INDEX TO VOLUME IX.

The asterisk (*) denotes that the subject is illustrated.

Abelia floribunda 377
 Abertia Caffra 14
 Abies pectinata, forms of, in Europe 273
 Abutilon Lavitzi 438
 — Souvenir de Bonn 98, 108
 Acacia Melanoxylo in California 348
 — tortuosa 62
 Acacias, species of 426
 Acalypha Sanderiana 414
 Acanthads, showy 66
 Acanthus longifolius 284
 — mollis 116
 Acer cissifolium 184
 Achimenes, cultivation of 327
 Acidanthera bicolor 378, 403
 Aconitum lycoctonum 336
 — Napellus 336
 Adenocalymna comosum 17
 Adhatoda cydoniocolia 46
 Adiantum Bessonianum 314
 — emarginatum 493
 — lineatum 244
 Adirondack Reservation, plunder of the 101
 Adonis Amurensis 93
 — vernalis 167
 Advertisements, regulation of publicily displayed 149
 — Esculus Californica 493, 518
 Africa, south, flora of 183
 Agapanthus maximus Krelagei 442
 — umbellatus 404
 Agave heteracantha 73
 Aglaonema Curtisii 474
 Agriculture, college course in 470
 — depression in 391
 — home classes in 11
 Agrostis nebulosa 357
 Aira caryophylla 173
 Ajuga, species of 256
 Akebia quinata 480
 Allamanda Williamsi 367, 379
 Allamandas, species of 383
 Allen, C. L., article by 196
 Allium giganteum 284
 — Margaritanicum 209
 Alliums 247
 Aloe Oregona in Alaska 69
 Aloë plicatilis 443
 Allosaurus acrostichoides 18
 Alpine plants, peculiarities of 153
 Alpinum in the Botanic Garden of Tübingen, the 372
 Althaea ficifolia 305
 Alyssum Wiersbeckii 207
 Amaryllis Belladonna 347, 374
 — cultivation of 66
 — hybrid 487
 Amorphia canescens 298
 Andromeda Japonica 184
 — Mariana 146
 Andromedas 129
 Andropogons, species of 153
 Anemone Caroliniana 298
 — Japonica 424
 — ranunculoides 188
 — Whirlwind 407
 Anemones, Japanese 188
 — species of 236
 Anemopaegma racemosum 383
 Angelonia salicariaefolia 414
 Anguloa uniflora 144
 Annuals, garden 128, 306
 Anona Cherimolia 14
 Anthericum vittatum 457
 Anthurium Sanderianum 333
 Antidesma Dallachyanum 14
 Antirrhinum 128
 — for florists 16, 530
 Apodanthera undulata 63
 Aponogeton distachyon 18
 Apple, a fungous disease of the 474
 — Blenheim Orange 15
 — crop, the 500
 — the Vermont 488
 — culture 280

Apple orchards, will it pay to plant more 68
 — Ralls' Genet 310
 — Tompkins King 10
 — trees, dwarf 310
 — in Illinois 360
 — twig blight 467
 Apples, American, in England 120, 210
 — 220, 500, 510, 530
 — in England, flavor of 161, 183
 — in Oregon 160
 — thinning 380, 450
 — top-grafting 9
 — two varieties in one fruit 380
 Aquatics in California 498
 Aquilegia Jonesii 365*
 — truncata 233
 Aquilegias, species of 217, 236
 Aralia spinosa 320
 Aralias, cultivation of 307
 Arbor day in Spain 270
 Arboretum of the Puget Sound University 110
 Architectural League, annual exhibition of the 88
 Ardisia crenulata 27
 Aristida, species of 153
 — tuberculosa 372
 Aristolochia elegans 497
 Aristolochias, species of 383
 Arizona, Cactus garden in 432
 Arnebia echinoides 295
 Arnicca montana 314
 Arnold Arboretum, notes from 208, 209, 476
 Arpophyllum giganteum 176
 Artemisia caudata 393
 — species of 323
 — stellarina 98
 Artichoke, Jerusalem, a variety of 448
 — the Globe 307
 Artistic supervision of public works 491
 Arundinaria macrospetma 172
 Arundo donax 457
 — versicolor 457
 Asclepias speciosa 298
 — tuberosa 299, 393
 Ash, the American 23
 Ashes, utilizing coal 434
 Asparagus, cultivation of 7, 157
 — rust 394, 420, 428
 Asperula agurea setosa 299
 Aspidistra destructor in Marquesas Islands 209
 Aspidiums, Californian 493
 Aspidistra lurida, hardness of 148
 — scale in California, the 118
 Aspidium cristatum X marginale 444*
 — 450
 — nunitum 272
 — simulatum 484*
 Asplenium Bradleyi 418
 — eburneum 95, 417
 — Trichomanes 96
 Aster alpinus 247
 — speciosus 256
 — infirmis 464*
 — 128
 — in Indiana 393
 — longifolius 504*
 — native 359
 — Chimensis 296
 Astilbe Japonica, propagating 187
 — Japonica, Monspessulanus 256
 Astrocaryum argenteum 6
 Atriplex canescens 194
 Audubon, home of 260
 — Society in Boston 250
 Autumn-flowering hardy bulbous plants 374
 — plants 377, 378, 497
 — the garden in 416, 424
 Avena sterilis 357
 Azalea, Diamond 244
 Azaleas at Brookline, Massachusetts 228
 — sets 248
 — cultivation for Easter 148
 — in England 254
 — cultivation of 187

B

Baccharis halimifolia 415
 Baden-Baden, Max Leichtlin's garden at 442
 — notes from 196
 Bailey, Prof. L. H., article by 42
 Balls from plant hairs in stomachs of animals 320
 Bamboos, cultivation of 517
 — in English gardens 206, 239, 354
 Bambusa Fortunei and other species 457
 Bananas, importations of 50, 530
 — wintering 458
 Baptisia exaltata 237
 Barber, John H., articles by 426, 474
 Barberries, edible 308
 Barker, M., articles by 407, 427
 Barnard College, botany in 40
 Bartram, John 121
 Bartram's garden to-day 122*
 Basella rubra 417
 Bauhinia Galpini 397
 — diphylla 397
 Baxter, Sylvester, article by 312
 Bay Ridge, New York, nurseries at 148
 Beach, S. A., article by 454
 Beal, Prof. W. J., article by 2
 Beans, bush, cultivation of, under glass 84
 — cultivation of garden 194
 — Lima 387
 — string, good varieties of 295
 Beaumontia grandiflora 384
 Bedding plants, propagating 107
 — removal to outdoors 186
 Bees, killed by spraying 170
 Beet sugar, manufacturing, in California 420
 Begonia Baumanni 524
 — Evansiana 30
 — Gloire de Lorraine 494
 — gracilis Martiana 394
 — manicata 457
 — Socotrana 64, 97, 107
 — umbraculifera 98
 Begonias, cultivation of, indoors 386
 — late-flowering 438
 — notes on 18, 76
 — Rex 226
 — winter-flowering 37, 527
 Bell, Stephen, article by 139
 Benincasa cerifera 70
 Berberis buxifolia 174
 — Fremontii 460
 — Nepalensis 174
 — Nevinii 415*
 — pruinosa 67
 — Steboldii 212
 — varieties of edible 309
 — vulgaris in winter 47
 Bertolonias, cultivation of 397
 Bessey, Prof. Charles E., article by 33
 Betonica rosea 306
 Bifrenaria tyrianthina 99
 Bignonia, species of 384
 — venusta 7, 17, 397
 Birds, autumn, in the Pines 452
 — relation to horticulture 58
 — song, destruction of 40
 Birch pest, a 269
 Biscutella Wislizeni 194
 Blackberries, winter protection for 298
 Blackberry plants, cultivation of 376
 Boltonia asteroides 424
 Bomareas, the 147
 Bone meal, nitrogen in 40

White's Selborne.

WHAT are known in a general way as Books about Nature have appeared in such abundance during recent years, that one is rather surprised in taking up the announcement of any publisher if he does not find one or two new ones, and, perhaps, a new writer in the list. This may be considered a wholesome tendency in literature, although the man who invades the privacy of nature for the distinct purpose of writing a book will write like a spy or an eavesdropper and try to tell what will please his readers. The man who flees to nature as he plunges into some other form of dissipation simply to escape the weariness of spirit which comes from artificial life, will also certainly fail to find anything in what he sees, and still less in what he feels, that is worthy of description. The man with no faculty for clear-seeing, no imagination, no insight and no sense of humor who writes about nature (and there have been more than one such in our unhappy country) cannot make an entertaining or a useful book, even on such an inspiring theme. From books of this class it is a delight to turn to an inspired book, one which throbs with the pulse of a self-sustaining vitality. *The Natural History of Selborne* was written before the love of Nature had become a fashion, and Gilbert White did not write it as a matter of conscience or of duty. No book was ever more spontaneous, and it is, therefore, one of the few books which the world will not willingly let die. It has delighted clean-minded men and women for more than a hundred years, and the beautiful new edition of it just issued by Messrs. Appleton & Co. of this city is in no way a doubtful venture. Every new generation will find for it a widening circle of readers, and although the scene is laid beneath the soft skies of southern England, it will delight the dweller in the prairie states who has never crossed the sea as thoroughly as it delights one who knows the Hampshire heaths and Sussex downs by heart.

It seems almost as much of an impertinence to attempt any analysis of the charms of this delightful old book as it is to offer explanations for our enjoyment of a woodland walk. Indeed, the sources of our pleasure in the two cases are identical, for in this book, more than in any other of its

class that was ever written, the author entirely forgets himself, and very rarely even records an impression, but simply holds before the reader the exact pictures which present themselves to his eye. We do not mean by this that the *Natural History* gives no idea of the personality of its author. There is the constant evidence of that sympathetic kinship with every living thing which discovers love and order and intelligence everywhere, and there is the faint suggestion of a pleasant humor. But what we really know of the man—his sincerity and kindliness, his broad charity and his reverent love of nature—is found in an atmosphere that hangs over every page rather than in any distinct expression. Thoreau was primarily a poet, and he held that “the poet writes his own biography.” To him human life was everything; nature at its best did nothing but reflect the man, and, therefore, this recluse, who seemed to live quite apart from his fellow-men, is now the most distinct figure in American literature. White was not a poet, though he constantly trod on the borderland of poetry. He chronicles phenomena for their own sake, and not at all for their relation to him, and yet we cannot help feeling, by some subtle sympathy, the impressions they left on him, so that the man himself in his essence is set before us in his pages almost as distinctly as if he, too, were consciously writing his biography. Thoreau declared of himself that he was a mystic as well as a natural philosopher, but there was nothing transcendental about Gilbert White. He was no seer of visions and no dreamer of dreams. He simply went about contentedly scrutinizing with the inquisitive eye of a child everything that came within the range of his vision, and he wrote down these impressions which came to him with all the freshness of new discoveries in language as simple and direct as a child's. He did not attempt to lift his subjects into the higher realms of imagination; he never told the world what manner of food they furnished for his spiritual nature. We cannot think of him pronouncing a Fern as Thoreau did, “another sacred scripture helping to redeem life,” but he painted the Fern itself so clearly that the reader can apprehend for himself its message of law and love.

This brief contrast between the two men who, standing a century apart, represent, perhaps, what is best in the literature of nature, is made not to set one before the other, but simply to give a hint of the range of their diversity. Our literature would be distinctly poorer if deprived of some of the eagle flights of Thoreau's imagination, and certainly nothing was ever written to fill exactly the place of the *Natural History of Selborne*. No more sane and wholesome book was ever penned. Jefferies was as keen-sighted a naturalist as White, and much more of a poet, but he had none of the serenity of a strong nature, and his work is feverish. He asked the reader into the fields to see him worship nature, and then begged for commiseration because his Deity would not satisfy all the cravings of his morbid desires. White does not say, as Thoreau does, that his profession is to find God in nature, but no one can accompany him in these rambles through Selborne without feeling

That he, and we, and all men move
Under a canopy of love
Broad as the blue sky above.

But it is impossible to say anything new of a book that has delighted the world for so many years. There is no need to speak of the singular clearness and beauty of the style which is the very perfection of descriptive English, nor to repeat that by his acuteness of observation White anticipated one, at least, of the discoveries of Darwin. It may be interesting to Americans, however, to know that he realized that the waste from forest-fires was not so much the wood that was burned as the destruction of future possibilities of the soil, on which point he says:

About March or April such vast heath-fires are here lighted up that they often get to a masterless head and, catching the hedges, have sometimes been communicated to the under-woods, the woods and coppices where great danger has ensued. The plea for these burnings is that when the old coat of heath

is consumed young will sprout up and afford much tender browse for cattle; but where there is large old furze the fires following the roots consume the very ground, so that for hundreds of acres nothing is to be seen but smother and desolation, the whole circuit round looking like the cinders of a volcano, and the soil being quite exhausted, no traces of vegetation are to be found for years.

The American public is to be congratulated on the opportunity to possess an edition of this classic in such a tasteful dress and with many attractive pictures of Selborne as it is, which probably differs less than we might suppose from the Selborne of White's day.

Village Streets and Country Roads.

FOR the enjoyment of prospects on streets, good sidewalks and well-made roadways are necessary. In the business portion of a village there is not much opportunity for growing trees successfully, but many other details go to make a favorable or unfavorable impression on citizens and visitors. Neat arrangements for hitching horses are appreciated by persons who are driving. A good and durable device is in use in the city of Hudson, Lenawee County, in this state. When the main streets were paved the merchants combined and put in three-inch gas pipes of uniform height for posts, with a rail of the same pipe passed horizontally from post to post on which are rings. A really good sign is a rarity in a village, and generally the signs of stores and offices are unattractive or disfiguring. Modern plate-glass windows of generous size help to give a town an enterprising air, as do cleanliness and freedom from all sorts of rubbish. The tasteful arrangement of goods in the stores is no small attraction, but a mixed variety is often allowed to remain in a window for months with little attention from the proprietor.

Any attempt to make country highways attractive is even more rare than an adequate appreciation of beauty in village streets. Some of the roads near which I have lived for the past twenty-five years I have made objects of observation and study. About twenty years ago a double row of American Elms, more than a mile long, was planted along the entire front of the Agricultural College farm. The trees in the street were forty feet apart and ten feet from the fence, alternating with others forty feet apart, four feet inside the fence. In all such designs for planting the idea seems to prevail that long, straight rows of one kind of tree, planted at uniform distance, must in time make a grand display. Such results are, however, rarely realized. In this instance the ground is far from uniform in fertility, and the trees are very uneven in size, some now having a diameter of trunk five times that of others nearly the same age. The shapes of the tops differ a good deal. Some trees are crowded by other trees along the road which have come up of themselves, and by orchard trees in adjacent fields. Occasionally a tree has broken off or been split down. In several instances trees have died, leaving unpleasant breaks in the rows. This season some were much damaged by two or three kinds of insects, while others were less molested. To the west, over a gently rolling surface on the same road, nature and the orderly, old-fashioned pathmaster have been at work. Native trees, shrubs and perennial herbs in great variety have taken possession of the road on either side, and the fences are hidden from sight for much of the distance. Here is a great variety of woody growth and some views such as an artist would select for sketching. I noticed in half a mile five or six kinds of Oaks, three of Poplars, two of Elms, two of Ashes, three sorts of Hickories, eight of Willows, three of Dogwoods, several kinds of Viburnums, one kind of Hazel, a Sumach, three kinds of Maples, a Blue Beech, Ironwood, Basswood, Wild Plum, Wild Crab-apple, Sassafras, Butternut, Black Walnut, Grapevines, Virginia Creeper, Button-bushes, two sorts of Wild Roses, Raspberries, several sorts of Thorns, Asters and Golden-rods in variety. Bunches of second growth or sprouts, where trees or shrubs have been cut down, make pretty clumps, and

groups of Hawthorns are beautiful when in flower, as also in autumn when full of fruit. There are bunches of Willows beyond a bog of Sedges, and over the Willows festoons of Virginia Creeper. On the knolls certain sorts prevail, in the lowlands others are found, while the wet places have still a different combination. The highway is in excellent condition most of the year.

To my way of thinking there is much more to admire along this highway of half a mile, where nature has made her mixed planting, than along the highway where stand the double rows of American Elms. And this illustration has a special application to village planting. I would plant along the village streets, or leave, if already there, some Hawthorns, Dogwoods, Virginia Creepers, Grapevines and a mixed lot of native trees and shrubs. Of course, they should not remain as thick as in the highway referred to, but choice selections could be placed or left in certain suitable spots. To a considerable extent the same general rule applies to the planting of roadsides in the country and to streets in the village, although trees for shade are more essential in the village.

But owners too often do as others have done, cut away all native plants, seed to grass and plant Maples thirty feet apart, exactly one or exactly ten feet from the fence. Along the road already referred to I recently sold an acre to each of two Germans, and made the request, which they seemed to assent to, that I might suggest some of the wild shrubbery that ought to be left. They built houses and began so-called improvements by cutting out all wild shrubs and trees, leaving only a few trees, which they trimmed up from the ground. Still farther west on the road under consideration a pathmaster has several times cut all the young trees and shrubbery, excepting a few nearly in line by the fence. He even cut down some of the largest and finest trees a foot or more in diameter because they were not near enough to the line to suit him.

In planting trees for streets I should first seek some native species, taking care to place each in soil suited for its best development. Once in a while a stubborn planter will persist in a straight row of Sugar Maples, and by so doing the streets become an object-lesson, as they should. It is well enough to plant trees thickly along the street, but the trouble begins when half or two-thirds of them should be removed to give the others room to make fine specimens. Not one man in a thousand has the foresight and the nerve to take out some of the pretty young trees before all become crowded, slim and unsightly. Then it is usually too late, and all are left to struggle with each other.

