelatine insoluble when reduced by the action of light in absence of any acid, and that skins may be tanned by

chromic acid subsequently reduced by alkaline sulphides.

It is only the M_2O_3 salts of these metals which will tan; neither chromic acid nor ferrous salts having that power, though they may both be used as a means of producing the required compounds in the skin. As neither manganese nor zinc form stable oxysalts of the required constitution, they seem to have little tanning effect.

In practice, tanning, or as it is generally called "tawing," with alumina salts, is nearly always done with solutions of alum, or normal alumina sulphate, with addition of common salt, although the use of basic salts formed by neutralising a part of the acid with an alkali offers some advantages, and was made the subject of a patent by Bertram Hunt, which has now expired. The method was proposed and described in 1858 by Knapp, with regard to iron and chrome salts, though he does not seem to have thought it necessary to apply it to aluminium salts.

The large German tanners of calf-kid have for some time abandoned the use of alum for that of aluminium sulphate, which is cheaper and more effective, as the sulphate of potash or ammonium in the former takes no part in the tawing process, and the sole advantage of alum is that in earlier times it was easier to obtain in a state of comparative purity. English tanners, however, still continue to a considerable extent to employ alum. The quantity of salt which is used is rather variable, but roughly amounts to about half the weight of the alum, though much more may be used without it in any way preventing the tawing. The strength of solution varies widely for different sorts of leather—sheepskins are alumed for rugs by applying a strong warm solution (containing say 15 per cent. of alum, and 10 per cent. of salt) repeatedly to the flesh side of the skin stretched on a frame, or in some cases even by rubbing powdered alum and salt into the wet skin, while in some sorts of lace leathers where something of a "raw hide" character is desired in the finished product, very weak solutions may be used; but for most purposes about 10 per cent. of alum and 5 per cent. of salt may be considered an average strength.

Alum and salt alone is only used on the cheaper sorts of leather; while for the finer white leathers, such as glove-kid and calf-kid, they are employed in a paste with flour and egg yolk, with generally some addition of olive oil. In the old-fashioned manufacture,

the paste was trodden into the skins by men with bare feet in a round tub, but in the present day, this primitive method is superseded by drums, like large barrel churns, into which the skins are placed with the tawing paste. In the case of glove-kid, the process is complete in about an hour and a-half, the skins being drummed three times for twenty minutes, with ten minutes rests, after which they are hung up to dry with the adhering paste. The quantities of egg yolk which are used in this manufacture are very large. A Leeds manufacturer of calf-kid told me that his firm alone consumed about sixty tons a year of preserved yolk, equal to, say, 3,000,000 eggs! Probably two or three times 60 tons of flour would be used, and the firm I refer to is only one out of several, so that the consumption of valuable foodstuffs is very considerable, and a pair of kid boots properly cooked might prove very valuable in extremities. It is much to be desired that cheaper substitutes could be found — the egg yolk is mainly useful on account of the very finely emulsified oil which it contains and for its albumen; the flour serves as a further source of albuminous matter by its gluten, while no large portion of the starch is absorbed. There is apparently nothing very special in the character of egg oil, which could be closely imitated by a mixture of olive oil with a little palm oil. Other albuminous matters are also capable of producing the same effect as the eggs, so that the problem is principally to find a cheap source of suitable albuminous matter, and to mix it sufficiently intimately with the oil. The casein of separated milk, and the finely ground kernels of some oily nuts are likely materials. Some compositions have been made which produced fairly satisfactory leathers, but unfortunately they were not materially cheaper than the materials at present in use. The albuminous matter is mechanically forced into the leather by the treading or drumming, and is fixed there by being tawed along with the skin fibre by the joint action of the alum and the oil. The oil serves not merely to give softness to the leather by lubricating the fibre, but takes part in the conversion of it into leather, and materially adds to its resistance to water.

After the skins are dried out of the tawing paste they are dipped for a moment in water, and allowed to lie in a damp place till they are somewhat softened, when they are trodden or lightly stocked, and afterwards stretched by drawing over a blade fixed on a post,

an operation which is known as "staking;" or, in some cases, they are fixed on a horizontal bar known as a "perch," and softened with a tool shaped somewhat like a shovel, which is called a "crutch stake." In the case of calf-kid this work is now generally done by machines. As the skin dries the process is repeated, producing a soft white leather, much like white glove leather. In this state, or sometimes before staking, it is stored in well-ventilated warehouses, for some weeks at least, to "age," which appears to effect a more intimate combination between the skin fibre and the tawing materials. It is now ready to be finished, but before it can be dyed it must be freed from its superfluous salt and alum by washing with water, and this, at the same time, removes a good deal of the egg, which must be replaced by re-egging, a process

FIG. 13.

STAKING ALUMED LEATHER.

which takes place before dyeing, when this is done by brushing the dyes on a table, but after it when the dyeing is done by dipping in a tray.

Alum-tawed leather does not resist the action of water for any great length of time, and by persistent washing most of the alumina may be removed, so that the alumed leathers are still available for the production of size or gelatine. Attempts made by Knapp to render the tannage more permanent by complete neutralisation of the acid present, and the fixation of the alumina as oxide were not successful, complete neutralisation apparently destroying the tanning effect; but he was more successful by converting the alumina compound fixed into an insoluble alumina soap. "Castor" or "Nappa" leather is now made in the United States by a method based on this principle,

and not only possesses considerable resistance to water, but is very tough.

Iron salts have not attained any commercial importance as tanning agents, though iron-alum, the double ferric potassic sulphate analogous in structure to common alum, has similar tanning properties, and, in conjunction with salt, produces a soft and pliable leather which, but for its colour, might in most cases be substituted for that made with alumina if the saving in cost were of sufficient importance. Knapp made many attempts to produce a practical sole leather with basic ferric salts; but though these are absorbed in large quantities by the raw hide, the product is thin and somewhat brittle, and not capable of competing with vegetable tannages. It is, however, quite possible that the problem may yet be successfully solved, and its cheapness and rapidity would then make the process one of commercial value.

Chrome, in this respect, now occupies a very different position to iron, since leathers tanned with its salts have been found to possess valuable properties not shared by any others. Chrome leathers, when rightly manufactured, are exceedingly soft, tough, and flexible, and the tannage is very fast, and completely resistant to water, even at a boiling temperature. Chrome leathers are often spoken of as "water-proof," but this is calculated to convey a wrong impression, since in their natural state they are porous, and easily permeated by water, although the fibres themselves remain unswollen. If desired, a considerable amount of actual waterproofness may be conferred on the leather by impregnating it with fats and insoluble soaps, but when this is not done, it is perfectly permeable by air, and the statement so often made that it is unhealthy and hot to the feet is a mere prejudice. Its most important applications so far have been to light shoe-wear in the form of black glazed kid and coloured calf, but its resistance to hot water and steam fits it for a variety of mechanical purposes, and probably for hose-pipes for steamers and fire-engines it will supersede all other sorts of leather. So far the process has not been applied successfully to sole leather, except for special purposes where its heat-resisting powers are advantageous.

Though a knowledge of the tanning powers of chromic salts is by no means new, the first process which attained any commercial success was that invented by Augustus Schultz in 1884. Schultz was employed by a firm of aniline colour dealers, and was not himself a

tanner, but his attention was turned to the subject by a friend who required a leather for the covering of corset steels, which would not rust them as alumed leathers do. He hit upon the idea, probably suggested by a mordanting process applied to textiles, of saturating the raw skin with chromic acid, which like all other acids is freely absorbed by the hide fibre, and of there reducing it to chromic hydrate, or a chromic salt by the agency of sulphurous acid, or an acidified solution of sodium thio-sulphate (hyposulphite of soda). He obtained a patent which he sold to a syndicate for \$50,000, and after several sales at higher prices and endless litigation it now remains the property of the Patent Tanning Company.

It is interesting and curious that, long before the date of the Schultz patent, Professor Hummel, of the Yorkshire College, reduced the chromic acid of a piece of leather produced by the earlier and unsuccessful Heinzerling process with sulphurous acid, in order to get rid of the unpleasant greenish-yellow colour; but the value of the suggestion was not understood, and, so far as is known, no publication took place, or the Schultz patent would have been invalidated.

The Schultz process consists in first treating the unhaired and delimed skin with a solution of about 5 per cent. of potassium bichromate, and $2\frac{1}{2}$ per cent. of commercial hydrochloric acid reckoned on the weight of the wet pelt,

FIG. 14.

TANNING PADDLES.

and dissolved in enough water for convenient treatment of the skins in the paddle-vat or the drum, as the case may be, and then, when the required quantity of chromic acid has been taken up, submitting them to a solution of 10 or 12 per cent. of sodium thiosulphate, acidified

with sufficient hydrochloric acid (generally about 5 per cent. of commercial hydrochloric acid), to convert the whole of the absorbed chromic acid into bluish-green chromic salt by reduction. The excess of acid retained by the fibre is then removed by treatment with a weakly alkaline solution, usually of borax. The process is thus, apparently, very simple in theory, but in practice considerable skill is required to yield thoroughly satisfactory results, and it cannot be said that the causes of all the variations which are apt to occur have been thoroughly mastered.

In the first, or chromic-acid bath, the chromic acid has no direct tanning effect on the skin, and is probably absorbed simply as all acids are absorbed, by gelatinous fibres. In a mixture of bichromate and free chromic acid, practically only the latter is absorbed, and the bath is exhausted, leaving neutral bichromate only; yet a bath of chromic acid alone is not found to give commercially satisfactory results, and the best are only obtained in presence of a considerable quantity of undecomposed bichromate. In this connection we may remember the effect of the presence of common salt in modifying the action of hydrochloric acid in the pickling of skins, and the similar action of sulphates on that of sulphuric acid. It is to be borne in mind, however, that chromic acid, unlike those just named, is a very weak acid—that is, according to modern theory, one which is little ionised in solution, while its salt, bichromate, like all other salts, ionises much more freely. It is pointed out by Ostwald that, under these circumstances, the effect of the presence of its salt in solution is still further to depress the ionisation of the weak acid, that is, to still further weaken its acid properties, but while it is pretty evident that these are the causes we have to consider, it is not easy to “visualise” clearly what takes place. Common salt is sometimes added to the solution, which tends to make a thinner and flatter leather, and, as I have proved by direct experiment, also enables the skin to take up some portion of chromic acid even from undecomposed bichromate; and as salt, or at least potassium chloride, is always present where hydrochloric acid is used to set free the chromic acid, the reaction becomes somewhat complex. Where alum is used, as it was in the earlier Heinzerling process in conjunction with bichromate, its sulphuric acid liberates a portion of chromic acid with formation of a basic alumina salt, and still further increases the difficulty of understanding exactly what

happens. Though, in conjunction with Mr. Carlton Heal (*Jour. Soc. Ch. Ind.*, 1895, p. 248, and “*Leather Industries Laboratory Book*,” p. 143), I have given methods which enable simple mixtures of acid and bichromate to be analysed with sufficient accuracy, they break down in presence of salts of alumina and chromic oxide. In consequence of these difficulties it has been almost impossible exactly to restore a used bichromate liquor to its original strength in acid and undecomposed salt, and many manufacturers have run these liquors to waste, still containing a large percentage of bichromate, rather than risk making a less satisfactory leather by their use. Little risk is, however, incurred by using at least a portion of old liquor a second time after strengthening. Practice varies as to whether the whole of the calculated quantity of acid should be added at once, or gradually during the process of tanning, but in my experience the latter is the better method.

When the skins come out of the chrome bath the surplus bichromate solution must be removed from them, either by draining well or by pressure, the Vaughan “putting out” machine being frequently employed for the purpose, and they are then ready for reduction. In the interval between the two baths the skins must be protected from light, which would reduce the chromic acid at the expense of the organic matter of the skin itself.

It is impossible to calculate the actual amount of thiosulphate required to reduce the chromic acid absorbed in the skin, as, without analysis either of the skin or the residual liquors, the actual quantity which it has taken up is unknown, and tanners are therefore generally content to use the reducing agent in excess. Even if the quantity were ascertained, the reaction is a somewhat uncertain one, and depends on a number of small conditions which cannot be strictly controlled. Neutral thiosulphate is incapable of producing any complete or satisfactory reduction, and when acid is added thiosulphuric acid is first set free, and then rapidly breaks up into sulphurous acid and free sulphur, thus:—

Tetrathionic acid is also formed as an intermediate stage of reduction. In the presence of chromic acid but little sulphurous acid is evolved, or free sulphur precipitated, and consequently a given weight of thiosulphate will do a larger amount of

reduction under these circumstances than it will if the thiosulphuric acid is first liberated and decomposed. It is, therefore, most economical in "hypo" to add the acid gradually during the reduction, and there is less tendency to "draw the grain of the leather" (*i.e.*, to make it run into wrinkles through unequal contraction), but, on the other hand, a part of the chromic acid is apt to bleed out before it can be reduced, and thus produce under-chroming and waste. Some manufacturers try to overcome the difficulty by drawing the skins first through a strong hypo liquor well acidified, in order to fix the chromic acid near the surface, and then complete the reduction in less acid baths. Probably the best way is to use the full required quantity of hypo at first, adding enough acid to produce a decided evolution of sulphurous acid, and then add more acid in small quantities, so as to keep the bath in a constantly acid condition till the reduction is complete and the leather has become a uniform duck-egg green. If the skin is put in neutral hypo solution, it seems to lose its plumpness and produce flat leather.

As soon as the reduction is complete the skins are effectively tanned, but still retain an amount of free acid fixed in the fibre which would cause trouble in the finishing process, and probably produce shrinking and hardness in the finished leather, and which, from the attraction of the fibre for acids, cannot be removed by mere washing. They are, therefore, thoroughly washed with warm, or even hot water, and are then treated with a solution of borax (about 3 per cent. on the pelt weight) to neutralise and remove the acid. Other weakly alkaline salts, and, notably, acid sodium carbonate, may be substituted, but as chrome leathers are easily injured by excess of alkali, they are not so reliable in their action. A very large proportion of the troubles which occur in finishing chrome leather may be traced to insufficient washing and removal of acid at this stage. The borax solution apparently removes not only free acid, but most of that combined with the chrome oxide.

If the tanning has been successfully performed, the skins should now dry tolerably soft, even without staking, but are generally submitted to a further process called "fat-liquoring," to lubricate the fibre, and increase the softness and fullness of the leather. The fat-liquor consists of a milky emulsion of soap and oil in water, and was originally the alkaline liquor which had been used for washing the superfluous oil out of oil leathers. Various oils

are used, as well as various soaps, but I have found a mixture of castor oil and castor-oil soap the most successful for fine coloured leathers. For coloured calf, about one-half per cent. of soap and three-fourths per cent. of oil on the weight of the wet pelt answers well, dissolved in sufficient water for convenient application in the drum. Before fat-liquoring, the skins should be partially dried by pressing or centrifugal machine, or by hanging in the air, and it is best to use the fat-liquor warm. Much of the success of the operation depends on the fineness of the emulsion formed, and the fat-liquor should therefore be made by a centrifugal emulsor, or by churning in a cylinder with a finely-perforated piston plunger. In some cases the skins are dyed before fat-liquoring, but usually afterwards, as many of the colours bleed a good deal into the alkaline liquid, and this is especially the case with the acid colours which are most successfully applied to chrome leather. In general the skins must not be allowed to dry out before dyeing, or the fibre becomes hard and un-absorbent, and will not take the dye. This difficulty may be overcome by adding glycerine or glucose to the extent of about 5 per cent. to the fat-liquor, which prevents thorough drying, while it allows the skins to be so far air-dried that the fat-liquor becomes fixed on the film, and does not interfere with even dyeing, which is one of the great difficulties of the manufacture.

The American patent rights in the Schultz process, which covered the use of hyposulphites, and of all other salts yielding sulphurous acid on acidification, have not only given rise to enormous litigation, but have led to the patenting of almost any other possible reducing agent which could be substituted. Many of these are of no practical use, but it is possible to make excellent leather by reduction with hydrosulphuric acid, either as gas or solution, and also with the alkaline polysulphides; but the normal sulphides of the alkalis, which are actually named in Norris's patent, do not make good leather from their strongly alkaline reaction, though possibly this might be overcome by the use of some weak acid to liberate the sulphuretted hydrogen. Another effect of the patent monopoly has been to draw attention to the possibility of tanning with a single solution of a basic salt of chromium, as originally proposed by Knapp.

The first attempt to introduce this commercially was made by Martin Dennis, who succeeded in getting a patent in the United

States on the ground that only basic chlorides were practically useful, a view which has since been shown to be entirely without foundation. He also obtained an English patent, which is registered under the name of his agent, Gallagher. The liquor which is covered by this specification is made by dissolving precipitated chromium hydrate in hydrochloric acid to saturation, and then adding sodium carbonate to neutralise the required amount of acid to produce a suitable basic salt. A similar basic compound may also be obtained direct from bichromate by reducing it in presence of a limited calculated quantity of hydrochloric acid, and about two years ago I published a formula for doing so by means of glucose, which produced a liquor with which successful commercial results have been obtained. My principal reason for alluding to this here is to state that I have since found that with many samples of glucose some organic compound is formed by the oxidation of the sugar if the action is carried to its limit, which produces a purplish liquor, which will not tan satisfactorily. An even more satisfactory result at a lower cost may be obtained by using ordinary chrome alum suitably neutralised with sodium carbonate, and generally used with an addition of salt. A 10 per cent. solution, with $2\frac{1}{2}$ to $3\frac{1}{2}$ per cent. of crystallised sodium carbonate, forms a suitable stock solution, and the tanning is performed by paddling the skins in a liquor which is gradually strengthened with the stock solution until the skins are completely tanned. The more completely the liquor is neutralised short of precipitation, and the fuller and finer the leather—acidity tends to hardness and short tannage, and the addition of salt to the liquor to fineness and softness and a thinner leather. The pelt, as would be expected from the explanation of mineral tannage which has already been given, fixes the more basic salts of the solution most freely, so that the residual liquor becomes acid, and generally contains some excess of chrome salt in too acid a condition to be easily absorbed, but it can be made suitable for use on another pack of goods by addition of soda in quantity insufficient to produce a permanent precipitate.

The results of the one-bath method are so certain and easy, once the proper conditions are understood, that it seems likely ultimately to supersede the two-bath process entirely. The basic chrome tannage must be followed by boraxing and fat-liquoring, as in the two-bath process.

Miscellaneous.

ROADSIDE FRUIT IN EUROPE.

The cultivation of fruit trees along the highways of France is being extended each year. The Government having first set the example, the communes in certain departments adopted this practice as a source of revenue, so that now roadside fruit cultivation has become an important branch of national industry. It is not, however, only in France that fruit trees have been planted along the roadside. The United States Consul at St. Etienne says that in Germany, Belgium, and the Duchy of Luxembourg, the system has been greatly developed, giving satisfaction to the State as well as to local interests. On the Wurtemberg roads, for instance, the fruit harvest from this source produced in 1878 over £40,000, and last year the returns had more than trebled. The annual revenue derived from the national roads of Saxony planted with fruit trees, rose from £1,800 in 1880 to £8,400 in 1892, furnishing a total sum of £68,000 for the 13 years. In Belgium, according to the statistics of 1894, over 2,875 miles of roads were planted with 741,571 fruit trees, which furnished the large sum of £400,000. In France the production of fruit trees is estimated at £12,000,000. In Westphalia, in the Duchies of Baden and Saxe Weimar, in Alsace-Lorraine, Switzerland, &c., the *employés* of the Administration of Roads and Bridges and the road supervisors, are instructed in fruit culture. In some of the southern departments of France the roads are bordered with cherry trees, producing the small fruit called *merise* (wild cherry), much appreciated for making wine *sui generis*, preserves, and even alcohol. In the Touraine, plum trees predominate, while in the Allier, the walnut trees transform the roads into shady walks. In Auvergne the chestnut tree flourishes; while in Normandy, place is naturally given to the apple tree. Some twenty years ago, the picturesque roads of the north-east of France were lined with stately poplars; but although ornamental, their roots went far and wide, rendering the adjacent meadows sterile, and ploughs were continually stopped by offshoots lying almost at the surface of the soil. The farmers appealed in such strong terms, that the communes decided upon the fall of the poplar, and soon axes and saws were brought into requisition, and the roads cleared of these trees in favour of the humble but more useful *mirabelle* (small plum), to the great satisfaction of the villagers. Thousands of baskets of this fruit are sent to Paris daily. Some thirty years ago the distillation of the mirabelle was unknown in the country districts, the people plucked it as food for their pigs, but to-day they have learned to make more profitable use of it. They distil it in large quantities, and find a ready market for it. A quart of this alcohol, slightly perfumed, sold five or six years ago for only about

10d. or 15d., to-day it brings not less than 2s. or 2s. 6d., while in Paris, the best kind cannot be obtained under about 4s. 3d.

THE RESOURCES OF ASIATIC RUSSIA.

Siberia and the Amur lands are rich beyond belief. Their 5,214,000 square miles are inhabited by only 4,000,000 souls. In recent years, however, the number of immigrants (400,000 in 1898) has been equalled only by the tide which poured into the United States in the past. The United States Consul at Chemnitz says that this vast territory, long looked upon as a barren waste, is destined to be one of the world's richest and most productive sections. In northern France wheat ripens in 137 days; in Siberia in 107. Even severe night-frosts do not injure the young seed. Oats required in Siberia, and in the Amur country, only 96 days, and in the region of the Yenisei only 107 to ripen. The frost period lasts only 97 days in Irkutsk country. Transbaikalia lies entirely within the agricultural regions, so, too, almost the entire territory traversed by the Amur, as far north as it runs. Efforts are being made to obtain along the Amur at least 116,000 square miles for the higher form of northern agriculture. Climatically, the best of Northern Asia's territory, for planting purposes, is the Usuri country, which, in spite of its vast tracks of wood and grazing lands, has 75,000 square miles of arable land. The building of the Trans-Siberian Railway has already added to the empire's wheat product. The mineral resources of Western Siberia are vast. Between Tomsk and Kooznesk lie 23,000 square miles of coal lands which have never been touched. The coal is said to be excellent. In Eastern Siberia, with its 108,000 square miles of fruitful soil, there are 400 places yielding gold. Rich mineral deposits—graphite, lapis-lazuli—iron mines particularly rich in quality, hard and soft coal—await hands willing to work for them. Russia's output in gold and silver is already very large, and is constantly increasing. Three-fourths of all the silver found in Russia is obtained in the Altai Mountains. Exclusive of the Ural gold-fields, there are 851 places in the empire where gold is found. Notwithstanding the number of places in which iron is found, there are only four large establishments for its production. The ores are rich—58 to 60 per cent. of raw iron. The industries of Siberia are in their infancy—still, they are growing, and are bound to grow, so rich are the rewards promised. Chemical, sugar, and paper mills have been put up in several places, and are paying well. Even Manchuria is looking to Russia for its future development. The wealth of this province, like that of Siberia and all eastern Russia, is ripe for harvesting. The traffic in Siberia and eastern Russia is, according to Consul Monaghan, increasing faster than even the advocates of the Great Trans-Siberian road anticipated. The Ob, one of the world's great

rivers, emptying through the gulf of Ob into the Arctic Ocean, has 102 steamers and 200 tugs running already. On the Yenisei ten steamers carry the mails regularly. The mouths of both these rivers were visited last summer by English and Russian ships. This proves the practicability of connecting eastern and western Siberia with Europe by water. The mouth of the Ob is to be deepened and wharves are to be built. On the coast of the Usuri country there is regular postal communication between Nicolajevsk, Vladivostock, and intervening places, as well as connection with Japanese ports and Port Arthur. From Odessa and St. Petersburg to various Asiatic ports runs the so-called volunteer fleet, established in 1878. It has fourteen steamers with 115,500 tons displacement. Siberia and the Amur country possess advantages very similar to those of North America, Australia, and parts of Africa. The great gain to Russia at present in developing Siberia is the guarantee that her harvests will come nearer to supplying her wheat requirements.

PAWNBROKING IN GERMANY.

In Germany, the pawnshops which originated in the 17th and 18th centuries were mostly public undertakings, conducted by the State or municipality. At the present time there still exist in the German empire the following State institutions:—The Royal Lending House in Berlin, the Grand Ducal Lending Houses in Weimar and Eisenach, the Ducal Lending House in Gotha, and the lending houses of the Ducal Brunswick Government in six cities in Brunswick. The governmental department of Cassel also maintains pawnshops in Cassel, Hanau, and Fulda. The pawnshops which originated in Napoleon's time in Strasburg and Metz, as well as those of Mainz and Mannheim, are institutions with independent government, in which, however, the city officials participate. The United States Vice-Consul at Cologne, in a recent report, gives a list of the municipal pawn institutions in Germany. The list is as follows. (1.) In Prussia:—Altona, Barmen, Bonn, Breslau, Bromberg, Celle, Coblenz, Cologne, Crefeld, Danzig, Dortmund, Düsseldorf, Duisburg, Elberfeld, Elbing, Erfurt, Essen, Frankfurt, Görlitz, Halberstadt, Halle, Hanover, Hildesheim, Königsberg, Leignitz, and Muhlhausen. (2.) In Thuringia:—Munich, Gladbach, Osnabrück, Posen, Schleswig, Stralsund, Trier, and Wiesbaden. (3.) In the South German States:—Augsburg, Bamberg, Bayreuth, Darmstadt, Freiburg, Fürth, Heidelberg, Karlsruhe, Nuremberg, Offenbach, Regensburg, and Würzburg. (4.) The North German States (exclusive of Prussia):—Altenburg, Chemnitz, Dresden, Gera, Hamburg, Leipzig, Lubeck, and Schwerin. Of German cities of more than 100,000 inhabitants, Magdeburg (since 1891), Bremen, Stettin, and Aix la Chapelle (since 1858) have no public pawnshops. On the whole, the number of these institutions is larger in Germany

than in France, but less than in Belgium, Holland, and Italy. Of the larger cities, Berlin has three offices, Munich four, Hamburg three, and Dresden two, for conducting this business. In several cities, the pledges can be made in sub-offices, and in some other cities, such as Cologne, they may be made to specially licensed persons. The business of pawnshops in the last three years appears, as far as can be estimated in the absence of uniform statistics, to depend less on general economic, than on special local causes. The erection of new sub-offices, as well as the decrease of the number of private pawnshops, is usually accompanied by an increase of business, while an increase in the private establishments is accompanied by a diminution in the public institutions. The capital for carrying on the business by the municipal authorities is derived from the city treasury or the city savings bank, which is usually worked in connection with the pawnshop. The cities of Munich, Augsburg, Frankfort-on-the-Main, Strasburg, and Metz make use of money borrowed from private persons at from 3 to 4 per cent. Besides these public, State, and municipal pawnshops, private business has developed to a large extent. Formerly, the German law allowed private persons to engage in this business only by special permission, and exercised strict control over them. These stringent regulations were enacted by the Prussian Trade Law in January, 1845. The projected trade regulations for the North German Confederation also insisted upon the necessity of a license. This proposal was, however, not sanctioned by the Diet, but a regulation was passed to the effect that persons who had been punished for a crime committed from avaricious motives could be prohibited from carrying on the pawnbroking business. The right was further conceded to the head officials to regulate the manner in which the pawnbrokers should keep their books, and the control of the police. These regulations in practice proved insufficient. Owing to the fact that private persons were allowed to engage in the business it increased in a manner previously unknown. In many cases it was carried on by persons of doubtful character, and by those who had been repeatedly punished by the law, if the offences for which they had been convicted were not of a nature to prohibit them from obtaining a license. The business methods of these people were often extremely onerous to those obliged to seek assistance in this direction; in some places the interest charged was more than 10 per cent. per month, or 120 per cent. per annum. All these irregularities were corrected by the statute of July 23rd, 1879, which is now the basis for the existing law for the German Empire. By this enactment those engaged in the pawnbroking business are obliged to have a license, and it is refused to people clearly proved to be unfitted for such business. Furthermore, the issuing of a license is dependent upon the fact that there is a necessity for such an institution. The supervision of the manner of conducting this business has been made more strict.