Agricultural College, Mich.

Opuntia arborescens in the South-west.

THIS large Cactus, the *Tasajo* of the Mexicans, which grows to be a tree on the Tucson plains (see fig. 1, p. 5), was among the first of these plants described from the south-west. It was brought back, with a number of other interesting Cacti, by Dr. A. Wislizenus, from his tour to Mexico in 1846 and 1847. His plants were entrusted to Dr. George Engelmann that he might study and describe the many novelties included in them; and since its discovery it has been cultivated by Cactus-growers, but it is not as popular as many of the smaller and more compact species.

This Cactus has a much more extended range than any other of our cylindrical *Opuntias*. It is found to some extent on the mountains and high plains of western Texas; extends northward into Colorado to the head-waters of the Arkansas and Platte rivers; westward to south central Arizona, and southward far into Mexico.

Although it has frequently been reported from the plains of northern New Mexico and southern Colorado, in this Territory it does not occur north of the great rim which separates the northern plateau from the southern plains. Throughout northern Arizona its place is occupied by the smaller, but closely related, *Opuntia whipplei*, which extends west nearly to California and east into New Mexico.

A plant, much larger than *O. Whipplei*, was found a number of years ago by Dr. Schott south of the Gila River, extending to Tucson. Dr. Engelmann considered this plant a variety of *O. Whipplei* (*O. Whipplei spinosior*). As before stated, *O. Whipplei* has a very limited range, and is confined to the southern portion of the Colorado plateau at elevations of from 5,000 to 7,000 feet. The so-called variety is confined to the low southern plains, growing at elevations of from 1,500 to 3,000 feet above the sea, where it is mingled with *O. arborescens*. After extended field observations, I conclude that *O. Whipplei spinosior* is much more closely related to *O. arborescens* than to the more northern plant, and may more properly be considered a variety of that species.

Opuntia Whipplei is readily distinguished from related species by its usually small size; subprostrate habit of growth; numerous, erect, small, elongated branches, glistening, white, loose spine-sheaths, and small, densely tuberculated, sweetish fruit, which does not turn yellow on ripening, but late in fall withers and dries on the plants. On the other hand, it is almost impossible to separate the southern variety from *O. arborescens*. Both are large, upright, loosely branched plants, with distinct trunks, frequently ten to twelve inches in diameter. The branches are horizontal or pendulous and arranged in whorls. When fully ripened the fruits of both are yellow and well-filled with juice. The seeds are numerous, dark-colored when moist, but becoming white on drying.

The greatest distinction seems to be in the flowers, but here there is so much variation no specific distinction can be drawn. The large magenta-colored flowers of *Opuntia arborescens* usually have numerous broadly obovate petals, while in the other plant the petals are fewer, much narrower and acute at the apex. The flowers of the latter vary in color from greenish yellow, as in *O. Whipplei*, to pink, purple and magenta. It is possible to find plants showing all of these variations only a few rods apart, and even flowers on the same plant show considerable variation.

The flowers of *Opuntia arborescens* appear in this locality during April and May, remain open for two or three days, and are fertilized mostly by bees. These insects, attracted to the flower, enter between the style and stamens, passing down to the base of the style to get the nectar. The numerous sensitive stamens immediately bend forward toward the style, closing over the insect and hiding it from view. It necessitates quite an effort on the part of the insect to escape, but it finally forces its way from beneath the stamens and climbs to the top of the slightly elongated stigma, whence it makes its escape, thoroughly dusted with the pollen from the numerous stamens. In a few minutes the stamens assume their normal condition and the flower is ready for the reception of other insects. I have frequently seen as many as three honeybees enclosed in a single flower.

The twenty to thirty pulvilli on the ovary are at first armed with a number of slender spines which are deciduous in December as the fruit begins to turn yellow. Throughout the summer the tubercles on the ovary are very prominent, but as the fruit ripens it increases considerably in size, becomes much more succulent, and as a result the tubercles are no longer prominent. The fully matured fruit is frequently two inches long and one and a half inches thick. After ripening the fruit remains on the plant through the winter and sometimes through the next summer. The persistency with which the ripened fruit hangs to the plant gives rise to the popular idea that the fruit does not mature until the second year.

Occasionally flowers develop at the pulvilli of a matured fruit, and other fruits are formed on the old one. In such cases the fruit is prolific, but of two seasons' growth. Most usually the fruit is clustered at the extremity of the branches of the previous year's growth, and during late summer, autumn and winter the verticillate branches are pendulous from its weight.

The spines persist for several years, increasing in num-

ber each year from the upper end of the pulvillus. The trunk and large limbs are destitute of spines, but are covered with a dark brown rough bark in elongated ridges.

The reticulated wood is used to some extent in the manufacture of light furniture, fancy articles, canes, picture-frames, etc. A factory was established in Salt River Valley some three years ago for the purpose of manufacturing articles from this wood.

Foreign Correspondence.

London Letter.

DENDROBIUM CÆLOGYNE.—This is the largest-flowered of the *Sarcopodium* section of the genus characterized by short, erect pseudo-bulbs, springing at intervals of two inches from a stout creeping rhizome and bearing a pair of leaves, the general appearance suggesting *Bulbophyllum*, or, as in the species under notice, a *Cœlogyne*. Sir Trevor Lawrence exhibited a plant of it in flower last Tuesday; otherwise I have never seen it in flower since it bloomed at Kew about seven years ago. I saw a group of healthy, recently imported plants of it in the Clapton nurseries of Messrs. H. Low & Co. a few days ago. The species was described from a plant flowered by the late Mr. John Day in 1871. It has pseudo-bulbs two inches long, elliptic-oblong leathery leaves six inches long and solitary flowers in which the sepals are lanceolate, the base of the two lateral forming a broad chin; the petals are linear and the lip is large, fleshy, scoop-shaped and colored deep purple on the front lobe, pale yellow with purple streaks on the side lobes, the other parts of the flower being dull yellow with reddish lines and blotches. In size the flower is about equal to *C. brunnea*, but fleshier. The species is a native of Moulmien.

DENDROBIUM TREACHERIANUM.—This belongs to the same section as *Dendrobium Cœlogyne*, which it resembles in habit, but the pseudo-bulbs are close together, longer and angulate, the leaves shorter, and the scape bears from two to ten flowers, which are two inches long with linear segments, colored pale rose-purple and a rose and dark crimson fleshy lip. It was introduced from Borneo in 1881 by Messrs. Low & Co., but is rare in cultivation, probably owing to the difficulty most cultivators experience in keeping it healthy. Sir Trevor Lawrence is, however, an exception in this respect, for he exhibited a plant this week which bore three spikes, carrying twenty flowers, which was deservedly awarded a first-class certificate and cultural commendation. A figure of this species was published a few years ago in *The Botanical Magazine*, t. 6591, from a plant flowered in a hot moist stove at Kew. It was named by Reichenbach in compliment to Mr. W. H. Treacher, a government official at that time in Labuan.

PHAJUS MISHMIENSIS is a handsome species, of which two examples are now in flower in a warm house at Kew, one of them being the plant described by Mr. Rolfe two years ago as a new species under the name of *Phajus roseus*, and erroneously stated to be from west tropical Africa (*Kew Bulletin*, 1893, p. 6). The other was imported from Calcutta this year as *P. Mishmiensis*, and the two are identical. *P. Mishmiensis* is a native of Assam, Sikkim and lower Burma, and has been known to botanists since Lindley's time, although only lately introduced. I believe Messrs. Low & Co. have some recently imported plants of it. In habit it resembles *P. Wallichii*, but is smaller; the scape is two feet high and bears a dozen flowers, each about one and a half inches across and colored rose-pink when first opened, changing to buff before fading. There are a few whitish spots on the lip and a ridge of white hairs down the centre. It thrives under the same treatment as *P. grandifolius*.

MELASTOMA MALABATHRICUM.—This is an old garden plant of considerable beauty which has fallen into general neglect, except in the Edinburgh Botanic Garden, where this year it formed a pyramid twelve feet high, clothed from top

to bottom with mauve-purple flowers two inches across. It is planted out in a bed of light soil in a sunny position in a large stove, and it has grown to its present size from a small plant in about two years. Grown in a pot this plant is scraggy in habit and flowers only indifferently; it is evident, therefore, from the success met with at Edinburgh that liberal treatment gives exceptionally good results. This is equally true of *Pleroma* (*Lasiandra*) *macrantha*, which, for several months, has been a sheet of flowers in a sunny greenhouse at Kew, where it is planted out and trained along wires close to the roof, exactly as if it were a *Gloire de Dijon* Rose. *Melastoma Malabathricum* is a native of India, where, according to Sir Joseph Hooker, it is called by the English "Indian Rhododendron," being common from sea-level up to 6,000 feet. It is a variable plant, as is shown by Mr. Bentham, who included under it no less than twenty-four species of another botanist, Naudin.

RED-BARKED WILLOW.—A beautiful winter effect is obtained at Kew by planting this Willow on the margin of the lake in a conspicuous place, so that the glow of its shining crimson stems gives warmth of color quite equal in effect to that produced by the Siberian Dogwood. This Red Willow is said to be a red form of the common White Willow, *Salix alba*. It forms a handsome bush, but to get the full value of its color in winter it requires to be well pollarded every spring. It is a first-rate garden plant. Here it is called *Sanguinea*.

YELLOW-BARKED WILLOW.—This is another variety of the White Willow, and is known at Kew as *Salix alba vitellina*. It is used in the same manner as the red-barked variety; in fact, the two are planted together, so that the golden yellow wands of the latter heighten the effect of the red shoots of *Sanguinea*.

WHITE-BARKED WILLOW.—This is a variety of *Salix daphnoides* which is grown by Mr. A. Waterer in his Knap Hill nursery as *S. acutifolia*. It is remarkable for the white-flour-like bloom which clothes the stems and makes them look as if it had been whitewashed. These three Willows should be in every garden where shrubs are valued.

RED-STEMMED DOGWOODS.—There are several varieties of *Cornus alba* which are remarkable for the shining red color assumed by the bark of the younger shoots in winter. The best of them is one which at Kew bears the name of *C. alba variegata*, the stems of this being as red as sealing-wax. What is generally grown under the name of *C. Sibirica* (really a variety of *alba*) is a shade or two darker in color, and therefore less effective. It may not be generally known that to obtain a plentiful crop of red-barked shoots on these plants the old stems must be cut out level with the ground every spring; this induces the development of long sucker-stems, and these always assume a rich color in winter. The difference between a specimen thus treated and one left unpruned is so great that they do not appear to be of the same species. At Kew these Dogwoods are planted in large masses in open sites on the lawns, and the color they give all through the winter is most valuable. They are planted in large round beds, and among them are placed spring-flowering bulbs with flowers whose colors harmonize with the red of the Dogwoods. Other red-stemmed Dogwoods grown at Kew are *C. amomum*, a native of North America, which has purplish shoots; *C. stolonifera*, also American, with red-purple shoots, and *C. Baileyi*, a Canadian species, with brownish red bark. This last was figured in *GARDEN AND FOREST*, 1890, page 465.

COMMERCIAL FIBRES.—The importance of fibre-yielding plants is shown by the fact that in 1893 the value of raw fibrous material imported into the United Kingdom alone was £50,000,000, and of the goods manufactured from this material £74,000,000. It is also shown by the correspondence conducted at Kew in relation to fibre-yielding plants, and the information published from thence in the *Kew Bulletin*. The Assistant Director, Dr. D. Morris, C.M.G., whose experience both at Kew and in the colonies constitutes him an authority upon the subject, has told the whole

story of commercial fibres in a series of lectures delivered before the Society of Arts, and since published in an illustrated pamphlet of forty-two pages.* The history and origin of fibre industries, the character and value of the various fibres, the nature and peculiarities of the plants that yield them, with other interesting information, are set forth with that care and thoroughness which characterize all Dr. Morris's work. The pamphlet will, therefore, be the recognized referee upon all fibre questions for some time to come, and, consequently, it will be valued by all who are interested in fibres commercially or botanically. As an instance of what Kew has done and continues to do in fostering plant industries the following is an example: The closing of the ports in Madagascar consequent upon the war with France sent up the price of *Raffia* bast, hitherto obtained only from that island. Several species of *Raffia* likely to yield a fibre are known to be abundant on the west coast of Africa. The curators of the botanical stations in our colonies were therefore advised from Kew to look into the matter, and, if possible, collect and send home samples of the fibre from the Palms there. The result has been the important discovery that *Raffia* as valuable commercially as the best hitherto obtained from Madagascar can be had in any quantity from our possessions in west Africa.

Plant Notes.

CATTLEYA TRIANÆ.—This noble and most popular of all Orchids is now in season. Wherever Orchids are grown it will be seen in its full beauty during the Christmas and New Year's season in an infinite number of varieties, from the costly forms with pure white flowers through all the delicate shades of blush and rose and crimson. There is great variety in the coloring of the lip, the throat being generally yellow or orange, while the apex of the lip is more or less intensely colored in purple, bright rose, violet or magenta. This species is becoming more and more popular every year, and as it is inexpensive and easy of culture it will, no doubt, soon be one of the most useful of midwinter flowers. The flowers are lasting and the plant will keep beautiful in a dwelling-house much longer than almost any other flowering plant. Orchids will undoubtedly be useful as house-plants when they become more generally known.

HELLEBORUS NIGER.—The Christmas Rose is the only hardy herbaceous plant flowering in midwinter, and as such deserves to be widely known and cultivated. The buds, as in the case of many other herbaceous plants, are formed during the preceding summer, ready to burst into flower during the earliest warm spell in midwinter. The flowers open more readily during the Christmas season if there has been a severe frost during the preceding months, but even with hardly any frost it is generally possible to have a rich supply of Christmas Roses during the holidays. Any failure in this respect is usually due to a lack of moisture. The freshness and snowy purity of the large-flowered Christmas Rose, *H. niger altifolius*, is unrivaled when forced under glass. Protected against all destructive winds and droughts in December the buds will soon swell and develop if the plants are kept moderately cool and moist and in a sunny position. The foliage and buds must be kept constantly wet, for if the buds are allowed to dry but a little, the beauty of the flowers will be marred. This need of moisture explains why the flowers expand and develop so remarkably well under the snow. When the warm rays of the sun in February melt the snow which snugly covers the leaves and buds, there is a constant moisture which seems to be essential for the preservation of the leaves and for the unchecked growth of the buds. All the varieties of *H. niger* may be forced, either in pots, when large clumps should be lifted

* William Trownce, Gough Square, Fleet Street, E. C. Price, one shilling.

and potted in the fall and stowed away in cool frames, or a frame may be placed over the plants where they grow in the open ground. Where there are only a few plants hand-glasses are useful. Plants will flower earlier when potted, partly because they may be kept more fully under control. A cool and moist place in a Carnation-house is also a very good place for forcing Christmas Roses.

Among the varieties *Helleborus niger angustifolius* is the smallest as well as the earliest. The flowers of this form are slightly greenish during the first days, at least, and gradually assume a reddish tint. This form differs but

Cultural Department.

The Garden in Winter.

DECEMBER is the one month in the year when the garden in this latitude is most nearly at rest. We are apt to think that our plants are perfectly quiet at this season, when frost and snow usually prevail, yet a garden is never at rest if planted with hardy plants and bulbs which flower at different seasons. The summer rest is, perhaps, the only one many of the hardy bulbs know. They start into growth when the cool rains fall in autumn, and it is as natural to many of them to flower in frosty winter or early spring as for others to bloom in

Fig. 1.—*Opuntia arborescens* on the Tucson Desert.—See page 2.

slightly in appearance from the type, but the flowers are smaller. *H. niger maximus*, or *altifolius*, is the largest as well as the purest white of the varieties. It must be remembered when the plants are forced for house decoration that the foliage must be preserved in its full beauty. The leaves in themselves are very handsome deep glossy green and of an elegant habit. They contrast beautifully with the white flowers and form a pleasing background to them. The calyx, which is the showy part of the flower, is persistent; it does not fall, but fades gradually into a reddish gray as the carpels develop.

summer warmth. Such hardy plants—to speak of the common ones—as Primulas, Saxifrages, Aralias, Aubrietias, Spanish Irises, Muscari, Sedums and even Crocuses, show green leaves all winter, and though these are often prostrated by frost, a few hours of sunshine starts them up vigorously. If a bulb is in the habit of flowering at a certain time it may be depended on to start into growth in due season and make constant progress toward maturity under very adverse conditions. The energy expended in growth develops warmth, so that even in a frozen investment there is some progress. It is only solidly frozen earth which will keep many of the Snowdrops under ground after this time of year, and they will always appear after two or three mild days in January. Looking over the

garden at Christmastide I found many of them just peeping up, forced by an unseasonable spell of mild weather. It would be interesting to know by what peculiar arrangement the leaves and flowers of these and many other plants are enabled to pass through such trying temperatures without disruption of their cells or apparent injury. Another interesting thing in the garden in winter is the germination of the various seeds which have fallen or have been sown. Scilla seeds were germinating the other day, and no doubt I should have found seedlings of Snowdrops had I looked for them, and, perhaps, of other plants which start under slight encouragement of warmth at this season. One of the primary lessons that the experimenter in hardy plants learns is that seeds of many of them have peculiar habits of germination difficult to tabulate. Some seeds, as those of Hollyhocks, will sometimes germinate on the plant in wet weather, and others germinate quickly enough, but a large majority require a certain seasoning and cannot be made to start without it, even though apparently well ripened. This is one of nature's little devices to perpetuate the species by deferring the germination to a fitting season, and we cannot always make haste even when we have fresh seeds at hand. Such seed the plantsman buries in earth or stratifies for such time as may be necessary for its ripening; if, in the mean time, it is frozen up a few times, it receives a quickening. The growing of seedlings is a fascinating pursuit too little appreciated by impatient gardeners.

Elizabeth, N. J.

J. N. Gerard.

Plants for Winter-blooming.

EUPHORBIA FULGENS is among the most beautiful of winter-flowering plants, and its long wreaths of brilliant scarlet flowers are effective for conservatory and house decoration. Although considered a difficult plant to establish, we have been fortunate enough to secure the conditions necessary for its successful cultivation. It is a subshrubby perennial which may either be pruned annually and grown on from year to year into large specimens or be grown from cuttings every year. The plan of annually raising new stock is generally the better one, and only where the proper conditions can be provided in partial rest from water during the latter part of the flowering season and during winter should old plants be grown on. These old plants are especially suited for training on pillars, rafters and walls and for conservatory decoration, and used in this way no more effective plants could be chosen.

Soft cuttings are taken with a heel, and placed at once in a propagating-bed with a bottom temperature of sixty-five degrees, Fahrenheit. They will be rooted in about thirty days, and then are potted into thumb-pots in light soil, with some charcoal for drainage. As they are needed they should be shifted, without disturbing the roots, into four, and ultimately into six, inch pots, in which size they bloom. We give them manure-water frequently during the summer. The plants grow luxuriantly, and before the flowering season they are very much pot-bound, a fact to which our success is probably due. A gardener of my acquaintance considers October a critical month in the cultivation of this Euphorbia, as his plants generally fall at this time. Although he is careful, he thinks his loss due to overwatering, perhaps once only at a time when the nights are cool and before fire-heat is in general use. Upon turning out several pots to show the condition of the roots we found all the feeders dead. With regard to fire-heat his experience and mine are the same, but my plants, being pot-bound, were in less danger of injury from overwatering. They are now well rooted through the pots into a gravel-bed, getting about all the moisture they need in this way.

A plant of *Daphne Indica* is enough to fill a large conservatory with its perfume. It is ungainly, not easy to grow, and difficult to propagate from cuttings, which may in a measure account for its comparative rarity. The practice of grafting *D. Indica* and other greenhouse species does not seem to be generally adopted in this country, owing probably to the difficulty of obtaining good hardy stocks. *D. Mezereum*, the principal species used in European countries, is doubtfully hardy here. The usual plan when propagating from cuttings is to take matured side shoots in the autumn and place them in pots in a cool greenhouse to callous over winter. In spring they are started in a gentle heat, and may be expected to root in four to six weeks. I have not, however, succeeded well by this plan, and last spring I tried taking half-matured shoots with a heel, and placing them in an ordinary propagating bed, without bottom-heat. They all calloused and some were rooted in two months; all were then potted into three-inch pots in a mixture of loam and peat and a little sand, with some charcoal for drainage, and they are now bushy little plants

about eight inches tall, and most of them have matured a small umbel of bloom.

Libonia Pentrosiensis is a handsome evergreen winter-blooming subshrub, a hybrid between the well-known *L. floribunda* and *Jacobinia (Sericographis) Gheisbreghtiana*. Grown every year from cuttings taken early in spring and planted outdoors for the summer, the plants make neat little bushes about a foot in diameter and a foot high, which can easily be lifted and potted into six-inch pots. The flowers are tubular, orange red, about an inch long, slightly labiate, and horizontally exerted in small panicles from the axils of opposite leaves. They are produced successively, and in sufficient numbers to make the plants effective and at the same time never untidy for a month or more; and when out of bloom these handsome little bushes of refreshing green are still serviceable.

Wellesley, Mass.

T. D. Hatfield.

Palm Notes.

Hydriastele Wendlandiana.—This rare and beautiful Palm is rare in this country. It is a tall and slender Australian species, with stems somewhat resembling those of *Seaforthia elegans*, but more slender, with regular ringed nodes. The stem, which under greenhouse cultivation is sometimes seen as high as ten or fifteen feet, carries a leafy crown of long, spreading, pinnate leaflets, with from twenty to thirty pinnæ, sometimes over a foot long, those of the apex confluent at the base and very irregular, with a square-cut ragged and toothed apex and slender petioles, sheathing at the base. This is a moisture-loving tropical Palm of great value for small conservatories, and one of the small Palms that ought to be introduced and grown more commonly. The pots should be comparatively small and well drained, the soil rich and fibrous, and during summer too much water can hardly be given. The species thrives best in a deep shady and warm position. In direct sunlight the leaves always become stunted and disfigured. Seeds are hard to obtain, but germinate readily when fresh.

Astrocaryum argenteum.—This ornamental Palm is a native of the tropical valleys of the United States of Colombia and neighboring countries. It has a distinct and peculiar beauty, with leafy crowns of silvery foliage and numerous black needle-like spines, very long and exceedingly fine and sharp. The leaves are wedge-shaped, pinnate and closely set at the apex of the stem. The lower pinnæ are comparatively narrow and distant, while the upper ones, especially in small specimens, are very broad and confluent, with a torn and toothed apex. While the upper surface is bright green, the lower side is covered with a silvery tomentum which makes the species highly ornamental. Specimens grown in conservatories and greenhouses are generally seen in a stemless condition, with bushy crowns about twice as wide as high, owing to the almost horizontal position of the leaves. Like most silvery plants, these Palms grow in the full glare of the sun, often in apparently dry and barren positions. Under cultivation they will thrive anywhere in a moderate shade or in a quite sunny position. They are of easy culture, doing well under ordinary treatment with moderate heat and moisture.

Triartia Bungerothii.—Sometimes when growing in moist places Palms assume a peculiar and curious habit. The stem, which from the first grows upward, is very slender, almost thread-like, and consequently unable to support the great weight of the plant in a more mature state, but as the plant increases in size adventitious roots are formed from the stem; like strong and slender buttresses, these support the stem high in the air. As the Palm increases in size stronger roots are thrown out for support. *T. Bungerothii* is the most beautiful example of this type. It is a rather small Palm with a stem one or two inches in diameter, and, as seen in greenhouses, from four to six feet high, smooth and polished. The leaves are pinnate, with very broad, wedge-shaped pinnæ, irregularly disposed along the slender rachis and obliquely cut and ragged on the edges. The leaves are beautifully green and shining. Lateral roots at first very slender; later on often half an inch in diameter, not unlike the well-known adventitious roots of a Screw Pine. This species will thrive in ordinary rich and fibrous soil in a half-shady position and an average temperature of seventy degrees.

Latania Commersonii.—This species is often grown in conservatories and greenhouses under the name of *Latania rubra*. It is one of the most beautiful and ornamental of all tan-leaved Palms, and a native of Mauritius. The leaves are spreading, eighteen inches to two feet in length, as commonly seen in cultivation, with from fifteen to thirty long and slender wedge-

shaped segments finely toothed at the edge and bordered with a narrow band of a reddish color. The slender petiole is but slightly longer than the blade and of a reddish chocolate hue. *L. Commersonii* is a dwarf species of elegant habit and desirable for all decorative purposes. As a small plant it is more graceful than *Livistona Sinensis*, but of a duller coloring. In conservatories and greenhouses it is thus far very rare, being found only in some of the larger establishments. Rich fibrous loam, with an addition of leaf-mold, well-decayed manure and sand, forms an excellent compost. The drainage must be good, and during summer an abundant watering is necessary, as well as frequent sprayings. Although a tropical Palm, it will do well in any warm greenhouse in a half-shady position.

Chamærops stauracantha.—This picturesque and graceful Palm has large palmate leaves divided into four to eight broad linear segments one foot or more long of a very dark green color. The petioles are very slender, not unlike the petioles of the well-known *Thrinax*, and about twice as long as the blade. The stem is covered with thin fibrous sheaths and protected at the base with enormous-branched spines of a needle-like sharpness. Leaves, in ordinary greenhouse specimens, are from eight to fifteen. This Palm is quite unlike the common types of *Chamærops* in foliage and habit. It is of a striking and unique beauty, and as it requires no special treatment deserves to be more generally grown. As yet it is very rare and expensive. It thrives best in a partial shade, and with ordinary greenhouse treatment in any rich and fibrous soil.

Asparagus Culture for City and Village Lots.

ASPARAGUS, considered as a vegetable, has some peculiarities which distinguish it from other plants of the kitchen garden. The growing plant is very beautiful. Its feathery masses of graceful foliage, its peculiar shade of green in summer, the bright red berries contrasted with the rich yellow of the maturing plant in the autumn, make it well worthy of a place among ornamental plants, particularly in the shrubby border. In cultivation the plant is injured rather than benefited by frequent stirring of the soil; all it asks is abundant room, not less than five feet square to each plant, and liberal feeding. It takes time to establish itself, but when this is well done a little care and free manuring each year will keep it permanently and enormously productive, a single plant under the Argenteuil system of cultivation having furnished thirty-seven pounds of the choicest asparagus in a season.

The beauty, the ease of culture, the permanency and productiveness of the plants, and the fact that asparagus, even more than most vegetables, should be used when perfectly fresh—should be cut and cooked the same hour—warrant the cultivation of this plant in places where the attempt to grow other vegetables might not be wise. A few plants can be introduced with good effect in highly kept pleasure-grounds. A few can be set in the corner of the fence or beside the shed in places too contracted to warrant the attempt to have a garden of any kind. In fact, there are very few town and village places that could not easily furnish the family with an abundant supply of this vegetable at a trifling expenditure of labor, and without detracting from the beauty or usefulness of the grounds. As a guide to those who may wish to undertake asparagus culture in the way suggested, I give the cultural methods followed in the Argenteuil district of France, which has the reputation of producing the finest asparagus in the world. A considerable proportion of that grown there is the product, not of Asparagus farms, or even of fields and beds, but of single plants or clumps standing by themselves, or in groups of from five to twenty scattered here and there in any open space that may chance to be left in corners or between trees and buildings. Wherever there is an unused bit of ground five feet in diameter, which is not in dense shade or liable to be covered with water, there the Argenteuil gardener sticks in a plant, gives it good care, and is well repaid for his labor.

The method of cultivation is simple. The spot is put in good tilth and made moderately rich; a vigorous plant is carefully set out so that its crown will be about four inches below the surface-level; weeds are kept down by shallow surface cultivation, and in the fall, after the tops are fully matured and dead, the surface for a circle of five feet in diameter is covered with rich and well-rotted manure. As early in the spring as possible this manure is well-forked into the surface, and the starting weeds kept down by shallow hoeing until the plant has made sufficient growth to take care of itself. The third season the treatment is the same as in the second, especial care being taken to take out any seedling Asparagus-plants which may spring up, they being treated as the worst

of weeds. The fourth season the harvest commences, though if the plants have made a good growth a few cuttings are made the third year, but it is considered better practice to wait until the fourth, in order that the plants may become well established. The manure is spaded in as early in the season as possible, and as soon as the first shoots appear at the surface the soil is heaped over the crown of the plant in a mound about a foot high, which serves to blanch the growing shoots. In gathering, the shoots are broken as far as possible below the surface. The covering soil being friable from its abundant manuring enables one to secure much longer shoots than if it were level. Care is taken to remove all the shoots at each picking and not to prolong the season far into the hot weather, so that the plants may have a chance to make a good growth in preparation for the next season's crop. At the close of the season the mound of earth is leveled with the surface, and about two quarts of fresh wood-ashes and a handful of salt are scattered about each plant and hoed into the surface. The treatment given the fourth year is repeated, and the shoots gain in number and size as the plant increases in age.

Class Work in Horticulture at Cornell.

To the Editor of GARDEN AND FOREST:

Sir,—You have said so much in recent numbers on the subject of horticultural education that I make bold to send you a brief account of certain class work as it is now conducted in this university. Course No. 1 in horticulture is a term's work in "The Evolution of Cultivated Plants." Necessarily, much of the discussion turns upon the general theories of evolution and a sweeping conspectus taken of the natural history of the plant-world. The course consists of lectures, but the following account of the incidental work will show something of the scope of instruction. This may be of interest, because we are told that no attempt exactly like it has heretofore been made in this country, and, perhaps, in the world, to apply current philosophical speculations to horticulture.

Aside from the regular class work, the students were called upon during the term for two original essays, one upon the subject, "Expound the Philosophies known as Lamarckism, Darwinism and Neo-Darwinism," and the other, "Why Do Plants Vary?" Each student was also obliged to read and assimilate chapter iii. of Wallace's *Darwinism*; Weismann's original essay on Heredity; a chapter of Cope's *Origin of the Fittest*; two chapters of Herbert Spencer's *Principles of Biology*; chapter xv. of Darwin's *Origin of Species*; Gray's essay on The Flora of Japan. These exercises were selected in order to acquaint the student with some of the leading types of philosophical writing. The final examination comprised the following questions:

- (1) What do you understand by the term evolution as technically used at the present time?
- (2) Name five reasons for the belief in organic evolution.
- (3) What are the dominant causes of the variation of plants?
- (4) In what directions does climate modify plants?
- (5) What is Neo-Darwinism?
- (6) Explain how bud variation is possible.
- (7) What, if anything, is the philosophy of pruning?
- (8) Expound the one chief agency which man can employ in the amelioration of plants.
- (9) Why does nature cross plants?
- (10) To what extent has agriculture modified plants?

Student.

Notes from Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—There are two species of *Bougainvillea* in cultivation here, which are extremely showy. One under the name of *B. glabra*, with very bright bracts, produced in great abundance through the summer and sparingly in winter, so that it is never without flowers. I have a specimen of *B. glabra*, as known in eastern greenhouses, which is not worth growing compared with the other, its bracts being a dingy rose-color and the plant flowering only once in the year. Both have smooth foliage. If the plant I speak of is *B. glabra* I should be pleased to know the correct name of the former. *B. spectabilis*, with bracts of rich crimson magenta, usually flowers from February to April. For some reason it has been in bloom with me during the past three months. This has pubescent leaves and bracts rather larger than the other.

Another climber which has been flowering out of season is *Bignonia venusta*. It bloomed in some gardens during October and November, its usual season being January to March.

We have no more showy winter-flowering vine than this. Last February I saw one vine which covered a large portion of the roof of a carriage-house with a mass of its brilliant orange flowers. During November *Dahlia imperialis* gave us much pleasure. A plant eight feet high, with a panicle of large, drooping white bell-shaped flowers at the top, appears more like a Tree Lily than a Dahlia. It flowers too late for open-air cultivation in the east, but it might be grown in tubs and removed to the greenhouse before frost. It would make a fine companion to *Chrysanthemums* at the fall exhibitions. *Poinsettias* are now in their glory, with dozens of fine heads upon a single plant, producing a blaze of scarlet color. *Lucula gratissima* is just passing out of flower with me. Its large, hydrangea-like trusses of pink flowers, with a rich fragrance somewhat resembling Apple-blossoms, make it a most desirable plant.

Among the wild flowers here there is no absolute pause in the season of bloom. Though there has not been rain enough to permeate the soil since last March and the hills are brown, yet in a walk of half a mile I have just gathered seven species of wild flowers.

A new society has just been organized in Los Angeles, its principal object being the establishment of a botanical garden. It has, therefore, chosen the name of "Botanical Society." The use of several acres of land within the limits of our largest public park has been granted to the society for this purpose. Flower shows will also be held under its auspices.

Los Angeles, Calif.

Edmund D. Sturtevant.

Poisoning Plants.

To the Editor of GARDEN AND FOREST :

Sir,—Plant physiologists tell us that the roots of plants have little or no power of selecting their food and can be poisoned like animals. Lindley further states that substances which are poisonous to animals will prove poisonous to plants. In order to put these questions to a practical test certain experiments have been conducted by Mr. R. A. Emerson, a student in the horticultural department of this university. Solutions were made in ordinary city water with alcohol in the proportions of 1 to 20, 1 to 100, 1 to 1,000, 1 to 10,000; corrosive sublimate, 1 to 100, 1 to 1,000, 1 to 10,000; pure sulphuric acid in the same proportions; aconite, powdered extract of root, 1 to 1,000 and 1 to 10,000; white powdered arsenic, 1 to 1,000 and 1 to 10,000, and strychnine and crystalline sulphate, 1 to 1,000 and 1 to 10,000.

Twenty water cultures were made, each containing one Bean and one Corn plant, which were started in soil three weeks before, and when transferred to the water solutions were four to five inches high and well rooted. For these cultures six-inch pots, holding about three pints each, were used, being painted outside and the hole in the bottom stopped with plaster of Paris. In addition to cultures in each of the sixteen solutions already mentioned, four were made in ordinary city water to serve as a check upon the others. Similar plants were also potted in soil and watered with each of the solutions used for water cultures. All were watered at once and whenever the majority seemed to need it, one of these solutions being used instead of clear water, except in the case of check plants.

The behavior of the plants under these different conditions was as follows :

In the 1 to 20 solution of alcohol: Both the Bean and Corn plant in the water culture wilted slightly within two days, but had nearly revived two days later. At the end of ten days the Corn was nearly dead, and wholly so at the end of two weeks. The Bean was alive after three weeks, but dead in four weeks. In the soil cultures watered with this solution the plants showed no effect at first, but the Bean failed to produce flowers, like most of the others. The Corn plant died within three weeks, but at the end of four weeks the Bean was still alive and slightly improved in appearance. In the weaker solutions no effect was noticeable under either method of culture. Being in open vessels the alcohol doubtless evaporated somewhat from these solutions, which were renewed about once a week.

In the one per cent. solution of corrosive sublimate in water cultures both plants were dead within two days, the Bean being bleached to the very tips of the leaves. In soil both were badly wilted at the end of two days and were dead in less than a week, the Bean dying first. In the solution one-tenth as strong, in water cultures, both plants were wilted within two days and dead within a week. In soil the plants were not visibly affected even at the end of four weeks. In the weakest solution, in water cultures, the plants wilted in a few days, but were both alive at the end of four weeks, though very light-

colored and not much larger than when placed in the cultures. No visible effect was produced on the plants in the soil.