Where there are no special local rules the central authorities are empowered to issue orders regulating the extent of the powers and obligations as well as the manner of carrying on the business of the pawnbrokers. The above-mentioned Imperial laws have been supplemented by special laws of the various German States. For example, the Prussian law of March 17th, 1881, determines a maximum rate of interest to be charged, compels the pawnbrokers to keep records of all the business transacted by them, and prescribes that the unredeemed pledges shall be sold at public auction. The number of private pawnshops in the German Empire is about 1,200. In Cologne there are ten independent private establishments, besides four sworn brokers, and about twenty-two persons authorised to act as mediators between the people and the public or municipal pawnshop. The business of these private institutions in Cologne is very active, for many prefer to go to private pawnbrokers, perhaps because they lend more money on the articles, or because the business is more expeditiously conducted than in the municipal house. Although they are compelled to keep a record of their transactions the amount of business done by the private brokers is not generally known, as they are obliged to give only authentic information to the police and tax officials. For this reason no statistics as to the exact amount of such business can be given. Under the head of "lombard business" are included loans on securities, mortgages, deeds, precious metals, wares, raw products, &c.; these belong to the active business of banks. The Imperial Bank lends money, to one-half or two-thirds of their value, on raw products, such as grain, spirits of wine, oil, sugar, petroleum, &c., which have been appraised by special inspectors.

MOTOR CARS.

The motor car has been with us for some years, and we are now in a position to form some idea as to its value. It is fortunately no longer considered worth the attention of the unprincipled speculator. Even the sanguine inventor seems to have made up his mind to stand on one side, and to permit the more or less trained engineer to try what he can do with self-propelled vehicles. We have at last some facts to go on; some experience has been acquired, and the merits and demerits of various attempts at the construction of self-propelled vehicles can be gauged with a moderate approach to accuracy. Broadly stated, the results of the expenditure of a great deal of time, skill, money, and energy, are comparatively insignificant on the one hand, and on the other, not full of promise for the future. Self-propelled vehicles are of two kinds, and the difference is strongly marked, namely, the pleasure carriage and the motor van. A qualified success has been achieved with the Daimler light oil or spirit-engine as a motor for various types of the first vehicle. For the second, steam generated by liquid fuel has given so far the best,

if not the only satisfactory result. In this country the manufacture of neither kind of vehicle has attained hitherto to any commercial importance. In France there is, however, a large demand for light carriages; and it is worth notice that dozens of them are always for sale second hand. Whether this is because the owners are dissatisfied with their performance, and want to get rid of them, or are so pleased with what they have already had that they wish for something better, we are unable to say. Probably both motives are at work. It is not too much to state that at least 90 per cent. of the French cars are driven by Daimler or Benz spirit-engines. The legal restrictions on the use of the dangerous benzine and other petroleum "spirits" are much less severe in France than they are with us. This no doubt facilitates their use. But the secret of the popularity of the motor car is to be sought in the fact that the French people do not love horses as we do at this side of the Channel; and that they are permitted to travel at speeds on the highway, and even in the streets, which would not be tolerated for a moment in Great Britain. The principal advantages possessed by a motor-car are, in French eyes, that it is not drawn by a horse, and that it can run much faster than any horse could travel. Lacking the same stimuli in this country very few motor-cars are in use. It is not possible to arrive at accurate figures, but we shall probably be near the mark if we say that there are a couple of hundred machines of the kind running; and, so far as the public are concerned, this lack of appreciation does not appear to be in any way a result of apprehension. It is not the fear of a burst up or a breakdown, but simply that the average Briton does not care for locomotion on the highway other than that which is provided by his own legs or that of a horse. The bicycle is the greatest enemy the pleasure motor car has had to contend against.—*The Engineer.*

Obituary.

JOHN DONALDSON.—Mr. John Donaldson, who had been a member of the Society of Arts since 1878, died, after a long illness, on the 4th inst., in his fifty-eighth year. For the last 25 years he has been a partner in the well-known firm of J. T. Thornycroft and Company, of Chiswick. The firm originally started as launch builders, but have since, as is well known, attained a high reputation as builders of high-speed torpedo boats, a position due in no small measure to the energy and mechanical ability of Mr. Donaldson. Previous to his joining his brother-in-law, Mr. Thornycroft, in this business, he had held some important engineering appointments in India, where he was chief mechanical engineer at the Dum Dum Arsenal, and afterwards chief assistant to the Calcutta Port Commissioners. Though a member of long standing, Mr. Donaldson never took any active part in the work of the Society.

General Notes.

FUMIGATION OF TREES.—The fumigation of trees for the destruction of insect pests has for some time been extensively used in California and other parts of the United States. The process will probably soon come into use in New South Wales, for Mr. W. J. Allen describes in the *Agricultural Gazette* of the Colony some very successful experiments in spraying and fumigating for red and other scales on orange trees. The tree to be treated, is completely covered with a tent, and is subjected for nearly an hour to the fumes of hydrocyanic acid, produced by the combination of sulphuric acid and potassium cyanide. The number of men generally employed in a fumigating gang is four or five, according to the size of the trees. One man introduces the chemicals, another looks out for the generator and measures the acid, and two or three handle the tents. Such a gang can handle from thirty to forty medium-sized tents, and cover four to six acres of orchard in a night. Fumigation is to be preferred above spraying, because the trees are not in any way damaged by the fumes, except in the case of a few of the tender leaves, while the solution used in the sprays must to a certain extent close the pores of the tree and slightly weaken it.—*Nature.*

SHIPBUILDING IN ENGLAND.—It is stated that during the month of September English shipbuilders put into the water 29 vessels, aggregating about 93,263 tons gross, against 21 vessels, of about 65,263 tons gross in August, 30 vessels, of about 58,572 tons gross in September last year, and 20 vessels, of about 31,566 tons gross in September, 1897. For the nine months English builders have launched 224 vessels, of about 634,460 tons gross, as compared with 255 vessels, of about 624,108 tons gross, in the corresponding period of last year, and about 448,882 tons gross in 1897. One steamer, of 11,850 tons gross, was launched at Belfast last month. For the year so far there have been launched in the United Kingdom 487 vessels, of about 1,067,143 tons gross, against 535 vessels of about 1,019,908 tons gross, for the first nine months of last year.

SWISS ELECTRIC RAILWAY.—The United States Consul at Marseilles reports that the Paris, Lyons, and Mediterranean Railway Company, headquarters at 88, Rue St. Lazare, Paris, has undertaken the construction and operation of an electric railway between Fayet and Chamounix, at the foot of Mont Blanc. The line is to be in operation within twenty months, and it is to be presumed that the company will be interested in propositions for machinery and equipment. Power is to be furnished by the River Arve. The cars are to be automobiles, each supplied with its own dynamo. The contract for building the road proper and providing the water power has been divided into two parts and awarded to Gagner and Frères, of Annecy, and Richard and Meynard, of Avignon.

Journal of the Society of Arts.

No. 2,448. VOL. XLVII.

FRIDAY, OCTOBER 20, 1899.

*All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.***Notices.****EXAMINATIONS, 1900.**

The dates fixed for the Examinations in 1900 are Monday, March 26th; Tuesday, 27th; Wednesday, 28th; and Thursday, 29th.

The Programme of Examinations is now ready. Copies of the Programme, with full details, and an Appendix, containing last year's questions and reports by the Examiners, can be had, price 3d., post free, on application to the Secretary, Sir Henry Trueman Wood, Society of Arts, Adelphi, W.C.

Proceedings of the Society.**CANTOR LECTURES.**

THE MANUFACTURE OF LEATHER.

BY PROF. HENRY R. PROCTER.

LECTURE IV.—Delivered May 8, 1899.

In the last lecture we discussed the various processes of mineral tannage: it now remains to us to consider those in which organic substances are the tanning agents; and, firstly, those in which oils and fats are the materials employed. Probably, in the primitive forms of rubbing with fat and fatty matters such as brains, these were the very earliest methods invented, but the typical oil dresses of the present, such as chamois and buff leathers, are something very different from their earlier prototypes. Besides these, the action of oils and fats on the skin plays its part in the manufacture of many other sorts of leather, if only in a secondary way; most markedly, perhaps, in the lace and belt leathers known as "Crown" and "Helvetia" leathers, and their congeners, but still distinctly in the mineral leathers in which egg yolk and fat-liquors are used, and even in tanned leathers which undergo the process of currying.

Before I can speak of the theory of oil dressing, the actual process of chamoising must be briefly described. Ordinary wash-

leather, which will be the most familiar instance to most readers, is made from the inner split of sheep-skins, often called "sheep linings." The skin, after being deprived of its wool by the fellmonger, is limed for a short time to plump it tolerably, and in this state is split into two thicknesses by a machine which draws the skin over a steel straight-edge against a straight blade to which a rapidly reciprocating motion is given by an eccentric. The grain split, which, curiously enough, is considerably the larger of the two, is used for the manufacture of the thin fancy leathers so often used for bookbinding and portfolio work, while the lining goes for wash-leather. It is first freed from lime by bran drenching, and the loose and fatty layer which exists in the centre of a sheep-skin is removed with a sharp knife on the beam. The skins are then placed in the "stocks" or fulling-mill, which has been already described as used for the softening of dried hides, and pounded till a part of the moisture is evaporated, and the fibrous structure has become somewhat loose and open, sawdust being generally added to facilitate the process. Oil is now added in small quantities, cod liver oil of a crude sort being generally used in this country, though on the Continent, whale oil and other marine oils are frequently substituted. The oil is gradually absorbed by the skins, replacing the water, which evaporates, the skins being occasionally hung up for a short time exposed to the air to facilitate the operation. When the water has been entirely expelled, the skins lose their original limy odour, and acquire a peculiar mustard-like smell due to the oxidation of the oil. They are now somewhat loosely packed in a box, where they heat rapidly from continued oxidation of the oil, and must be taken out and exposed to the air at intervals to prevent overheating and consequent injury, since the oxidation of drying oils take place so rapidly as in many cases to produce spontaneous combustion. During this heating process, much pungent vapour of acrolein is given off, the colour of the skins changes to a pronounced yellow, and the tanning process is complete; but it still remains to rid them of the superfluous oil. In the old English process this is accomplished by washing with warm soda solution, by which the oil is partly saponified and partly emulsified, so that it can be washed out. In France, where the oxidation takes place more gradually, the skins being freely exposed to the air by hanging frequently during the stocking pro-

cess, and the final oxidation being also accomplished by hanging in warm rooms, the oil is much less viscid, and a large portion of it can be removed by dipping the skins in hot water, and then wringing or hydraulic pressing. The oil pressed out in this way constitutes the pure *moellon dégras*, or *première torse*, which, after mixing with tallow and other cheaper fats, constitutes the *degras* of commerce so much esteemed in currying. The oil obtained in the English way by washing out with soda, and afterwards acidifying the solution, is known as *sod oil*, and is much less esteemed, but as some English *chamoisiers* now work in a way very little different from the French, and obtain their oil by pressing, it is hard to see why it should not be equal to the French product, if properly used. White wash-leathers are made by bleaching in the sun, the skins being moistened with water and the alkaline fat-liquor obtained in washing out the remaining oil; or the bleaching is accomplished by oxidising agents, such as permanganate, followed by treatment with sulphurous acid to remove the manganese peroxide formed; or by sodium peroxide. Oil leathers are the only ones except chrome leather which will stand the action of hot water, and indeed immersion in hot water is constantly used on buff leather to shrink or "tuck" the leather so as to make it thicker and more compact.

The chemical explanation of the process of *chamoising* is as yet by no means certain. The oils used are invariably drying or semi-drying oils, and *Fahrión* has shown that even with linseed oil the effect can be produced, though marine oils are always used in practice. Though the outlines of the chemistry of oils are now pretty well understood, there are yet many details to be filled in. All oils, with the exception of sperm and others of its class, which are chemically liquid waxes, are ethereal salts of glycerine and certain organic acids, in which glycerine plays the part of a base. The simplest class of fatty acids are those of the acetic series, in which the CO.OH group, characteristic of all organic acids, is combined with a hydrocarbon group. This is practically a paraffin in which the place of one of the terminal hydrogen atoms is taken by the CO.OH group. I need hardly explain that the carbon atom is tetravalent, or has the power of linking itself to four other atoms, as in the case of marsh gas CH₄, which is the simplest type of a paraffin, and which, when carboxyl is substituted for one of its hydrogens, forms the type acid of the fatty

series, acetic acid or vinegar. Now it is possible to replace another H of the CH₃ or methyl group in acetic acid by a second CH₃ group, and so on, building up a chain, plain or branched, in which each carbon, except the end ones, is linked to two H atoms, and two other carbon atoms. Such acids are called "saturated," because all the combining powers of the carbon atoms are fully satisfied, and nothing can be added without displacing something already there. The higher members of this group are hard crystalline fatty bodies, such as stearic and palmitic acids. This is, however, another class of acids, in which, somewhere in the chain, two carbon atoms are linked to each other by a double bond, which replaces two of the hydrogen atoms. The higher members of this class are oily bodies like oleic acid, the glyceride of which is the main constituent of olive oil. When these unsaturated acids are exposed to the action of iodine, bromine, chlorine, or oxygen, the link gets broken open, and additional atoms of the elements named take the place of the hydrogen atoms of the saturated acids. In oleic acid, oxygen is not readily absorbed, and hence its glycerides form excellent lubricating oils, little prone to change by exposure to the air. Other fatty acids exist however, in which two, or three, or possibly even more of the carbon atoms are double linked, and these, under favourable conditions, absorb oxygen greedily from the air, becoming converted into gummy solid bodies. Such oils, as for example linseed, are called drying oils, and are much used as varnishes, and for vehicles for paints, since they harden by exposure to the air, not by evaporation, but by actual conversion into insoluble and solid bodies. All the fish oils contain unsaturated acids such as I have described, and are possessed more or less of drying properties, and some few of them, as for instance menhaden or "porgie" oil, are used for rough painting. The oxidation undergone by such oils is by no means a simple one, and varies in character with the conditions, and in most cases as well as solid bodies, volatile aldehydes, and ketones are produced by the breaking up of the hydrocarbon chain and the direct double linking of the separated fragment with oxygen. The glycerin also becomes dehydrated during the heating process, producing large quantities of the very pungent acrylic aldehyde or acrolein. Knapp supposed that the formation of oil leathers was sufficiently explained by the coating of

the fine fibrils of the skin with the varnish-like and waterproof products of the oxidised oils. No doubt this action does take place, and in many classes of leather is of real importance, but that it does not completely solve the problem is shown by the fact that washleather can be treated with warm alkaline lyes in which these bodies are easily soluble, without losing its character. Cotton impregnated with drying oils and exposed to air, as in the case of oilskins, has its fibres covered and coated as Knapp supposed, but the coating is easily removed by washing with alkalis. I had supposed that the action might be explained by the fatty acid having actually become dissolved in the leather fibre, while in the case of cotton it merely coated the surface, but I am now inclined to look for an explanation in another direction. It has long been known that formaldehyde, the simplest body of the aldehyde class, had the power of rendering gelatinous fibres insoluble even in hot water, and several patents have been taken for its use in tanning. Messrs. Pullman, of Godalming, indeed have recently succeeded in producing by its aid leathers which have all the good qualities of chamois leathers, but in which no oil is used. It appears that this power of hardening gelatinous fibres is a general one of the aldehyde class, and as it has just been stated that considerable quantities of these bodies are among the products of oxidation of many oils, it may well be that the special action of drying oils is not due to the varnish-like coating which they produce on the fibre, but to the direct tanning action of the aldehydes which are formed during their oxidation.

In 1852, a German cabinetmaker named Klemm, who had turned his attention to the manufacture of lace and belting leathers, sold a process to a Mr. Preller, by whom it was patented in England, and the patentee set up works in Southwark, and adopted a crown as a trade mark. The leather was thence named "Crown" leather, but later the term "Helvetia" leather has been more commonly applied in England to leathers of the same type. The material used in the manufacture of Klemm's leather was a mixture of barley meal, ox brains, butter, milk, and soft fat, with a little saltpetre to act as an antiseptic. It is hard to believe that the milk and butter were ever really used in practice, and it was soon found that of the materials named, only the flour and the fats were essential, though ox brains, where they could be obtained, were a useful addition. The process was, in fact,

the primitive one of kneading the raw skin with fats and albuminoid substances, and only the gluten of the flour really entered the leather. The hides, unhaired in the usual way, but not specially freed from lime, are coated with a thick layer of the pasty mixture which has been described, and introduced into a large drum or barrel churn, fitted with means by which damp warm air can be circulated through it while in motion through the hollow axles. After some hours drumming, the hides are taken out, slightly dried, and given a second coating of the paste, and so the process is repeated two or three times, when the hides are simply set out and dried ready for use.

Even the flour is not essential for the process, as leather equally tough, but not so full and plump, can be produced with fat alone. Any fat can apparently be used for the process, so long as it is liquid or semi-liquid at the temperature of the drum, and soaps are sometimes added with advantage, as they assist in the emulsification and penetration of the oils. Eitner, who examined many of these leathers, found that if the albuminoid matter of the flour or brains were removed by washing with an alkaline lye, a sort of imperfect buff or chamois leather remained. Probably, little by way of scientific explanation can be added to what has already been said of the action of fats and albuminoids in tanning. As in the case of calf kid, the albuminous matter of the flour is drummed into the skin, and becomes fixed there by the same tawing or tanning action as converts the skin itself into leather.

Klemm invented another sort of lace leather prior to the "Crown" leather, in which the raw hide was first treated with alum and salt, and then washed so as to free it of all which could be removed in this way, after which it was treated with a fat and flour paste in the same way as the "Crown" leather. Excellent leathers, known as "Rawhide," have since been made on the same principle for such purposes as laces and picker bands, where great toughness is required. Their similarity to calf or glove kid, in principle at least, is at once apparent.

I must now enter on the consideration of the vegetable tannages, and perhaps I should first offer an apology for leaving what is still, commercially, by far the most important tanning process to so late a place in the course of lectures. My excuse must be that I have aimed in these lectures rather to deal with the scientific aspects of leather manufacture than its practical side, and that while vegetable tan

ning is one of the most ancient and important branches, it is also one of the most difficult to explain. What explanation can be given must be based on what we have learnt of the simpler processes.

The vegetable tannins form a large class of bodies varying very considerably in their chemical structure, but having in common the properties of precipitating gelatine from its solution, of forming dark-coloured compounds with ferric salts, and converting skin into leather. The function of the tannins in plant life is not very clear. They are widely distributed through almost all classes of flowering plants, and occur at times in almost all parts of the plant, but perhaps most abundantly in fruits and barks. They are also very frequent in galls caused by the attack of insects and aphides, though they are sometimes credited with being deterrents of insects. A curious point is that even in the same plant different tannins may exist in different parts; thus the tannin of the bark, the wood, the acorns, and the galls of the oak is distinctly different, though it is quite possible that all of them are mixtures; since, from their uncrystallisable character, any very accurate separation of the different tannins has so far proved impossible, and it is by no means certain that the number of really distinct tannins is a large one.

Beside the chemical reactions which I have stated to be common to the whole class of tannins, there are certain relations in chemical structure which must be briefly mentioned. All tannins belong to the great class of "aromatic compounds," which also includes most of the coal-tar colours, and many of the most important products of manufacturing organic chemistry. The peculiarity of this class is that all the bodies belonging to it contain a group of six carbon atoms, usually supposed to be linked together in a ring form, which remains unbroken through all the combinations into which it enters. The simplest of these compounds is ordinary coal-tar benzene, a colourless volatile liquid, the molecules of which consist merely of the six-carbon ring combined with six atoms of hydrogen. Closely allied to this is phenol or pure "carbolic acid," which differs only from benzene in having an $-O-H$ group substituted for one of the hydrogens. Other phenols exist containing two $-O-H$ groups replacing hydrogen (dihydric phenols), and three $-O-H$ groups (trihydric phenols). If we represent the benzene ring, as is usual, by a hexagon, of which the angles correspond to the carbon atoms, it is obvious that so soon as we have

more than one substituted hydrogen there will be a possibility of different compounds identical in the number and kind of their atoms, but varying as the substituted groups occupy respectively the 1-2, 1-3, 1-4 positions, and so on. Such bodies actually exist, and are known as "isomeric." Thus there are, as might be predicted, three different dihydric, and three trihydric phenols. From each of these bodies organic acids may be derived by substituting the $CO.OH$ group for yet another of the hydrogens. All the natural tannins contain either the dihydric phenol, catechol, or its corresponding acid, protocatechuic acid; or the trihydric phenol, pyrogallol, or its corresponding acid, gallic acid. No natural tannins seem to be formed from any of the isomeric members of the phenol class, though some, in addition to catechol, contain the trihydric phenol phloroglucol; but it is stated that bodies having many of the properties of tannins have been artificially formed from other phenols.

The tannins therefore fall naturally into two great classes—those derived from protocatechuic acid, and which yield catechol on dry distillation, and which may therefore be called the catechol tannins, and those from gallic acid, which yield pyrogallol on heating, and may similarly be called the pyrogallol tannins. It is possible, though not certain, that tannins may exist which contain both these groups at once, and it is certain that there are catechol-phloroglucol tannins, containing both the dihydric phenol catechol, and the trihydric phenol, phloroglucol. This difference in constitution corresponds to a marked difference in properties. The catechol tannins generally give green-blacks with ferric salts (though infusions of some of the mimosas give violet-blacks, probably from the presence of colouring matters). Their infusions are precipitated by excess of bromine water, and, employed in tanning, or boiled with acids, or even alone, they give dark-coloured, and generally red and difficultly soluble products, which are deposited on the leather, as in the characteristic case of the hemlock bark of America. Similar red products of oxidation or dehydration are produced by exposure to the sun, so that pale leathers from these tannins, such as East Indian sheep and goat skins, tanned with "turwar" bark (*cassia auriculata*), are rapidly darkened by light, and may even be printed under a photographic negative. The catechol-phloroglucol tannins, such as those of cutch and gambier, behave in this respect very similarly to the

ordinary catechol tannins. Pyrogallol tannins, on the other hand, give blue-blacks with ferric salts, and no precipitate with bromine water, and usually a pale precipitate of ellagic acid with acids, and on the surface of leather, constituting what the tanners term "bloom." This deposit is not due to the decomposition of gallotannic acid, the "pure tannin" of the shops, and the most important of the pyrogallol tannins, but to the presence in larger or smaller proportion of an allied tannin, ellagitannic acid, of which the constitution is very imperfectly understood. Gallotannic acid itself gives no "bloom," though ellagic acid is easily formed from it by the action of dehydrating agents. Divi-divi, myrobalans, sumach, and galls are good instances of pyrogallol tanning materials, the proportion of ellagitannic acid present being largest in the first and smallest in the last. The only tannin of which the structure is approximately understood is gallotannic acid, which was proved by Schiff to be a digallic acid, or acid anhydride of gallic acid; but even in this case it has been lately shown that Schiff's synthetic digallic acid is not absolutely identical with the natural product.

The precipitate which is formed when gelatine and tannin solutions are mixed is not of constant composition, but varies considerably, according to whether the gelatine or the tannin have been in excess at the moment of combination. Its composition is also altered by washing with hot water, so that it has not the characteristics of a definite chemical compound, but suggests rather the result of a chemical equilibrium, such as has been described in connection with the pickling process, though no explanation on these lines has yet been attempted. It is possible that there may be more than one compound formed between gelatine and the tannins, and that the observed irregularities of composition are due to the presence of the two compounds in varying proportions.

The popular idea that modern tanning is done with "chemicals" as opposed to vegetable tanning materials is altogether erroneous. The great changes which have taken place in tanning methods since the days of our forefathers have been in the first instance mechanical; much work which was formerly done by hand is now accomplished by steam-power. In the second place, advantage has been taken of the vegetable products of other lands, often cheaper and richer in tanning matter than our indigenous oak bark, and, therefore, enabling

leather to be more quickly produced by the use of stronger infusions, and still more by their systematic change and renewal. The best leathers of the present are probably not only cheaper, but actually better than those of earlier date, and I do not believe that those who are willing to pay a reasonable price for a good material were ever better shod than at present; though it must be admitted, on the other hand, that at a low enough price worse rubbish can be obtained than our forefathers knew how to make, and that, at the same time, it is so well got up that no one but an expert can judge by its appearance.

In older times, oak bark was practically the only tanning material used in England, and its great virtue was that leathers made with it alone were applicable to a great variety of purposes, and that with an honest tannage it was hardly possible to produce other than a fair wearing quality of leather. Among the host of materials now at the disposal of the tanner, there is scarcely one with the same wide range of applicability, and, therefore, much more skill is required in their proper use and combination, while some of them lend themselves readily to the production of qualities, such as weight and colour, which are profitable to the tanner, while offering no guarantee of wear to the purchaser. One of the most important of modern materials, though now in its turn somewhat eclipsed by later introductions, is valonia, the large acorn

FIG. 15.

THE VALONIA OAK (*Quercus agrifolia*).

of an evergreen oak of Asia Minor and Greece, which contains about three times as much

tannin as the strongest oak bark, but of a somewhat different character, giving a harder and heavier leather owing to the presence of a larger proportion of ellagitannic acid, which yields much of the white deposit known as "bloom." Another exotic material of somewhat the same character, but yielding a rather lighter and more porous leather, is myrobalans,

is somewhat more interesting. The Arabic name, *al kharrouba* (the locust bean), was introduced into Spain by the Moors, and under the Spanish form *algaroba* is the general name in Spanish-speaking countries for a bean-like pod, of which *algarobilla* is of course the diminutive. All these materials contain tannins, mainly of the pyrogallol group, and to

FIG. 16.

OAKWOOD EXTRACTION IN SLAVONIA.

the dried fruit of a large Indian tree, *Terminalia chebula*. Akin to this in the character of its tannin, but yielding still lighter coloured, softer, and lighter-weighting leather is the sumach, the leaf of the *Rhus coriaria*, of Sicily, which is used mainly for soft and light leathers such as morocco, in which resistance to water is of small importance. The tannin of sumach is nearly pure gallotannic acid, allied with a colouring matter giving yellow dyes with alum and tin mordants, and which has been shown by Perkin to have interesting chemical relations to the tannin with which it is associated. I must also mention *divi-divi* and *algarobilla*, the pods of South American trees closely allied to logwood, which are amongst the richest of natural tanning materials, *algarobilla* being perhaps six times as strong as oak bark. The curious name, *divi-divi*, has a legendary connection with David Davis, who is said to have been the captain of the ship in which it was first imported, but the history of the word *algarobilla*

them one more may be added, which is of constantly increasing importance. The wood of the oak, like most other parts of the tree, contains tannin, yet in very small proportion, say only one-fourth as much as in a good oak bark. It is therefore, in itself, a practically valueless tanning material, but one to be had in enormous quantities, especially in the great oak-forest districts of Slavonia, as a waste product from the timber industry. It is, therefore, converted into an extract of at least ten times the tanning strength of the original material. The timber is first reduced to shavings about one-eighth of an inch thick by the action of a machine, of which the essential part is a drum fitted with powerful plane blades on its circumference, against which the timber is pressed. The shavings are carried by elevators and chain-conveyers to a series of large vats fitted with steam-pipes for heating, and by pumping from one to another of these, tolerably strong liquors are obtained, but of a colour too dark to meet the somewhat exacting require-

ments of the tanner and his customers, both of whom are ready to sacrifice a good deal of real quality and cheapness to the appearance of boot soles which the first day's wear will irretrievably disfigure! The liquors, therefore, after settling and cooling to a temperature of about blood heat, are treated on precisely the same principle as the cook uses to brighten her jellies, but in the place of white of egg the cheaper substitute of dried blood or blood-albumen is employed. This is dissolved in water and well mixed with the liquor by revolving stirrers, and the temperature is then raised till the albumen coagulates and carries down with it a good deal of the colour and suspended impurities, together with a certain portion of the tannin. The liquor is now settled, and the muddy portion filter-pressed; the clear infusion thus obtained is run to vacuum pans and concentrated, at a low temperature, to an extract of about the consistency of treacle, and containing about 25 to 30 per cent. of tanning matter. Another kindred industry is the manufacture of extract from the wood of the Spanish chestnut, principally carried on in the South of France where this tree is abundant. The chestnut contains more tannin than oak wood, and the manufacture of the extract is carried on in a similar manner. The product differs but little from oak wood in its tanning properties, and is so like it in appearance and chemical characteristics that it is frequently substituted by unscrupulous dealers.