In the one per cent. solution of sulphuric acid, in water cultures, both the Bean and Corn were wilted in two days and dead in four days, the Bean-stalk being bleached. In soil the Corn was not as large as in untreated soil, but showed no indication of dying at any time during the experiment. In the next solution at the end of two days the Bean in water culture was badly wilted and dead in four days. The Corn was slightly wilted in two days and dead in ten days. No visible effect was produced on the soil cultures. In the weakest solution no visible effect on soil cultures, and the water cultures only slightly less vigorous than those in pure city water.

In the solution of arsenic (one-tenth of one per cent), the plants in water were wilted in one day and both were dead at the end of two days, but no apparent effect was produced upon those in soil. In the weakest solution the plants in water were badly wilted after two days, but lived for some time. At the end of four weeks the Bean was dead and the Corn light-colored and not growing. In soil the Corn was smaller at the close than that under ordinary conditions, but its color was good.

In the aconite solution (1 to 1,000) both plants in water were wilted in one day, and continued so during the second day, but at the end of four days had revived. Plants in soil were not affected. All the plants continued their growth during the four weeks that the experiment lasted, the Beans blossoming and forming pods the same as those treated with city water. In the weak solution of aconite results were precisely the same.

In the strychnine solution (1 to 1,000) both plants in water wilted in a day. The Bean was badly wilted the second day, and died within three weeks. The Corn soon revived, and at the end of four weeks was nearly as vigorous as that in city water. In soil cultures the plants were not affected. Plants treated with the weak solution behaved exactly the same as those treated with aconite.

Plants in the aconite and strychnine solutions wilted even sooner than those in corrosive sublimate and arsenic, but, with one exception, revived in four days, while the latter were dead in two days. Additional plants taken from city water and placed in aconite and strychnine cultures after the first plants had revived did not wilt.

The experiments seem to suggest the following conclusions :

1. Irritant poisons, such as arsenic, corrosive sublimate and sulphuric acid, kill plants in water cultures in a very short time, except in .01 per cent. solutions, and in such solutions plants were less vigorous than in city water.

2. The neurotic poisons, alcohol, aconite and strychnine, killed no plants, with the exception of the very strong solution of alcohol, and one plant treated with strychnine.

3. All the poisons used, except alcohol, affected Beans more quickly and more severely than Corn. Alcohol, on the contrary, affected Corn more than Beans.

4. The poisons produced much greater effects in water than in soil cultures.

The strongest solutions of aconite and strychnine contained only one-tenth of one per cent.; hence it is possible that a stronger solution might have a different effect, yet the same strength of arsenic and corrosive sublimate killed plants very quickly. These results are more striking when it is remembered that from twenty to forty times as much arsenic or corrosive sublimate is required to prove fatal to animals as of strychnine sulphate. The irritant or corrosive poisons, however, attack and decompose tissue; hence may be expected to injure plants as well as animals. The neurotic poisons, on the other hand, effect only the nerves of animals, and are, therefore, less likely to injure plants.

Meetings of Societies.

Meeting of the Iowa State Horticultural Society.

THE thirtieth annual meeting of the Iowa State Horticultural Society, which met in Des Moines on December 10th, was largely devoted to fruit-growing. The subject of Plums received much attention. The opinion prevailed that the most profitable varieties for Iowa are those belonging to the Americana and Chickasaw types. Mr. Silas Wilson, of Atlantic, said: "It may be interesting to many of our people to know that many of the Americana and Chickasaw varieties of plums have sold in the markets of Denver and Salt Lake City in competition with domestica varieties, bringing fifty to sixty cents a peck, while those of European origin were begging at twenty-five to thirty cents a peck. There can be no question about

the value of the Americana and Chickasaw varieties for culinary purposes as compared with those of the domestica type." Of the Americana type he placed Wyant first because of its productiveness and quality; Hawkeye second, a fine large plum of good quality, which produces a better tree than Wyant. He also considered the De Soto, Forest Garden, Rockford and Wolf excellent. Of the Chickasaws, Milton should be placed first, the earliest of all of our native plums, ripening at Atlantic July 10th. Second place should be given to Charles Downing; quality excellent, a good keeper, with a fine color. Of European plums, the Tutge, a seedling that originated in Benton County, Iowa; the Communia, originated in north-east Iowa, has been before the public a much longer time. Mr. Wilson insisted that in order to grow good large plums of the native sorts there should be little fear of giving too high cultivation or too much manure, as no fruits seem to respond more readily to high feeding than our native Plums.

Mr. H. A. Terry, of Crescent City, in a paper on "Propagation of Plums," considers the Hawkeye, De Soto, Hammer, Wolf and Wyant best of the Americas; Milton and Charles Downing best of the Chickasaws. An extensive grower of commercial Plums, J. G. Berryhill, of Des Moines, thought the season of plums could be prolonged by introducing the Japan varieties; some of those now grown in Iowa do not mature their wood; in fact, these are still experimental in Iowa. They are good growers and produce good fruit. He considers the Miner a most profitable Plum, but it will not bear if planted by itself. It needs to be associated with some good pollen bearer, like Forest Garden or Wyant. C. L. Watrous also testified to the superiority for Iowa, at least, of our native Plums over the foreign kinds. C. G. Brackett, as director of state horticultural experiment stations, found that foreign kinds met with little favor at most of the experiment stations. They are subject to black-knot and bear but little.

Of Grapes, the old varieties, Concord, Worden and Moore's Early, still meet with most favor. Mr. Elmer Reeves stated that the best general-purpose grape is the Worden. He thought, however, that in the state of Iowa more money can be made in growing cherries and strawberries than by growing grapes of any variety. Mr. M. J. Wragg estimated the net profit from an acre of Grapes in six years at \$140, while the net profit from an acre of Cherries the same length of time was estimated at \$1,087. The best Cherries for commercial orcharding in Iowa are Early Richmond, English Morello, Dyrhouse. Of the Russians, Cerisede, Ostheim, Bessarabia, Brusslar Braun have met with most favor, especially in north Iowa.

The subject of Top-grafting the Apple in Commercial Orchards was considered by William Bomberger. It is a well-demonstrated fact that the hardness of variety may be very materially advanced by top-working. R. P. Speer, of this society, has strongly advocated this method for several years. The Ben Davis, Arkansas Black, Jonathan, Grimes' Golden, Fameuse, not hardy in central or northern Iowa, are productive, and withstand natural influences much better when top-worked on Duchess, Hiberna, Virginia Crab or Tetofsky. Account must be taken of the growth of the variety which is top-worked. Mr. Bomberger says, "In producing the trees it would be best to confine operations principally to the Virginia Crab, but on light prairie soil Haas is good, and to it could be added the Duchess to work slow-growing varieties upon, as Red June, Early Joe, Wealthy, and for moderate growers Benoni, Dyer." He advocated the use of top-working in town lots that will admit of but few trees. The entire fall list could be on one tree, as Wealthy, Haas, Snow; the summer list could be grown on another tree, as Duchess, Red June, Sweet June, Benoni; the winter list on another, as Ben Davis, Jonathan, Grimes' Golden and Janet. A pleasing lot of combinations can be made, not only in regard to color but flavor and time of ripening.

Professor J. L. Budd, in a paper on The Management of our Hill Soils, said the tree rows or small fruit-rows should run at right angles to the slope of the hill. Hence the rows may be straight or curved, depending on the character of the slope. Hill land may so vary in slope that the rows may be straight at one point and curved at another. The cultivation is all in one direction. If the slope is quite abrupt, Currant or Gooseberry bushes can be planted between the rows to form a network of roots to prevent the water of heavy rains from breaking through the ridges. In south-east France this is called "zone planting." While it may not be necessary in many parts of Ohio to practice zone planting, the writer said it could be used with advantage on the Missouri slope, and more attention should be given to it so that moisture and fertilizing elements can be saved. In his annual report he referred to the unusual

drought conditions and its effects upon the quality of the fruit, as follows: "Over the state, and, indeed, over all the prairie states, where the fruit was not destroyed by the May freeze, all orchard fruits set a full crop. But at picking-time the size and perfection of the fruit were varied by soils and subsoils to an extent not before observed. Trees standing on porous soils and subsoils down to the water-level gave crops of large and perfect fruit with unusual high color, but they did not keep as usual, unless they were picked early." But on soils underlaid with blue clay or hardpan too near the surface, Cherry and Plum trees showed more or less imperfection of foliage, and the fruit was small and imperfect.

Professor Herbert Osborn, in a paper on Spraying in Theory and Practice, said that kerosene emulsion can be used in condensed form in winter for scale insects, and the possibility of the invasion of the San José scale should lead all orchard districts to be prepared to meet it. Professor Pammel's paper treated of botanists and botanical discoveries of the last decade. He said that horticulturists have been specially benefited by the study of fungous diseases and the discovery of effective germ killers. They have also been greatly benefited by the discovery of such botanical facts as the appropriation of atmospheric nitrogen by leguminous plants.

Recent Publications.

Window and Parlor Gardening. By N. Jönsson Rose. With illustrations by the author. Charles Scribner's Sons.

This neat little volume is correctly described in its subtitle as a guide for the selection, propagation and care of house-plants—a subject well worth a handbook, since it is perfectly true, as the author states, that the practice of growing plants in windows and apartments is one of the most rational and instructive of home amusements. Many people undertake to grow house-plants, and the fact that a large proportion of them make discouraging failures is proof that some plain instruction is needed in the principles which underlie success in the art. Mr. Rose's book begins with a few pages on plant physiology, with instructive illustrations, and then follow chapters on the various appliances needed, on the methods of growing plants from seed and from cuttings, with full directions for giving proper supplies of water, light and air. Then follows a list of the plants which will thrive best in living-rooms, with a description of their appearance and habits and special needs. The reader will find here many plants which are rarely seen in windows, but which will thrive as well as a Geranium; indeed, one of the most useful features of the book is this invitation to test unknown or neglected plants for windows, for the trial of new things will give a zest to the pursuit that nothing else can furnish. The cultural directions are plain and judicious, and they have evidently been prepared by one who has experience and who writes out of the abundance of experimental knowledge. Very rarely does a book of this size contain so much direct and helpful instruction, and, no doubt, its neatly printed and well-illustrated pages will help to make many a home more pleasant and cheerful.

Notes.

The California Wine-makers' Association have sold eighty-five per cent. of the dry wine of the present year's crop at prices which yield a good profit to the growers. This is the first time for years that there has been a combination between the makers of wine and the growers of grapes, and the result is a profit for all and the avoidance of glutted markets.

Gilbert White writes in *The Natural History of Selborne* that when timbers were wanted to repair the bridge at the Toy, near Hampton Court, there were found in a small wood in Selborne, consisting of a few—we wish he had told just how many—acres, twenty Oak-trees of the dimensions called for, namely, fifty feet long and twelve inches in diameter at the little end. Indeed, several of them were found to answer the description at sixty feet long. The trees were cut probably about 1745, and it is interesting to know that a century and a half ago Oaks of this size were sold at twenty pounds apiece.

Dandelions were opening on the sheltered lawns in the parks and gardens of this city wherever the sun shone on Christmas

and several days during the holiday week. Of course, Chickweed, which is another immigrant, was showing its white flowers, but it does this almost any day in winter when the thermometer is above the freezing point where it is in a sheltered and sunny position and is not covered with snow. During the past week, however, the flowers have been unusually abundant, the bright green foliage of the prostrate stems being starred all over with little white blossoms which look so delicately beautiful that one almost forgets that the plant is a disagreeable weed.

Several varieties of the European Chestnut have come into cultivation in this country during the past few years, among them the Numbo, which is sometimes said to be an offspring of our native Chestnut and sometimes of the Japanese species, but it is really European. The burs are usually single, and this is, perhaps, one reason why the nuts are so large. The Numbo will weigh two or three times as much as the so-called Spanish chestnuts, and it is, therefore, more popular. The Paragon will average about twice as large as our ordinary wild chestnut, and it is a most promising variety.

The New York Gardeners' Society was regularly organized in this city on December 21st by representative private gardeners from Long Island and many other sections of this state, New Jersey and Connecticut. The following officers were elected to serve one year: J. M. Logan, president; William Plumb, Charles Webber, Peter McDonald, vice-presidents; William Anderson, treasurer; J. I. Donlan, secretary. A committee to draft rules and by-laws was formed, with William Falconer as chairman. The next meeting will be held on Saturday evening, January 4th, at 51 West Twenty-eighth Street, when all private gardeners who care to join an association for mutual advantage and the advancement of horticulture are invited to be present. Such an association ought to be useful in many directions, and it ought especially to be helpful in giving variety to future flower shows in this city, which have hitherto mainly consisted of plants and flowers exhibited by commercial growers to the exclusion of the rarer plants and well-grown specimens which are alone to be found in private collections.

But 2,000 boxes of Florida oranges have reached this city thus far against 500,000 boxes during the same term a year ago, when the crop of that state was estimated at 6,000,000 boxes. With half the crop frozen on the trees the season closed abruptly early last February, whereas the previous season Florida oranges were in our markets nearly the year through—from September 20th, 1893, to August, 1894. The few now offered cost \$3.50 to \$5.25 a box at wholesale, fully double the prices of last year. The main portion of the West India crop, amounting altogether to 400,000 barrels, has already been sold in the United States. Jamaica oranges are now commanding prices so high as to make rather slow sales, \$4.50 a box being asked for the best repacked fruit by wholesale dealers. The crop of the Valencia district, in Spain, is variously estimated at 3,000,000 to 6,000,000 cases, which contain 420 to 714 oranges each. This fruit has recently been in unusual demand here, large lots selling readily for \$5.50 a box, while Sicily fruit, rather immature and unsound, brought about one-third as much. The Sicily crop is said to reach fully 10,000,000 boxes. Car-loads of Navel and seedling oranges are now coming from California, and, although some of the fruit is as yet lemon-colored and tinged with green, it is of good weight and quality and promises well for the ripe fruit later on. The total production in California is estimated at three and a half to four million boxes.

The California fruit-growers who ship their products to San Francisco complain that they made no profit last year because of low prices, although fruit at the commission-houses and retail stands has been dearer in that city than it was in New York or any of the large eastern cities. They complain that when the market is glutted tons of choice fruit are dumped into the bay by commission men to maintain prices, so that California really produces hundreds of tons that are never marketed. In New York the truck-farmers and market-gardeners are making this same complaint against the middlemen. One of them lately stated to a correspondent of *The Tribune* that Long Island celery, for which they received from sixty cents to a dollar for a dozen bunches containing six roots each, are sold at retail for a hundred per cent. profit, and the same is true of cauliflower, turnips and other vegetables which come into the Gansevoort market in hundreds of wagons every night. The complaint of the farmer is that the greengrocers combine and hold off from buying until the farmers are forced to accept any offer, so that they can return home for another load, and that the expenses for stands, for stabling, etc., eat up all the

profits. On the other hand, the grocers lay stress on their high rents, losses through credits, and particularly on the deterioration of vegetables on their hands, since they are so perishable that in summer the losses from wilting and decay amount, perhaps, to twenty-five per cent. of what they sell. There is no question, however, that for such perishable articles as fruit, vegetables and milk, consumers in cities pay extravagant prices when compared with those which the producers receive. The wastes and expenses of distribution are enormous, and it is a fact that the consumer could pay much less for what he uses and the producer receive more for what he raises, while a reasonable profit would still remain for the middleman.

There is much uncertainty about the origin of the Apple now known as Tompkins King and formerly called King of Tompkins County. Some people hold that the original Tompkins King tree stands at Jacksonville, six or seven miles north-east of Ithaca, and in a recent lecture to one of his classes Professor Bailey showed a picture of the tree, now about sixty years old and two feet in diameter at the ground. It was plain, however, that the tree had been grafted, and, therefore, it cannot be the genuine seedling. It was brought from Dutchess County to Rockland County by the early settlers, where it was known as the Flat Spitzenburg, and it came originally from New Jersey, though from just what point no one knows. In Tompkins County the tree became best known, where the fruit is large and showy, and would rank ten in the scale of quality in any apple exhibition. It does not thrive, however, over as great an extent of territory as many other apples. The tree is broad, the apples are heavy and they are likely to fall in heavy winds. It is not as productive as the Baldwin and some other varieties. The fruit is borne on the outside of the tree, so that when it comes to be picked it does not fill so many barrels as other varieties do which make less of a show. The trees, too, are short-lived. They begin to die at the base and the bark peels off in strips. Professor Bailey has observed in some places where Baldwins and Greening trees are just in their prime that the Tompkins tree is already going to pieces. It is not so short-lived, however, in Tompkins County and in the adjoining region as it is in other parts of the country. Professor Bailey is not prepared to say whether this failure is due to climate or some varietal weakness, but the fact is that it is an apple of comparatively local merit, and is most profitable in this particular section of New York state. It is almost entirely unknown south of Mason and Dixon's line and west of Michigan.