So far, I have spoken only of tannins belonging more or less definitely to the pyrogallol group. I must now mention some of the derivatives of catechol. Of indigenous European representatives of this class the barks of the larch and the spruce fir are the most important representatives, larch bark being used in Scotland for tanning sheepskins, while spruce bark is one of the most important materials in eastern Germany and Austria. Curiously, spruce bark is not used in Scotland, and larch bark but little on the Continent, while what becomes of the enormous quantities of spruce bark which must be produced in the Scandinavian forests I have never been able to discover. Both barks make leather of a pale colour, and, for many purposes, of excellent quality.

Of much greater importance than the European pine barks is that of the American hemlock spruce (*Tsuga* or *Abies Canadensis*), which is one of the principal tanning materials of North America, and which is used not only

for the red hemlock sole leather, but either alone or in combination with other tans or with alum, for a large proportion of the dressing leather which is exported to Europe. Another tannin of the group which, in the form of extract under various names, is gradually finding its way into English yards, is from the bark of various trees of the mangrove family, and especially from *Ceriops Candolleana*, which is very abundant in the swampy creeks of tropical Africa and the East Indies. Quebracho, the very hard and heavy wood of a tree from the Argentine, belongs to the same class of tannins; and canaigre, the tuberous root of a large dock, is also a catechol tannin, though different in many respects from those already noted. The various mimosas and acacias also belong to the catechol group.

The modern tanning process consists in submitting the hides or skins, previously prepared by the methods of liming and bating which have been already described, to infusions of tanning materials, which are gradually increased in concentration as the process advances, and of which the strength is frequently maintained in the later stages by layers of the ground tanning material dusted in between the leather. In earlier days, this dusting was the principal means of bringing the tanning matter in contact with the skins; and much of the increased rapidity of modern processes is due to the use of strong infusions which keep up a better supply of the tannin. The making of such strong liquors without wasteful expenditure of the material is therefore an important branch of the tanners' art. Much of the success of the operation depends on the suitable pulverisation of the material in the first instance. The tannins are formed in cells with cellulose or woody walls, through which, from their uncrystallisable character, they diffuse very slowly, and it is therefore important that the cells should be as much broken up as possible in grinding and crushing. On the other hand, in dealing with large quantities, it is found that too finely powdered material, when it is wet, presses together into a mass so solid that the liquor will not percolate through it, and it is necessary that it should be sufficiently coarse, or in such a condition that this does not take place. The best way of accomplishing this is dependent on the nature of the particular material. With woods, it is found that shavings cut transversely to the grain, so as to divide the sap tubes into short lengths, are very satisfactory; barks are best ground in such a way as to rag them as completely

as possible without the production of too much fine dust; while many fruits, such as myrobalans and valonia, are better crushed into flakes rather than actually ground. The extraction takes place in large vats or leaches, provided with a latticed or perforated "false bottom," to allow of drainage; and in the best yards these are generally connected in series of 6-10 vats in such a way that the liquor from the bottom of the weakest and nearly exhausted vat flows by gravitation on to the top of the next stronger, forcing its liquor down through the false bottom and up a tube on to the top of the next, and so on. This method greatly diminishes the labour of pumping, and makes it possible to secure a much more constant and systematic change of liquor, which is of great importance, since the dissolved tannin in the material will only diffuse out into liquor weaker than itself, and no length of mere soaking in liquors which are not sufficiently changed will accomplish satisfactory exhaustion. The use of heat is also of great service. Hot liquors not merely extract more rapidly, but bring portions of the tannin into solution, which cannot be extracted in the cold. On the other hand, the colour of these "difficultly soluble tannins" is generally darker and redder than that of the more soluble part, so that in many cases it is a question of judgment how much tannin it is worth to sacrifice for the sake of improved colour. It has been shown by the work of Parker, myself, and others that each tanning material has an *optimum* temperature of extraction, at which more tannin can be removed than at any other, but this is sometimes too high for the best results in colour. As a general rule, however, considerably increased quantities of tannin can be extracted by the use of heat, say, up to 60° C., on the weaker and nearly exhausted leaches, without any commensurate injury to colour.

The hides for sole-leather are generally brought into the liquors without bating, and still swollen with lime. In this case it is of essential importance that the first weak liquors in which they are "coloured" should contain a sufficiency of weak vegetable acids, such as lactic and acetic, to neutralise and remove the lime, which will otherwise combine in an insoluble form with the tannin in the surface of the hides, forming easily oxidisable compounds which darken seriously on drying, and frequently make the grain of the leather brittle. If previously to bringing the hides into liquor any portion of the lime has been

allowed to become carbonated by exposure to air, or to "temporary-hard" water, this is much less soluble in the very dilute weak acids present, and so is almost certain to result in dark stains and brittle leather. In modern yards the hides are generally suspended in the liquor, so as to expose their surfaces freely to its action, and they are frequently kept in gentle motion by some mechanical device, while the liquor is circulated by a system of tubes and troughs, similar in principle to that used in the leaches, but in the reverse direction.

Where sole-leather hides have been unhaired by "sweating" or by the use of concentrated solutions of sulphide of sodium, which does not sufficiently swell and split up the fibre bundles, it is absolutely essential for the production of satisfactory sole-leather that the liquors should be acid enough gradually to plump the fibre. The natural acids in the liquors are produced, not from the tannins, but by the fermentation of sugary matters present in the barks; and in the older methods where weaker liquors were used, and the time of tanning was proportionately longer, their quantity was often sufficient to produce all the swelling effect required. Now, with more rapid processes, and the use of extracts and other materials which do not readily yield acids by fermentation, this is rarely the case; and hence attempts to tan sweated hides in English tanyards, without knowing the conditions essential to success, have generally proved abortive. In America the difficulty is got over by the use of sulphuric acid; but this is never added to the liquors, both because it precipitates the tannin, and because, perhaps partly on that account, its use produces dark and brittle leather, not unlike that due to imperfect removal of the lime. To avoid this, the sweated hides are first coloured and slightly tanned on the surface in weak sweet liquors, and are then suspended in water to which the requisite small quantity of sulphuric acid has been added. The slight tanning protects the colour of the grain, as on tanned leather sulphuric acid is practically without action, but below the tanned surface a dark layer may generally be detected, caused by the action of the acid. Even the natural and comparatively weak acids of the liquors are capable of producing discolouration and brittleness if they are present in excess. After the hides have been coloured in suspenders, they are laid flat in pits; first, with liquors of constantly increasing strength, in which they are moved, and the liquor changed every day or every other day

("handlers"). After some weeks of this treatment, and when the tannage has pretty completely penetrated the leather, it is placed in pits with stronger liquors, and with valonia or other tanning material dusted between the hides ("layers"). In these pits it is allowed to lie for longer periods, beginning with a week or ten days at the least, and increasing to a month or six weeks, but, of course, details of this sort vary much in different yards, and according to the nature of the tanning material employed. The leather is now washed free from loose bark, &c., partially dried, and finished by rolling and other mechanical processes designed to render it solid and smooth.

The tannage of dressing leather differs but little in principle from that of sole leather, but the hides or skins are freed from lime by bating, or puering and drenching, which, at the same time, reduces the swelling of the fibres, and the skin gains in surface area while it loses in thickness. In this condition the surface is tanned and fixed by the first weak liquors. As the tannage proceeds the skin possibly swells somewhat by the acids of the liquors, and its inner fibrous structure is contracted by the astringent action of the tannins, with the result that its area is again reduced, and the outer grain surface, which was first tanned, is drawn into fine wrinkles or "grain," such as we are familiar with on many soft leathers. This effect is the greater, the stronger the liquors with which the leather is first treated, and the more extended and softer the condition in which it was introduced into them, and it is also favoured by motion in the liquors. If the liquor is too strong, or the colouring or "graining" is carelessly done, the wrinkling becomes coarse and irregular, and we have the defects known to the tanner as "drawn" or "old" grain. If too strong liquors are used at first, or if the hides are carelessly creased, similar defects may occur even on leather which has not been bated, as, for instance, on sole-leather. Where grain is desired, as in moroccos and levants, the colouring is generally effected in a paddle vat, but in some cases where perfectly smooth leathers are required, as in coloured calf, it is best done in suspension, as in the case of sole-leather. The subsequent tannage is similar to that of sole-leather, except that weaker liquors are used, and frequently different tanning materials are selected; the entire process is shorter in proportion to the thinner character of the skin, and dusting material is used less freely, or not at all.

It will be noticed that the whole process of tanning is one of diffusion, which from the colloid character of both skin and tannin is necessarily slow. Many attempts have been made to force the tanning liquors into and through the hides by mechanical means, and tannage can be much quickened by treating the goods in a drum, in which they are continuously tumbled about. In this case, not merely is fresh liquor constantly presented to the hides, but they are continually doubled and squeezed and relaxed, so that the liquor is, as it were, pumped through the spaces between the fibres, but is not materially assisted in its penetration of the fibres themselves, so that leathers produced in this way tend to be rapidly and evenly tanned through, but without very complete tannage of the interior of the fibres themselves, which, for certain purposes, is advantageous, while for others it is not. Leathers tanned in this way are likely to be tough rather than solid; and it is doubtful whether the very best class of sole-leather can ever be produced by the quick processes. Lieing "dusted down" with solid materials for long periods, as in the ordinary sole-leather process, produces a sort of solidity which cannot be got by liquors alone; since the liquors contain mostly the easily soluble tannins, while in the dusting down process, the less soluble also dissolve in small quantity, and are eagerly absorbed by the hide, while the liquor dissolves further quantities from the tanning materials, and in this way these bodies, which contribute greatly to the solidity of sole-leathers of the old sort, are gradually transferred to the leather. To a certain extent the same effect is produced by the use of warm liquors in drumming, as by the aid of heat many of these bodies are rendered much more soluble.

Several processes of "electric" tanning have been patented, but as yet no very convincing proof has been given of their commercial success. There is no doubt that the passage of an electric current increases diffusion through membranes, and at the same time warms the liquor, and both of these effects should tend to quicken tanning, while, so far as is known, the tannins are not electrolytes, and are therefore not directly destroyed by the current. On the other hand, currents cannot pass without the decomposition of water and the salts it contains; and in many cases the products of these decompositions act destructively on the tannins. It may probably be taken as proved in practice that the

passage of a current quickens tanning; but wherever accurate experiments have been made, there is an apparent consumption of tanning material in excess of that actually absorbed by the skin.

The limited time at my disposal does not allow of any detailed consideration of the processes of currying and finishing which all tanned leathers must undergo before they are ready for the market; and I pass them over the more readily because, though important to the technologist, their interest is mechanical rather than scientific.

The finishing of sole leather aims simply at producing a smooth and even-coloured surface, and a compact and solid material; and is limited to scouring and compressing the surface with stones, brushes, and an implement called a "striking pin," and then submitting to heavy pressure under a brass roller. All these operations are now generally effected by machines.

FIG. 17.

SCOURING.

The softer leathers (dressing leathers) which are used for the upper parts of boots and many other purposes, have not only to undergo mechanical treatment for the purpose of smoothing and stretching, but must be "stuffed" or saturated with oils and fats to increase their resistance to water, and to add to their flexibility, and are frequently dyed or stained in black or colours, and submitted to mechanical processes to produce various forms of grain surface. The first operation in almost all cases is "scouring," which is done by machine, or by hand on a flat table, as shown in Fig. 17. The thickness must now in many cases be reduced or rendered uniform by "shaving" with a two-handed knife with a peculiar turned edge, an operation which is shown in Fig. 18. This is frequently accomplished by an in-

genious machine of American origin, with a drum with spiral blades kept sharp by an emery wheel. The operation of "splitting" now often takes the place of shaving, especially on the heavier leathers, the hide being separated into two or more thicknesses by a long, keen blade, which is sometimes fixed, but is now more frequently a thin belt of steel, running at a great speed through guides above a solid roller, the distance of which regulates the thickness of the split.

"Hand-stuffing" is accomplished by covering the leather, which must be in a partially wet condition, with a thick layer of "dubbing," which is essentially a mixture of tallow and oils. A crude cod-liver oil is mostly used by English curriers, but other materials, and especially sod-oil and degreas from the chamois leather industry, are frequently added. The leather is now hung up in a moderately warm room and allowed to dry very slowly, when the

FIG. 18.

SHAVING

oils gradually take the place of the water, which escapes by evaporation, and coat and lubricate the fibres, while at the same time, in lightly tanned leathers, a sort of imperfect retannage or chamoising probably takes place. It is for this reason no doubt that semi-drying oils are generally employed in currying, though recently both mineral hydrocarbon oils and animal non-drying oils have been used with success.

In the process of hand-stuffing, it is obvious that only oils and fats, liquid or semi-liquid, at the temperature of the drying-room, can be absorbed by the leather, the tallow of the dubbing being mainly useful to retain the oils on the leather, and being largely left on the surface when the drying is complete. This difficulty is obviated by the method of

“drum-stuffing,” which has revolutionised many branches of the currying industry. For this process, a drum is used like an enormous barrel churn, and provided with means by

FIG. 19.

PREPARING FOR JANNING.

which it can be heated by steam to the temperature of melting fat. The leather in a suitably damped condition is introduced into the hot drum, which is closed and set in rotation, and the melted fats, which in this case may be of tolerable high melting point, are introduced through a hollow axle of the drum, and in less than half an hour are completely absorbed by the leather. In some American leather works a weight of solid greases exceeding that of the dry leather is thus introduced.

FIG. 20.

SCOURING MOROCCO SEALS.

The subsequent processes of finishing vary too much with different kinds of leather to be dealt with here. A word or two, however, may not be out of place with regard to “patent” and enamelled leathers, which are

not without chemical interest. The varnished surface of these leathers is produced by a “japan” of which the essential constituents are linseed oil and Prussian blue, boiled

FIG. 21.

MOROCCO DYEHOUSE.

together to a viscous mass. The japan is not blue, but brownish black, and it is possible that the Prussian blue is broken up by the heat, and that the iron oxide serves as a

FIG. 22.

MOROCCO FINISHING SHOP.

“drier,” as well as to produce a black compound with the linseed oil; and it is worth the study of manufacturers whether a cheaper compound of iron might not be found to answer

the same purpose, and, in fact, the whole question of the preparation of the japan would well repay investigation. The leather which is to be japanned is stretched on large boards, as shown in Fig. 19, which are fitted to slide like drawers into drying chambers heated to 140°-160° Fahr. The japan is applied with a sort of toothed steel plate, and after the coating is dry, it is smoothed down with pumice before a second coat is applied. Frequently seven or more coatings are given, the final one being mixed with copal varnish to produce a more glossy surface.

Moroccos, and coloured leathers are not usually stuffed, though a good deal of oil is often used in the finishing processes. Fig. 20 shows the scouring of sealskins for black morocco or for enamelling; while Fig. 21 represents a morocco dyehouse. The seal-skin which is used for these purposes is not that of the fur seal, but the coarser skins of several species common in the Arctic regions.

Miscellaneous.

THE GERMAN BEER INDUSTRY.

The German beer industry has grown year by year, and the increasing capacity of the establishments has made it necessary for the brewers to search for new markets where their overproduction could be disposed of. In the year 1885, the export of German beer reached its maximum, amounting in that year to 1,318,000 hectolitres (28,996,000 gallons), representing a value of 24,000,000 marks (£1,200,000). The next year, however, showed a decrease, and since then the export has gone down to about one-half of what it was in 1885. According to the United States Consul at Kehl, the reason given for this decline is that the countries which were Germany's best customers—France, Belgium, and the Netherlands—have increased their output sufficiently to nearly meet the home demand. The high duty placed on foreign beers by France has also had the effect of considerably reducing the import of German beers into that country. In all those years the export of German beer in bulk (barrels) has been greater, contrary to general belief, than in bottles. German beer once had nearly a monopoly of the beer trade of South America, but there also, it is stated, the demand has decreased, while at the same time, according to trade reports, the demand for the United States has increased. The decline of the German beer trade in Brazil alone, during the year 1896 and 1897, is given as amounting to fully three-fourths of what the German brewers had exported to that country in former years. It is a noticeable fact that while the

export has declined year by year, the production of beer in Germany has advanced steadily, showing that the home consumption has greatly increased. At present, the United States is the best foreign customer for German beer, importing in 1895, 522,138 gallons; and in 1896, 689,456 gallons. The export of beer from Germany to Venezuela, Japan, and China together, did not in the years given amount to one-half the exports to the United States alone. Brazil and British India, as consumers of German beer, come next to the United States. The German brewing industry has strong hopes of entirely supplanting the English in Australia and other British colonies.

Obituary.

VICE-ADMIRAL PHILIP HOWARD COLOMB.—Admiral Colomb died suddenly on Friday night, 14th inst. He was elected a member of the Society of Arts in 1873; he took much interest in its work, and was a frequent attendant at its meetings when subjects in which he was interested were discussed. The last paper which he read before the Society, was on February 20, 1895, on "The Rule of the Road at Sea." Colomb began to study the question of signalling at sea at night, both experimentally and practically, in 1858. His invention of the flashing lantern was completed in 1861, but it was not finally adopted in the Navy until 1867, and by that time the principle of his invention had been extended so as to apply to signals by day as well as signals by night. On March 12th, 1873, Captain Colomb read a paper on "Signalling at Sea with especial reference to signals of distress." On November 29th, 1882, he read a paper on "Some of the Causes of Collision at Sea," which attracted so much attention that an additional evening was devoted to the adjourned discussion. Colomb was born in May, 1831, and he entered the navy in 1846. He attained the rank of Vice-Admiral on the retired list in 1892. An appreciative record in *The Times* of Admiral Colomb's life-work concludes with an expression of the opinion that his true reward "was the gradual but ever-widening acceptance of those views of naval policy which he held and showed to be vital to his country's security and prosperity, and to the maintenance of her Imperial position."

THOMAS HENRY LORD FARRER.—Lord Farrer, who died on the 11th inst. at his residence, Abinger-hall, Dorking, was elected a member of the Society of Arts in 1882. He was born in 1819 and educated at Eton and at Balliol, Oxford. After he was called to the Bar he joined the Board of Trade and was for a time Assistant-Secretary, Marine Department, and he afterwards became Permanent Secretary to the Board, from which post he retired in 1886. He was made a baronet in 1883, and in 1893 he was created Baron Farrer of Abinger.

Journal of the Society of Arts.

INDIAN SECTION COMMITTEE.

A meeting of the Committee was held on Tuesday afternoon, 17th inst. Present: Sir Steuart Colvin Bayley, K.C.S.I., C.I.E. (Chairman), Sir George Birdwood, K.C.I.E., C.S.I., H. M. Birdwood, C.S.I., LL.D., F. C. Danvers, Colonel Sir T. Hungerford Holdich, R.E., K.C.I.E., Sir W. Lee-Warner, K.C.S.I., Sir Roper Lethbridge, K.C.I.E., Sir James Broadwood Lyall, G.C.I.E., K.C.S.I., Edmund Neel, C.I.E., Sir George Scott-Robertson, K.C.S.I., Sir John Scott, K.C.M.G., Sir Charles C. Stevens, K.C.S.I., T. H. Thornton, C.S.I., D.C.L., W. Martin Wood, with Sir Henry Trueman Wood, Secretary of the Society, and S. Digby, Secretary of the Committee.

The arrangements for the Session were considered.

Miscellaneous.

THE CIVIL ADMINISTRATION OF BRITISH INDIA.*

The subject for our consideration this evening is so wide, and suggests so many different methods of treatment, that the task of dealing with it in any adequate manner within the limits of a single paper is somewhat perplexing. Clearly we must be content to leave untouched many matters connected with the Civil Administration of India; and perhaps our safest plan will be to restrict our view to some of its more striking phases only. In his introduction to Vol. I. of "The British Empire Series," which relates mainly to India, its people, its industries, and its literature, Sir Raymond West puts the case for British rule in India concisely by describing it as "specially distinguished from all previous Governments by the inestimable blessings it has conferred

in security, justice, and material development." The description does not embrace the whole field of our Civil Administration, but it covers a great deal of the ground. Let us take it as a text and illustrate it by adducing some relevant facts.

In reference to the fact that the people of India are now protected from violent disturbances of the public peace, and are safe in the enjoyment of personal rights to an extent never realised under any native dynasty, Sir Raymond West tells us, in picturesque language, which I am tempted to quote, that "the lawless hordes who, as armies or as dacoits, once ravaged India almost from end to end, have been suppressed. The peaceful husbandman has no longer to keep his spear and buckler within reach while guiding his plough or reaping his crop. The vigilant watchman on a tower or tree, prepared to give warning of the distant shimmer of lances, is no more needed. The village walls with bastions and embrasures have become an anachronism to a generation whose grandfathers cowered behind them for shelter against Rohillas and Pindaris." The picture is not over-drawn; and an Indian poet, Syed Husain Bilgrami, in an invocation to England, has finely said:—

"England! 'tis meetest that, for weal or woe,
In calm or storm, our chosen place should be
Where honour calls us by the side of thee.
Thy friend be friend to us, our bitt' rest foe
The trait'rous knave who schemes thy over-throw;
For, like to Israel in captivity,
We once were thralls, till thou did'st set us free
And give us peace unknown from long ago.

Aye, peace unknown! when we were sore bestead,
And grievous were the burdens that we bore;
But now, if peace there be, and rest divine,
Good-will 'tween men, and peace, and all that's bred
Thereof, when lawless might is feared no more,
To thee we owe them all, these gifts are thine."

Lawlessness cannot be repressed by gentle means, and the measures by which the enemies of peace have been fought, whether within our borders or on our borders, are matters of history. But even now, when the *Pax Britannica* has been established throughout India, it would be folly to forget that the presence of an effective force of British and Indian troops is still essential to the orderly working of our system of civil administration. It is right, however, to add, and as a nation we may be proud of the fact, that the occasions are rare indeed when it becomes necessary for the civil power to seek military aid for the maintenance of the public peace. And yet an Indian army of twice its present strength would not suffice for the preservation of order if the people themselves were dissatisfied, instead of being well satisfied with the substantial advantages of our rule, as secured for them by the combined efforts of our civil establishments in various departments of the State, and by our courts of civil and criminal justice. They have learned, indeed, to know that our institutions are the outcome of a genuine resolve to maintain an efficient administration for the purposes of righteous government,

* Notes of a lecture by H. M. Birdwood, C.S.I., LL.D., M.A. (late Member of Council, Bombay), given at the Greater Britain Exhibition, on the 29th July, 1899. The chair was taken by Colonel M. McNeill Rind.

according to British standards, in co-operation, "so far as may be," with themselves, as promised in Her Majesty's gracious proclamation of 1858, and that, in giving effect to this resolve, we have acted, in the main, in a spirit of fairness and justice.

We are sometimes described as unsympathetic rulers. So far as I can judge, from my own experience, the people at large do not so regard us, but are accustomed to look upon English officers in the rural districts as their truest friends, who know their wants, listen patiently to their grievances, and give redress impartially. Such an attitude on the part of district officers towards the peasantry is in accordance with the best traditions of the public service, and there is no ground for supposing that these traditions have been weakened of late years. On the contrary, there is ample evidence to warrant the assertion that, in no previous century of the history of India, has more practical sympathy been shown by the rulers for the dumb millions than in the century now coming to a close.

The peasantry certainly know what oppression means, and what good government means; and they are true, as a body, to their law-abiding instincts, not because they are apathetic and do not care whether they are badly off or not, but, whether they love us or not, because they are shrewd and know well that, under a settled Government, with its carefully revised assessments of land revenue, its regular administration of justice, the protection it affords to life and property, its energy in improving and extending means of communication and of water supply, its encouragement of new industries, its care for the public health, its readiness to confer larger municipal privileges and rights of local self-government, wherever evidence is given of capacity for extended powers, they enjoy a measure of freedom and personal prosperity to which their ancestors were utter strangers.

The dwellers in towns and cities also realise that, under the broad ægis of Britain, they are prospering and can exercise their civic privileges and attend to their private affairs in safety. In such a city, for instance, as Bombay, which has been afflicted with sore troubles during the past three years, abounding evidence may still be found of material prosperity.

The plans and aspirations of that wise statesman, Sir Bartle Frere, who acquired, in the ranks of the Indian Civil Service, the wide experience and the knowledge of the people which so eminently fitted him for the various high offices he held in India, have now been largely realised. The magnificent public buildings on the Esplanade were the first-fruits of his labours; and now, for years, the merchant princes, the great mill-owners, the successful members of learned professions, who have accumulated wealth under our rule, have shown that they are no longer content with the dingy dwellings in the native town in which they spent their youth, and are building substantial stone houses for themselves on such noble sites as Malabar Hill, Cumballa Hill, and Mahalaxmi; while, as regards the native

town itself, proposals for the better housing of the poorer classes and the completion of other important measures connected with public sanitation, have, for some time, been engaging the earnest attention of the responsible authorities.

Any general proposition that is true of the state of the people of the Bombay Presidency may be assumed to be true, generally, for the whole of India; for the officers who control the whole administration, and those who are employed in the collection revenue and the administration of justice, are recruited—for all provinces—from the same classes, and have similar qualifications and similar training and supervision. I can, of my own knowledge, speak with confidence of the good work done in the Bombay Presidency, and the satisfactory results produced, as regards the general appreciation of British rule, in spite of occasional manifestations of a different estimate of its advantages. I am persuaded that similar results have been produced generally throughout India.

It would be strange, indeed, if carefully devised schemes for the recruitment of the public service, modified from time to time, as the need arose or seemed to arise, were to fail in their object. How carefully we have sought the best available material a little consideration will show. Leaving out of account the clerical and ministerial staff employed in all courts and offices, the members of which are generally appointed by the heads of offices, we find that the judicial and revenue departments, to which we must mainly direct our attention this evening, are controlled and administered by an Imperial Service recruited in England, and by Provincial and Subordinate Services recruited in India. It is by the members of the Imperial Civil Service that the highest responsibilities of administration are borne. That service includes all natural-born subjects of Her Majesty, from all parts of the empire, who choose to enter it, through the open door of competition, in accordance with the prescribed rules. A certain proportion of the appointments, held a few years ago by members of the Imperial Service, are now held by qualified Indians, selected in India, under the Provincial Service Rules, and in a small number of cases by "statutory" civilians, also selected in India, under a special Act. The concessions made under that Act and the Provincial Service Rules are in furtherance of the policy to freely and impartially admit, "so far as may be," British Indian subjects of whatever race or creed to offices in the service of the Crown, "the duties of which," in the words of the proclamation of 1858, "they may be qualified by their education, ability, and integrity to discharge." The object in view in recruiting the Imperial Civil Service by open competition in England—and it is one in perfect harmony with the spirit of that proclamation—is to obtain for the more responsible posts in the administration men possessing such physical, intellectual, and moral qualities as will enable them to bear the severest strain that is likely to be put on them, not merely

in the ordinary course of daily duties, but in times of exceptional stress also; and not only that, but they must be sound exponents also of principles of good government essentially English; men patient to hear both sides in a quarrel; yet capable of quick and energetic action when once a course of action has been decided upon; foes to every form of wrong, brave and self-reliant. We have been able to secure men of the right stamp by the processes hitherto in force, and though we have been taunted with selfishness for practically reserving the Indian Civil Service as a hunting ground for our sons, the fact still remains that a vigorous English schoolboy, of average, or more than average talent, who is adventurous enough to seek an Indian career, and enters the Service after his character has been moulded by the thousand healthful influences and associations of school and university life in England, and of an English home, is about as good material as can be desired for the purposes of the public service in India, as of public life in England; and a youth so equipped for his life's work soon develops all that is manliest and best in him, when he once assumes large official responsibilities, and acquires fresh stores of earnestness and zeal with every year of his official life. And as for the taunt of selfishness, it is scarcely justifiable, for, as I have already pointed out, the requisite material can, under existing regulations, be procured from any part of the empire—from India, from Australia, from the Cape, from Canada. Still, for the present, at any rate, if my judgment is not altogether astray, such material can be best worked up in England for use in India.