The showiest pears now offered in the choicest collections of fruits are Forelles, from California, known also as German Trout pears. They are of medium size, a clear yellow, with brilliant red cheek, and sell for fifty cents to one dollar a dozen. Another pear sure to attract attention is Block's Acme, specimens of which weigh as much as two pounds each and measure fourteen inches around. These immense pears are uniformly pyriform, crisp, sweet and slightly musky in flavor. The sun-ripened fruit shows a glowing red on the exposed side, but these midwinter specimens, which were gathered before they were ripe, are olive and russet colored. They cost \$3.00 a dozen. Winter Nelis, Winter Seckel, Easter Beurre and Beurre d'Anjou are also seen in the best shops. Catawba grapes from the Lake Keuka district, this state, fresh-looking as when gathered more than two months ago, cost but twenty-five cents for a box holding nearly three pounds. Cornichon and Emperor grapes, from California, are becoming scarce, and command thirty-five cents a pound for the best. Heavy-shouldered bunches of rose-tinted Almerias, weighing two pounds and more apiece, sell for thirty-five cents a pound. Luscious-looking Gros Colman grapes, from England, the immense clusters cut with a section of the woody vine, sell for \$2.25 a pound. Other beautiful fruits which now add to the rich and attractive displays are hot-house Mandarins, from Hackensack, three to five on a stem, with fresh-looking foliage, and costing \$2.50 a dozen. Oranges from Jamaica, with stems and leaves, bring \$1.50 a dozen. Beautiful pineapples, from Florida, with luxuriant-looking tops, are \$1.00 each, and persimmons still come from the same state. The choicest vegetables are no less delicate and bright than the fruit. Hot-house tomatoes are coming from Pennsylvania, and slender stems of asparagus about as long as a finger, from along the Hudson River. Asparagus is also being received from California. Domestic and foreign nuts in large variety increase the interest of high-class fruit-stores, such as that at the corner of Sixth Avenue and Fiftieth Street, where, besides well-known and rare nuts in the shell, the meats of almond, hickory and pecan nuts are kept in stock. These all cost seventy-five cents a pound.

What is Forestry?

THE question is often asked us what the word forestry, which appears now so frequently in American periodicals and newspapers, signifies in its technical acceptation. Judging by the number of different things this word is made to stand for, its meaning is not generally understood in the United States, where the term forestry is made to cover any and all operations in which trees play any part whatever, with the exception of those of the lumbermen, whose business it is to turn them as quickly as possible into money.

Forestry is the art of maintaining and perpetuating forests. It is successful in proportion as the forest yields the largest annual income in perpetuity. Forestry is not the planting of trees in parks or in the streets of cities. A man who sets a wind-break on the western prairies is not a forester, although it has become the fashion in this country to call him so, just as the man who lays out the flower-beds in one of our cities bears the official title of city forester. A knowledge of trees does not make a man a forester any more than a knowledge of grasses makes a man a good wheat farmer. A landscape-gardener may know trees perfectly, from his point of view, but his point of view is not that of the forester, the one planting for beauty, the other for profit of a more tangible character. The word is certainly used vaguely, and this vagueness, by confusing the whole subject in the popular mind, increases the difficulty of those who are working to establish a scientific system under which forests in the United States can be successfully and properly managed.

Forestry as a branch of scientific agriculture is less than three centuries old, although in Japan silviculture in a restricted sense has been practiced for more than a thousand years. Its importance, however, to the welfare of the community is considered so great by the most enlightened nations that men of first-rate ability have found reward in bringing this art in a comparatively short time to its present standing of almost an exact science. In Germany and France no other branch of agriculture is more carefully studied and practiced, and, in the long run—that is, in periods of centuries—no other pays a larger return upon the invested capital.

In this country we have wasted in less than a century enough forest to have supplied for all time a considerable part of the world with lumber, just as we have robbed through ignorance much of our best arable land of its fertility. What seemed boundless wealth of natural resources has made us reckless, and wealth has melted away before we realized what the end was to be. It is fortunately easier to restore plant-food to exhausted soil than it is to build up a forest once destroyed. The Carolina phosphates have brought back the lost fertility to many cotton fields of the south, and the wheat fields of western New York now produce a larger average yield than those of the Willamette Valley, in Oregon, which men not many years ago boasted were to be productive forever. The wasted forest, too, can be rendered productive again, and it is within the possibilities of science not only to do this, but to make any forest more productive, and, therefore, of more value, than it could have been without the intervention of forestry. Just as the care of the gardener makes the fruit-tree more productive of fruit, the care of the forester makes the timber-tree more productive of timber. When we come to realize that forestry is just as important a part of the economy of the nation as wheat-growing is, and understand what forestry really means, we shall certainly attempt to take advantage of the experience of other countries and adopt those general principles of forest management which they have found successful. The great difficulty we have to encounter in this country, however, will be the establishment of a continuous management free from political interference and uninterrupted by current events. A forest crop may take from one to three centuries to come to maturity. During all this period, if it is to earn a fair return, it must be managed consistently under a plan made before the seeds are sown and intended to cover every operation in the forest, including its regeneration when the original trees have passed to the saw-mill.

The necessity of permanency, the idea that a forest can and should last and continue productive for all time, cannot be repeated too often in discussions of this subject; and if the Government of the United States decides to manage the forests on the public domain in the hope that their productiveness in timber will increase rather than diminish, the public must understand that forestry is not possible unless it is permanent and that politics will destroy the best forest as swiftly and surely as it will destroy the efficiency of an army or a navy.

DURING the year past we have commented on efforts in several states to furnish to farmers, and especially to fruit-growers, instruction which is at once practical and scientific. Some of this work has already proved to be of substantial value, and all of it is promising. Not altogether novel in character, but with some distinct features of its own, is a project of the New Hampshire College of Agriculture and Mechanic Arts, from which circulars for a non-resident course of study under the title of Home Classes in Agriculture have just been sent out for a second year. This is nothing more than a phase of University extension, which recognizes the fact that since few persons can go to college, the college, so far as practicable, will go to the homes of the people. What the New Hampshire College definitely proposes is this: If ten or more persons in any grange or agricultural organization will read certain books and pamphlets on different subjects named in the list the college will furnish one or more lectures upon such subjects, provided the simple expenses of the lecturer be paid. The books will also be furnished at a reduced rate.

It is very often the case that the isolated lectures at institutes produce little permanent good, because the hearers come with no special preparation in that line of thought, and although they may be amused they fail to get the full benefit of the teaching. On the other hand, a long reading course is alarming to the majority of people, so that the present proposition offers a medium between these

extremes, giving the people of each locality an opportunity for a short course of study on one or more subjects in which they are specially interested, with the use of a few books at small cost and the privilege of instruction from a specialist to whom they can apply for such particular information as they need. Books are named for courses of reading on the following subjects, and others will be added as the circumstances demand: Apple Culture; Small Fruits; the Principles of Agriculture; Vegetable Culture; Field Crops; Dairying; Soils and Tillage; Floriculture; the Enemies of Crops. There can be no question that a class of men and women, whether young or older, who enter with seriousness into such relations with the college faculty and with the books they recommend, will derive immediate practical benefit in their calling, and, what is of much more importance, they will receive a mental stimulus and enlargement of thought which will give them more accuracy of observation and breadth of view.

Japanese Lilies as Articles of Food and Commerce.

LILIES possess the quality of combining beauty with gastronomic value; indeed, in Japan they are considered even more useful than ornamental, and in books on horticulture and botany we find these plants treated more frequently under the group of edible than of ornamental subjects; that is, far more account is made of the bulbs of the Lily than of its flowers. I do not mean that the beauty of the many varieties, in their manifold shapes and sizes, in their rich coloring of crimson, pink-vermilion, yellow, white, purple and orange, is not appreciated by us; far from it, and not a flower garden is regarded complete without them. At the same time, there never is a well-chosen menu which does not include this bulb among its dainties. Moreover, from time immemorial we find Lilies thus mentioned, both for their utility and beauty. No wonder, as different varieties grow wild and luxuriantly on hills and along dales throughout the length and breadth of the country, our forefathers could but notice their flowers, conspicuous even in the rich flora of Japan, and a little examination could not fail to convince them of the abundant store of nutritive material in their bulbs. According to Miquel, and to Franchet and Savatier, there are no less than seventeen Japanese species of *Lilium*, but these include a large number of varieties.

The Ainu, an aboriginal race supposed to have once inhabited the whole country, but now confined to a few scattered hamlets on the northern islands of Hokkaido (Yesso of older maps), where they still subsist by fishing and hunting, depend for their vegetable diet chiefly on the bulbs of *Lilium Glehni*. From the bulb of this plant, called *Turep* in their language, the Ainu extract a comparatively pure kind of starch. This they make into a hard cake with a hole in the middle, through which a string is passed to hang it by. We can easily imagine that our ancestors may have done likewise, since many varieties flourish in the south, although the climate and the soil there are not as favorable to the growth of Lilies as are those of the Hokkaido, whether we consider the color or number of the flowers or the size of the bulbs. On Hokkaido we often meet with a stalk bearing as many as thirty flowers, and that without any fertilization. Especially where there is moisture do they thrive well. By the side of brooks, which are found everywhere in the mountainous districts of the country, our eyes are constantly greeted by the various members of this charming family. Even in their wild state the flowers of *Lilium auratum* attain a size of over six inches in diameter. The bulbs of nearly every variety are edible, but those of wild growth always taste sweeter than those under cultivation. It is said that over one hundred different varieties were known to the gardeners of past centuries, though at present only a little over half that number are cultivated.

The two kinds most used for culinary purposes are the

Lilium tigrinum, known here as the Oni-yuri (literally, the Ogre Lily), or Ryori-yuri (the Cooking Lily), and the *Lilium concolor*, var. *parchellum*. This latter is also called Hime-yuri (the Princess Lily). Chemical analysis has shown that we have not been deceived in our appreciation of this plant. It proves that the bulbs contain no small amount of nitrogenous matter. I will here give the result of the analysis made at the Government Sanitary Bureau:

Water,	69.630
Nitrogen,	3.402
Fat,	0.015
Starch,	19.100
Dextrin,	1.915
Glucose,	0.620
Pectose,	2.444
Fibre,	1.416
Ash,	1.350
Total per cent.,	98.587

From this table it is clear that the Lily-bulbs furnish an important source of nutriment. A little plot of six feet square can be made to yield from sixty to seventy bulbs, and at this rate an acre will produce some eighty thousand bulbs. There are produced, according to official statistics of 1888, four hundred and thirty thousand pounds of bulbs in the market gardens of Japan, valued at nine thousand and three hundred yen. These numbers do not and cannot include those raised in private gardens. In price they range from half a cent to two cents apiece, according to their size and to the season. They are usually boiled and eaten with sugar; otherwise they would be too bitter to be palatable. When they are boiled soft they remind us of beans, both in their consistency and taste. The bitterness seems to lie especially along the edge of the bulbous scales; and, consequently, by slicing the edge before cooking greater sweetness is insured. The bulbs are also very often boiled with rice. The starch made from them will keep indefinitely, and was, therefore, in former times, stored to ward off the sufferings of famine. The variety *Longiflorum*, Thunb., called the *Teppo-yuri* (the Gun Lily), otherwise known as the *Riu-kiu-yuri*, because of its supposed original habitat, is esteemed for its flowers, but its bulbs are too bitter for kitchen uses. They give, however, starch of excellent quality. A variety known as *Aka-kanoko*, which grows to the height of four feet, with flowers spotted crimson, has bulbs of a purplish color, bitter, and altogether unfit for cooking, but furnishing starch of no mean quality. The best way to cook the bulbs for the American table is, we have found from experience, to boil them and use them as salad, with a dressing of cream and eggs. The small bulblets that appear at the axils of Lily-leaves can also be eaten roasted, and the petals of some varieties growing wild in Hokkaido make an exceedingly pretty salad.

This reminds me that some years ago a Harvard professor said that the future food-supply of America could be greatly and advantageously increased by acclimatizing foreign, and especially Japanese, edible plants. I was, therefore, pleased to hear, recently, that the Department of Agriculture has been circulating reports regarding the cultivation and culinary uses of Lilies. But, as it will take some time to naturalize them in America, the importation of bulbs will not at once be perceptibly decreased. In fact, these bulbs have for some years been an article of export to Europe and America, and we at one time thought that they would soon become naturalized abroad, and were afraid the trade in them must soon cease, but thus far it shows no diminution. Take, for instance, the amount exported from but one firm in Yokohama, the *Ueki-shokai*, in 1890—some 913,880 bulbs were sent out, including thirty-one different varieties. Among them the so-called Mountain Lilies (*Yama-yuri*) were by far the most important, their number amounting to 550,569. The next most important variety was the Gun Lilies (*Teppo-yuri*), and these amounted to little over 136,000.

The following table gives later statistics of the extent of foreign trade in Lilies, as exported from the country at large :

COUNTRIES.	1894.	1893.	1892.
Australia.....	1,550 Yen*	185 Yen....	610 Yen.
France.....	1,308 "	485 "	281 "
Germany.....	11,261 "	5,562 "	2,620 "
England.....	29,630 "	38,754 "	17,948 "
Hongkong. ...	4,328 "	6,480 "	2,166 "
United States..	19,410 "	12,679 "	9,461 "
Other countries,	737 "	1,283 "	392 "

Total, 68,224 Yen. 65,428 Yen. 33,478 Yen.

The Yama-yuri, mentioned as playing such an important part in exportation, is of wild growth, and, although its good qualities are appreciated at home, the Japanese consider it inferior for table use to the Ryori-yuri, and the demand for it here is not so great as for the latter. During an epidemic of cholera a few years ago it was, however, sold in large quantities to supply the deficiency of starchy food in the market.

The readers of GARDEN AND FOREST may be interested to know what care is taken in raising the bulbs. In October or November, when the stems of the Lilies wither, the bulbs are gathered; but, as they are too small for trade in this natural state, and, moreover, as they are so often more or less bruised when dug out, they are planted in a garden to undergo artificial cultivation for a year or two—a process of fattening, as it were, for the market. Those designed for export to European countries require particular care, since they must endure the heat of the Indian Ocean during their journey. Then, too, European taste demands large bulbs, and plants with about twenty flowers, which only bulbs of two years' artificial cultivation can bear. Americans, on the contrary, like smaller bulbs, and desire plants that bear only half a dozen flowers. Bulbs of one year's rearing, therefore, meet their wishes; but these die the next year, and hence the regular annual exportation of new bulbs to the United States.

The Yama-yuri is indigenous to Kadsusa, Shimoso, Sagami and other central provinces. The transplanted bulbs, reared in a rich garden mold, become quite strong after a year's growth, but those intended for food are not allowed to flower. Sometimes, when the soil is not of the proper kind, the bulbs, though they may grow large in size, are decidedly inferior in weight. Perhaps on this account they do not do well in Europe, except in the Netherlands, the classic land of bulbs. Some of our best bulbs measure a foot or a foot and two inches in circumference, and weigh as much as a pound. I may state here that for choicest cooking only the twelve best scales are selected from a bulb; indeed, usually eight or nine scales only are taken from each. The size and shape of the bulbs are most remarkably affected by the time when the flower buds are nipped; and some Lily gardeners think the right choice of this time is the most difficult and delicate part of their labor. When the bulbs are harvested, they are cleaned and then packed in boxes large enough to contain forty or fifty. In price, they range for export trade, according to size (taking for granted that the quality remains the same), from 2.20 to 2.50 yen per hundred for the largest; 1.20 to 1.50 for the next size—of, say, ten inches in circumference; and 60 yen or so for bulbs of a year's growth, which are usually about eight inches.

In view of the fact that the Lily, at least according to Dr. Hehn (*Cultivated Plants and Domesticated Animals in their Migration from Asia to Europe*), came from Media by way of Armenia and Phrygia, and that it now has found its entrance to America, it is interesting to note that the annual importation of the same plant from Japan completes the circle, as it were, in its journey round the world. Dr. Hehn's opinion as to the original habitat of this plant is by no means a conclusive one. His arguments are founded chiefly on philological affinities, and, though I in no wise assume to contradict his assertions, I may serve him

* A yen is equivalent to an American silver dollar.

and the public by furnishing a few further linguistic statements which may possibly suggest that the original habitat of the Lily is still further east. The English word "Lily" comes from the Greek "leiron" (White Lily), which in turn is derived from the Persic "laleh." When we take into consideration the absence of the sound of "L" from the Japanese language and the substitution of "R," does "Yori" become unlike "laleh"? "Yori" in its turn gives place to "Yuri." Such a variation will seem the more likely when we remember that in our language the change from *ra, ri, ru, re, ro* to *ya, yi, yu, ye, yo* is of very frequent occurrence. Moreover, we observe that Dr. Hehn derives the Greek "krinon" (Colored Fire Lily) from the Persian Susa or Shushan. Now, in the oldest Japanese records the Lily is called Sai, from which Sai-yuri. In some districts it is called Saku or Sasa, thus nearly approaching Susa. This philological digression may amount to little; but I wish only to pass it on for what it is worth to those better authorized than myself to speak in that line of inquiry.

Sapporo, Japan.

Inazo Nitobe.

Populus heterophylla.

UNDER the name of black poplar the wood of this tree is now manufactured in considerable quantities in southern Alabama and in some parts of the Mississippi valley and is used as a substitute for yellow poplar (the wood of *Liriodendron*) in the manufacture of cheap furniture and the interior finish of houses. The Swamp Poplar, as this tree has usually been called, is one of the most interesting Poplars of North America, where there are no less than nine species. Although one of the rare trees of the Atlantic seaboard, it was the first American Poplar known to science, it having been described in the *Natural History of Carolina* as early as 1733 by Mark Catesby, who published an excellent figure of a sterile branch. It long remained, however, very imperfectly known, and its true position among the species of the genus was not established until Professor Britton correctly described the structure of the flowers in 1887. One of the remarkable things about this tree is the bark of large trunks. On other Poplars the mature bark is divided into broad rounded, more or less connected, ridges, which are roughened by small, closely appressed scales, but the bark of *Populus heterophylla* is broken into long, narrow plates, attached only at the middle and sometimes persistent for several years, so that an old trunk resembles that of a Shellbark Hickory. This peculiar bark is shown in our illustration on page 15 of this issue, made from a photograph of a tree in a swamp of the Wabash River in southern Illinois, for which we are indebted to Dr. Jacob Schneck, of Mt. Carmel, Illinois.