I spoke just now of the large responsibilities of Indian Civil servants, and I will now refer more definitely, and yet in general terms, to the kind of duties which individual members of the Civil Service are called upon to perform. And here, again, my remarks, though applicable mainly to the Bombay Presidency, will probably hold good, in a general way, for other provinces also. In India the lowest territorial unit of administration is the village, the Patell or head-man of which represents in his own person the cause of law and order, and, according to his degree, the magisterial and executive functions of the Government generally. Sometimes the duties are shared with a Revenue Patell, and he is assisted by the village accountant, who keeps most elaborate and accurate accounts of the public revenue and other matters. A collection of a certain number of villages constitutes the geographical and administrative area known in the Bombay Presidency as a Taluka, which is under the special charge of a native collector, or Mamlatdar, who is also a magistrate, his head assistant being also generally a magistrate; and a certain number of Talukas constitutes a collectorate or district, at the head of which is the collector, who is also the district magistrate, and is practically the local Governor, invested with large powers for the maintenance of the public peace, through the agency of the district

superintendent of police, for the collection of the public revenue, and for promoting in every conceivable manner the well-being of the people. The collectors have each two or more assistants, who are also magistrates, and are controlled by the Commissioners, who are rulers, under the immediate control of the Governor in Council, of divisions consisting each of several collectorates. In the Bombay Presidency, including the Province of Sind, there are four Commissioners. The average area governed by each of them exceeds 31,000 square miles, and is, therefore, a little more than one-fourth of the area of the British Isles. The average population of each commissionership exceeds 4,700,000. That is, it is about one-eighth of the population of the British Isles. Including Sind, and excluding the city of Bombay and Aden, there are twenty-three collectorates or districts in the Bombay Presidency. The average area of each district amounts to 5,436 square miles, and the average population to 784,142. The two members of the governor's council—who, in the Madras and Bombay Presidencies, exercise co-equal powers jointly with the governor, and are appointed to their offices by Her Majesty—the commissioners of provinces or divisions and the collectors and their assistants, with the exception of the small number of officers already referred to, belonging to the Provincial and Statutory Services, are members of the Imperial Civil Service. This is the case also as regards the higher judicial officers, including, in the Bombay Presidency, three of the seven judges of the High Court (who are appointed to their offices by Her Majesty), the judicial commissioner and judge of the Sadar Court (the highest court of appeal) in Sind, the judges of first appeal in each district (who preside in the district courts under the code of civil procedure, and are also sessions judges under the code of criminal procedure) and their assistants. The secretaries and under-secretaries to Government, except in the Department of Public Works, the Municipal Commissioner of Bombay, and the Deputy Municipal Commissioner, the Postmaster-General, the Accountant-General, and some political officers are also at present members of the Indian Civil Service. The offices of Municipal Commissioner, Postmaster-General, and Accountant-General are not, however, reserved by law to the Civil Service. The office of Director-General of Agriculture is also held in the Bombay Presidency by a Civil servant, and the office of Inspector-General of Police at one time was so held. Two of the members of the Viceroy's Council, and the Lieutenant-Governors of Bengal, the Punjab, the North-Western Provinces, and Burma are also members of the Imperial Civil Service. It is, obvious, therefore, that duties of special importance, on the right performance of which the safety and progress of the empire largely depend, are demanded from the comparatively small staff of officers composing that service. The area of British India, including Upper and Lower Burma, but excluding the Feudatory

States, comprises about 965,000 square miles, or nearly eight times that of the British Isles; and the population, at the date of the last census, in 1891, amounted to more than 221,000,000, or to nearly six times that of the British Isles. The administrative requirements of this wide extent of territory and this enormous population are provided for by about 1,000 officers of the Imperial Civil Service. That is to say, the proportion, roughly speaking, is one such officer to every 965 square miles of territory and 221,000 inhabitants. Other officers of the higher grades, who are not members of the Imperial Civil Service, are employed on important and responsible duties connected with the control of public works, public education, State forests, medical institutions, and public sanitation. Hence the necessity for special care in recruiting for the higher civil offices of the public service, and the real justification of the policy which is content with no poorer recruiting ground than that which meets so completely the requirements of public life in England. The policy has been justified by its results. The high tone imparted to the civil administration by the great men—soldiers and civilians—who broadly laid its foundations, has been maintained by the civilians and the soldier-civilians who have raised the edifice to its present dimensions; and the touchstone of trouble has, in the recent years of plague and famine, revealed to the whole civilised world the worth of the men who have borne with steadiness the strain which has been put upon them.

The Provincial, Statutory, and Subordinate Services are, as I have already said, recruited in India, and many members of these services have been educated in colleges affiliated to the Indian universities, which were established by the Government of India in the dark days immediately following the outbreak of the Indian Mutiny. Though these universities, by their constitution, are not teaching institutions, but boards having the control of examinations, on the model rather of the London University than of Cambridge, Oxford, Edinburgh, or Dublin, yet, by the exercise of the powers conferred on them by law, for regulating the examinations for degrees and the course of instruction to be undergone by candidates for degrees, they can clearly influence the course of study in all teaching institutions. The avowed object of their establishment was "the better encouragement of Her Majesty's subjects of all classes and denominations . . . in the pursuit of a regular and liberal course of education." But quite apart from any considerations having reference to the advancement of learning, it may be assumed that one of the principal objects of the Government of India, in making provision for the requirements of higher education, was to raise up a staff of indigenous officers, well prepared by a course of liberal education, in the English sense, to appreciate and assimilate our methods of civil government and so to become qualified to take their share in the work of administration, in co-operation with the officers who

enter the Imperial service by open competition in England. Such an assumption is entirely consistent with the terms of the proclamation of 1858; and in the Bombay Presidency, of which alone I can speak from personal knowledge, the policy of our University Acts, which must be regarded as an essential feature of our Imperial system, has been successful; certainly so far as the Hindu and Parsi communities of that Presidency are concerned; but, unfortunately, as regards the Mahomedan community, which has never fallen into line with our educational policy, no such proposition can be affirmed. Young Mahomedans, as a rule, avoid our educational institutions, and thus fail to acquire the requisite qualifications for the public service.

From a statement prepared for me by the Registrar of the Bombay University, two years ago, it appears that, in 36 years, 3,641 degrees had been conferred in the four faculties of arts, law, medicine, and civil engineering. It is estimated that, during the same period, 1,200 graduates had entered the liberal professions in the Bombay Presidency and that there were, in 1897, about 465 graduates in the public service of that Presidency, of whom 182 were employed in the Educational Department. We have thus succeeded in securing the co-operation of educated Indian officers which has been of the highest value. In the judicial, revenue, educational and public works departments, and also in the departments which deal with medical affairs, the administration of hospitals and dispensaries and public sanitation, educated Indians are rendering efficient and loyal service, and in some conspicuous instances, brilliant service of a high order. Indeed the great majority of Civil officers are necessarily and always have been natives of India, though the fact seems sometimes to be lost sight of.

I should like to say a few words regarding the state of the several departments which, in Western India, are classed under the general head of "judicial," and are the departments mainly concerned with the protection of life and property, and the administration of justice; that is, in securing for the people of India some of the special benefits which Sir Raymond West has described as peculiarly characteristic of British rule. The police force throughout India has, in recent years, been called upon to discharge duties which have been exceptionally severe and has acquitted itself satisfactorily. When serious riots occurred, a few years ago, between Mahomedans and Hindus in many places, far apart from each other, they were invariably put down with promptness and vigour by the ordinary police force, with the aid, of course, of the troops in exceptionally serious cases; and the utmost vigilance was used to prevent possible disturbances of the peace in places where the relations of the two communities were known to be strained. It was only the restraining presence of British authority that often prevented bloodshed and rapine; and indeed, as I have already observed, the maintenance of public order is the key-stone of our administrative system,

on which depends the stability of our whole scheme of impartial government. It is by the systematic repression of all forms of lawlessness that we place ourselves in a position to give effect to plans for the welfare of the people. As regards the police of the Bombay Presidency, much undoubtedly still remains to be done for its improvement, especially in the unarmed branch employed on the detection and investigation of crime. Its deficiencies have not been overlooked, and the entire force has been reorganised within the past few years, one of the objects having been to secure a better class of men for these particular duties.

And when crime has been detected and the offender brought before the magistrate, the proceedings are thenceforth conducted by the criminal courts with the fairness and regularity demanded by the provisions of the Criminal Procedure Code of 1882, which has assumed its present comprehensive form only after repeated deliberations in the Council of the Governor-General, beginning with the year 1860—the year in which Macaulay's famous Indian penal code was enacted—which has stood the test of time, having been rarely amended by subsequent Acts. The decisions of the criminal courts, according to their grades, are subject to appeal to the District Magistrates or to the Courts of Session or the High Courts; and the proceedings of all courts of inferior jurisdiction are subject to revision by the High Courts. Every opportunity is afforded for the rectification by a superior court of irregular or illegal proceedings prejudicing the course of justice; and there can be no sort of question that the people appreciate our judicial system, as administered under the judicial control of a succession of most capable Chief Justices and Judges in the several High Courts. It is in the administration of justice in the civil and criminal courts that native talent has most effectively aided the cause of good government, the great majority of the magistrates throughout the country and the judges of the civil courts of first instance outside the Presidency towns being Indians, who are represented also in the District Courts and the High Courts. In the Bombay High Court two of the seven judges are Indians. And as regards the judicial branch of the Provincial Civil Service, I have no hesitation in saying that, in the Bombay Presidency, at all events, it has distinctly improved in tone during the last thirty years; and I would add that, though this improvement is due partly to the enhanced attractions of the service, consequent on a liberal revision of salaries, it must also be ascribed in part to the extension of higher education. In the Bombay Presidency, about 25 per cent. of the Subordinate Judges (who are members of the provincial service, and judges of the civil courts of first instance, a few only having appellate powers) are graduates, yet the remaining 75 per cent. have qualified themselves for their appointments by passing a severe examination in law prescribed by the High Court. The judicial service is, therefore, practically manned by the educated classes.

And here I should like to direct your special attention to some noteworthy matters connected with the actual administration of justice in British India. Although, in respect of criminal proceedings, the legislature has (by chapter 33 of the Code of Criminal Procedure of 1882) made special provision for the trial of European British subjects, who, in certain cases can, if so advised, claim that the presiding magistrate or judge shall himself be a European British subject, yet in civil matters, in all courts of original jurisdiction outside the Presidency towns, they have no similar privileges, but must sue or be sued before the presiding judge, whatever his nationality may be, that is, practically, before a native judge. "Equality, uniformity in such matters," as observed by Sir Raymond West, "has appeared to the English as the natural and necessary course of things. To any other dominant people it would have been intolerable."

And then, again, chapter 27 of the Code of Civil Procedure provides for the institution of suits against the Secretary of State in Council, or any public officer, in respect of acts done in an official capacity. Subject to certain exceptions, enacted in the Bombay Revenue Jurisdiction Act of 1876, the legality of any executive action taken by the Government, or by any officer of the Government, can thus be questioned and redress obtained by the injured party, in proper cases, in the civil courts having jurisdiction in such cases. England is, I believe, the only European country in which any similar system is in force.

And, again, since the days of Warren Hastings, respect has been shown for the ancient usages and institutions of the country by the adoption of a policy, at once truly sympathetic and considerate, in pursuance of which our civil courts decide all disputes as to rights of inheritance and succession, and the devolution and distribution of property, and various other civil matters of vital importance, in accordance with the personal law of the party concerned; that is, according to the Hindu law or the Mahomedan law, as the case may be; though, as regards the administration of criminal justice and the application of rules of evidence and procedure to judicial proceedings, and also as regards certain civil matters provided for by express enactment, the laws of British India prevail generally.

When offenders are sentenced to imprisonment or transportation, their lives are thenceforward regulated according to a system of jail management, the details of which have been settled by some of the best minds in India. I doubt whether any other country possesses a punitive and reformatory system worked on sounder principles than that in force under the Indian Prisons Act of 1894. The late Austro-Hungarian Consul-General in India, Herr Schmucker, once expressed to me the surprise and pleasure it gave him to inspect the arrangements at the great Central Jail at Yeroda, near Poona, which he described as admirable beyond all his anticipations.

In conclusion, I will adduce a few facts only in

illustration of Sir Raymond West's third contention as to the material prosperity of the people which the Indian Government has always striven to secure. I have already spoken of the evidence of increasing wealth in the city of Bombay, and similar indications are not wanting elsewhere. I do not propose to give even a summary of the operations of the departments more immediately concerned with the material advancement of the Indian ryot—of such departments, for instance, as the great Land Revenue Department, the Forest Department, the departments concerned with agriculture and mineral resources, or with the control of factories, and the great Public Works Department, which is concerned not only with public buildings and ordinary civil and military works, but with railways and other means of communication, and with irrigation schemes. The most cursory perusal of such an official document as the Statement, exhibiting the moral and material progress and condition of India, annually presented to Parliament, will serve to show how wonderful the progress has been. "Practically," as Sir Raymond West observes, "a new world has been created, a new faculty conferred on the millions heretofore condemned to live and die in stagnation, prevented from gathering the riches of the teeming earth by physical, political, and fiscal isolation." A measure, the merits of which have been much discussed, is the Bombay system of survey and settlement, on which, as on all such systems throughout India, the welfare of the peasantry must largely depend. Though this particular system may have its defects, there is nothing, so far as I know, to show that the general standard of comfort in the rural districts was ever so high under any former rule as it is now in British territory. The general condition of the people has, I believe, vastly improved in our time; and on this point I can adduce the evidence of Sir Bartle Frere, contained in a speech made in the Bombay Legislative Council at the time when the Survey and Settlement Act of 1865 was under discussion. One of the strongest opponents of certain provisions of that Act, the late Rao Saheb Wiswanath Narayen Mandlik, a man of sturdy independence of character, whose worth was recognised both by the Governor and by the Viceroy, of whose Legislative Councils he was a member, was always ready to bear cordial testimony to the advantages generally conferred by our revenue system on the Indian ryot. And then such specific facts and figures as these, taken almost at random from the last Material and Moral Progress Statement, speak for themselves. Inclusive of a few mills in feudatory States and in French territory, there are now 163 cotton mills in India worked by steam, of which 114 are in the Bombay Presidency. They represent a nominal capital of 150,000,000 rupees, and employ a daily average of more than 148,000 hands. They contain nearly 37,000 looms, and 4,210,756 spindles, and use more than 4,500,000 cwts. of cotton. This industry dates only from 1851, when the first mill was started. Since 1879 it has increased threefold.

Among other large industries reported on in the Statement are 7,612 indigo factories, 1,745 saltpetre refineries, 674 cotton ginning factories, cotton presses, jute presses, 174 oil mills and wells, 151 tanneries, 134 clutch and lac factories, 109 pottery and tile factories, 96 sugar factories, 86 iron and brass factories, and, in small numbers, silk mills, soap factories, coffee works, cotton and woollen spinning and weaving establishments, not classed as mills, rope factories, flour mills, ice factories, bone crushing factories, tobacco and cigarette factories, and dye works.

The largest number of factories subject to the Indian Factory Act is in the Bombay Presidency, there being 130 in the City of Bombay alone; and factory labour there is attractive, the condition of the factory hands being somewhat better than that of the ordinary cultivators.

In reference to the tea industry in Assam, I note the fact that, in 1897-98, the number of persons working in tea gardens increased from 465,000 to 478,200. The number of labourers who immigrated into Assam was 95,900, as against 81,000 in the preceding year. Throughout India the tea gardens employ 662,000 labourers. The total exports of Indian teas by sea increased from 78,750,000 lbs. in 1886-87 to 151,500,000 lbs. in 1897-98. About 137,000,000 lbs. were exported in the latter year to the United Kingdom; and, whereas, in 1865, only 2 per cent. of the teas imported into the United Kingdom were Indian teas, 93 per cent. being from China, in 1898 India sent 53 per cent. of our tea imports, the per-centage from Ceylon being 36, and that from China only 10. The exports of tea by land into neighbouring countries amounted, in 1897-98, to 870,000 lbs., and the value of the total tea exports to more than 80,000,000 rupees.

Again, in 1898, the railway lines on the standard metre and special gauges extended to 21,865 miles, as against 20,877 in 1897. With an increase of more than 4 per cent. in the open mileage, there was an increase of about $7\frac{3}{4}$ per cent. in the net earnings. The total number of passengers in 1898 showed an increase of 461,373, and the number of tons of goods handled an increase of 1,732,070, as compared with 1897.

These are mere samples of the results recorded; but I trust I have said enough to show that England has done her duty by her great dependency, and that the system of civil administration she has established in India is a sound system, capable, so long as the civil establishments are rightly recruited and wisely controlled, not only of meeting the present wants of the country, but of steady development also, in view of future requirements.

MINERAL STATISTICS.

The third part of Dr. Clement Le Neve Foster's "Report on Mines and Quarries for 1895" has just

been issued. It contains the statistics relating to the output and value of the minerals raised in the United Kingdom, the amount and value of the metals produced during the past year. The total value of all minerals raised in the United Kingdom in 1898 exceeded £77,000,000, an increase of more than £5,000,000 compared with the previous year. This increase in value is mainly attributable to the higher prices obtained for coal, thus the quantity of coal obtained in 1898 was 202,054,516 tons, as compared with 202,129,931 tons in 1897, while the value at the mines in 1897 was £59,740,009, and in 1898, £64,167,382.

Taking the various divisions of the United Kingdom separately, it appears that England produced minerals worth £55,000,000, Wales £10,500,000, Scotland £11,000,000, Ireland less than £250,000. The principal mining counties, whether judged by the minerals produced, or number of persons employed, are:—Durham, with an output of 34,737,347 tons of coal; Yorkshire, with 25,639,021 tons of coal, and 5,785,588 tons of iron ore; Lancashire, with 24,324,685 tons of coal, and 749,429 tons of iron ore; and Glamorganshire, which yielded no less than 19,140,742 tons of coal, in spite of a strike lasting five months. In these four great coal counties is concentrated nearly one-half of the mineral industry of the kingdom.

The export of coal was about half a million tons less than in 1897, but it still amounts to 36,500,000 tons, and Dr. Foster considers that this is quite enough to cause anxiety in the minds of those who dread the depletion of the national supply.

Dr. Foster adds that the proper husbanding of the coal resources of the kingdom is a question of national importance, and he calls attention to the warning of Mr. T. Forster Brown, who, in his paper upon "Our Coal Supplies," read before the Society of Arts (*Journal*, ante p. 506), stated that in another fifty years the dearth of cheap coal will begin to be felt.

In the case of iron ore the British mines and quarries are increasing their supplies, though the total output is still nearly 4,000,000 tons below the high-water figures of 1880 and 1882. In the case of the ores of copper, tin, and zinc higher prices for the metal have had the natural effect of increasing the output, but even this stimulus has been insufficient to prevent the continuous fall in the production of lead ore. A small quantity of gold continues to be found in Merionethshire, but in 1898 the output dropped to 395 ozs., the amount obtained for which as bar gold was £1,299. The amount of gold obtained in 1897 was 2,032 ozs.

PEAT FUEL IN CANADA.

According to the United States Consul at Stratford (Quebec) the most serious problem that confronts the Canadian people of the future is material for fuel. The gigantic lumber industries and the great annual

forest fires have so denuded the timber area of Ontario that the people are thoroughly alarmed about the future fuel supply. It has been well known for years that there were extensive beds of peat bogs in Canada and particularly in the province of Ontario. An effort has been made during the past six months to utilise this product of nature, and the recent invention of machinery, by means of which vast areas of hitherto unused bogs can be converted into marketable peat has opened up a new Canadian industry. The origin of peat bogs is well understood. They occur in low situations or where some natural or artificial obstacle impedes the drainage. Abundant moisture favours the growth of a low order of plants, such as the *sphagnum* mosses. This plant is noted for its absorption of water. Its structure is that of reservoirs in successive layers, which are kept filled by capillary attraction, even when the plant itself is above water level. The same properties of the moss tend also to its decay. It requires a constant supply of moisture, yet it is continually pumping up to the surface of its tufts the water in which it stands, thus promoting evaporation, while at the same time, by regularly decaying at the roots, it deposits the detritus which adds to the solid contents of the bog. This process goes on until the bog is raised above the level of the surface waters, when *sphagnum* vegetation ceases. The best authorities say that there are 100,000 acres of this undeveloped peat bog in Ontario, principally in the counties of Perth, Welland, and Essex. The largest area lies in the county of Perth, eight miles north of the city of Stratford, on the Grand Trunk Railroad that extends from Port Dover to Owen Sound. Here is a swamp of 40,000 acres with a depth of great bog that varies from a foot to 20 feet. About a year ago the Canadian Peat Fuel Company was organised, and early in the summer active operations to put the fuel on the market began. The process of manufacturing is as follows:—The peat is cut and air dried, after which it is pulverised by being passed through a pickler, and automatically deposited in a hopper which feeds a steel tube about two inches in diameter and fifteen inches long. The pulverised peat is forced through the tube by pressure and formed into cylindrical blocks three inches in length and almost equal in density to anthracite coal. In weight the fuel compares with coal as follows:—83 pounds per cubic foot of peat equals 73 pounds of bituminous, or 93 pounds of anthracite coal. It is claimed for peat that it is superior to coal in its absolute freedom from sulphur and the absence of smoke, soot, dust, and clinkers during consumption. In a great measure this solves the problem of furnishing a cheap, clean, uniform, and reliable fuel for all domestic purposes, as it is equally serviceable for grates, stoves, cooking-ranges, and furnaces, giving a long bright flame and intense heat almost from the moment of ignition. It has been tested in locomotives with excellent results, showing that the thermal value of 100 pounds of peat is equal to 95.15 pounds of coal. It was also tried at the power-house

of the Metropolitan Street Railway, Toronto, and gave great satisfaction. The heat produced was much greater than that of coal, but it was 8 per cent. deficient in lasting power. The machinery used in manufacturing fresh fuel is not expensive and requires but little attention when in operation. The company claims that when the works are fairly started it can produce compressed peat fuel for about 2s. 6d. per ton.

COTTON INDUSTRY.

The Board of Trade returns for the past month respecting our total shipments of cotton piece-goods show an increase on the same month of last year and the year before. The figures for the past nine months are:—4,096,376,400 yards; the amount for the same period in 1898 was 3,842,208,100 yards.

The countries showing an increase this year on the same period in 1898 are:—

	Yards.
Bombay	95,900,000
Bengal and Burmah.....	63,600,000
Foreign West Indies	36,600,000
China	25,300,000
Morocco.....	23,600,000
Venezuela	21,500,000
U.S. of America	18,600,000
Central America	10,000,000
Chili	10,000,000
Phillipine Islands.....	9,300,000
Madras	8,700,000
Egypt.....	6,300,000
Dutch Possessions in India.....	5,800,000
West Coast of Africa, Foreign....	5,500,000
Portugal.....	5,500,000
Persia	5,300,000
Mexico	4,500,000
West Coast of Africa, British ...	4,100,000
Republic of Colombia.....	3,600,000
Canada	3,600,000
Australasia	3,300,000
Greece	2,700,000
France	1,700,000
Argentine Republic.....	1,300,000

The chief cases of decrease are:—

Brazil	47,800,000
Turkey	40,000,000
Japan	23,700,000
Straits Settlements	14,600,000
Germany	3,600,000
British Possessions in South Africa	5,600,000
Uruguay	2,700,000
Malta	900,000
British West India and Guiana....	800,000
Italy	800,000
Austrian Territories.....	500,000

A feature of interest in our shipments so far this year is that India has taken about 44 per cent. of our total exports of calico. China has done fairly well, and so has the United States. Japan is doing a

little better at the moment, but during the last three-quarters of the year she has disappointed Lancashire. Manufacturers in this country continue, on the whole, deeply engaged for some months to come. All available looms are fully at work, and it would not be surprising, in view of the present state of affairs, to see more loom sheds erected in North and North-East Lancashire. The margin between cotton and cloth and between yarn and cloth has been more remunerative than for some time back. The whole appearance of the weaving trade is healthy, with no discouraging prospects for the next six months. The recent upward movement in cotton has restricted business to an important extent; that is to say, few contracts from the great consuming markets of the East have been placed at the advanced quotations. Business, in point of fact, has been upset. Until the raw material assumes its normal state, trade will not be fully resumed. The home department is also healthy, with no special feature worth mentioning.

Our shipments of cotton yarn for last month were pretty much the same in weight as in the corresponding month of last year, but the aggregate shipments for the past nine months do not look well as compared with the same three-quarters of the year 1898. The amount for the nine months ended September 30th, 1899, was 160,214,100 lbs., while for the same period in 1898 the amount was 184,140,400 lbs.

Lancashire spinners from American cotton for home consumption have all this year experienced a fairly remunerative trade. Just now, as previously stated, business has been largely restricted by the important advance in cotton. Users of cop twist and weft have operated very sparingly indeed. We should say that during the last month scarcely one-third of the output of the spindles has been sold, still producers have heavy order-books, though they are lighter than a month ago. The production is fully absorbed by the looms, no stocks being heard of in any direction. There are a number of new mills being built, and last week several additional factories were projected. It looks as if in twelve months' time from now there will be close upon 1,000,000 more spindles running than to-day. Shipping yarns have rather lagged behind. Bolton spinnings have been very strong indeed. It is a long time since the finer counts were so deeply under contract.

Mr. Henry Neill has made a statement of a definite character relating to the probable growth of the American cotton crop. He considers that there will be a yield of at least 11,000,000 bales, however early a real killing frost may come. These figures are to be looked upon as his minimum estimate. Other authorities have given out lower figures, and it remains to be seen what the output will be. In the meantime Lancashire spinners, on the whole, are putting their faith in Mr. Neill. During all the recent excitement they have bought sparingly on spot, not being disposed to follow the upward course of prices. The Egyptian cotton crop is understood to be of satisfactory dimensions.

An agitation is on foot amongst cotton operatives to reduce the hours of labour by one hour, the present legal time being $56\frac{1}{2}$ hours. The Cotton Employers' Parliamentary Association, which covers the whole of the staple industry, are preparing to strongly oppose the proposal in view of the keen competition abroad and the longer hours worked there. The masters' secretary (Mr. W. Tattersall) has asked the Foreign-office for a return of the hours of labour in foreign cotton mills.—*Economist*.

CITY AND GUILDS INSTITUTE.

The annual report of the Examination Department of the City and Guilds of London Institute for the advancement of technical education for the session 1898-99, has just been issued, from which it appears that the total number of students in the classes registered by the Institute was 36,155 as compared with 34,990 in the previous session, and the number of candidates examined was 14,978 as compared with 14,148.

The exhibition of the students' practical work, executed in connection with this year's examination, was on a larger scale than usual, and was arranged in the North Gallery of the Imperial Institute. The exhibition was opened on June 9th by the Duke of Devonshire, Lord President of the Council, who in his address reviewed the work of the Institute.

Its special work has been to supplement the scientific and artistic teaching of the Science and Art Department by practical classes in what is termed "technology"—*i.e.*, instruction whose object is to familiarise a student with the processes and details required in the trade for which he is destined, and to show him how the knowledge he has acquired at lectures or from books may be applied to the practical performance of his business.

The record of the Institute's work is a tale of continual progress. In 1885, six years after its commencement, there were 263 classes held at 167 centres, attended by 6,396 students. In the year just ended (1898-99) there were 1,764 classes at 397 centres, attended by 34,176 students, the number of subjects for examination being 63, as compared with 42 in 1885 and 24 in 1880. The number of candidates' papers was 14,004, and the number of passes 7,962. The subjects which attract the largest number of students appear to be wool and worsted weaving, cotton spinning, cotton weaving, telegraphy, and telephony, electric lighting (preliminary work), plumber's work (preliminary), typography, carpentry and joinery, dressmaking, millinery, and plain cookery. The committee report that the relations between the Institute and various trade organisations have been strengthened and widened during the past session, and the examinations in typography and millinery are specially mentioned in this connection.

The operations of the Institute are not confined to London. In 276 towns of the United Kingdom

technical instruction is given in connection with the Institute, while examinations have been held this year in India, New South Wales, New Zealand, Barbadoes, and Jamaica. Applications have been received for the holding next year of examinations in other colonies. It is in the large manufacturing towns of the north that most energy has been thrown into technical instruction. Manchester and Salford, for instance, with a united population of three-quarters of a million, have nearly half as many students as London, with a population of four and a half millions.

The committee note with satisfaction that the powers of the new Education Board have been so widened as to enable it to recognise the educational work done under the direction of the institute. It is now generally understood that technical education must form a distinct branch of that Board's work; and a well-organised Technical Instruction Department will probably include sections for science, art, technology, and agriculture. The work of the City and Guilds of London Institute will thus fall directly within the scope of the reorganised Education Department. Its committee recommend that the teaching of technology be placed on the same basis in regard to State aid as that of science and art.

LIQUID AIR AS A BLASTING AGENT.

The *St. James's Gazette* quotes from a foreign source an account of a series of tests of liquid air made a few weeks ago by the Vienna Crystal Ice Company in the presence of representatives of the Austrian Technical Military Committee. The fluid was obtained from Linde's works in Munich, and conveyed to Vienna in open flasks, having the Dewar vacuum jacket to check evaporation. When it was dispatched the mixture contained 75 per cent. of oxygen; but 72 hours later, when the stuff was used, enough nitrogen had evaporated to make the per-centage of oxygen 85. Cartridges were made of liquid air, mineral oil (petroleum), and Kieselguhr. The oil seems to have taken the place of charcoal in gunpowder in supplying an inflammable material which would develop a large quantity of gas. The liquid air was almost pure oxygen, and tended to promote combustion. The Kieselguhr served the same purpose that it does in dynamite. It is a silicious earth used as an absorbent to hold the nitro-glycerine. The cartridges are spoken of technically as "oxylignite." They were prepared in two ways. First, the Kieselguhr and oil were mixed in a basin, and the liquid air was added gradually. The resulting paste was ladled into the cartridge case, which was coated with asbestos, probably to check the absorption of heat from surrounding substances. The second method of preparation was to charge the cartridge with Kieselguhr and oil, and add the liquid air later. The second set of cartridges were encased in sheet lead. Owing to the intense cold the men did not care to handle the cartridges vigorously,

and there was difficulty in attaching detonators and fuses. In the meantime much of the oxygen evaporated, especially from the cartridges having lead cases. These latter proved weaker than the first set. One of them missed fire altogether. The cartridges were inserted in holes thirty inches deep in the rock when fired. Artillery General Engineer Hess made the following comment on the tests:—"The preparation of the cartridges is wasteful and dangerous to the eyes, and, owing to the rapid evaporation, it is further impossible to guarantee the strength of the cartridge, even in the roughest way. Kieselguhr and oil seem to be suitable absorbents, and oxylnignite an effective blasting agent, though comparative tests have not been made yet. The cartridges must be used within, say, fifteen minutes of their preparation. There is no danger, hence, from missing fire. But, on the other hand, it will be difficult to fire many cartridges simultaneously, and, strictly speaking, the cartridges should be made on the spot, and be in a very hard condition. That would scarcely be possible below ground; the spurting liquid might break the glasses of the hot safety lamps, and it remains to be investigated whether the large volumes of oxygen might not lead to spontaneous ignition of marsh gas or coal dust. The evaporating oxygen would, on the other hand, improve the air, and the blasting would not contaminate it."

AUSTRALIAN QUICKSILVER.

Although quicksilver has not hitherto occupied other than a minor position among the metals of New South Wales, there are indications that in the near future it will be found one of the most valuable of the numerous metallic products of the colony. The presence of native mercury, or quicksilver, in New South Wales was ascertained so far back as 1841, when the Rev. W. B. Clarke, the well-known Australian geologist, received a sample from a creek on the Cudgegong River, an auriferous stream, rising in the Australian Alps, and flowing through a portion of the western goldfields of the colony. Cinnabar had previously been found in the same locality. It has also been discovered in a few other places, but although Mr. Clarke, with a view to stimulating systematic search for the metal, published a popular description of the ores of mercury, little or nothing further was done. In later years mercury, in the form of cinnabar, was found at Bingara, where there are several diamond mines; in the vicinity of the Solferino goldfields; and at Cooma, at the entrance to the New South Wales snow country, where the assays of ore yielded 25 per cent. of quicksilver. The richest deposits have, however, been discovered near Yulgilbar, in the Clarence River district, one of the most fertile and beautiful in Australia, sugar cultivation being a staple industry. Some four years ago prospecting was carried on in the hope of finding a payable quicksilver deposit, and

the New South Wales Department of Mines dispatched its mineralogist, Mr. J. E. Carne, to inspect and report upon the workings, with the result that that gentleman, after a most careful examination, recommended that a portion of the Government prospecting vote be devoted to assisting the prospectors in their search for the lode which was suspected to exist, and, if successful, to ascertain whether or not the deposits would eventually become payable. Since then considerable developments have been made, and six distinct shafts have been put down on three parallel lodes. Several tons of the ore from these lodes have been brought to Sydney, and quantities of it distributed among the various Government departments for examination and testing purposes. The ore is expected to yield from 3 to 5 per cent. of mercury, and it has been ascertained that the "spent" ore contains gold and silver. The area of the ground examined by the Government geologist is about 120 acres, but it is believed that with the progress of prospecting operations other lodes, more or less rich, will be found. A further examination of the locality is being made by the Government geologist, and his opinion is being anxiously awaited. He has definitely ascertained the existence of three distinct parallel lodes, the first discovered in the colony, and improving as they go down. When the quicksilver mining industry is fairly established, a large population will become attracted to this part of the colony, which has been for many years portion of an immense pastoral property, and but little known. Machinery is being erected, and a preliminary testing of about one thousand tons of ore will be made. Should the results prove satisfactory the New South Wales quicksilver trade will become revolutionised, as the poorest assays show the ore to be richer than those of the American and Spanish mines. They will also encourage the search for other cinnabar deposits, which, there is every reason for believing, are more numerous and richer than generally assumed. The value of the discovery in connection with the colonial gold-mining industry can hardly be over-estimated. It simply means that the work of gold production will become enormously stimulated, thereby greatly increasing the already large auriferous output of the colony.

ELECTRIC HEATING.

The new Carmelite Hospice on the Canadian side of the Niagara Falls is provided with complete electric heating and cooking apparatus, and the following description of the installation, taken from the *Electrical World and Engineer*, is printed in *Science Abstracts*:—

"Three-phase current at 2,200 volts is carried on No. 3 bare copper wire from a supply station distant two miles. It is transformed to 110 volts by two 30-kilowatt and one 25-kilowatt transformers at the Hospice. A switch-board, with double-throw switches,

controls two phases of the current, and the third phase is controlled by an adjacent switch-board, and is used for cooking, lights, &c. Power amounting to 100 horse-power is taken by contract, 25 horse-power of which are used for lighting (200 16-candle-power lamps), cooking, and heating water, while the remaining 75 horse-power is applied to heating the lower floor of the building, containing eleven bedrooms, dining-room, reception-room, and corridor. Each bedroom is 15 X 12 X 10 ft. high, and contains one 4 horse-power heater, with two heats. The corridor is 120 X 15 X 10 feet high, and contains nine 4 horse-power heaters. The kitchen contains one electric range and three ovens. The range has 6 square feet of heating surface, each square foot consuming 15 amperes, and having a two-heat switch. The small ovens take 23 amperes at 110 volts, and the large one 50 amperes. Four 25 lb. roasts can be handled at one time. The pantry has three 5-gallon electric urns for tea, coffee, and hot water. Close to the switch-board are two electrically-operated boilers, one holding 400 gallons and the other 150 gallons. The former, which supplies the laundry and baths, takes 120 amperes and has three heats. The latter supplies the kitchen, and takes 125 amperes, being principally used for quick boiling. On the opening day the kitchen electrically cooked dinner for 250 people. The big boiler will heat water from 60° Fahr. to 212° Fahr. in six hours. The small ovens bake bread in 18 minutes. The large oven is furnished with a thermometer. The current for water-heating, cooking, and lights costs \$25 per horse-power, or \$625 a year, while the 75 horse-power used in warming the building is secured at about one-fifth of this price per horse-power. The plant, as a whole, requires little care for its operation, and gives great satisfaction."

STORAGE OF WATER.

Under ordinary circumstances the open storage of water tends to improve quality, owing to beneficial action by aëration and light, and the only exception is in the case of deep-well water. In the vicinity of towns, however, experience has shown the desirability of covering reservoirs, so that dust and other matters floating in the air may be excluded. Different methods have been adopted for this purpose. At Vienna, the main distributing reservoir is covered in by a roof supported on granite pillars, in other places on the Continent and in Great Britain, arched roofs supported on cast iron columns or by groined arches have been largely employed, and the latter form of construction is chiefly followed in the United States. Perhaps one of the most interesting contributions to hydraulic engineering literature of recent date has been a paper presented to the American Society of Civil Engineers. The paper in question evidences careful study and research, whilst the tabulated results add materially to its value. It is mentioned by the author that all the examples of the groined

arch in waterworks engineering which have come to his notice are to be found in the United States. As we have already indicated, such applications are by no means new in Europe, and the reservoirs of Menilmontant, Belleville, and Montsouris include notable instances of such construction. The last-named has arching in the "Guastavino" method, which, as a matter of fact, was recently introduced into America. Many advantages are, no doubt, offered by grained elliptical arches; the quantity of material is moderate, there is clear head room in each direction, and the arrangement is favourable for ventilation. Brick has been hitherto chiefly employed as the material, but the use of concrete is now becoming more popular. As a general rule, the cost of the latter may be taken at one-half that of brick masonry, and it is suitable for almost any kind of arch. Piers are more frequently built of brick, and it is probable that no financial or other advantage is to be gained by departing from this practice. There can be no doubt that masonry coverings are pleasing to the eye, and are, at the same time, in every way satisfactory. The cost is, nevertheless, unnecessarily high, and it is likely that other designs will ultimately supersede groined arches. Concrete and steel tie-bars combined are equally durable, strong, and efficient, besides being considerably cheaper.—*Builder*.

TEXTILE DESIGNS BY PHOTOGRAPHY.

Professor Roberts Beaumont, in his introductory address in opening the Session of the Evening Classes of Yorkshire, described the new photographic process of preparing textile designs invented by Jan Szczepanik, which has attracted much attention, and his remarks on the subject are reported in the *Textile Mercury*.

On behalf of the Yorkshire College, Professor Beaumont recently went to Paris to investigate the invention. One of the results of his visit was that a number of specimens of designs prepared by the new process were on view in the lecture-room. Professor Beaumont also secured the loan of some of the actual apparatus used by Szczepanik.

Professor Beaumont prefaced his address by saying that he had spent a considerable time in examining the inventions of Szczepanik, and had seen designs worked out by the new process in the temporary premises in Paris. He also stated that the Szczepanik Company have already a plant for the preparation of designs at work in Barmen, and that they are about to form a company for the same purpose in Great Britain. The object of the photographic appliances of Szczepanik was to take the artistic sketch, and, without any modification of the same, to enlarge it to scale, to transfer it on to ruled paper or point paper, and mark it with the thousands and millions of dots arranged in the proper orders for the development of the several parts of the pattern, in the weaves necessary for giving to each suitable precision of character

when woven. The methods of working the designs were explained by lantern slides, diagrams, designs, and experiments. Professor Beaumont observed that it had been made plain that the apparatus of Szezepanik was capable of producing designs in which there was considerable diversity of woven detail, so that it was purely a question of whether the designs thus obtained were legible for all practical purposes. It was recognised that there must be limitations to its utility, as there were to all automatic and mechanical appliances. Yet if it could be employed in accelerating the process of designing large patterns, it should have the serious attention of all who desired the further development of the weaving industries. It had been thought by some that if the invention became commercially useful the sphere of the designer would be considerably restricted. This was an unsound doctrine to hold in regard to mechanical and scientific innovation. The place of the designer, the brain worker in textile factories, where fancy and decorative textures are produced, could not be assailed.

WREN'S COPYING INSTRUMENT.

In his fifteenth year Christopher Wren took out a royal patent for seventeen years, for an instrument to write with two pens at the same time, which the young inventor thus describes:—"That by its help every ordinary penman will be enabled to write two several copies of any deeds and evidences from the shortest to the longest lines in the same compass of time and with as much ease and beauty, without any dividing or ruling, as without the help of the instrument he could have written but one. That by thus diminishing the tedious labour of transcriptions of the greater sort of deeds, indentures, conveyances, charters, and all other duplicates, the works of the pen are not only shortened, but the penmen themselves both relieved and recompensed by an honest gain with half the wonted toil. That there will be in both copies thus drawn such an exact likeness in the same number and order of lines, and even of words, letters, and stops, in all places of both copies, that being once severed there shall hardly be discerned any difference between them, except such as are merely casual, as spots and marks in the parchment. That this instrument will, undoubtedly, prevent the mischievous craft of corruption, forgery, and counterfeiting of hands and seals, or if any such foul practice be attempted, will effectually and manifestly discover it; for what will it avail to counterfeit a seal, or the hand that signs, unless a duplicate could be made in every line, letter and dot, like the twin copy, which without the help of the same instrument, is impossible? So expedient might it be to all intents and uses of the State, in matters of the greatest consequence, that public Acts be written by this instrument for testimony and assurance to all times." Wren had scarcely promulgated his in-

vention when others claimed its authorship. These assumptions excited his indignation, and he asserted his right in a letter to a friend, supposed to have been Dr. Wilkins, calling to his mind the circumstance of having seen and commended it "to the view of the then great, now greatest person in the kingdom," Oliver Cromwell. He concludes his expostulatory claim by writing, "Although I care not for having a successor in my invention, yet it behoves me to vindicate myself from the aspersion of having a predecessor."—*The Architect*.

General Notes.

ARTIFICIAL PAVING STONES IN GERMANY.—Artificial paving stones are being successfully produced in Germany. The demand in all larger cities is said to be so good, and the expense attached to their production under former methods is so large, that any improvement on the older systems, whether in saving money or in producing a better stone, will be welcomed by almost all countries. The newest process in Germany is to mix coal-tar with sulphur and warm thoroughly; to the resulting semi-liquid mass chlorate of lime is added. After cooling, the mass is broken into small pieces, and mixed with glass, or blast-furnace glass slag. This powder is then subjected to a pressure of 200 atmospheres, and reduced to the form or forms wanted. The resistance to wear and tear in use is fully half as great as that of Swedish granite. Thus it commends itself through durability equal to that of many stone roads, resistance to changes of temperature, roughness of surface—giving horses a good foothold—and, finally, non-transmission of sound. Inasmuch, as the joints are very small, dirt is avoided, and cleaning is very easy.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, OCT. 30.—Farmers' Club, Salisbury Hotel, Salisbury-square, E.C., 4 p.m. Mr. Orlebar, "Foreign Agricultural Education."

THURSDAY, NOV. 2.—Linnean, Burlington-house, W., 8 p.m. 1. Rev. Prof. Henslow, "The Proliferous State of the Awn of Nepal Barley." 2. Dr. W. G. Ride-wood, "The Hyobranchial Skeleton and Larynx of the new Aglossal Toad, *Hymenochirus Boettgeri*." Mr. Harold Wager, "The Eye-spot and Cilium in *Euglena viridis*."

Chemical, Burlington-house, W., 8 p.m. 1. Mr. J. Lewkowitsch, "The Theory of Saponification." 2. Mr. F. G. Edmed, "The Action of Dilute Nitric Acid on Oleic and Elaidic Acids." 3. Messrs. Siegfried Ruhemann and H. E. Stapleton, "Tetrazoline." 4. Mr. Bevan Lean, "Ethylic Dibromobutanetetracarboxylate and the Synthesis of Tetrahydrofuran-*a,a'*-dicarboxylic Acid." 5. Mr. M. O. Forster, (a) "Camphoroxime" (Part III.—Behaviour of Camphoroxime towards Potassium Hypobromite); (b) "Optical Influence of an Un-saturated Linkage on certain Derivatives Bornylamine."

Journal of the Society of Arts.

No. 2,450. VOL. XLVII.

FRIDAY, NOVEMBER 3, 1899.

*All communications for the Society should be addressed to the Secretary, John street, Adelphi, London, W.C.***Notices.****ARRANGEMENTS FOR THE SESSION.**

The First Meeting of the One Hundred and Forty-sixth Session will be held on Wednesday evening, the 15th of November, when an Address by SIR JOHN WOLFE BARRY, K.C.B., F.R.S., Chairman of the Council, will be delivered.

Previous to Christmas there will be Five Ordinary Meetings, in addition to the Opening Meeting. The following arrangements have been made:—

NOVEMBER 15.—Opening Address of SIR JOHN WOLFE BARRY, K.C.B., V.P.Inst.C.E., F.R.S., Chairman of Council.

NOVEMBER 22.—“National Forestry.” By D. E. HUTCHINS, Conservator of Forests, Cape Town. GENERAL MICHAEL, C.S.I., will preside.

[In Mr. Hutchins's absence at the Cape, Prof. W. R. Fisher, of Cooper's-hill, has kindly consented to read the paper on his behalf.]

NOVEMBER 29.—“The Great Seals of England.” By ALLAN WYON. RICHARD R. HOLMES, M.V.C., F.S.A., will preside.

DECEMBER 6.—“Artificial Silk.” By JOSEPH CASH. SIR THOMAS WARDLE will preside.

DECEMBER 13.—“Sea Angling and Legislation.” By F. G. AFLALO.

DECEMBER 20.—“Bi-Manual Training by Black-board Drawing.” By H. BLOOMFIELD BARE, F.R.I.B.A.

Papers for meetings after Christmas:—

“Electric Traction.” CHARLES H. GADSBY.

“Steam Motors for Common Roads.” By JOHN I. THORNYCROFT.

“The Diffraction Process of Colour Photography.” By PROFESSOR R. W. WOOD.

“Coal in South-Eastern England.” By PROFESSOR W. BOYD DAWKINS, M.A., F.R.S.

“A National Repository of Science and Art.” By PROFESSOR W. M. FLINDERS PETRIE, D.C.L.

“The Electrical Induction Motor on Mountain Railways.” By PROFESSOR CHARLES A. CARUS-WILSON, M.A.

“Ventilation without Draught.” By ARTHUR RIGG.

“The Undeveloped Resources of the Bolivian Andes.” By SIR MARTIN CONWAY.

“The Orloff Process of Colour Printing.” By W. H. WARD.

“Continuation School Work in Rural Districts.” By H. MACAN.

INDIAN SECTION.

The meetings of this Section will take place on the following Thursday afternoons at 4.30.

December 14, January 18, February 8, April 26, May 17.

DECEMBER 14.—“Round the Andamans and Nicobars.” By COLONEL R. C. TEMPLE, C.I.E.

“India in the 19th Century.” By SIR WILLIAM LEE-WARNER, K.C.S.I., M.A.

“The Industrial Development of India.” By J. A. BAINES, C.S.I.

“New Projects of Railway Communication with India.” By J. M. MACLEAN, M.P.

“Indian and English Criminal Procedure.” By SIR JOHN SCOTT, K.C.M.G., D.C.L.

FOREIGN AND COLONIAL SECTION.

The meetings of this Section will take place on the following Tuesday afternoons, at 4.30 and the first meeting on Thursday:—

November 23 (Thursday), January 23, February 27, March 20.

NOVEMBER 23.—“Old and New Colombo.” By JOHN FERGUSON. SIR THOMAS SUTHERLAND, G.C.M.G., LL.D., M.P., will preside.

“The Colonies in the 19th Century.” By The Right Hon. SIR CHARLES DILKE, Bart., M.P.

APPLIED ART SECTION.

The meetings of this Section will take place on the following Tuesday evenings at 8 o'clock:—

January 30, February 13, March 13, April 3, May 8, 29.

CANTOR LECTURES.

The following courses of Cantor lectures will be delivered on Monday evenings at 8 o'clock:—

HENRY HARDINGE CUNYNGHAME, “Art Enamelling upon Metals.” Four Lectures.

LECTURE I.—NOVEMBER 20.

What enamel is—Various styles of enamelling—Cloissoné—Champlevé—Medieval art—The Renaissance—Limoges enamels—Choice of a style in enamelling.

LECTURE II.—NOVEMBER 27.

Method of executing Limoges enamels—Preparation of the metal plate, of the enamels—The firing pailions.

LECTURE III.—DECEMBER 4.

The method of making enamels—Fluxes—The metallic oxides.

LECTURE IV.—DECEMBER 11.

The application of enamel to jewellery—Gold working—Gilding.

BENNETT H. BROUGH, "Metalliferous Deposits." Four Lectures.

January 22, 29, February, 5, 12.

E. SANGER SHEPHERD, "Photography of Colour." Four Lectures.

March 5, 12, 19, 26.

MAJOR PHILIP CARDEW, R.E., "The Control, Regulation, and Measurement of the Supply of Electrical Energy." Three Lectures.

May 7, 14, 21.

JUVENILE LECTURES.

Two Lectures, suitable for a Juvenile audience, will be delivered on Wednesday Evenings, January 3 and 10, at Seven o'clock, by HERBERT JACKSON, on "The Phenomena of Phosphorescence."

 Miscellaneous.

THE KID GLOVE AND KID SKIN
INDUSTRY IN FRANCE.

The kid glove industry of Grenoble is of ancient and doubtful origin. The town itself is situated in the centre of the finest kid skin region in France, and is surrounded by mountains where the cheap labour of the peasant women can be economically employed in hand sewing. Several centuries ago Grenoble won a well-deserved reputation for the quality of its gloves. The actual quantity of gloves manufactured was small in comparison with the output of to-day, but it appears that in 1691 the glove corporation of Grenoble was organised and founded, and that ever since that time records have been kept which testify to its importance. Since the invention of the sewing machine this industry has been gradually decentralised, and kid gloves are now made in almost every country of the civilised world. The American Consul at Grenoble says that commercial competition—notably in Belgium, Germany, England, Italy, and Austria—following closely upon the heels of this invention, has been perhaps the chief reason why

Grenoble has lost its pre-eminence in this branch of manufacture. It may justly be said, however, that Grenoble always has been, and is still, the centre of the kid glove industry, especially for the finer qualities of gloves. This industry may be conveniently divided into four main branches or departments—viz. (1) The raw skin business; (2) the dressing or alum tanning process; (3) the dyeing or staining process; (4) the actual glove-making, *i.e.*, the stretching and thinning down of the skin to its proper size and thickness, the cutting out into the shape and size required, the sewing together of the different parts, and the embroidering. The quality of the skin is best judged after the dyeing and tanning process is complete, and may be said to be based on the strength, softness, and pliability of the leather, and on the size of the skin, the fineness of the grain, and its freedom from defects, which are mainly caused by scars or diseases. These qualities of the raw skin depend on the care given to the young kid, on its breed, on the nature and abundance of its food, and on climatic influences. The finest kid skins are undoubtedly to be found in France, but this does not mean that French skins are uniform in quality. For instance, in the departments of Savoy and Upper Savoy, the skins, as a rule, are large and heavy, with a fine grain for the size; they are soft and elastic, and at the same time strong, and well suited for men's gloves. The rich pasturage of this country is an important element in the superior quality of these skins as a class. In the region of the Vosges, in the north eastern part of France, kid skins are much smaller and less elastic, owing to the fact that the animals are not so well cared for. Here the poverty of the soil is one of the reasons for the inferiority of the skins. To the west of the Vosges, on the line between Paris and Lyons, the kid skins are of a better quality. Still further west, towards the centre of France, in Touraine especially, where the pasturage is good, and the animals well cared for, the grain of the skin is fine, the skin itself is thin and strong and comparatively free from scars and disease. Farther south, towards the Spanish frontier, the quality of the skin is inferior as a rule, the poorer pasturage and hotter climate having a marked effect upon it. The peasants in this part of France are careless in their methods of work. They neglect the kids while alive, and after they have been butchered, take the skins off carelessly and prepare them for market in a slovenly manner. At least one-third of these skins are so dry that they are fit to be used only as linings for boots and shoes. Kid skins have the same general characteristics throughout the south-west of France—that is, from the Rhone to the Spanish border and the Bay of Biscay. Kid skins generally pass through several hands before reaching the glove maker or his agent. The skins of kids which are bought by the butchers in the towns, and used as a substitute for lambskins, are sold to the skin merchants or their agents. The skins of kids which are butchered by the peasants themselves, are

sold to country peddlars who wander through the region from cabin to cabin, collecting them in order to finally dispose of them at a town fair to the skin dealers or to the agents of the manufacturers, tanners, or large skin merchants. The more important butchers of the large towns sell their kid skins directly to the agents of the glove manufacturers or skin merchants. Formerly the regular fair or market brought together all the dealers in the neighbouring district, who exhibited in the market place their lots of kid skins, varying in number from five, ten, and twenty to several hundreds, and sometimes thousands. These fairs were watched with the greatest interest by those who were in the skin business, as the prices obtained there for skins were an indication of the probable prices for the entire season. This is, to a certain extent, true to-day, but the town fairs no longer play the important part that they did twenty years ago. The railways, the Press, and general education, as well as the enormous importation of skins from the Argentine Republic, Chile, the Cape of Good Hope, Arabia, Mexico, Russia, and Asia Minor have brought about a revolution in the skin business. The leading fairs, where kid skins are particularly on evidence, are held at the following places:—Romans (Drôme), Anneyron (Drôme), St. Marcellin (Isère), Valence (Drôme), Clermont (Oise), Tours (Indre et Loire), Poitiers (Vienne), Lusignan (Vienne), Riom (Puy de Dôme), Aurillac (Cantal), Chalons sur Saône (Saône et Loire). At one time the annual fair at Valence was considered by kid skin dealers to be the most important of all those held in France, because the prices obtained there regulated the year's prices for France, and probably for other countries as well. Its great importance in this business was due to the fact that Valence is situated in the centre of a large, fine, kid skin producing country, and its fair was held at the beginning of the season for the southern central portion of France. These conditions brought many fine lots of raw skins, several thousand dozens, to the Valence fair, which fact was sufficient to draw thither the big purchasers or their agents from Grenoble, Annonay, Paris, and other places. This fair still exists, and its prices are quoted every year, but it has lost its former importance, because its importance being recognised, speculators have manipulated the market in order to bring about fluctuations to their own advantage. In Italy the finest kid skins, many of them equal to the best French skins, come from the north, above the line from Turin to Venice. A heavy coarse skin is found in the neighbourhood of Genoa, and a finer smaller skin in Tuscany. In Rome the kid skins are very small, and the market unimportant. Naples, a great centre for the manufacture of cheap gloves, is noted for a low grade skin, as well as Sicily, Sardinia and Corsica. Those that come from the Abruzzi district, north-east of Naples, are very much better. Switzerland stands next to France in the high quality of skins produced. Spain and Portugal both produce

large quantities, but as a rule they are far inferior even to those of Southern France. The best Spanish skins are to be found in Saragossa and the surrounding country. Germany produces a large number of kid skins, of which the best come from Saxony. Bavaria, Baden, Thuringia, and Silicia furnish large quantities. The best Austrian skins are to be found in the Tyrol and Styria, those from Bohemia, Hungary, and Transylvania are not so good. Kid skins from Eastern Europe, Northern Africa, South America, and Mexico are used principally in the manufacture of Suède gloves.

MANGABEIRA RUBBER.

The current number of the *Kew Bulletin* contains an important article on the source of Mangabeira rubber (*Hancornia speciosa*). In consequence of certain objections to its use, the price has been but half of Para rubber. Recently, however, the price of Mangabeira rubber has advanced by reason of the improvement in the purity, and on account of its great suitability, when pure, for certain purposes. In consequence, the disparity between the price of the best sorts and that of Para rubber is much diminished. At the end of last year, a kilogramme (2 lbs. 3 ozs.) of the best Mangabeira rubber sold for upwards of 12 milreis (almost 8s.), a price not far short of that of Para rubber. An additional cause of the advance in price is to be sought in the change in making up the rubber; for, owing to the constant watch which is necessary to guard against adulteration by addition of iron or stones put in to make weight, pieces of rubber only half to three-quarters of an inch thick and two feet long by ten inches broad, the so-called "sheets" of commerce, are welcome in the trade.