Populus heterophylla is a tree often eighty or ninety feet in height, with a tall trunk from two to three feet in diameter, and short, rather slender branches, stout branchlets, marked with elongated pale lenticels, and filled with a thick orange-colored pith, and large, slightly resinous broad acute buds. The leaves are broadly ovate, short-pointed or rounded at the apex, heart-shaped, truncate or rounded at the broad base, which is usually furnished with a deep narrow sinus, and are finely or coarsely crenate with small incurved glandular teeth; they are thick and firm in texture, dark, rather dull green on the upper surface, pale and glaucous on the lower, from four to seven inches long and from three to six inches broad, turning dull yellow or brown in the autumn before falling. The flowering aments appear from March at the south to the beginning of May at the north; those of the staminate tree are broad, densely flowered, about an inch long, and erect when the flowers first open, and then gradually become pendulous by the elongation of the thick peduncle, being sometimes when fully grown two and a half inches in length. One of their peculiarities is the brittleness of the rachis, which, as Professor Britton has pointed out, is easily broken by the wind before the ament has attained its full length; the scales are narrowly oblong-obovate, brown, scarious, divided at the apex into numerous long, thread-like red-brown

lobes and fall as the ament lengthens. The aments of the pistillate tree are slender, pendulous, few-flowered, and from one to two inches long with thin glabrous stems; their scales, which are concave and enfold the flower, are linear-obovate, brown and scarious, laterally lobed, fimbriate above the middle and caducous. The ovary is ovoid, terete or obscurely three-angled, with slightly concave sides crowned by a short stout or elongated style, deciduous from the fruit, and by two or three much thickened and dilated two or three lobed stigmas, and is surrounded at the base by the thin and scarious wide cup-shaped deciduous disk, which is irregularly divided into numerous triangular or linear acute teeth. In maturing the fruiting aments become erect and from four to six inches long and the petioles half an inch in length. The capsules ripen in May, when the leaves are about a third grown, and are ovate, acute, dark red-brown, rather thick-walled, two or three valved, and about half an inch long.

The most northern place where *Populus heterophylla* is known to grow naturally is in a swamp near North Guilford, Connecticut. It grows also near Northport, Long Island, on Staten Island, and southward near the coast to southern Georgia, through the Gulf States to western Louisiana, and through Arkansas to south-eastern Missouri, western Kentucky and Tennessee, and southern Illinois and Indiana. In the North Atlantic states the Swamp Cottonwood grows in low wet swamps and is rare and local, but becomes more common in the South Atlantic and Gulf regions, and is abundant in the valley of the lower Ohio River, in south-eastern Missouri, eastern Arkansas and western Mississippi, growing to its largest size on the borders of swamps with the Texas Oak, the Swamp White Oak, the Red Maple, the Sweet Gum and the Sour Gum. Apparently it has not been found yet anywhere in Florida, although as it is common on the delta of the Mobile River in southern Alabama it might be expected to grow as far east, at least, as the valley of the Apalachicola River.

Populus heterophylla was introduced into European gardens before the end of the last century, and is still described in nearly all catalogues of trees cultivated in Europe. It probably, however, is exceedingly rare there as it is in cultivation in this country. Planted a few years ago into the Arnold Arboretum, it has proved perfectly hardy in the climate of eastern Massachusetts, but, like other cultivated Poplars, it suffers seriously from insects boring in the trunk and branches.

Foreign Correspondence.

London Letter.

ANONA CHERIMOLIA.—A pot-grown plant of this, the Cherimoyer of the Andes of Ecuador and Peru, fruited this year in the Palm-house at Kew, and on its being noted in *The Gardeners' Chronicle* attention has been called to its merits as a useful fruit-tree by several who have essayed its cultivation in this country and elsewhere. It was the subject of some interesting observations in the *Kew Bulletin* in 1887, where it is described as a tree fifteen to twenty feet high, with loose, spreading branches and ovate velvety leaves. The fruit is about the size of an ordinary hen's egg, and it has a leathery skin inclosing a rich brown-yellow firm pulp. As in most plants which have been a long time under cultivation, there are numerous varieties, more or less differing as regards the size and character of the fruit, but it is generally agreed that the Cherimoyer is the most delicious of its kind, the flesh being firm, of a flaky character, and possessing a slight agreeable acidity mingled with a luscious sweetness. The flowers are pendent and velvety; they are generally closed in the day and open at night, giving out a delicate odor like that of *Magnolia fuscata*. The Cherimoyer is common in the mountains of Jamaica, and it is said to have been cultivated from time immemorial

in Chili. It is also cultivated in Madeira, whence the fruits are sometimes sent to the English market. It also grows and fruits freely at a high altitude in Ceylon. There is abundant evidence of its being adapted for cultivation in the open air in subtropical climates such as that of Florida and other of the southern states, and that it will fruit under glass has been proved at Kew and elsewhere. I tasted a fruit produced at Kew and am, in consequence, able to endorse all that has been said in its praise as a dessert fruit. The Creoles say that it is the most delicious fruit in the world. Cultivated on somewhat similar lines to those which are successful for the peach, the Cherimoyer would probably soon take a prominent place among favorite fruits. A figure of a plant in fruit is given this week in *The Gardeners' Chronicle*, where it is stated that in Constantinople the fruits are obtainable from December to February.

SARDA MELON.—Last year seeds of this interesting Melon were distributed from Kew among the principal gardens of the colonies and England. They had been obtained from Kabul by Dr. Aitchison, who stated in the *Kew Bulletin* for January that in western Afghanistan this variety is grown as a field-crop and is exported to India in great quantities during the winter, where it is much appreciated. The word Sarda means cold, and it appears that the fruits of this Melon only develop the rich flavor for which it is held in high repute in India when exposed for a time to a comparatively low temperature. The fruits collected from the plants while the season is hot and there is still no frost, are, comparatively speaking, of ordinary quality, but when the night frosts set in they are covered to prevent their being frozen, and are collected when not quite ripe. They then ripen slowly, keep well through the winter and improve in flavor the longer they are kept. Fruits have been grown this year in the Queen's garden at Windsor, and Mr. Thomas, the gardener, speaks highly of them. They were nearly a foot long, yellowish, netted, and the flesh was yellow, firm, very sweet and of good flavor.

ABERIA CAFFRA.—Attention has recently been called to this plant in colonial and English papers on account of its usefulness for fences and also for its edible fruits. When I was in South Africa nine years ago I saw some excellent fences of it, yards in thickness and absolutely impenetrable, owing to the number and strength of its stout straight spines, from two to six inches in length, which clothe the interlacing branches. It appeared to be as accommodating as the common Quick (*Cratægus*) is in this country and to grow as rapidly. Its fruits are spheroid, an inch in diameter, yellow when ripe, with a juicy acid pulp and an agreeable odor. At the Cape it is known as the Kei Apple, from the Kei River, in Caffraria. It is used for jam-making, and Professor Macowan, in a note recently published in *The Cape Journal of Agriculture*, says that mixed with tomato it would make a first-rate jam. It fruits annually in Mr. Hanbury's garden at Mentone, on the Riviera, whence samples are sometimes sent to Kew. The raw fruit is too acid for most palates, although this acidity is reduced by overripeness. The plant is easily multiplied from seeds or cuttings.

QUEENSLAND CHERRY.—There are so very few edible fruits in Australia that the discovery of this quality in a species of *Antidesma*, native of that country, is noteworthy, especially, too, as this genus belongs to the Spurge-worts (*Euphorbiaceæ*), an order exceptionally poor in edible-fruited species. *A. Dallachyanum*, the species under notice, is a shrub which, according to Mr. Bailey, who described it, has "fruit equaling in size that of large cherries, with an acid flavor like that of red currants, and, like them, capable of being made into a rich-colored refreshing jelly, grateful to the parched palates of persons suffering from fever." Fruits of this plant have lately been received at Kew. *A. Bunius*, a native of Java, also yields edible fruits used for jam-making. The Queensland Cherry would be worth a trial in the southern states. Seeds of it could be obtained from New South Wales.

APPLE, *BLENHEIM ORANGE*.—This is one of the best three apples grown in English gardens, the other two being Cox's Orange Pippin and the Ribston. The history of the first-named is somewhat remarkable. It was told recently at a plant exhibition in Oxford, and is as follows: "Mr. G. Kempster, who lived at the end of the last century at Woodstock, in Oxfordshire, when a young man, discovered a plant growing in a crevice in the window-sill. He carefully removed and planted it. In due time it became a tree and bore apples, which were at first called Kempster Pippins, and which were so fine and of such excellent flavor

LOMARIA GIBBA, var. *BLECHNOIDES*.—A supposed bigeneric hybrid Fern has lately been sent to Kew by Mr. A. MacLellan, of Newport, Rhode Island, who says it is from *Lomaria gibba*, crossed with *Blechnum Brasiliense*. There is no reason why such a hybrid should not occur, these two plants being much more closely related than is indicated by their names. On the other hand, *L. gibba* is a variable plant, and I incline to the view that this and other supposed hybrids of the same kind are merely sports from that plant. At Kew there are plants of *L. gibba* which are as broad in both barren and fertile pinnæ as the *Blechnum* and others showing

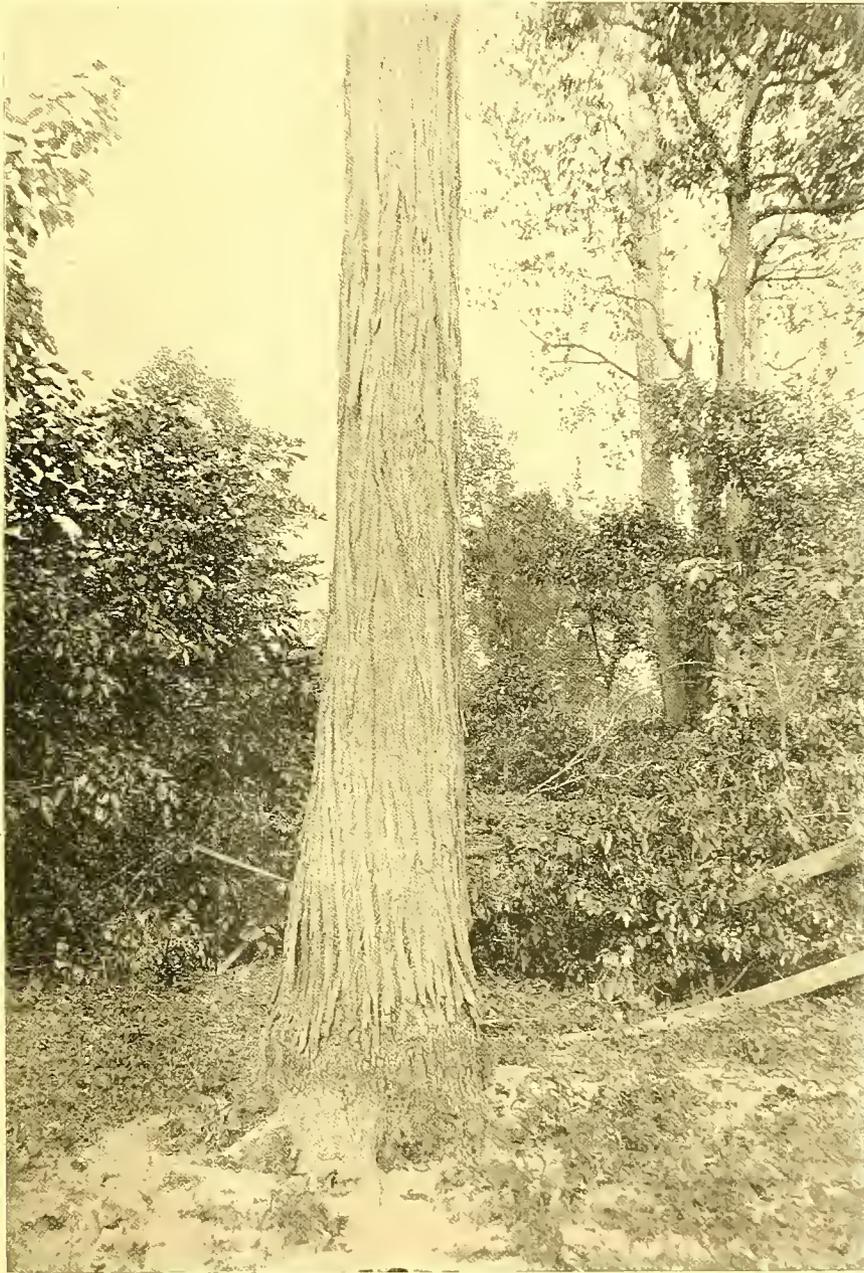

Fig. 2.—*Populus heterophylla*.—See page 13.

that they soon became famous. In 1811, the gardener at Blenheim, the residence of the Duke of Marlborough, near Woodstock, placed some of the apples on his Grace's table, and he so highly approved of them that the name was changed to Blenheim Orange. The original tree was standing in 1826. In September, 1822, five apples were gathered from it weighing from fifteen to twenty-one ounces." Where it thrives, this Apple is one of the most profitable; it does not fruit freely until the trees are of large size. It is good both as a dessert and as a cooking apple. It is ripe from November to February.

intermediate characters. The late Mr. T. Moore described in 1868 a seedling under the name of *L. gibba major*, which is very similar to Mr. MacLellan's plant, and it was said to be a cross between *L. gibba* and *L. ciliata*. He also refers to a cross between *L. gibba* and the *Blechnum* which occurred at Chiswick in 1870. Messrs. Veitch & Sons had a broad-leaved *L. gibba*, which was at first called *Blechnum platyptera*. This is identical with Mr. MacLellan's plant, the name now adopted for it by Mr. Baker being *L. gibba*, var. *blechnoides*. Finally, the late Dr. Asa Gray sent to Mr. Baker fronds from a Fern which he described as

follows: "Here are fronds of a *Lomaria gibba* in which the outer fertile fronds are all *Blechnum* and the inner *Lomaria*. I send fronds of these also for comparison." Ferns display a most extraordinary disposition to vary under artificial treatment, and this is especially true of those which have long been in cultivation and are largely grown, as, for instance, *Adiantum cuneatum*, *Pteris serrulata*, *Gymnogramme calomelanos*, etc. In the face of this it is better to look upon all such seedlings as that of Mr. MacLellan's as a variation rather than a hypothetical hybrid.

London.

W. Watson.

Plant Notes.

SCHIZOSTYLIS COCCINEA.—Many plants of the *Iris* family are useful winter-flowering subjects, and among these none are more grateful and floriferous than this bright and showy African plant, often called the *Crimson Flag*. In habit of growth it resembles many kinds of *Iris*, the leaves being long, narrowly sword-shaped or almost linear, equitant, springing from a fleshy rhizome. The flowers are large, sessile, eight to fifteen in a bracteate spike on tall, leafy peduncles. The color is a bright red or scarlet. The perianth consists of six uniform, acute segments, united into a tube at the base, the entire width of the limb being about two inches. The time of flowering is from October until after Christmas, the flowers remaining in perfection a considerable time. It flourishes out-of-doors in England, but as it is of little importance in this country, except for indoor use, it should be grown chiefly for this purpose in pots or for cut flowers. Late in spring or early summer the plants should be divided, from three to five buds being left on each root. These should be planted out in a bed of loose humus-rich soil six to eight inches apart. During the summer, when dry weather is prevalent, the bed should be occasionally soaked, so as to insure a robust growth. In the fall the plants may be lifted, cleaned and potted for winter use. They should be kept in a sunny position in a cool greenhouse, where they will flower without forcing, some coming earlier, others later, thus giving a succession of flowers for months. After flowering the plant may be left in the pots and stowed away in a frame or cool greenhouse until the time comes to divide them and plant out-of-doors for the next winter's use.

Cultural Department.

Seasonable Greenhouse Notes.

PRIMULA FORBESII is a charming little plant for cool greenhouse decoration in winter, its delicate yellow-throated lavender flowers, borne in verticils from ten to twelve in each on scapes a foot or more in length. The scapes stand erect during the opening of the first few umbels, and in this condition they are very serviceable for bouquet work. Later, unable to support the weight of flowers, they arch gracefully over the sides of the pots, making charming subjects for the front row of the conservatory. The plants are tufted, with fiddle-shaped leaves, slightly pilose. The whole plant is covered with a delicate white farina. *P. floribunda* is another tender species, a fit companion for *P. Forbesii*, with yellow flowers, also in verticils, or whorls, in erect scapes. Both are easily raised from seeds, and usually enough are found scattered under the benches, self-sown, where they seem to thrive, if anything, better than under pot-culture. Some self-sown plants are growing on the walls of the Violet-house, and really it is hard to tell where they get their support from.

Here in America, for some reason, we have not generally made the true *Heaths* a success. They are frequently seen, but it is seldom any but *E. Caffra* and *E. Melanthera* succeed thoroughly. It is argued that the true *Heaths* not being natives of the North American continent, our climate is unsuited to them, and, furthermore, the peat necessary in their cultivation must be such as is obtained from moors where they abound, and this cannot be obtained here. The most successful growers import their peat from Europe. The varieties already named will grow almost anywhere and succeed well in common loam in the open garden, providing plenty of water is given them during the growing season. They also

lift well in the autumn, which is another advantage. One thing must be remembered, that a period of rest must intervene before the plants are brought into bloom. After this they force fairly well, but I have noticed that such as have been brought in early have lost the greater part of their lower foliage.