Of recent years, the exploitation of this source of rubber has taken a considerable extension. While the intelligent collectors, who start from Bahia and work toward the interior, have only tapped mature trees, improvident itinerant collectors, making their own profit out of the pressing demand of the time, have in many places mischievously drawn on the supply and threatened its continuance.

The chief centres for export of Mangabeira rubber are Bahia and Pernambuco. A large supply is brought down the river São Francisco, and so to Bahia; and from this town, in 1889, 134 tons were exported; in 1892, 4,362 bales, to the value of £22,826; and in 1893, 3,293 bales, to the value of £20,362. From Pernambuco were exported, in 1896, 54 tons to the value of £1,800.* A small amount of caoutchouc from the Province of Matto Grosso (probably Mangabeira rubber) is exported down the Parana through Paraguay, and great quantities from Minas Geraes are shipped through Rio de Janeiro.

Recently the Province of São Paulo has begun to

* Probably an error for £18,000.

demand a place in the consideration of rubber export. Regions here, such as that through which the Mogyana railway runs, are exploited, even by persons coming from Bahia for the purpose, the owners of the land receiving, in return for the permission they grant, one-third of the clear profits. A worker can collect about $6\frac{1}{2}$ lbs. of rubber per diem, and receives on the spot 75 milreis (£2 9s. approximately) per arroba $3\frac{1}{2}$ lbs.). The arroba is sold in London for 200 milreis. In the first half of the year 1898 no less than 76,498 kilogrammes (approximately 78 tons) of rubber were passed over this railway, and yet the railways of Paulista and Sorocaba equally traverse the country where the Mangabeira tree grows. In consequence of the increasing trade, Santos has become an important centre for rubber, and there, as at the town of São Paulo, now exist mercantile houses whose principal concern lies in this business.

In this Province an idea of the importance of cultivating and protecting the tree is arising. Many coffee-planters are turning their attention to the sowing of *Hancornia*, and seed is already hard to procure. The Government hoping, by means of the duty on rubber (now standing at 13 per cent. ad valorem), to recuperate its finances, which have become disordered by the depreciation of coffee, has instructed Dr. A. Uchoa Cavalcanti, Acting Director of the Agricultural Institute at Campinas, to inspect the territory in question; and, further, the Congress of the State has decreed that the Mangabeira tree shall be protected, and its cultivation extended, as is advisable.

Although but little is known so far of the cultivation of Mangabeira, it may be said that there is a considerable probability of it becoming an important tree in rubber-culture. The apparently easy accommodation of the tree to soil and climate, its early and considerable yield, together with the fact that even under the rough treatment of the Indians it preserves its fruitfulness, and also the facility with which it can be cultivated, promise a future. And, taking a wide view of its possibilities, from its presence in the red coffee-growing soils of the west of the Province of São Paulo, it appears suitable for the red earths of the German colonies of Africa, Usambara and Togoland alike, such, for instance, as occur at Misahöhe, in the latter colony. For these soils it promises to be considerably better suited than the Ceara rubber plant (*Manihot Glaziovii*), and the Para rubbers (*Hevea*), and will probably give better results than *Castilloa*, than which it is more hardy, earlier maturing, and smaller.

CHELSEA PHYSIC GARDEN.

The history of "physic gardens" in England begins in the year 1567 when John Gerard, of London, first cultivated a garden for the botanical study of plants; he was followed by the Earl of Danby who endowed a garden at Oxford in

1652; while the most famous example — that of the Apothecaries' "garden" at Chelsea — was founded in 1673. This interesting, ancient, and historic institution has recently been discussed in the public Press with a view to the necessary steps being taken to rescue it from the risk of falling into the hands of the builder, as well as to draft some permanent and satisfactory scheme by which it might continue effectually to promote the scientific and educational purposes for which it was originally intended. Sir Hans Sloane, whose liberal munificence bequeathed a lastingly valuable legacy to the citizens of London, both in connection with this garden and with our "national treasure house," the British Museum, in the year 1722, granted to the Company of Apothecaries the land for this garden, subject to this important proviso that "the said garden may at all times hereafter be continued as a Physick Garden and for the better encouraging and enabling the said Society to support the charge thereof for the manifestation of the power, wisdom, and glory of God in the works of the creation, and their apprentices and others may better distinguish good and useful plants from those that bear resemblance to them and yet are hurtful, and other the like good purposes." The expenses entailed on the Society of Apothecaries in maintaining the garden in an efficient state have undoubtedly been heavy, this financial burden having induced them on more than one occasion to endeavour to obtain some relief from, or possible dissolution of, their trusteeship; thus we find that in 1893 they made application to the Charity Commissioners but with no definite result until 1897 when a Treasury committee, consisting of Sir Henry Longley, Sir W. T. Hiselton-Dyer, and Mr. Spring Rice, made an exhaustive investigation of the whole subject, directing their attention specially to the practical utility of the garden for the purposes of its original foundation—*i.e.*, the scientific and educational study of botany. They thereupon recommended the formation of an entirely new administrative body which would be able to maintain unimpaired the true instructive object of the garden and to furnish the necessary funds for its future welfare and efficiency; consequently the Treasury Committee appointed the trustees of the London Parochial Charities to be the sole trustees of the garden, the committee of management to consist of 17 members. Now the representatives appointed by the trustees of the London Parochial Charities are: the Hon. Mrs. Evelyn Cecil, the Right Hon. Sir M. E. Grant-Duff, Mr. W. Hayes-Fisher, M.P., Mr. R. B. Litchfield, Mr. L. B. Sebastian, Sir Owen Roberts, Mr. Sidney Webb, the Rev. R. H. Hadden, and Mr. Evan Spicer. The Lord President of the Council has appointed the Right Hon. Sir Herbert Maxwell, Bart, M.P., while the Treasury has nominated Mr. A. B. Freeman-Mitford as its representative. The Royal Society is represented by Dr. D. H. Scott, F.R.S.; the University of London by Professor S. H. Vines,

F.R.S.; the Society of Apothecaries, which is to appoint in rotation with the Royal College of Physicians of London, by Mr. J. R. Upton; and the Pharmaceutical Society by Mr. Michael Carteighe. Earl Cadogan, as hereditary "lord of the manor" with concurrent rights, or his nominee, is an *ex-officio* member of the committee, and the Chairman of the Technical Education Committee of the London County Council will in all probability represent that well-known and useful metropolitan parliament. Lastly, we understand that Mr. H. Howard Batten, of 3, Temple-gardens, E.C., is the honorary secretary to this representative committee. We note with pleasure that this ancient "charity" with its endowments will in the future be administered exclusively for the advancement of botanical study, with special reference to the varied requirements of scientific instruction and original research, to those of our "materia medica" and technical pharmacology, in so far as they relate to the practical culture of medicinal plants, and last, but not least, to the increasing requirements of our general educational system. When for one moment we recall the historic past of this old "Physic Garden," the great and learned men who in bygone days strolled between the neat beds of various herbs and rare plants, when we gaze at the august statue of Sir Hans Sloane standing in the middle of the garden, when we remember that Linnæus himself visited this picturesque field of flowers, that old Thomas Wheeler lectured there to many generations of the "Society's" students, and that the famous Lindley there arranged the plants into their "Natural Orders" in contrast to the old "Linnæan system," we cannot but naturally feel that the efforts to keep alive the floral beauties, the many botanical advantages, and the rare historic associations of this quaint and pleasant garden, are indeed worthy of the sincere support of all intelligent Londoners as well as of our Imperial Government.—*Lancet*.

ARTIFICIAL INDIGO.

In connection with the production of artificial indigo, the following letter from Dr. Armstrong, F.R.S., has just appeared in *The Times*:—

"The question of the likelihood of artificial indigo becoming a serious rival of the natural product, raised in your article of the 4th inst., is of such importance to Indian growers that it is desirable to correct the false impression which might be conveyed by some of the statements made in the letter of Mr. G. J. Lavers in your issue of the 19th inst.

"Quoting Messrs. Mewburn and Ellis's statement 'that eventually synthetic indigo will have a very serious effect on the natural indigo trade,' Mr. Lavers says 'I think not,' and gives as his reason 'that articles dyed with real indigo preserve their colour and wear better than those dyed with substitute.' Even Messrs. Parsons and Keith, in their letter to

Sir William Hudson, which you publish to-day, seem to think that there may be a substantial difference in the properties of the natural and artificial products.

"It should be clearly understood that it is no question of introducing a substitute for 'real indigo,' if by this is meant the blue colouring matter in commercial indigo, but of using a substance identical with that produced by Nature, and differing from it only by being 'made in Germany'—of using an article differing only from that produced in India (apart from the presence of indigo red in the latter) by being of superior quality owing to its freedom from the foreign matters often present to a considerable extent in commercial natural indigo. Unless these impurities play an important part in the dyeing process—and this is improbable—the artificial product should be at least as good a dye in all respects as the natural indigo.

"I am told that, as produced by the Badische Company, artificial indigo does not lend itself to the dyers' use quite so readily as the natural product. Indigo, properly speaking, is not a dyestuff, but an insoluble pigment. To dye with it the blue must first be converted into soluble indigo white. It is said that the artificial substance is not quite so easily reduced to white as is the natural product; but this involves no real distinction. Crystalline substances are often less amenable to treatment than are amorphous ones, and probably little difficulty will be experienced in making artificial indigo just as easy to treat as that from any natural source.

"I had the opportunity when in Germany a few days ago of discussing the outlook with friends interested in the manufacture of indigo. I found them entirely hopeful of success, while in no way disguising the difficulties, and my belief is that Messrs. Mewburn and Ellis have by no means exaggerated the danger ahead.

"No reliance can be placed on a rise in price of crude materials. There should be no difficulty in increasing the production of naphthelene and toluene, should a demand arise; enormous quantities of tar are now allowed to go to waste in coking coal.

"The stake for which the German chemical manufacturer is playing is a very big one—far bigger than was offered by madder 30 years ago. Indigo is more difficult to make than is alizarin, but such is the persistence of the German attack upon the position, and so great is the improvement in our methods, that it is far from improbable that all difficulties will ere long be overcome. The manner in which the German factories are organised for such work is marvellous, and calculated to excite the admiration and envy of all who can understand it. I have been astonished at the progress made only in the course of two or three years since I was last in the Rhine district. Thus one firm I find has a scientific staff of 110 skilled chemists, whilst that of another has risen to no fewer than 150, and the works are in proportion. Nature has no chance in the long run against such odds.

"The one lesson to be learnt, I believe, is that

planters should without delay put their house in order, and seek in every way to improve the cultivation of the plant and the extraction of the indigo from it. It would be interesting to know whether a single competent chemist is at present engaged in studying the subject, and whether the Indian Government has in any way had its attention directed to the importance of scientific aid being given to the industry.

CUBAN TOBACCO INDUSTRY.

The exportation of cigars from Havana in 1897 and 1898 amounted respectively in number to 123,417,000 and 91,812,000. It is estimated that the increase in the production of tobacco in 1899 will be 40 per cent. more than in 1898. In a recent report, the British Acting Consul-General in Havana quotes some interesting remarks by Mr. Gustavo Bock, and states that there can be no doubt that important measures are necessary for the protection of the tobacco industry in Cuba. To insure a planter the sale of his crop at a price in proportion to the cost of production, it is absolutely indispensable that the present regulations, prohibiting the importation into the island of all foreign manufactured or unmanufactured tobacco, should continue in force, excepting only snuff and chewing tobacco, which have always been imported, and in no way injured Cuban trade or agriculture. Of the many laws and decrees which the Madrid Government has issued to favour this colony none has been wiser than this prohibition of the importation of foreign leaf tobacco, thereby avoiding the importation of a leaf of inferior quality by unscrupulous persons, who after manufacturing the cigar in the way usual in the country, made perhaps with a small portion of Cuban leaf, would export it as genuine Havana. This business would prove most profitable to the adulterator, but in time would totally ruin the reputation of Cuban products, both agricultural and industrial, bringing about a decrease in prices which would cause a cessation in the cultivation of tobacco. The production of tobacco in normal times is estimated at 260,000 bales in Pinar del Rio, Vuelta Abajo; 70,000 bales in Havana (called Partido); 130,000 bales in Las Villas, Sta Clara Remedios; and 100,000 bales in the eastern provinces called Mayari and Gibara: making a total of 560,000 bales. This, on an average of 50 kilogrammes per bale, is equivalent to 28,000,000 kilogrammes, or 62,173,800 lbs. In Vuelto Abajo there is a good deal of uncultivated land, and with permanent peace and a stable government, protection would be insured to capitalists. It is said that this production could easily be increased in the province of Vuelta Abajo alone to 500,000 bales; the province of Havana, Las Villas, and the eastern provinces, could increase in the same proportion. In the manu-

facture of cigars, cigarettes, and packages of smoking tobacco for home consumption the following number of bales of tobacco are used:—Vuelta Abajo 140,000, Partido 10,000, Santa Clara 30,000, and Gibara 40,000; total 220,000 bales. This leaves for export as follows:—Vuelta Abajo 120,000 bales, Partido 60,000, Santa Clara 100,000, and Gibara 60,000; total 340,000 bales. At 50 kilogrammes per bale this amounts to 17,000,000 kilogrammes, or 36,956,000 lbs. The United States bought and imported from the island 20,000,000 bales in 1895, 26,000,000 in 1896, and 4,400,000 bales in 1897. The universal reputation which this leaf enjoys, owing to the excellence of its quality and the perfection of its manufacture, would, it is said, increase three-fold if the industry were promoted. It is to-day the most important industry in the country, and in the province of Havana and Pinar del Rio, it is the foremost. With 100,000 cwts., the following has been manufactured:—For exportation, 250,000,000 cigars; for home consumption, 50,000,000 cigars; making a total of 300,000,000. In addition to this, the manufacture of cigarettes represents a value of from £600,000 to £800,000 per annum. Even if, under the auspices of peace and by the adoption of proper measures for the future of agriculture and the production of tobacco, a brilliant and promising future is assured, the same cannot be said of its industry and manufacture. The future of the former is promising. The latter, besides, being handicapped by excessive competition, has the insurmountable obstacle of being taxed by the Treasuries of countries burdened by a heavy national debt. As a proof of the above, attention is called to the following figures, showing the gradual decrease of the manufacture of tobacco in the island, a decrease which nearly reaches 50 per cent. in eight years. In 1889 the number of cigars imported amounted to 250,000,000; in 1890, 212,000,000; in 1891, 197,000,000; in 1892, 168,000,000; in 1893, 147,000,000; in 1894, 134,000,000; in 1895, 159,000,000; in 1896, 186,000,000; and in 1897, 133,000,000. On the other hand, the exportation of leaf tobacco has increased 50 per cent.; from 197,000 bales exported in 1889 through the port of Havana, the exports in 1895 increased, approximately, to 250,000 bales. The exportation of cigars to the United States shows a considerable falling off during the last few years. In 1889, the number exported to that country was 111,000,000; in 1893, 46,000,000; and in 1897, 34,000,000.

EXHIBITION OF TUNBRIDGE WARE.

Tunbridge Wells has awakened to the fact that it has a much neglected industry in its Tunbridge ware, and has lately held a special exhibition of it, old and new together, with examples of kindred work lent from South Kensington Museum. Tunbridge ware is formed by building up slips of wood

having a square or triangular section, to make a pattern. The strips are glued together into a solid block, from which thin transverse sections are cut. These are used as veneers to decorate flat surfaces. Modern pieces of Tunbridge ware have been made containing nearly one thousand different pieces of wood to the square inch. Considerably over one hundred and fifty different kinds of wood are used. Holly is boiled to increase its whiteness, Hungarian ash and maple are steeped in chalybeate water for several days for the purpose of turning them into different shades of grey; oak is sometimes attacked by a certain fungus which turns it into a beautiful blue-green. Artificial dyes are not used. The history of the ware is shrouded in some obscurity, but it seems to have been introduced from Germany by the sale of inlaid woods and toys of German manufacture upon the Pantiles. T. B. Burr, in a history of the town dated 1766, says that it was customary for those departing from the town to take away "Tunbridge fairings to their friends at home." The first record of local manufacture was in 1720, when a man named Burrows started the production of wood mosaics in diamonds, triangles, and stars, some of which are still in existence. The process of manufacture seems to be identical with that used in the production of Indian inlay work, and it seems probable that the impetus to the special method of construction may have been received from the same source. The art in India was introduced into Sind from Shiraz, in Persia, towards the end of the eighteenth century. From thence it was introduced into Bombay in the early part of the nineteenth century. There is an air of Orientalism in the conception of the work and in the skilful manipulation that is required in its execution.

The object of the present exhibition is to show the public examples of old and recent Tunbridge ware, and to stimulate the improvement of its artistic possibilities by the production of new designs. To this end the Technical Education Committee offered premiums in open competition for the best designs suitable for the ware. Mr. Walter Crane adjudged the prizes and gave an address on the opening day. The designs submitted were not satisfactory, owing in all probability to Tunbridge ware being so little known to the majority of designers. The use of the decoration is at present confined to cabinets, tables, tea-caddies, glove and card boxes, picture-frames, and small fancy articles. There is no reason why it should not be used on a larger scale, say for the interior decoration of Atlantic liners or railway carriages. If it were controlled and properly guided it might have a large demand for superior cabinet and furniture decoration. There are at the present time only two firms producing this ware, one of which we are informed is giving up, and the promoters of this revival say that the difficulty they have to face is that it does not pay. It would be a pity for it to die out from lack of public appreciation. Why should not a small company be started, even at a small financial loss at the start, of art

students and others under a recognised art director, and set to work, say, for two years to see what can be done with it? At no time has there been so increasing a demand for and interest in good inlay work: witness the interest in and prices taken for inlay work of the Queen Anne period; and we must credit the public with admiration for the decoration as for its antiquity. They like inlay work because it adds interest to common and familiar things about their house, and they would sooner have things that so grow into their affections of decorative value than the ugliness of early Victorian furniture.

The exhibition is strengthened by objects from South Kensington Museum, inlaid and marquetry work at its best, which should rouse some enthusiasm in those who have the future welfare of this art before them. The exhibition is a conscious cultivation of art, and an endeavour to interest the public in its life and preservation by calling special attention to the most important side of art, that of decorating utilities by giving them genuine artistic finish, the work of cultivated minds as opposed to trade or shop standards of excellence. "For the hand can never execute anything more beautiful than the character can inspire."
Builder.

AGRICULTURE IN MEXICO.

In Mexico irrigation is necessary in the greater portion of the country, and, on account of the scarcity of water, a large extent of land cannot be utilised. When the owner of land has sufficient water for the purpose indicated, he retains his property, and rarely can be induced to sell, as it is of permanent value to him. For the last three hundred years large tracts of land have been owned by individuals or families, who have spent heavy sums of money for canals and dams in order to make them productive. The United States Consul-General at Monterey says that on account of this, and the attending expenses of irrigation, there are fewer small farmers in Mexico than there are in the United States. Until recently farming in Mexico has been of the primitive order; but the Mexican is an expert in irrigation, and if he can get the water, his land becomes fertile and yields generously. During the last two decades decided improvements have been accomplished through the introduction of modern improvements into farming in Mexico. The increase in production corresponds to the improvements in farming apparatus. The great railroads of the country have been important factors in this advance, enabling farmers with a surplus of production to supply those less fortunate. The cost of labour is from 6d. to 1s. per day, depending on the locality. There are two crops of corn a season, upon which the former averages about £5 per acre gross. Sugar cane, turned into *piloncillo* or brown sugar, averages from £14 to £19 per acre gross; beans, from £6 to £8 per acre; rice, from £7 to £9 per acre; all other products realising correspondingly

high prices. Thus it will be seen that the profits of the farmer must be large. Hay is not made in any great quantity, but corn fodder is sold to advantage. Near the cities, a lucrative trade is carried on in green barley and corn, which are cut before maturity and delivered in the cities to owners of horses and cows. Cattle breeding is, and always has been, a profitable business in Mexico, consequent upon cheap labour, low taxes, and the large tracts of cheap land which are suitable for grazing only. Until recently, no attempt has been made to improve the stock, but certain large cattle men have now undertaken to do this, and steady improvement is certain henceforth. The demand created during the late war with Spain, and the high prices which obtained in the United States, increased the price of cattle to such an extent that the northern portion of the country has become depopulated of its stock, which, it is said, will take several years to replenish. Dairy farming in the neighbourhood of large cities is lucrative, milk selling at 1s. per gallon, and butter at 1s. 6d. to 2s. per pound. Those engaged in this business make money rapidly. Fruit and vegetable farming are beginning to attract attention. Formerly this amounted to simply enough for the home market. Now an effort is to be made to supply the United States with early fruit and vegetables. The movement is in its infancy, but it is expected to grow into large proportions. Oranges, lemons, tomatoes, beans, &c., are produced in Mexico from four to eight weeks earlier than in the United States. Hence this is expected to be a profitable business in the near future. Wheat is cultivated in the high table-lands of Central Mexico, and is fairly profitable. It is not the equal of that grown in the United States, either in quantity per acre, or quality. Para and Bermuda grass give pasturage in many sections of the country. They are said to be equal to any in the world. Parts of the country are adapted to the growth of tropical products, viz., coffee, vanilla, rubber, cocoanut, cocoa, &c., the quality of all being excellent. It is said that the best vanilla of the world comes from the State of Vera Cruz, and the best cocoa from the State of Chiapas. The coffee of Michoacan is said to be equal to any; the tobacco of Vera Cruz is preferred by many to that of Havana, and the sugar production of Southern Tamaulipas, or Northern Vera Cruz, is said to be surpassed by that of no country save Hawaii in quantity, and it is more profitable to the producers, for the reason that seven to ten crops are the result of one planting, whereas the Hawaiian planters get only two. Taken as a whole, farming in Mexico is an inviting field for persons of capital and intelligence.

THE LYONS SILK TRADE.

The Chamber of Commerce of Lyons has recently published its report of the silk production of the city for the year 1898. The value of the total product of

pure silk stuffs was, in round numbers, £6,140,000, or £240,000 in excess of 1897. The American Consul at Lyons reports that these figures are inferior to those of 1895 and 1896; but they are considered encouraging as marking a resumption of activity. There has been an increase this year in the manufacture of faille, of taffetas, of velvets, of moires, of stuffs for umbrellas, parasols, and muslins. On the other hand, the production of black armures, of all kinds of pongees, of surahs, and similar goods has been less than in 1897. There has been an excess in the manufacture of foulards, stuffs of pure silk, marcelines, and goods used for the furniture of churches, but a decline is observable in the production of linings, *erges*, lustrine armures, and striped satin pekings. The production of mixed goods in 1898 rose to £4,800,000, an increase of £220,000 over 1895 and a decrease of about the same figure as compared to 1897. A large number of looms were occupied during the year 1898 in making plush for hats and modes, liberty satin, torquises, cotton-back armures for modes and linings, mixed stuffs for collars and cravats, carriage trimmings and figured and bordered velvet for the Orient and the Indies. Demands from the two latter quarters have been steadily increasing for the last three years, especially for the two species of goods named. Stuffs worked in gold and silver have also found a largely increased demand in the Orient and the East Indies. The output in this line aggregated about £200,000 during the year 1898, and the largest of any year. The manufacture of crepes is reported as assuming largely increased proportions, the production for 1898 being nearly double that of 1895. *Crepes de chine* increased during the same period from £40,000 to £80,000; the production of muslin increased six-fold; that of grenadines nearly doubled; gilded stuffs used for military uniforms rose from £32,000 to £40,000; and silk, cotton, and woollen passementeries from £40,000 to £60,000.

While Lyons continues to stand at the head of other cities in the production of all fine silks, satins, velvets, and kindred goods, Milan seems to have definitely wrested from her the trade in "thrown" silk. In 1878 the sales of thrown silk—that is to say, of silk yarn—in Milan amounted to 2,475,280 kilograms (5,457,000 lbs.), against 4,244,141 kilograms (9,356,600 lbs.) in Lyons. In 1888 the sales of Milan had risen to 4,538,305 kilograms (10,005,100 lbs.), while Lyons had advanced to only 5,183,520 kilograms (11,427,500 lbs.). Milan continued steadily diminishing the gap until 1898, when she took her place in the lead with a business of 7,549,395 kilograms (16,643,400 lbs.), against 6,462,639 kilogram (14,247,500 lbs.) for Lyons.

Several reasons may be cited for this change of business in the interest of Milan. The Lyons dealers attribute it to the new means of transportation and to the French duty on raw silk. Some years ago, before the balance of this trade began to turn to the side of Milan, the great bulk of the transportation to the Orient was in English and French ships, which made

Marseilles the principal stopping place in the Mediterranean. The German line, which now does much of the business between the Peninsula and the Orient, made Genoa its principal stopping point in the Mediterranean; and as a consequence, the raw silk brought from the Orient goes into Italy and on to Milan, where it is thrown, and by means of the St. Gothard Tunnel forwarded to Switzerland, Germany, and Russia. It is estimated that about 11,000 bales of raw silk are annually landed at Genoa which were formerly put down at Marseilles.—*Board of Trade Journal.*

SAVING LIFE AT SEA.

Information respecting a prize of 100,000 francs that has been founded by the heirs of the late Mr. Anthony Pollok, of Washington, to be awarded during the Paris Exhibition in 1900, to the inventor of the best apparatus for the saving of life at sea, is given in the *Board of Trade Journal*. This prize, which is open to universal competition, is a donation of 100,000 francs. This sum is now on deposit with the American Security and Trust Company of Washington, D.C., and will be paid over to the successful competitor when a decision shall have been rendered by an appointed jury, and formally communicated to the Secretary of State of the United States, through the Commissioner-General of the United States to the International Exhibition of 1900.

The juror selected on behalf of the Government of the United States is Lieutenant William S. Sims, U.S.N., Naval Attaché of the Embassy of the United States at Paris. In considering the award the jury will be governed by the following conditions:—

(1) The total amount of the prize may be awarded to a single individual on condition that the invention is of sufficient practical value and importance to justify the proposed award.

(2) Should several persons enter inventions of equal value, the jury, as it shall consider right and just, may award a portion of the prize to each.

(3) Should none of the inventions entered be of sufficient value to entitle it to the prize, the jury may reject any and all of them, but at the same time shall be empowered to indemnify competing inventors in such amounts as may be deemed advisable. The essential details as to this prize have been agreed upon between Mr. Ferdinand W. Peck, Commissioner-General of the United States to the Paris Exhibition of 1900, and the Honourable Alfred Picard, Commissioner-General of the Universal International Exhibition of 1900. They have also had the substantial assent and approval of the French authorities to the end that the competition for the prize may take place during the exhibition. The instructions to competitors will be issued in due season by the jury, with the sanction and approval of the authorities of the French Exhibition.

THE MANUFACTURE OF SILKWORM GUT IN ITALY.

Some of the inhabitants of the island of Procida manufacture very fine gut from silkworms. They call the product "fili di seta," or "silk threads," their special properties consisting in their strength and flexibility. They are made from the stomachs of silkworms just before they begin to spin their silk, and from their cocoons. Not many worms, in proportion to the gut put on the market, are reared in Procida itself, but the makers buy them from Torre dell' Annunziata, and other neighbouring towns, in great quantities. The following, according to Consul Neville-Rolfe, is the process of manufacture:—The worm is selected when fully matured, that is to say, at the moment when his nourishment ceases, and just before his metamorphosis. He is then cut open, great care being taken not to injure the membrane of the stomach. This is then removed, and the stomachs are then put into a pickle, which is the keynote of the whole process, and the secret of which is carefully kept. When the pickling process is over the workpeople, who are mostly women, take one end of the stomach in their teeth, and draw the other end with their hands. This part of the work requires great dexterity, for the threads are drawn out to a considerable length, the whole value of the product depending, in fact, upon its length in relation to its thickness, and the strain it will carry. There are two seasons for the production, namely, in spring, when the best gut is produced; and in autumn, when the quality is inferior. There is one important market for this specialty, and the whole production is exported to Northern Italy and abroad, at the average price of £3 per pound. The gut is of very small specific gravity, so that a great deal of it goes to a pound-weight. The cost of production is also considerable, as the worms must be bought just at the moment when they are coming into profit for making silk, that is to say, when they are dearest. Again, the results are frequently disappointing, many worms being found, on dissection, not to be suitable, and have to be discarded. The various operations require a good many hands, and though labour is cheap it runs away with a good deal of money, as skilled hands are alone satisfactory. The gut is used for fishing tackle, brushes, and any purpose where fineness and tenacity are jointly requisite.

FOREIGN INDUSTRIAL DESIGNS AT THE PARIS EXHIBITION.

The United States Consul at Berne says that the High Court of Appeal in Paris has recently given an important decision in the case of a Swiss firm, which in its application is far reaching, and affects foreign manufacturers who intend to present to the world in 1900 their best efforts and products. The Swiss manufacturer perceived that certain designs of his,

although registered in France, were extensively copied by a French firm. He brought an action, and a judgment of the High Court of Appeal, to which the case was carried, was entered against him. In announcing the decision, the Court said: "We assume and acknowledge that imitations of registered designs are proved. This case is based on the law promulgated by Imperial decree of 1861, by which foreigners are allowed to register designs in Paris if their country has a reciprocal treaty with France; but the law has fallen into disuse, with a great many others at the epoch of Free Trade agreements. Under international agreement of 1883, foreigners are placed on the same footing as the French, and by virtue of the text of the law of 1866, amended by a decree of 1825, a manufacturer is obliged to deposit his designs, to be protected, with the competent authorities of the district in which his factory is located." "Therefore," says the Consul, "manufacturers who have no factory in France are at the mercy of the French imitators, since under the ruling of the highest court, imitation of designs, &c., is lawfully allowed. Manufacturers registering their designs in Paris, and paying a handsome sum for supposed protection, is in this case a fallacy, although the authorities accept thousands of francs annually for these purposes, based on the Imperial decree of 1861."

THE ARTIFICIAL HATCHING OF SALMON IN NORWAY.

As a result of a visit paid by Herr Landmark to the United States, a new departure has been made in connection with the artificial hatching of salmon in Norway. Formerly the young fry were allowed to escape as soon as they began to require food, and, therefore, when in a very delicate and defenceless condition. They are now retained in captivity, and fed four times a day upon the raw liver of slaughtered animals, until the autumn, after the system which obtains in America. According to Consul Nelson, of Bergen, the results of the first year's experiment at the Government hatchery on the Drammen were satisfactory; on 280,000 ova treated, the loss was only 2 per cent., and in the middle of October about 211,000 fry were turned out, while the per-centage of loss has been still further reduced of late years. A belief is prevalent among the coast fishermen that salmon and sea-trout spawn successfully in salt water, and in this connection a series of experiments were conducted under proper supervision, from which it appeared that (1) roe taken from salmon captured in a river, or from sea-trout which have remained until the spawning time in sea water, cannot be successfully developed in salt water, and (2) salmon and sea-trout roe impregnated in fresh water may be hatched out in brackish water containing a small per-centage of salt up to eight or nine per mille, that is to say, rather less than one-third of the salt contained in the sea water on the Norwegian coast.

PEARL INDUSTRY OF NEW CALEDONIA.

The pearl and oyster industry of New Caledonia is as yet in its infancy. To those who are familiar with these products, which have been supplied for the last half century, and more, from the coral reefs of Torres Straits, Tahiti and Samoan groups, and, later still, from New Guinea, in all of which localities the trade in pearl shell and pearls has obtained the distinction of a regular European market quotation, it may be surprising that the resources of the vast seaboard of New Caledonia and its dependencies have not, ere this, become known and seriously worked. Acting-Consul Erskine is of opinion that the oversight may be accounted for by the fact that the great mineral wealth of the colony has no doubt drawn off the attention of the commercial community; but since the advent of the present governor, great encouragement has been given to the development of the other industrial and commercial resources of the islands, hence large concessions having been granted by the French Government. Syndicates were formed for the working of pearls and pearl shells on the coasts of New Caledonia and the adjacent islands, with the result that at the present moment extensive prospective operations are being carried out to determine the existence and locality of shell banks. There are now two separate parties of concessionaires. The syndicate occupying the whole of the east coast of the island as well as the Chesterfield, Wallis, and Belep groups, is busily engaged in exploring its concessions with the aid of a patent sub-marine apparatus, which is said to be capable of descending to the depth of 100 fathoms, although 40 or 50 fathoms will be all that is required for the present. This machine is carried by a small ketch of about 38 tons, and it appears from the reports received to be working admirably and discovering large banks of shells especially off the north end of the island. Some 12 banks of large extent have been discovered and chartered, one of them, according to information given to Consul Erskine, being about four miles long by about 100 yards wide, at a depth of 25 fathoms. The company working the concessions on the west coast, whose head-quarters are at Paris, is stated to be making valuable finds. From one pound weight of pearls and upwards are said to be exported monthly. Large numbers of these pearls are sometimes found in each shell, which is mostly of a small size and called in New Caledonia the "Pontadine," and apparently of small value for trade purposes. The shell banks found on the north coast of the island lie principally in shallow waters and the oyster is collected by the Loyalty Island boys, who are employed for this purpose by the company at a wage of 30 francs (24s.) a month and rations. It, is however, proposed to import native divers from Tahiti, as they are more experienced at the work than the natives of the Loyalty Islands. Very little export of pearls and shells has so far been made, though parcels of a few tons of shells are occasionally despatched to Europe and fetch from

£40 to £60 per ton. Some of the pearls are valued at from £20 to £120 each. The concessions already mentioned are granted for a period of ten years, with the option of a further extension of ten years to the concessionaires, who must be of French nationality. Consul Erskine says, "If my information can be relied upon it seems likely that the pearl and pearl shell industry of New Caledonia has a very successful future before it, and will no doubt establish a reputation equal to any of the celebrated pearl fisheries in these latitudes."

Correspondence.

ARMoured GLASS.

The note on this subject, on p. 850 of the *Journal*, would seem to have been written by someone unaware that this glass (called here "wired glass") has been in use for some time in this country, where its valuable qualities are fully appreciated. I enclose one of the British Fire Prevention Committee's reports of a test made last July, the results of which agree with those made in Vienna.

One great advantage from its use in sky-lights is that it will not fall readily if accidentally fractured, and of this I have had satisfactory experience.

Gauge-glasses, or rather guards for them, are not only proposed, but in use.

R. LANGTON COLE.

23, Throgmorton-street, E.C.
October 26, 1899.

[Mr. Langton Cole's statements seem quite to be borne out by the report he sends of the tests made on sky-lights of wired glass.]

Notes on Books.

OVER-PRESSURE. By S. De Brath and F. Beatty.
London: G. Philip and Son, 1899.

In this book, the authors have considered very thoroughly both the causes of over-pressure and the means to be taken for the mitigation of this evil. The first three chapters deal with the nervous system, nervous energy, and mental economics, and the titles of the remaining chapters (4 to 8) are "Science Teaching," "History Teaching," "A High Standard," "Without Over-strain," and "the Great Examination Question." The main object of the book, therefore, is to point out how over-strain can be avoided while a high standard is maintained.

The authors point out the importance of moderate hours of brain-work, rising gradually from 4½ hours at eight years old to 7 hours at sixteen years, and under Mental Economics the essentials of method are explained. It is shown that in much teaching the first principles of science are completely misunder-

stood, and on taking three school text-books on mechanics, geography, and algebra at random, the first principles there stated are said not to be first principles at all from an educator's point of view, but "either (a) highly abstract generalisations from an enormous mass of experiment, apart from which they can scarcely be understood; (b) inferences from a great body of facts which are remote from, or opposed to, ordinary perceptions, and were only discovered after centuries of research or exploration; or (c) conventions which should not be introduced at all till the need for them arises." In place of this the authors affirm that "all knowledge is in minds and not in books, and in minds it passes through two main stages, the inductive and the deductive. These two are halves of one process, and the former precedes the latter in the national growth of science, and should likewise precede it in the individual mind."

In the chapter on "Science Teaching, what and how" the mode of teaching is specially considered, "Herbert Spencer brings out the vital fact that science is nothing else than exact knowledge of the natural forces around us learned by exact methods. It is not distinctively the study of any particular one of them—the knowledge of mechanical forces, nor of molecular affinities, nor of the laws of life, but the mental habit of exactitude working towards ascertainable truth by data open to and verifiable by all." It is the acting upon this view rather than upon the cramming of conclusions and formulæ of the 'ologies, got up for examinations, that the true principles of science-teaching rest.

The proposed remedy for over-pressure is based on the physical laws of health, and stress is laid upon the necessity for adapting the teaching to the powers of the child at each stage of his growth. Also the educational sequence of the subject-matter is to be marked, so that the boy may experience a sense of unity in his instruction.

In the last chapter special attention is given to the great examination question, and the line to be taken in order to remedy the evils of the present system. The evil of regarding all knowledge not as valuable or interesting in itself, but as good to pass an examination with, is censured. An intelligent boy of sixteen once asked: "What is the use of trying to remember all the stuff we have to learn? No one uses Euclid to get his living by—nor Latin or Greek either, unless he is a mere schoolmaster." Thus education is considered solely as a help to success in life, and not as a life-long possession.

THE LIBRARY.

The following books have been presented to the Library since the last announcement:—

Abbott, A., and Arthur Key.—Progressive Lessons in Science. (London: Blackie and Son, 1899.) Presented by the Publishers.

Boulvin, J.—The Entropy Diagram and its Applications. (London: E. & F. N. Spon, 1898.) Presented by the Publishers.

Crosskey, L. R.—Elementary Perspective. (London: Blackie and Son, 1898.) Presented by the Publishers.

DeBrath, S., and F. Beatty. — Over-pressure. (London: C. Philip & Son, 1899.)

Frost, Robert, B.Sc.—Patent Law and Practice. (London: Stevens and Haynes, 1898.) Presented by the Author.

Henderson, J., B.Sc.—Practical Electricity and Magnetism. (London: Longmans, Green and Co.) Presented by the Publishers.

Luff, Arthur S., M.D., B.Sc. — Text-Book of Forensic Medicine and Toxicology. (London: Longmans, Green and Co., two vols., 1895.) Presented by the Author.

Lyon, J. B., C.I.E., F.C.S.—Medical Jurisprudence for India. (Calcutta: Thacker, Spink and Co., 1890.) Presented by the Author.

Mann, J. Dixon, M.D., F.R.C.P.—Forensic Medicine and Toxicology. (London: Charles Griffin and Co., 1898.) Presented by the Author.

Preece, Sir W. H., and Sir James Sivewright.—Telegraphy. (London: Longmans, Green and Co., 1899.) Presented by the Publishers.

Procter, H. R., F.C.S. — Leather Industries. (London: E. and F. N. Spon, 1898.) Presented by the Author.

Shadwell, Arthur, M.A., M.B. — The London Water Supply. (Longmans, Green and Co., 1899.) Presented by the Author.

Slingo, W., and A. Brooker.—Electrical Engineering. (London: Longmans, Green and Co., 1898.) Presented by the Publishers.

Unwin, W. Cawthorne, F.R.S.—The Testing of Materials of Construction. (London: Longmans, Green and Co., 1899.) Presented by the Publishers.

General Notes.

INTERNATIONAL STATISTICAL INSTITUTE.—This Institute held its seventh biennial session at Christiana in September last. The meetings in previous years were held at Rome, Paris, Vienna, Chicago, Berne, and St. Petersburg. The session continued for five days, in two sections, one for demographic and the other for economic subjects.

CYCLE TAX IN FRANCE.—According to a report recently issued by the Department of Indirect Taxation in France the revenue derived from the tax on cycles (*velocipedes*) amounted in 1898 to £194,344, and the number of machines taxed to 483,414. In 1897 the number assessed to duty was

408,869; in 1896, 329,816; in 1895, 256,084; and in 1894, 203,026.

PROPOSED CONGRESS AT PARIS.—An international congress on the numbering or "count" of yarns and threads will be held, under the patronage of the French Government, during the Paris Exhibition of 1900. Among other uses of a settlement is the common basis for estimating tariff duties on most textiles. The organising committee has addressed a circular to French manufacturers to explain the present state of the case. Four international congresses have been held—at Vienna in 1873, at Brussels in 1874, at Turin in 1875, and at Paris in 1876—with a view to the general adoption of the metre and the gramme as bases of universal numbering of textile threads. The resolution proposed received only a partial sanction, and it is hoped that the question may be brought to a successful issue at the Paris Exhibition.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, NOV. 6...Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.
 Engineers, in the Theatre of the United Service Institution, Whitehall, S.W., 7½ p.m. Mr. Sherard Coles, "The Electrolytic Treatment of Complex Sulphide Ores."
 Chemical Industry (London Section), Burlington-house, W., 8 p.m. Mr. Walter F. Reid, "Velvill' material, a new Substitute for India-rubber and Gutta-percha."
 British Architects, 9, Conduit-street, W., 8 p.m. Opening Address by the President, Mr. William Emerson.
 London Institution, Finsbury-circus, E.C., 5 p.m. Prof. W. Boyd Dawkins, "The Place of the Welsh in the History of Britain."
- TUESDAY, NOV. 7...Civil Engineers, 25, Great George-street, S.W., 8 p.m. Opening Address by the President, Sir Douglas Fox, and Reception afterwards by the President.
 Colonial, Whitehall-rooms, Whitehall-place, S.W., 8 p.m. Mr. John Ferguson, "Ceylon in 1899."
- WEDNESDAY, NOV. 8...Geological, Burlington-house, W., 8 p.m. 1. Dr. C. Davison, "The Cornish Earthquakes of March 20th to April 2nd, 1898." 2. Prof. T. T. Groom, "The Geological Structure of Portions of the Malvern and Abberley Hills."
 Patent Agents, 19, Southampton-buildings, W.C., 7½ p.m. 1. President's Opening Address. 2. Discussion on paper by Mr. J. C. Chapman, "Some Aspects of Disconformity and the Judicial Functions of the Patent-office in regard to the same and other Matters."
- THURSDAY, NOV. 9...London Institution, Finsbury-circus, E.C., 6 p.m. Prof. W. M. Flinders Petrie, "Pre-historic Egypt."
 Camera Club, Charing-cross-road, W.C., 8¼ p.m. Dr. W. Thompson, "Liquid Air."
- FRIDAY, NOV. 10...Astronomical, Burlington-house, W., 8 p.m.
 Physical, in the Physical Laboratory of the Central Technical College, Exhibition-road, South Kensington, 5 p.m. 1. Mr. F. S. Spiers, "Contact Electricity." 2. Mr. J. B. Taylor, "The Heat of Formation of Alloys."

Journal of the Society of Arts.

No. 2,451. VOL. XLVII.

FRIDAY, NOVEMBER 10, 1899.

*All communications for the Society should be addressed to the Secretary, John street, Adelphi, London, W.C.***Notices.****ARRANGEMENTS FOR THE SESSION.**

The First Meeting of the One Hundred and Forty-sixth Session will be held on Wednesday evening, the 15th of November, when an Address by SIR JOHN WOLFE BARRY, K.C.B., F.R.S., Chairman of the Council, will be delivered.

Previous to Christmas there will be Five Ordinary Meetings, in addition to the Opening Meeting. The following arrangements have been made:—

NOVEMBER 15.—Opening Address of SIR JOHN WOLFE BARRY, K.C.B., V.P.Inst.C.E., F.R.S., Chairman of Council.

NOVEMBER 22.—“National Forestry.” By D. E. HUTCHINS, Conservator of Forests, Cape Town. GENERAL MICHAEL, C.S.I., will preside.

[In Mr. Hutchins's absence at the Cape, Prof. W. R. Fisher, of Cooper's-hill, has kindly consented to read the paper on his behalf.]

NOVEMBER 29.—“The Great Seals of England.” By ALLAN WYON. RICHARD R. HOLMES, M.V.C., F.S.A., will preside.

DECEMBER 6.—“Artificial Silk.” By JOSEPH CASH. SIR THOMAS WARDLE will preside.

DECEMBER 13.—“Sea Angling and Legislation.” By F. G. AFLALO.

DECEMBER 20.—“Bi-Manual Training by Black-board Drawing.” By H. BLOOMFIELD BARE, F.R.I.B.A.

Papers for meetings after Christmas:—

“Electric Traction.” CHARLES H. GADSBY.

“Steam Motors for Common Roads.” By JOHN I. THORNYCROFT.

“The Diffraction Process of Colour Photography.” By PROFESSOR R. W. WOOD.

“Coal in South-Eastern England.” By PROFESSOR W. BOYD DAWKINS, M.A., F.R.S.

“A National Repository of Science and Art.” By PROFESSOR W. M. FLINDERS PETRIE, D.C.L.

“The Electrical Induction Motor on Mountain Railways.” By PROFESSOR CHARLES A. CARUS-WILSON, M.A.

“Ventilation without Draughts.” By ARTHUR RIGG.

“The Undeveloped Resources of the Bolivian Andes.” By SIR MARTIN CONWAY.

“The Orloff Process of Colour Printing.” By W. H. WARD.

“Continuation School Work in Rural Districts.” By H. MACAN.

INDIAN SECTION.

The meetings of this Section will take place on the following Thursday afternoons at 4.30.

December 14, January 18, February 8, April 26, May 17.

DECEMBER 14.—“Round about the Andamans and Nicobars.” By COLONEL R. C. TEMPLE, C.I.E.

“India in the 19th Century.” By SIR WILLIAM LEE-WARNER, K.C.S.I., M.A.

“The Industrial Development of India.” By J. A. BAINES, C.S.I.

“New Projects of Railway Communication with India.” By J. M. MACLEAN, M.P.

“Indian and English Criminal Procedure.” By SIR JOHN SCOTT, K.C.M.G., D.C.L.

FOREIGN AND COLONIAL SECTION.

The meetings of this Section will take place on the following Tuesday afternoons, at 4.30 and the first meeting on Thursday:—

November 23 (Thursday), January 23, February 27, March 20.

NOVEMBER 23.—“Old and New Colombo.” By JOHN FERGUSON. SIR THOMAS SUTHERLAND, G.C.M.G., LL.D., M.P., will preside.

“The Colonies in the 19th Century.” By The Right Hon. SIR CHARLES DILKE, Bart., M.P.

APPLIED ART SECTION.

The meetings of this Section will take place on the following Tuesday evenings at 8 o'clock:—

January 30, February 13, March 13, April 3, May 8, 29.

CANTOR LECTURES.

The following courses of Cantor lectures will be delivered on Monday evenings at 8 o'clock:—

HENRY HARDINGE CUNYNGHAME, “Art Enamelling upon Metals.” Four Lectures.

LECTURE I.—NOVEMBER 20.

What enamel is—Various styles of enamelling—Cloissoné—Champlevé—Mediæval art—The Renaissance—Limoges enamels—Choice of a style in enamelling.

LECTURE II.—NOVEMBER 27.

Method of executing Limoges enamels—Preparation of the metal plate, of the enamels—The firing pailions.

LECTURE III.—DECEMBER 4.

The method of making enamels—Fluxes—The metallic oxides.

LECTURE IV.—DECEMBER 11.

The application of enamel to jewellery—Gold working—Gilding.

BENNETT H. BROUGH, "Metalliferous Deposits." Four Lectures.

January 22, 29, February, 5, 12.

E. SANGER SHEPHERD, "Photography of Colour." Four Lectures.

March 5, 12, 19, 26.

MAJOR PHILIP CARDEW, R.E., "The Control, Regulation, and Measurement of the Supply of Electrical Energy." Three Lectures.

May 7, 14, 21.

 JUVENILE LECTURES.

Two Lectures, suitable for a Juvenile audience, will be delivered on Wednesday Evenings, January 3 and 10, at Seven o'clock, by HERBERT JACKSON, on "The Phenomena of Phosphorescence."

 Miscellaneous.

ELECTRIC TRACTION IN CHICAGO.

In view of the approaching convention of the American Street Railway Association, which takes place this year in Chicago, the American papers have published articles containing a survey of the electric traction systems in that city. There are no less than nine companies operating street railways in Chicago, and the track mileage amounts to 844 miles. There are 1,919 motor cars and 987 trailers. Besides these there are four elevated railways, which have altogether 70 miles of track, 146 motor-cars, and 418 passenger cars.

The city contains examples of all kinds of practice, from fairly ancient down to the most recent. Of the latter the South Side Elevated Railway may be taken as an example, this railway having 18.62 miles of track, 46 motor cars, and 180 passenger cars. Its present power-house equipment consists of four 800-kilowatt 12-pole Westinghouse compound-wound machines with a large overload capacity. The field pieces are vertically split, and slide at right angles to the shaft, thus giving access to the armatures, which

are mounted directly on the engine shaft. Each is directly connected to a horizontal cross-compound Allis engine, rated at 1,200 horse-power. The generators are guaranteed to operate continuously at 1,835 amperes, the voltage being 650. Two additional units of double the size are being put in. The boilers, 12 in number, are of the Babcock-Willcox type, fitted with mechanical stokers, and there is a complete system of coal-handling apparatus. Not being situated favourably with regard to condensing water, a Wheeler cooling tower is employed, 34 feet high, 16½ feet wide, and 64 feet long. It contains vertical wire screens, down which the water flows. Ten fans, 10 feet in diameter, operate in pairs from the same shaft, forcing air into the tower. Two large storage batteries, situated on the line, each three miles from the generating station, provide for the fluctuations in the load. Each consists of 263 cells, and has a capacity of 750 kilowatts, delivering 2,400 amperes to the line, and at times 4,300 amperes have been taken from one battery. The only attendance on the battery is that given by the ticket agent at one station and the train despatcher at the other, who have merely to attend to the circuit breakers. The cars, which are operated on the Sprague multiple unit system, require 2 kilowatt hours per car mile in summer, and 3.35 in winter, these figures including lighting, heating, station lighting, and all auxiliary motors. During the first six months of the present year the company claims to have produced electrical energy at an average of .427 cent. per kilowatt-hour.

The Calumet Street Railway is chiefly interesting through the illustration it affords of the progress in the equipment of power houses. There are four 150-kilowatt railway generators belted to Ball cross-compound engines which have been transformed from non-condensing to condensing; also a 500-horse-power Buckeye engine directly connected to a 50-kilowatt G.E. generator. The Walker generators were substituted for the original Detroit generators, and one is at times operated as a booster to raise the voltage to 900 or 1,000 volts if required. When condensing was introduced, two Deane condensers were put in and a system of cooling tables installed. By this means a vacuum of 22 inches or 23 inches is secured when the temperature of the atmosphere is 90° and the cooling tank 120°. The tables are 12 feet wide and 70 feet long, the water passing from the delivery pipe to one extremity of the first table, flowing to the other end in a thin sheet, thence falling upon a second table, from which it finally flows into a pond and is pumped to the condensers.

The largest power station in Chicago is that of the Chicago Union Traction Co., recently formed by the consolidation of two other companies, and operating 249 miles of track and 607 motor cars. It contains six engines—four of 2,000, one of 1,700, and one of 1,000 horse-power. They are of three different makes, but all cross-compound and directly connected to their generators. The dynamos first put

in had commutators on the periphery of the armature, but the majority of these have been altered and the usual shaft commutators substituted. The Chicago City Railway Co., operating 157 miles of track, 776 motor cars, and 749 trailers, has three stations, with an aggregate capacity of 10,700 kilowatts, all the dynamos being rope-driven and all the engines non-condensing.—*Electrician*.

USES OF TOBACCO JUICE IN FRANCE.

All tobacco shops in France are compelled to keep a stock of what is called "tobacco juice, rich in nicotine and guaranteed." This is manufactured by the tobacco monopoly in Paris. The article, it is claimed, possesses the following advantages:—(1) It is free from all matter susceptible of fermentation, and keeps for an indefinite period if in closed vessels. (2) It contains no resinous matter, and is almost transparent, therefore, it does not injure or clog the spraying machines, and does not stain plants or flowers or the wool of sheep. (3) It has a Government guarantee as to the proportion of nicotine it contains, which never varies. This product, it is also claimed, contains from five to six times the quantity of nicotine that may be found in ordinary tobacco juice, and that, therefore, one-fifth to one-sixth of the quantity will accomplish the object to which it is applied. For spraying purposes the product is employed in the proportion of one part of juice to one-hundred parts of water. It is stated that the spraying of plants should be done after sunset, and that they should be sprinkled with clean water on the following day. For fumigating hot-houses the proportion is one part of juice to five of water. The mixture is sprayed upon bricks or iron sheets heated to a temperature sufficiently high to produce rapid evaporation. It is claimed that insects and parasites are absolutely destroyed by this process. It is said, furthermore, that the proportion is most efficacious for the destruction of all insects in cattle, as well as being a preventative of all manner of parasite attacks. For these purposes the juice is mixed in the proportion of one part to twenty of water. It is recommended that the lotion be not used as a general bath, but applied gradually on limited surfaces. It should not be brought in contact with sores or erosions of any kind. The benefits accruing from the use of these mixtures are said to be greatly enhanced by mixing 100 grammes (about 3½ ounces) of soda crystals with each litre (1·7 pints) of diluted juice. Regarding the use of this product in the Alpes Maritimes, the United States Consul at Nice says that it is rapidly coming into general favour for all the purposes mentioned above. He has seen it used with complete success in curing what is popularly called "le noir." This parasitic affliction is not confined to orange, lemon, olive, and other trees, but has been most disastrous to such

vegetables as potatoes, beans, peas, tomatoes, &c. He has also seen whole rows of orange trees so thickly coated with parasites that every leaf appeared coated with soot (hence the popular appellation, "le noir,") and he has been enabled to verify the fact that three or four applications of the lotion have prevented the disease from attacking new leaves, and have caused the disappearance of the black deposit upon those attacked. A proprietor of an olive grove in Nice has recently stated that the use of the juice in combating "le noir," which has destroyed many thousands of olive trees in the department, is most costly, but at the same time very efficacious. The spraying machines used to spread the mixture are the same as those employed in applying sulphate of copper to vineyards. Efforts have been made to ascertain whether the use of tobacco juice would not be more desirable in treating vines for the cure of the oidium—a parasitic disease of the vine leaves—than sulphate of copper, but it appears impossible to discover anyone who has experimented with the two treatments. It would appear, at first sight, that tobacco juice would be preferable, as sulphate has always been considered a preventative of attacks upon the grapes themselves, especially after the bunches are completely developed, whereas the oidium attacks only the bases and indirectly the vitality of the plant.

IRON AND STEEL WORKS OF JAPAN.

The iron and steel plant which the Government of Japan is now building is situated at Kiushiu, about ten miles from Moji, near Wakamatsu. The works face a bay called Dokai. It is intended to dredge out this bay, so that there will be a fair way to the wharf now building at the works, by which vessels of about 3,000 tons burden may reach the wharves and discharge iron ore. The ore will have to be brought either from the Yangtze, in China, or from the Kamaishi mines, in the north of Japan. There is an abundance of coal within a radius of 100 miles from the works. The ore will be carried from the wharf by electric cranes to the rear of the works, where the ore bins are placed. These bins are designed to hold ore enough to keep two blast furnaces going for two months. The blast furnaces will have a capacity of 350 tons of ore each in 24 hours, and each is calculated to produce 165 tons of pig iron in this time. The blast and roasting furnaces are well supplied with electric hoists. In fact, all over the works as many labour-saving appliances as possible have been adopted. The system is American, though the plant has all to be made in Germany. The molten metal from the furnaces will generally be transferred direct to the mixers, which are of 160 tons capacity. The total annual capacity of the works is 90,000 tons—that is, 45,000 tons each of Bessemer and open-hearth steel, for which 120,000 tons of pig iron will be

required. It is proposed to roll rails of all sections and sizes, plates up to 2 inches thick and 7 feet wide, rounds, squares, and angles of all sizes, and joists up to 12 inches high. With the exception of that for the locomotives the steam generated for driving all of the machinery will be heated by the waste gases from the different furnaces.—*Feilden's Magazine.*

TEXTILE PLANTS OF RUSSIA.