Antirrhinums have recently been added to the florists' stock in trade. The purchasing public appreciate them, and they have proved a profitable acquisition. It is evident, however, that considerable selection will be necessary before they are thoroughly adapted to the florists' needs, just as we have had to do with other plants which are properly herbaceous, as *Carnations* and *Mignonette*. It seems to me the ideal variety is one which does not develop more than ten or twelve flowers on a raceme. More flowers would require more energy from the plant, which would mean fewer flower-stems; besides, the lower flowers on a large raceme would wither before the upper buds open, and in this way a large number of extra buds would be worthless. The dwarf varieties will probably come soonest into favor, and already we have one white variety, *Star of the North*, fairly well fixed, coming true from seed.

Grevillea robusta in a small state is one of the handsomest foliage plants we have. Its graceful Fern-like leaves and pyramidal habit make it an acceptable plant in any grouping. It is equally useful for bedding purposes, and helps well to break up the monotony of a too even piece of summer bedding. It can also be used as a centrepiece in any circular design. Seed sown now will germinate in five to six weeks in an ordinary greenhouse, and the young plants grown in pots should make pretty plants from one to two feet high by next winter. It is seldom the plants remain in presentable shape for more than two years, and they can hardly ever be pruned back into acceptable plants. It is better to raise a few seedlings every year. Good loam and ordinary cool greenhouse treatment are all they need. *G. Hillii* is a very distinct species, but little known. It is much slower in growth. We have a handsome specimen now four years old and five feet tall, just a single cane, but with foliage down to the pot; the leaves have a distinctly classical cut. They are widely and irregularly pinnate, staghorn-like, deep shining green on the upper surface and covered with a closely appressed, shining, silver-gray pubescence on the under sides, as also are the upper part of the stem and the young unfolding leaves. It is a peculiarly effective plant when used singly in church decoration, being very effective under artificial light.

Dracæna australis is a common but acceptable plant when small, and I know of plants that have been used in a dwelling-house window for a year which have scarcely lost a leaf. Seed is cheap and germinates freely in an ordinary greenhouse temperature in about five weeks. Good soil, good drainage and plenty of water are the only requirements. Young plants, however, do not lift well when planted out. They should always be established in pots first; afterward they will hold the original ball of earth.

Our French *Cannas* have been repotted after a season of comparative rest, though, really, they have been growing all the while, but slowly. Now, started in a higher temperature, they will soon make strong stems and bloom finely during the spring months. Those who have roots of good varieties of French *Cannas*, and can find room, will lose nothing by growing them through the winter; all the growth made is so much gain. We have never known any constitutional injury to result, and our plants have invariably bloomed well during the succeeding summer.

Wellesley, Mass.

I. D. Hatfield.

Euphorbia Jacquinaeflora.

THESE showy winter-flowering plants have been in bloom for the last four weeks, and their long wreaths of bright orange-scarlet bracts still retain their beauty and are a cheering addition to the greenhouse flora at this season. The plant may be used to good advantage as a climber if planted in a permanent situation against a wall or pillar, well cut back after flowering and freely encouraged to grow through the summer. A method usually more convenient is to grow it in bush form in pots or boxes. For this purpose we raise young plants from cuttings every spring. The old plants may be cut down and grown on a second year, but the young plants always prove the more vigorous and produce much finer flower-sprays.

For cuttings, well-ripened wood should be chosen. They strike better in an intermediate than in a warm house, and as they suffer easily from damp are better placed in an open propagating-bed than in a close propagating-frame. If they are to be flowered in boxes the one shift after striking will suffice. If intended for pots they will require about three shifts. We find boxes more convenient for their growth, but

they cannot always be used to the same advantage for decoration as plants in pots. Thorough drainage is in all cases essential, as the plants require plentiful supplies of water during the growing season, and thrive best in a rich fibrous soil. They should be planted out-of-doors in June for the summer. At first they will require a little protection, but when hardened off a little may be fully exposed to air and sunshine. They will require pinching back once or twice to get them to break, but this should not be overdone, as a few fine long shoots are preferable to a number of smaller ones. A plant with four or five shoots generally proves the most satisfactory.

William Scott.

Notes on Garden Vegetables.

WITH one week's exception, the weather of December was abnormally mild, and outdoor gardening operations could be carried on without hindrance. For two weeks we had an entire absence of frost or precipitation of any kind, and the ground was as dry as it ever is at seed-time in early April. It is unusual to see tree-planting, digging, plowing and similar operations in full progress on both Christmas and New Year's days, but I observed quite a number busily employed on such work during holiday week. But trying weather must be near, and winter protection should be made ready for everything which needs it. This is the best time to complete digging, trenching, draining and road-making operations. We like to dig and enrich all the ground possible at this season, as it gives the vegetable garden a neater appearance, improves the ground by allowing the frost to penetrate and pulverize it, and greatly lessens the strain in spring. While the ground is open a fresh plantation of Horse-radish may be made at leisure. Onions seem to do fully as well on the same land year after year; we have known them to succeed without a change for over twenty years. As a general rule, however, a rotation of crops is advisable. With plenty of ground at command, this is more easily carried out than where the space is limited; in our own case, by trenching a piece of ground each year, and thus practically renewing it, we secure good returns.

Our perennial borders have recently had a mulching of well-rotted and broken-up manure, for herbaceous plants, with hardly an exception, like liberal fertilizing. Too often they are starved for want of it. *Helianthus multiflorus plenus* and some few other Sunflowers are doubtfully hardy here and occasionally winter-killed unless protected. We usually place a few forkfuls of leaf-mold or half-rotted leaves over the crowns of such plants; cocoanut-fibre refuse also is serviceable for covering Lilies and other bulbous plants, which are more injured by excessive moisture than by frost. Pansies in the open we have protected by covering lightly with leaves, over which we lay a few Spruce-branches to keep them in place. Those in frames we cover with dry leaves when hard frozen, and remove them about the end of February; it is necessary to place over them strong sashes with good glass, as the plants are liable to rot if the leaves become wet and heavy and air is not freely given. Half-hardy biennials, such as Canterbury Bells, *Antirrhinums*, etc., do not require any sash protection until severe frost, but they need free ventilation during favorable weather. Beds containing Tulips, Hyacinths and Crocuses should now have a coating of light straw manure. Crocuses and Snowdrops in sheltered nooks are already above ground, and on New Year's day we noted Violets and Pansies in flower in the borders.

A common practice prevails of allowing old stools of Horse-radish to stand in gardens year after year. These become dense and the roots matted, so that they are small and tough, and the ground completely impoverished for some distance around. It is a good plan to trench out all the roots and start a fresh bed, carefully removing even the smallest pieces of root, as every one will grow. In planting a new bed we select the straightest and thickest roots, each with a crown attached, trim from them all side-rootlets, and plant with a dibble in deeply trenched well-manured ground, a foot apart each way, burying the crown three to four inches below the surface. The result will be fine crisp roots next year.

Celery in the open has kept remarkably well during the present winter; a sufficient body of leaves has now been placed on our supply to secure it from severe frosts. At the recommendation of a friend in the south of Scotland, we earthed up half a trench of Kalamazoo Celery with leaf-mold instead of the ordinary garden soil. On opening into this trench on December 24th we found it to be the whitest, most free from blemish and best-flavored celery we had. The difference between it and the part earthed up with loam is very striking. The leaf-mold, being light and more porous than loam, allows air to more easily reach the plants; there is less

danger of breaking the rather brittle stalks in using it, and it is a better frost-resister than ordinary loam. Leaf-mold is not, as a general rule, to be had in sufficient quantities on private places to use for Celery blanching, but as it can be easily wheeled away when the Celery is lifted and used for any other purpose, it is certainly worth giving a trial. So many good practical gardeners fail to carry celery through the winter that any discovery of a means to preserve it should be of service. When lifted and stored in cellars or frames a great proportion of the heads rot and the stalks lack that sweet nutty flavor characteristic of those kept outdoors where they grow.

Frames containing Parsley, Lettuces, or any of the Brassica family, need abundance of ventilation on all fine days. We look over these once a week to remove decaying leaves. A bed of leaves in which a few barrow-loads of horse-manure are mixed makes a capital bed for Lettuces, and we find no difficulty in having a supply all winter by these means. Leaves alone give a gentle heat which keeps Lettuces growing nicely. Sowings indoors of Lettuce, Radish, Cauliflower (such as forcing Erfurt) and Tomato are seasonable. The Lettuces can be transferred to frames when of sufficient size. Radishes, if no bed is at command for them, do nicely pricked off in boxes. For an early supply of tomatoes, such varieties as May's Favorite, *Chemin Rouge* or *Comrade* are very good. By the time these plants are large enough to place in their fruiting-pots or plant out the weather will be sufficiently warm to allow of their being grown in almost any ordinary greenhouse. Plants which commenced to ripen toward the end of October are still fruiting finely. In about a month we will remove these and place another batch in their places which are now in three-inch pots. Our third lot is now in six-inch pots, and will shortly be shifted into their fruiting-pots. These plants will yield a good crop in March. To make certain of a good set artificial pollination is still necessary, and decaying foliage and laterals are removed to give the plants as much sunlight as possible.

W. N. Craig.

Plants in Bloom at the United States Botanic Garden.

THE flowers of *Reinwardtia trigyna* closely resemble those of the better-known *R. trigyna*, often called *Linum trigynum*. They are of a lighter yellow and much more freely produced; in fact, the plants, if not looked after, have a tendency to flower themselves to death. This species is a very desirable one for the greenhouse at this season, and it lasts quite a time in bloom. Cuttings of it should be put in during the early summer, and if given liberal treatment they will be well-furnished plants in eight-inch pots by autumn. There is nothing difficult about their culture. Old plants can be kept over, but it is preferable to take off the young shoots for cuttings and discard the old ones.

Schaueria calycotricha, better known as *Justicia calotricha*, is an old favorite which well repays a little extra attention, as a few plants of it help to brighten up the greenhouse during the dull months. The individual flowers are about an inch in length, bright yellow, the calyx and bracts being of the same color. The flowers are arranged in a terminal head. The successful flowering of this plant depends on keeping it in a healthy growing state during the summer. It is very liable to the attacks of scale insects.

Bignonia venusta can be depended on to give two crops at least of flowers during the year, the principal one with us coming in about Christmas. Where there is an abundance of roof-room in a large conservatory, this vine should certainly have a place, as it is by far the most showy of the species suited for indoor cultivation. We cannot expect to have it in a satisfactory condition if the roots are confined in a pot or tub; it should be planted out in a well-drained position, raised a little, if possible, from the level of the floor. There is no danger of the plant occupying too much room if grown to, say, one or two stems and the lateral growths kept in bounds by trimming; this operation should be gone through twice annually—once at the end of January, and again after it is done flowering, shortly after midsummer. The growths which push out after pruning should be allowed simply to hang down, because when in bloom they show to better advantage. The corymbs of flowers are both terminal and axillary, coming on the strong growths in great profusion; sometimes the shoots are covered with flowers for four or five feet of their length.

Another Bignoniaceous vine, called *Adenocalymna comosum*, is now in gorgeous bloom. The flowers, which are bright yellow, are arranged in upright racemes springing from the axils of the leaves and at the ends of the shoots. This vine does not require pruning to make it flower, but simply to keep

it within bounds, as it seems to delight in smothering everything within reach. Some of the books give its height as only ten feet; the specimen in the garden here is at least sixty feet high, and I do not doubt that it would grow twice that height if allowed to.

Washington, D. C.

Notes on Begonias.

BEGONIA NITIDA has been in cultivation for more than a century and still holds its own with the latest introductions of this large genus. It is a West Indian species and was introduced from Jamaica in 1777. It flowers nearly all the year round, but is most useful in winter. At this time some large, bushy plants, from three to four feet high, are laden with pink-colored flowers. The stems are fleshy and slightly woody at the base; the leaves are four to six inches across, glossy green, obliquely ovate, and crenated at the margin. The flowers are produced plentifully in terminal and axillary panicles and are of a deep rose color. The staminate flowers measure one inch and a half across and have two broad and two narrow petals, while the pistillate ones are not as large and have five equal petals. The flowers last well when cut, and are specially useful at this season. Young plants are easily obtained from cuttings made from the young growth and root freely at any season. We find the two or three year old plants most useful, as they produce more flowers than the younger ones. In May the old plants are cut back and taken out of the pots, and most of the exhausted soil removed from the roots. They are then planted out in the garden in a shady position, where they are left until the first week in September, when they are potted and put into a warm greenhouse. When the pots are well filled with roots, weak liquid-manure is given about once a week. We use this fertilizer for all the strong shrubby kinds. For good, healthy plants and plenty of flowers Begonias need good light and sufficient room between the plants, so that air can circulate freely among them.

Begonia Gogoensis is a species with variegated leaves, introduced from Gogo, in Sumatra, by Messrs. James Veitch & Sons, of Chelsea, in 1882. This *Begonia* is valuable as a foliage plant, and when well grown makes a distinct specimen. The leaves are peltate and oval in shape and measure from six to nine inches in length. When they are young they have a bronzy metallic hue, but when older they are a deep velvety green interlaced with the paler midribs and veins. When the leaves are full grown the under side is of a deep red color. The petioles are reddish, four-angled and about six inches long and rise from a short tuberous stem. This species is now in bloom; the flowers are not showy, being small, of a rosy pink color, and produced in loose panicles on erect peduncles which raise the flower slightly above the foliage. *B. Gogoensis* is grown in an intermediate house the year through, in a slightly shaded position during the hot months of summer. It flourishes in a light, loose, rich soil.

Begonia manicata is an excellent free-flowering species, and large plants are handsome at this time with their abundant crop of flowers. It is a robust plant and easy to grow. In the latter part of May, when the weather is favorable, the plants are taken out of the pans, divided and planted out singly in the garden. Early in September they are lifted and some of them put into large shallow pans, over the edges of which the large leaves soon hang, so as almost to hide them. Large masses of this *Begonia* are more showy than small individual plants, and they have a pleasing effect now when in bloom. The short stems are clothed with smooth shining green leaves that are ovate, obliquely cordate and measure six to eight inches in length; they have many scale-like hairs on the under side. The pink flowers are produced on long peduncles and are arranged in large loose panicles. A variety of this plant grown here is named *Aureo-maculata*, and is a handsome foliage plant when well grown. Its leaves are large and glossy and prettily marked with creamy white blotches.

Another old favorite is *Begonia fuchsoides*, which has been cultivated since 1847. It makes a good pot-plant, but is in best condition when planted out in a cool greenhouse and trained to a pillar or tied loosely to a stout stake. Under good treatment it attains a height of five or six feet, and its stems are clothed with numerous ovate green leaves about one and a half inches long. The flowers are borne on drooping branched panicles and their color is a rich scarlet.

Botanic Garden, Harvard University.

R. Cameron.

Kœlreuteria paniculata.—I am well acquainted with a few specimens of this desirable little tree at McPherson, Kansas. These examples are twenty-one years old; they are healthy and sound, withstanding the dry weather and the hot winds to

which they are exposed in a clearly successful manner. For about ten years they have been blossoming and bearing fruit, and are altogether very interesting.

Manhattan, Kansas.

F. A. Waugh.

Notes from the Botanic Garden of Smith College.

Lopezia coronata.—This plant is now in flower in the cool temperate house, and is certainly a most striking and beautiful plant for any cool greenhouse. The flowers are disposed in racemes at the ends of the branches; they are white, with the under side a rosy purple. The plant branches so gracefully as to give it, when in flower, a candelabra appearance. The leaves are alternate and about one inch long, ovate, with very short petioles. Clusters of smaller leaves or undeveloped branches are situated in the axils of the leaves. It is a native of Mexico and belongs to the family Onagraceæ. I find the best way to grow *Lopezias* is to take cuttings about the end of February (they root readily in the propagating bed), afterward potting them in small pots, and plant them out during summer. I lift them about the middle of September, keeping them well shaded till established. I should think this plant would make an excellent one for commercial use, either for cut flowers or pot plants, as it remains in flower several weeks.

Aponogeton distachyon.—This plant is a most beautiful subject for an aquarium in a cool greenhouse. It has been in flower in a cool house here for several weeks. The leaves are narrowly elliptical, entire, about eight inches long by two wide, and float on the surface of the water. The flower is rather remarkable, a two spiked scape, and looks as though the scape had been split at the upper end to form the spikes. Instead of petals there are small, white ovate bracts, alternately disposed on the spikes. The pistils, which are apparently four-cleft, are situated at the base of the bracts and surrounded by a number of stamens with dark brown or purplish anthers. The flowers rise just above the surface of the water and have a very sweet perfume. It is a native of the Cape of Good Hope, and is sometimes called Cape Pondweed. Like most aquatic plants it delights in a rich soil; a good sandy loam, with plenty of rotten cow-dung, suits it admirably. It is also very essential that it be placed in a light position with an abundance of air on mild days. It belongs to the family Naiadaceæ, and is closely related to the lace-leaf plant of Madagascar, *Ouvirandra fenestralis*. According to *Index Kewensis*, *Ouvirandra* is now included under *Aponogeton*.

Northampton, Mass.

Correspondence.

Habits of Ferns.

To the Editor of GARDEN AND FOREST:

Sir,—If one visits the forest at this season, before the ground is covered with snow, he will find the Christmas Fern, *Allosaurus acrostichoides*, and other evergreen species with fronds procumbent. In summer these same species stand nearly upright, the fronds of *A. acrostichoides* being especially firm and rigid. As winter approaches, however, the plants become prostrate, and so protect themselves from being broken by the heavy snows and winds of the winter months.

About the middle of September I took from the woods three plants of *Allosaurus acrostichoides*, put them in pots and brought them into the house. They stood the transplanting well and proved very ornamental until about the middle of November, when these plants, like those outside, became prostrate. Cold weather could not have been the ruling factor in bringing this about as these plants were in heated rooms. It seems rather strange that this lying down of the fronds takes place at so nearly the same time with plants placed under such different conditions. It would be interesting to know if this old habit can be broken up by continued cultivation under changed conditions, and if so, how long it will take to overcome it.