It is a well-established fact that Russia has for several years past furnished nearly four-fifths of the flaxen tow consumed by all countries. The growth of flax covers a large territory, which is worked by peasants, and as a rule the product is of inferior quality. Its export, however, is a source of great wealth, and has been one of the principal factors in the industrial development of Russia. As a greater extent of land is covered by flax than by any other product, Russia is in the foremost rank as a flax producer. Owing to the fact that flax thrives under severe climatic conditions, it was planted extensively in Russia at a time when this country had very little trade with European countries. The United States Commercial Agent at Roubaix says that in the western districts and Baltic provinces the Upper Volga in Joroslav, Kostroma, and near Lake Lodoga, flax is grown with a view to the production of tow. In 1886 an area of over 1,000,000 hectares (2,471,000 acres) was covered with flax, and the yield was 275,000,000 kilogrammes (606,265,000 lbs.) of flaxen tow against 225,000,000 kilogrammes (496,035,000 lbs.) produced by all countries combined. In 1897 more than 2,300,000 hectares (5,683,000 acres) were cultivated, and the yield was 562,585,000 kilogrammes (1,238,000,000 lbs.) The exportation in 1897, which was almost entirely through Europe, amounted in value to £8,000,000, and it was this superabundance of Russian flax which arrested the production in Belgium, where it had been grown under the most favourable conditions, and with large profit. Germany is the natural outlet of the Russian commercial current; she imported more than £1,300,000 worth of Russian flax in 1897, and exported about £540,000 worth. Hemp covers a smaller area than flax in European Russia; this is due to the climate. The principal plantations are in Koursk, Toula, Kalouga, Riazan, and in the western districts Kovno, Vilna, Smolensk, and Mohilew. During the past few years the surface cultivated has not increased very rapidly, but it is worthy of note that while the culture of hemp is almost stationary in all Europe, the Russians have stepped to the front. Central Siberia, connected by rail with the centres of textile industry in European Russia, is a large producer of hemp. In 1897 Russia sold more than 5,000,000 hectolitres (13,700,000 bushels) of seed and 200,000,000 hecto-

litres (550,000,000 bushels) in round numbers of tow, of which 98,000,000 hectolitres (269,000,000 bushels) came from Siberia. The total exportation from Russia to Germany was quite equal to that of flax, and the total sales amounted to £1,370,000. Russia is about to become a large producer of raw cotton. The Trans-Caucasian country has cotton lands in the valley of Koura, near Elizabethpol, in the high plain of Erivan, as well as in other localities, and judicious irrigation will extend these fields. Russian Turkestan is, however, destined to become the greatest cotton-producing district, and will, it is said, shortly be a rival to Egypt. The Commercial Society of Central Asia, through the aid of the Minister for the Colonies, has introduced "upland" cotton into Ferghana, Samarcand, and the oases of Syr Daria and Amou Daria. It is planted by the side of native cotton of inferior quality, and each year marks an advance in the surface sown, as well as yield. Irrigation will reclaim from the steppes of Turkestan several hundred thousand acres for agricultural purposes. The greatest drawback is the climate, which is exceedingly dry in summer, while the autumn is marked by early frosts. In 1890, Russian Turkestan had 60,000 hectares (148,000 acres) planted with "upland" cotton, of which 35,000 hectares (86,000 acres) were in Ferghana. This land yielded 14,880,000 kilogrammes (32,736,000 lbs.) of cotton. There were planted with native cotton 31,960 hectares (78,941 acres), which yielded 5,500,000 kilogrammes (12,100,000 lbs.). In 1893, 175,000 hectares (432,000 acres) were planted with "upland," and 25,000 hectares (61,000 acres) with native cotton. In 1895, the production amounted to 80,000,000 kilogrammes (176,000,000 lbs.) of "upland," and 9,335,000 kilogrammes (20,537,000 lbs.) of native cotton. Russian Turkestan should produce more than 120,000,000 kilogrammes (264,000,000 lbs.) of textile growth. To this may be added the production of Bokhara and Khiva, which are under the control of Russia, and which export more than 40,000,000 kilogrammes (88,000,000 lbs.) of cotton. Through the Trans-Siberian road Russia will inevitably drain the basin of the Yang-tze-kiang in China of a part of its harvest of 290,000,000 kilogrammes (638,000,000 lbs.), until the textile industry of the Chinese is better organised than at present. Without counting the contribution from the latter source, Russian mills consumed more than 150,000,000 kilogrammes (330,000,000 lbs.) of raw material in 1897. Russia can already do without Egypt, India, and the United States. In Trans-Caucasia and in Turkestan (Khokand) Russia grows silk also, and in 1897 exported £37,500 worth of cocoons. She will buy largely, however, for many years to come from Italy, China, and Persia, as well as through Germany. In 1897 she bought £1,311,000 worth of raw silk. The extension of the Trans-Caspian railroad from Samarcand to Khokand and the completion of the Trans-Siberian road will, however, change these conditions.

General Notes.

FLAX CULTURE IN ENGLAND.—It appears from a recent return that the acreage under flax cultivation in this country has fallen off from 895 acres in 1898 to 465 acres in 1899. Lincolnshire has dropped from 109 to 20 acres, Norfolk from 10 to 5 acres. The area in the East Riding, the largest flax growing county, is reduced from 258 acres in 1898 to 106 acres in 1899.

ELECTRIC TRAMWAYS.—Electric tramways, or street railroads, as they are called in the United States, now produce nearly as large an income as the steam railroads. The *Electrical Engineer* states that the total invested capital in the street railway systems of the United States is estimated at £350,000,000. The annual income is estimated at £35,000,000, while the annual income of the steam railroads is estimated at £54,000,000. The electric street railroads carry 5,000 million passengers annually, or ten times as many as the steam railroads.

COMPRESSED AIR FOR STREET TRACTION.—Ten cars driven by compressed air are now running in New York, and the experience derived from actual operation is reported to be satisfactory. The cars run smoothly, and, with the exception of a slight sound from the exhaust, there is practically no noise. It is pointed out that, with everything equal in the matter of operating the system, there should be a decided advantage in the economy of the air cars, for the reason that there is no expense corresponding to such items as the maintenance of overhead or underground trolley, the cost of switchboards, and the burning out of motors.

IMPORTS OF CLOCKS AND WATCHES.—The value of clocks and parts thereof imported into this country during the month of August last was £47,521, as compared with £39,732 in August of 1898, and £37,059 in the same month of 1897. The clocks and parts thereof from France were valued at £10,832; from the United States, £6,594; and from other countries, £30,095. The total value of the clocks imported during the eight months ending August was £360,229. The value of watches and parts thereof imported during August last was £142,117, as compared with £109,678 in the same month of 1898, and £84,874 in the same period of 1897. The total value for the eight months ending August, 1899, was £1,004,989, as compared with £779,890 for the same period of 1898, and £775,169 for the same period of 1897.

MEETINGS FOR THE ENSUING WEEK.

- MONDAY, NOV. 13.**...Surveyors, 12, Great George-street, S.W. 8 p.m. Opening Address by the President, Mr. T. M. Rickman.
Geographical, University of London, Burlington-gardens, W., 3½ p.m. 1. Introductory Address by the President. 2. Mr. W. K. Rickmers, "Travels in Bokhara."
London Institution, Finsbury-circus, E.C., 5 p.m. Mr. H. B. Wheatley, "The Tower of London: Fortress, Palace, and Prison."
- TUESDAY, NOV. 14.**...Civil Engineers, 25, Great George-street, S.W., 8 p.m. 1. Mr. H. H. Dalrymple-Hay, "The Waterloo and City Railway." 2. Mr. B. M. Jenkin, "The Electrical Equipment of the Waterloo and City Railway."
- WEDNESDAY, NOV. 15.**...SOCIETY OF ARTS, John-street Adelphi, W.C., 8 p.m. Opening Meeting of the 146th Session. Chairman's Address.
Meteorological, 25, Great George-street, S.W., 7½ p.m. 1. Mr. Richard H. Curtis, "The Diurnal Variation of the Barometer in the British Isles." 2. Mr. G. J. Symons, "Note on Earth Temperature Observations."
Microscopical, 20, Hanover-square, W., 7½ p.m. Exhibition of *Foraminifera*, by Mr. A. Earland.
Entomological, 11, Chandos-street, W., 7 p.m.
Mining and Metallurgy, Geological Museum, Jermyn-street, S.W., 8 p.m. 1. Mr. J. A. Richard, "The Cripple Creek Goldfields." 2. Mr. H. H. Greenway, "Notes on the Cyanide Process."
Manchester Geographical Society, Memorial-hall, Albert square, 7½ p.m. Colonel Mellor, M.P., "Egypt and Her Monuments."
- THURSDAY, NOV. 16.**...Royal, Burlington-house, W., 4½ p.m.
Linnean, Burlington-house, W., 8 p.m. 1. Mr. A. C. Worsdell, "The Comparative Anatomy of certain Species of Encephalartos, a genus of the Cycadaceæ." 2. Mr. W. T. Calman, "A Collection of Brachyura from Torres Straits."
Chemical, Burlington-house, W., 8 p.m. 1. Messrs. W. J. Sell and F. W. Dootson, "The Chlorine Derivatives of Pyridine;" (Part IV.) "Constitution of the Tetrachloropyridines." 2. Messrs. Wyndham R. Dunstan and H. M. Read, "Contributions to our knowledge of the Aconite Alkaloids;" (Part IV.) "Japaconite and the Alkaloids of Japanese Aconite." 3. Dr. H. M. Dawson and Mr. P. Williams, "The Determination of Transition Temperatures."
London Institution, Finsbury-circus, E.C., 6 p.m. Mr. G. Langley, "Music in its relation to Painting and Poetry."
Electrical Engineers, 25, Great George-street, S.W., 8 p.m. Opening Address by the President, Prof. Silvanus P. Thompson.
Historical, St. Martin's Town-hall, Charing-cross-road, 5 p.m.
Imperial Institute, South Kensington, 8½ p.m. Mr. B. Worsfield, "England in South Africa." (Lecture II.). "The Dismemberment of European South Africa."
- FRIDAY, NOV. 17.**...North-East Coast Institute of Engineers and Shipbuilders, Newcastle-upon-Tyne, 7½ p.m. Mr. B. G. Nichol, "Worm Gearing."

CONTRIBUTIONS TO THE READING-ROOM.

The Council beg leave to acknowledge, with thanks to the Proprietors, the receipt of the following Transactions of Societies and Periodicals.

INDEX TO VOL. XLVII.

A.

Abraham, Dr. Phineas S., *disc.*, leprosy in India, 432
 Acetylene, paper on, by Prof. V. B. Lewes, 661
 ———, *Cantor lectures* by Prof. Vivian B. Lewes, 105,
 117, 129, 141; *syllabus*, 2
 ——— exhibition, report of council, 677; report of com-
 mittee on generators, 289; *notice*, 315
 ——— at Budapest, 775; acetylene genera-
 tors, 80r
 Acworth, H. A., C.I.E., *paper*, leprosy in India, 415
 Acworth, W. M., *disc.*, the cost of municipal enterprise, 239
 Addenbrooke, G. L., *disc.*, long distance transmission of
 electric power, 35
 Africa (West), the gold mines of, *paper* by James Irvine, 305
 Agrarian conditions under British and native rule, *paper* by
 Michael Francis O'Dwyer, I.C.S., 575
 Agriculture in Mexico, 893
 Agricultural education in France, 703
 ——— products of Togoland, 663
 Air (compressed) for street traction, 903
 — (liquid) as a blasting agent, 883
 Albert medal, list of awards, 339, 383; awarded to Sir William
 Crookes, F.R.S., 672; report of council, 672
 Algeria, wine production in, 1898, 529
 Alldridge, T. J., *disc.*, the gold mines of West Africa, 311
 Amazons, production of rubber in the, 824
 America (Spanish), textile industries in, 74
 Andamans, penal system of the, *paper* by Col. Richard
 Carnac Temple, C.I.E., 292
 Anderson, Sir William, K.C.B., F.R.S., *obituary*, 103
 Argentina, destruction of locusts in, 150
 Argols, by R. Hedger Wallace, 803
 ART (APPLIED) SECTION:—Meeting of committee, 41; annual
 report, 670; list of committee, 743
 1st Meeting:—"The Senefelder centenary exhibition of
 lithographs, 1898-9," by Edward F. Strange, 245
 2nd Meeting:—"Vitresous enamels," by Cyril Davenport,
 315
 3rd Meeting:—"Intarsia," by Stephen Webb, 499
 4th Meeting:—"Picture frames," by I. Hunter Donald-
 son, 595
 5th Meeting:—"The revival of tradesmen's signs," by
 J. Starkie Gardner, 611
 Arts and crafts, central school of, exhibition, 694
 Ashbee, J., *disc.*, fruit growing in Kent, 558
 Ashmead, E., *disc.*, Cornish mines and Cornish miners, 377
 Asylums (metropolitan) board, 814
 Attorney-General, G.C.M.G., Q.C., M.P., *chair*, the cost of
 municipal enterprise, 224
 Aumonier, W., *disc.*, intarsia, 504
 Australian quicksilver, 884
 Automobiles in France, 652
 Ayton, Prof., F.R.S., *disc.*, Nernst's electric light, 256

B.

Bacon, Rev. John M., *paper*, the balloon as an instrument of
 scientific research, 277

Bacteria, influence of, on the decay of cement, 837
 Bacterial purification of sewage, *Cantor lectures* by Dr
 Samuel Rideal, 683, 695, 707, 719; *syllabus*, 140
 Baden-Powell, Captain B. F. S., presentation of medal to,
 for paper, kites: their theory and practice, 21; *chair*
 the balloon as an instrument of scientific research, 277
 Bahamas, pine apple industry of the, 55
 Baker, T. A., *disc.*, commercial education, 101
 Balloon (the) as an instrument of scientific research, *paper*
 by the Rev. John M. Bacon, 277
 Barker, Reginald, *disc.*, the law of trade marks, 571; *letter*,
 protection of inventions and trade marks in ex-Spanish
 colonies, 593
 Barry, Sir John Wolfe, K.C.B., F.R.S., *chairman*, opening
 meeting, 6; address, the streets and traffic of London, 7;
chair, long distance transmission of electric power, 25;
chair, award of Swiney prize to Dr. J. Dixon Mann, 173;
chair, annual general meeting, 670; re-elected chairman of
 council, 695
 Bauerman, Hilary, *chair*, Cornish mines and Cornish miners,
 359
 Bayley, Miss Clive, presentation of medal for *paper*, the
 revival of hand-loom weaving, 21
 Bayley, Sir Steuart, K.C.S.I., C.I.E., *disc.*, railways in
 Burma, 189; *chair*, leprosy in India, 433; *disc.*, the port of
 Calcutta, 651
 Beer industry in Germany, 874
 —, production of, in Hamburg, 138
 Beighton, T. Durant, *disc.*, agrarian conditions under
 British and native rule, 587
 Belgian vicinal railways, 740
 Belgium, commercial education in, 114
 ———, poultry breeding in, 705
 Bell, Horace, *disc.*, railways in Burma, 189
 Bell, Prof. F. Jeffrey, *Juvenile lectures* (1) hands and feet,
 129; (2) some ways in which animals breathe, 141
 Bergamot (Calabrian), 395
 Berne educational exhibition, 653
 Berry, W. W., *disc.*, fruit growing in Kent, 557
 Bessant, C., *disc.*, intarsia, 505
 Biffen, R. H., methods of preparing rubber, 111
 Birdwood, Sir George, K.C.I.E., C.S.I., *disc.*, vitresous
 enamels, 322; *disc.*, picture frames, 605; *chair*, the
 revival of tradesmen's signs, 611; annual general meeting,
 682; pottery as a historical document, 689
 Birdwood, Herbert Mills, C.S.I., LL.D., presentation of
 medal to, for *paper*, the plague of Bombay, 21; *disc.*,
 leprosy in India, 437; *disc.*, judicial reform in Egypt, 541;
 hill forests of western India, 731; civil administration of
 British India, 875
 Bishop, Miss Isabella L., *disc.*, Persian trade routes, 356
 Blasting, liquid air as a blasting agent, 883
 Blow-pipe work, 52
 Bohemia, forest preservation in, 103
 ———, graphite in, 126
 Bolas, Thomas, tallow lamp for glassblowing, 52
 Bolivia, coffee in, 529

BOOKS, NOTES ON:—

 Bothamley, C. H., F.C.S., *paper*, photographic developers and development, 42; award of silver medal for his *paper*, 657
 Boulton, Mr., *disc.*, ætheric telegraphy, 525
 Boyle, Sir Cavendish, K.C.M.G., *disc.*, leprosy in India, 439
 Braby, Mr., *disc.*, ætheric telegraphy, 524
 Bramwell, Sir Frederick, Bart., D.C.L., F.R.S., *opening meeting*, 21
 Brazil, carbons in, 662
 Brewing industry in Germany, 473
 Bright, Charles, *disc.*, ætheric telegraphy, 524
 Bromhead, S., *disc.*, the law of trade marks, 571
 Bronze casting, improvements in, 23
 Brooks, W., *disc.*, photographic developers and development, 51
 Brough, B. H., *disc.*, Cornish mines and Cornish miners, 378
 Brown, T., Forster, *paper*, our coal supplies, 506
 Bruce, Eric S., *disc.*, the balloon as an instrument of scientific research, 284
 Bruce, Robert, *disc.*, liquid fuel, 392
 Brussels, electric lighting in, 706
 ———, exhibition of electrical appliances, 397, 473
 Bryce, Right Hon. James, M.P., D.C.L., *disc.*, judicial reform in Egypt, 542
 Brydges, Mr., *disc.*, the cost of municipal enterprise, 238
 Budapest, acetylene exhibition, 775
 Bunsen, Robert Wilhelm, For.Memb. R.S., *obituary*, 778
 Bunyard, George, *paper*, fruit growing in Kent, 545
 Burke, Colonel, *disc.*, tuberculosis in animals, 203
 Burma, railways in, and their proposed extension across Yunnan, *paper* by Dr. J. Nisbet, 173
 Burne, Sir Owen Tudor, G.C.I.E., K.C.S.I., *opening meeting*, 21; *chair*, Egypt and the Soudan in 1897-98, 57; *disc.*, the penal system of the Andamans, 304; *chair*, Persian trade routes, 341; *chair*, fruit-growing in Kent, 545; *chair*, annual general meeting, 681
 Burns, John, M.P., *adjourned discussion*, cost of municipal enterprise, 268

C.

- Calabrian bergamot, 395
 Calcium carbide factories in Norway, 754 (*see* "Acetylene")
 Calcutta, the port of, *paper* by Sir Charles Cecil Stevens, K.C.S.I., 628; *letter* by Sir C. C. Stevens, 718
 Calendar of session 1898-9, 5
 Camphor industry (Formosan), 848
 Canada, mineral production of, in 1898, 778; peat fuel in, 881
 Canals, *see* "Navigation" (inland)
 Canary Islands, trade of, 24

CANTOR LECTURES:—Annual report, 671

- 1st Course:—"Acetylene," by Prof. V. B. Lewes, 105, 117, 129, 141; *syllabus*, 2
 2nd Course:—"Bacterial purification of sewage," by Dr. Samuel Rideal, 683, 695, 707, 719; *syllabus*, 140

CANTOR LECTURES (continued):—

- 3rd Course:—"Cycle construction and design," by Archibald Sharp, A.M.Inst.C.E., 755, 767, 779, 791; *syllabus* 264
 4th Course:—"Manufacture of leather," by Prof. Henry R. Procter, 827, 837, 851, 863; *syllabus*, 452
- Carbons in Brazil, 662
 Carpet industry in Silesia, 527
 Carter, R. Brudenell, F.R.C.S., *chair*, tuberculosis in animals, 197; appointed Chadwick Trustee, 679
 Carter, E. Tremlett, *disc.*, electric traction, 409; *disc.*, ætheric telegraphy, 524
 Cement, influence of bacteria on the decay of, 837
 Chadwick, Andrew D., F.C.A., *obituary*, 397
 Chadwick trust, report of council, 678
 Champagne production, 1893-99, 826
 Chelsea physic garden, 890
 Chile, mineral production of, 836
 China, the Yangtze Basin and the British sphere, *paper* by Archibald Little, 77
 Chinese coins, 705
 Cider production in France, 473
 City and Guilds of London Institute, report on examinations, 1899, 483
 Cleaning (dry), process of, 812
 Clocks and watches, imports of, 903
 Cloth pressing by electricity, 560
 Coach building prizes offered by Coachmakers' Company, 39
 Coal (our) supplies, *paper* by T. Forster Brown, 506; *letter*, Prof. E. Hull, 561
 Coal in Kent, 610
 Coal dust in mines, 747
 Coal field, South-Eastern, 823
 Cobb, Francis, annual general meeting, 682
 Cocoa palm and its products in the Philippine Islands, 849
 Coffee in Bolivia, 529
 Coldstream, W., *disc.*, Agrarian conditions under British and native rule, 589
 Cole, Mr., *disc.*, ætheric telegraphy, 524
 Cole, R. Langton, *letter*, armoured glass, 87
 Colfax, H., *disc.*, Nernst's electric light, 258
 Collins, B. A., *disc.*, the gold mines of West Africa, 312
 Collins, J. H., *paper*, Cornish mines and Cornish miners, 359; award of silver medal for his *paper*, 657
 Colomb, Admiral P. H., *obituary*, 874
 Columbia (British), forest wealth of, 285
 ———, salmon fisheries of, 116
 Commercial development of Germany, *paper* by C. Rozenraad, 443
 ——— education, 393
 ———, *paper* by Sir Albert Rollit, 84
 ——— in Belgium, 114
 ——— in England, by Sir Henry Trueman Wood, 573, 590, 624
 ——— in Russia, 751
 ———, international congress on, report of council, 678
 ——— museum at Sofia, 116

COMMITTEES:—

- Lists of sectional committees, 743
 Acetylene generators, report, 287
 Applied art section, 41
 Foreign and colonial section, 25
 Indian section, 875
- Congo Free State, preservation of rubber trees in, 530
 Consular agents, 263
 Conversazione, 657; report of council, 679
 Cook, J. M., *obituary*, 381
 Copying instrument (Wren's), 886
 Cornish mines and Cornish miners, *paper* by J. H. Collins, 359
 Cotton, Sir Arthur Thomas, K.C.B., *obituary*, 742
 Cotton industry, 1899, 482

Council, 1898-99, 1; report, 667; new council, 1899-1900, 680; elected, 682; Sir John Wolfe Barry, K.C.B., F.R.S., elected chairman, 695
 Cowdroy, Arthur R., *obituary*, 626
 Crane (Mr.) *disc.*, Senefelder centenary exhibition of lithography, 1898-99, 250
 Crookes, Sir William, F.R.S., Albert medal awarded to, 672
 Cuban tobacco industry, 892
 Cunningham, Lieut.-Col. Allan, *disc.*, ætheric telegraphy, 524
 Cycle construction and design, *Cantor lectures*, by Archibald Sharp, A.M.Inst.C.E., 755, 767, 779, 791; *syllabus*, 264
 ——— tax in France, 898

D.

Danvers, Sir Juland, K.C.S.I., *chair*, ætheric telegraphy, 519
 Davenport, Cyril, *paper*, vitreous enamels, 315
 Davies, Dixon H., *paper*, the cost of municipal enterprise, 224; *adjourned discussion*, 275; award of silver medal for his *paper*, 657
 Dawes, Sir Edwyn S., K.C.M.G., *chair*, liquid fuel, 384
 Dawkins, W. Boyd, F.R.S., *chair*, our coal supplies, 506
 Dawson, Philip, *paper*, electric traction and its application to suburban and metropolitan railways, 399; award of silver medal for his *paper*, 657
 Day, Lewis F., *disc.*, vitreous enamels, 323; *disc.*, intarsia, 504
 De Segundo, E. C., *disc.*, tuberculosis in animals, 203
 Diamond production of the Transvaal, 849
 Diamonds in New South Wales, 800
 Dicey, Prof. A. V., *disc.*, judicial reform in Egypt, 544
 Donaldson, John, *obituary*, 862
 Donaldson, I. Hunter, *paper*, picture frames, 595; *disc.*, the revival of tradesmen's signs, 623
 Donnelly, Major-General Sir John F. D., K.C.B., *chair*, Senefelder centenary exhibition of lithographs, 1898-99, 245
 Douglas, Prof. James, presentation of medal to, for his *paper*, progress of metallurgy and metal mining in America during the last half-century, 21
 Doulton, Sir Henry, reredos in the chapel of St. Thomas's Hospital to his memory, 414
 Drawing Society's prizes, report of council, 673
 Düsseldorf exhibition, 1902, 128, 397
 Dvorkovitz, Dr., *disc.*, liquid fuel, 305
 Dykes, A. H., *disc.*, Nernst's electric light, 259

E.

Ecclesiastical art exhibition, 1899, 742
 Education (agricultural) in France, 703
 ———, commercial, 393
 ———, *paper* by Sir Albert Rollit, 84
 ———, in Belgium, 14
 ———, in England, by Sir H. Trueman Wood, 573, 590, 614
 ———, in Russia, 751
 ———, international congress on, report of council, 678
 Education (higher) of women in Germany, 777
 Educational exhibition at Berne, 653
 Egypt, judicial reform in, *paper* by Sir John Scott, K.C.M.G., 531
 ——— and the Soudan in 1897-98, *paper* by W. T. Maud, 57
 Electric cabs, 653
 ——— heating, 884
 ——— light (Nernst's), *paper* by James Swinburne, 253
 ——— light in the Society's house, 497; report of council, 679
 ——— lighting in Brussels, 1706
 ——— power, long distance transmission of, *paper* by Prof. George Forbes, 25; *letters* by Prof. Forbes, 103, 139, 626; B. H. Thwaite, 207
 ——— power at Niagara, 775
 ——— railway (Swiss), 862

Electric railway construction in Germany, 662
 ——— railways in Germany, 381
 ——— street railways in Germany, 529
 ——— traction and its application to suburban and metropolitan railways, *paper* by Philip Dawson, 399
 ——— in Chicago, 900
 ——— tramways, 903
 Electrical appliances, exhibition of, at Brussels, 1899, 377, 471
 ——— machinery on board ship, 818
 Electricity, cloth pressing by, 560
 Electro-metalling, recent applications of, 850
 Elgin and Kincardine, Earl of, K.G., G.C.S.I., G.C.I.E., *chair*, port of Calcutta, 627
 Emigration from British India, 380
 ——— (German) in 1898, 654
 Enamels that co-exand with metals, 742
 ———, vitreous, *paper* by Cyril Davenport, 315
 Engineering, science and, Sir W. H. Preece's address to engineering conference, 657
 Erskine, R. S., *disc.*, Nernst's electric light, 257
 Eves, C. Washington, C.M.G., *obituary*, 517
 Ewing, Prof. J. A., F.R.S., presentation of medal to, for *paper*, Liqde's method of producing extreme cold and liquefying air, 21

EXAMINATIONS, SOCIETY OF ARTS, 1899, results, 767; report of council, 673; 1900, notice, 611
 Music, practical examinations, 1898, report of council, 676; 1899, notice, 499; report of council, 677; results, 731

EXHIBITIONS:—

Berne, education, 653
 Bordeaux, food, 115
 Brussels, electrical appliances, 1899, 397, 473
 Düsseldorf, 1902, 128, 397
 Budapest, acetylene, 775
 Ghent, 1899, 38
 London: Acetylene, report of council, 677
 Arts and crafts, 694
 Ecclesiastical art, 742
 South Kensington Museum, lithographs, 1898-99, 37; report of council, 677
 Senefelder centenary exhibition, *paper* by E. F. Strange, 245
 Paris, 1900, foreign industrial designs at, 895
 Philadelphia, 1899, 263, 397, 473
 Rustchuk, 1899, 626
 St. Petersburg, horticultural, 1899, 397, 497
 Eyre, J., *disc.*, leadless glazes, 334

F.

Fairfield, C., *adjourned discussion*, cost of municipal enterprise, 271
 Farrer, Lord, *obituary*, 874
 Felt, iron, 287
 Fibre plants, American, 336
 Fibres of the Philippine Islands, 705
 Filberts in Italy, cultivation of, 150
 Finance, report of council, 680
 Financial statement, 1899, 655
 Fisher, Hayes, *disc.*, law of trade marks, 570
 Fisheries of New South Wales, 663