Experiment Station, New Haven, Conn.

North Carolina Bulbs for Forcing.

To the Editor of GARDEN AND FOREST:

Sir,—Some time since you noted the fine appearance of bulbs grown in this state and sent to a firm in New York, and remarked that though apparently much superior to the imported bulbs, it remained to be seen whether they would force as well. About the same time the firm to whom these bulbs were sent wrote to me that it was hardly worth while to grow the Chinese *Narcissus* here, for the bulbs, though very fine, would

not bloom in water as the Chinese ones do; at least, that had been their experience with bulbs grown in Bermuda. I then put some of our bulbs in water, and at the same time some of the imported Chinese. To-day our bulbs are a mass of flowers, while the imported ones are just showing buds. I have been accustomed to the forcing of bulbs for thirty years and have never seen any bulbs do better than those we grow here. In addition to the *Narcissus tazetta*, we are forcing some of all the bulbs we grow, including various *Narcissi*, Tulips, Lilies, Roman Hyacinths and Freesias, and all, without exception, are first-class. I believe our bulbs of *Lilium candidum* will at least make twice as many flowers as the French bulbs. Roman Hyacinths are excellent, and Freesias are extra fine, though our house (we have but one) is rather too warm for them. We are confident that bulbs grown in North Carolina will compare favorably with any in commerce for forcing, as well as for any other use.

Recent Publications.

Agriculture. By R. Hedges Wallace. Philadelphia: J. B. Lippincott & Co.

The natural laws on which profitable agriculture is based are of universal application. There is no agricultural science for America which is not true for the latitude of England or of Australia, and yet the art of agriculture varies widely when it comes to be adapted to the climate and soil of different countries. This little book discusses the science proper. Although prepared by a lecturer and examiner in the Department of Agriculture in Victoria, it treats of those broad principles which not only underlie the practice of agriculture, but gives the reasons why this practice varies under different conditions. For an American text-book it might be more immediately useful if the illustrations were drawn more generally from American plants, American crops, American machinery and American surroundings generally; nevertheless, it would be hard to put within a brief compass a clearer and more comprehensive statement of the essentials of agricultural science. Subjects of such fundamental importance as the composition of plants, their methods of assimilating food, the physical and chemical properties of soil, the effects of cultivation on land and crops, the use of natural and artificial fertilizers, the rotation of crops and many more elemental problems are so treated that the student who masters these pages ought to be able to carry out intelligently the daily routine of farm procedure. Of course, we do not expect in such a compendium any of the refinements of biology or botany or chemistry, and, in fact, these would be out of place, since the author is careful not to confuse these special sciences with the science of agriculture, the object of which is solely the production of crops and the breeding and feeding of animals. Questions are added to each chapter, and this old-fashioned method of instruction adds materially to the value of the book. Besides this, the important words which constitute the topics of a given paragraph are printed in broad-faced type, and this, although it does not add to the beauty of the page, makes it much easier for the student or for one who is hastily looking the book through to pick out the thread of the argument.

We are glad to see that this book has been put on the reading list in the University extension movements in some states where provision is made for agricultural instruction. Part of it, at least, or a book arranged on a similar plan, might well be adopted as a text-book in all the common schools of the country. It is universally admitted that the study of the natural sciences ought to have some place in every curriculum as a factor in wholesome intellectual development, if for no other reason. In our high schools and colleges the principles of astronomy are taught, not because the students expect to become expert astronomers, but simply to broaden their field of view and exercise certain powers of thought and imagination. The elements of chemistry and botany and geology and other sciences are taught largely to discipline the mind and furnish it with material for use in civilized society, and there is no reason

why the study of agricultural science should not be recognized for its value in furnishing mental training and exercise. No branch of study would have a more immediate effect in establishing habits of careful personal observation, and certainly one familiar with the elements of this science would derive a life-long pleasure from it, even if he never made direct practical use of his knowledge. One who has an intelligent idea of what is going on in the orchards and gardens, the grain fields and pastures about him in any country where he may chance to be, is more adequately equipped and lives a fuller life than he does to whom all procedures on every farm and vineyard are mysteries—mere movement without any intelligible plan or purpose.

Periodical Literature.

MR. W. BOTTING HEMSLEY, in an interesting review of Dr. Cordemoy's recently published *Flora of Bourbon*, calls attention to the following facts:

"Bourbon is about the same size as Mauritius, from which it is now separated by about a hundred miles of sea, though it seems probable that they were joined at some remote period. The mountains rise to an altitude of more than 9,000 feet, or nearly three times the height of the highest summits in Mauritius, and the island presents a great variety of climatic conditions. . . . At 7,000 to 7,500 feet ice is sometimes found as late as November.

"Formerly nearly the whole island was covered with forest from the seashore up to an altitude of about 6,500 feet. But for half a century all the available land in the lower region has been cleared for cultivation, and the native vegetation is replaced, where not actually under cultivation, by foreign weeds. At the present day the forest region commences at 600 to 2,500 feet.

"Most of the prominent and useful forest-trees are common to Mauritius, as are all of the Palms. But what is more remarkable, few of them are found elsewhere, though many of the genera of the region extend to Madagascar. In fact, there are very few genera peculiar to either Bourbon or Mauritius, but several restricted to the two, indicating that these islands are separated remnants of a formerly more extensive area of land. On the other hand, peculiar species are very numerous in both islands. Dr. Cordemoy and his collaborators (for he has not worked out all the orders himself) describe upward of two hundred species of flowering plants as new, in a total of less than a thousand. More than seventy of these new species are Orchids, and the author expresses his conviction that many terrestrial species yet remain undiscovered, as they are, many of them, very small and inconspicuous, and their period of vegetation is of very short duration. Indeed, as it is, the number of species of Orchids enumerated is 172, or more than double the number of any other order of flowering plants. The island is also exceedingly rich in Ferns and Lycopods, which number together about 220 species. It is true that the author takes a narrower view of species than he probably would do if he were dealing with the Ferns of the whole world; but even after deducting twenty per cent. on this account there remain nearly a third more than there are in the Fern-flora of New Zealand. Not only are the species numerous, but between thirty and forty genera are represented. Tree and Filmy Ferns are present, though they do not abound to the extent they do in the far-away southern country.

"The intermediate and upper zones of vegetation comprise species of *Phyllipia*, dwarf shrubby *Ericaceæ*, *Hypericum*, *Phyllica* (very numerous in south Africa), *Psiadia*, and shrubby species of *Senecio*, prominent among which is the endemic *S. Ambavilla*. *Faujasia* and *Eriothrix* are other characteristic shrubby *Compositæ*. Plants of an alpine character are entirely wanting. *Cardamine Africana* is the only native Crucifer, and *Stellaria villosa*, the only member of the *Caryophyllaceæ*. There are, however, two endemic species of *Ranunculus* high up on the mountains. *Agauria salicifolia* is an ericaceous shrub or small tree common to Bourbon, Mauritius, Madagascar and the mountains of tropical Africa. Altogether it is an exceedingly interesting flora."

As early as the middle of the last century Bourbon was visited by the French botanist Commerson. The result of his investigations was not published, although his plants are still preserved in the herbarium of the Museum at Paris. In 1795 another French botanist, Aubert du Petit-Thouars, visited Bourbon, where he remained for three years, publishing, after his return to Paris, important works on the botany of this and

the neighboring islands, including Madagascar. Gaudichaud, another French botanist, visited the island in 1818, but his collections were lost in the wreck of the French man-of-war Uranie. Returning to the island seven years later in the Bonite, he subsequently wrote the botany of the voyage which, although still incomplete, Mr. Hemsley pronounces one of the most interesting of the earlier contributions to peninsular floras.

Notes.

A correspondent of *The Gardeners' Chronicle*, writing from the Botanic Garden in Grenada, West Indies, states that the Avocado pear, the fruit of *Persea gratissima*, is one of the few vegetable substances which are relished by cats. It is said that these animals will leave milk when an opportunity offers and eat this fruit voraciously.

In one of the late bulletins of the Cornell Experiment Station the Russian Thistle is spoken of as one of those weeds whose mission is to educate the farmer and ameliorate the soil. Weeds only prosper on fields which have been mismanaged, and judicious tillage and cropping will keep them down. If the Russian Thistle spreads seriously it will be because our scheme of farming makes room for it by not keeping the land in full use.

The experiment has been recently made in France of forcing Strawberries under different colored glass, with the following results: (1) The best and earliest fruit was raised under ordinary glass; (2) orange-colored glass stimulated the vegetation, but was prejudicial to the quality, size and earliness of the fruit; (3) the plants under violet glass yielded a great deal of fruit, but it was small, inferior in quality and not early; (4) red, blue and green glass all proved detrimental to the plants in the experiment.

The botanical garden at Smith's College, Northampton, Massachusetts, is only a little more than three years old, but during the past year more than one thousand trees and shrubs were added to the collection, and the same number of herbaceous plants. Five glass houses were built during the year, including a large Palm-house, so that there are now seven greenhouses altogether. The policy of the college is to make the garden primarily educational, but it is also interesting from an ornamental point of view.

During last week 8,625 barrels of apples were shipped to this city for local trade, making 505,000 barrels since September 1st, an increase of 124,864 barrels over the supply for the same period last season. The exports from this port for last week amounted to 1,734 barrels, 220,455 barrels since September 1st, and nearly 3,000 barrels less than during the same weeks last season. Northern Spies, Virginia Wine Saps and Kings sell for the highest price, \$4.00 a barrel to retail buyers, followed closely by York Imperials; Greenings, Baldwins and Ben Davis cost fifty cents a barrel less.

Among house-plants easy to manage, Joseph Meelian mentions *Begonia maculata* and *B. Saundersii*; *Ruellia macrantha*, with its large trumpet-shaped rosy purple flowers; *Ardisia*, with its clustered berries; *Cypripedium insigne*, which will thrive among other plants under ordinary window-culture and its flowers will remain open for six weeks or two months; *Rubus rosæfolius*, with double white flowers; *Streptosolon Jamesonii*, with abundant orange-colored flowers in late winter, and *Libonia Penrhosensis*, which is covered with its crimson bloom throughout the winter months.

Fruit-growers in the Hudson River Valley consider the Lucretia dewberry as profitable as any of the blackberries, because it ripens early, and as grown there it is large, uniform in color and of good appearance, while the plants are very productive. These are set about six feet apart each way; the vines are allowed to creep over the ground and are well mulched at the beginning of the winter. Five or six of the strong shoots from each hill are tied to a stake in the spring and the rest are cut off and removed, and this insures clean fruit and protects the plants from being bruised when it is gathered.

Florida is now sending limited quantities of lettuce, cucumbers, squashes and tomatoes to northern markets, besides egg-plants, string beans and peas, the latter selling at fancy prices when choice. Lettuce is also coming from Louisiana, and new-crop cauliflower, spinach, kale and radishes from Virginia, and beets from South Carolina. Tomatoes, from California, sell for twenty-five cents a pound, and celery from the same state at twenty-five cents for a bunch of three stalks. Tender

green stalks of asparagus, fifteen inches long, a dozen to a bunch, have been credited to California, but these are grown under glass in northern Illinois. They sell for \$1.00 a bunch, and two dozen blanched shoots less than half as long, from glass houses in this state, cost seventy-five cents. The cranberry crop of the United States, while considerably larger than that of 1894, is still insufficient for home use, and some have recently been imported from Europe. Other importations are new potatoes and beets from the Bermudas, and cabbage from Denmark.

Monsieur Charles Naudin announces in the last number of the *Revue Horticole* of the year the flowering, in his garden at Antibes, of *Vigna strobilophora*, the beautiful leguminous vine discovered by Mr. C. G. Pringle in Mexico in 1893, and described by Dr. B. L. Robinson. A figure of this plant, which promises to be a first-class addition to garden vines, was published in this journal (vol. vii., page 155), and seeds collected by Mr. Pringle were distributed, through the agency of the Arnold Arboretum, among American and European collections. At Antibes the seed sown in 1894 has produced stems several yards in length, which were covered during October and a part of November of last year with racemes of purple and rose-colored pea-shaped flowers. According to Monsieur Naudin, "*V. strobilophora* will rank among the most ornamental of the Mexican plants cultivated in Europe, and will make a sensation in northern greenhouses as well as in the gardens of southern Europe, where it will be especially valuable for covering trellises and summer-houses."

Small even sized Tangerine oranges, from California, of bright orange-red color, now bring a dollar a dozen in the fancy-fruit stores. The few coming from Florida are of uneven size, the color varying from lemon to russet, and these command the same price a dozen, as much as \$14.00 a box being obtained for them at wholesale. Tiny Mandarins, from Italy, cost sixty cents a dozen. Small shipments of unusually fine oranges are coming from Citra, Florida, and sell for \$1.00 a dozen, grape-fruit from the same section commanding \$2.50 to \$3.00 a dozen. The choicest Navel oranges from California are offered at \$1.20 a dozen. Large showy Japanese persimmons, in excellent condition, cost sixty cents to \$1.20 a dozen. California strawberries, with considerable suggestion of the luscious summer fruit, are in moderate supply at seventy-five cents a box, and the first hot-house strawberries from Hackensack, New Jersey, cost \$3.00 for a cup holding six or seven immense berries. Lady-apples, brilliant and lustrous, cost thirty to fifty cents a dozen. Lychee nuts, from China, sell for thirty cents a pound, the best pecans from Texas bringing the same price, and new-crop Paradise nuts, from Brazil, fifty cents a pound. English filberts, or cob nuts, in their husks, are also offered in the best stores, and cones of *Pinus Pinea*, each scale enclosing two edible seeds known as *Pignolia* nuts.

The highest grades of roses were among the flowers that sold most readily during the holiday season, when choice American Beauties brought \$36.00 a dozen in the retail shops. New Year's sales were more active than in recent seasons, and holiday prices were fairly maintained then, though they had fallen fifty per cent. and more by the Saturday following, when a half-dozen sprays of purple lilac cost \$2.00, the white variety bringing a third more. New carnations, as Maud Dean and Lily Dean, then commanded \$2.00 a dozen; the popular pink William Scott and deep red Meteor \$1.50, and Lena Saling and the scarlet Tidal Wave \$1.00. Mignonette has been one of the most popular flowers, the largest spikes costing as much as fifty cents each. Easter lilies have sold well at \$3.00 a dozen, and Marie Louise violets at \$2.00 for a bunch of fifty flowers. Spikes of white Swainsonia cost fifty cents a half-dozen. Other cut flowers seen in florists' collections were lily-of-the-valley, forget-me-not and heliotrope. Narcissus, hyacinths and tulips have been forced into flower in large quantities, but have failed to supersede more seasonable flowers. Among flowering and fruiting plants the most delicate, as the most showy, are thickly flowered Ericas. Cyclamens and Primulas of many hues and bright-colored Azaleas enliven the florists' windows, as do well-berried plants of *Ardisia crenulata* and Otaheite Orange in abundant fruit.

The death is announced, at Anhalt, Germany, in his sixty-sixth year, of Professor Hermann Hellriegel, the distinguished agricultural chemist, whose name will be associated with the discovery that organisms growing in the root tubercles of many leguminous plants help to fix the free nitrogen of the air and make it available as plant-food.

Municipal Art Again.

A FEW weeks ago we alluded to the report of the Fine Arts Federation of this city on the location of the proposed monument to the soldiers and sailors who died in the war for the Union, for which a quarter of a million dollars had been appropriated by the Legislature. The legally appointed trustees of this monument fund had invited an opinion from the Federation, which consists of members of ten different societies in the city which are connected with various branches of the arts of painting, sculpture and architecture, and the Federation gave its reasons for considering the vestibule of the park known as the Plaza objectionable as a site. Further than this, and in order to give a definite and practical character to their views, the associated artists named another site and gave the reasons why they considered it an appropriate one. The commission did not adopt this report, but, on the contrary, voted in favor of the site condemned by the Federation. We expressed our regret at this decision, because we believe that if the city is to be made attractive by works of art these must be designed by artists of the first rank and their positions must be selected by men whose taste and training have fitted them in a peculiar way for deciding questions of this character. A committee of thirty picked men, three from each one of the affiliated societies, devoted a great deal of time and study to this subject, and no argument is needed to show that their judgment on such a point ought to be worth more than the offhand opinions of men who do not pretend to have any special education or experience to prepare them for work of this character.

The last number of *The Engineering Magazine* contains an instructive article on the Value of Good Architecture in Cities, in which it is shown how insignificant are the efforts to supply American cities with monumental and architectural adornment, when compared even with the second-rate cities of the Old World. Taking the City Hall Park of New York, for example, and the streets that surround it, attention is called to the fact that although this is a comparatively small space the buildings on the east and west are sufficiently distant from each other to escape any appearance of crowding. Not to speak of the meaningless public building occupied by the general government as a post

office at the southern end of the park, ten million dollars would be a conservative estimate of the amount expended within the last decade upon the great buildings which now look down upon the little City Hall in the centre of the green. This sum of money, if it had been expended in Paris, for example, would have probably secured for that city one monumental building and a series of structures, each one of which would have been a genuine municipal ornament. Without criticising the buildings about this park, it is safe to say that, with one or two possible exceptions, if they were all destroyed no one would feel that the city had lost any priceless art treasures; and yet this is the very heart of the municipal life of the metropolis of the New World, and it is the one point in the city where careful artistic treatment is desirable, and where splendid surroundings would be constantly exerting their influence upon the taste and ministering to the pleasure of tens of thousands of people who daily pass through it. If the contemplation of objects of art which embody noble thoughts is more wholesome than the daily contact with objects which offend the sense of beauty, then the city which does not furnish dignified buildings, monuments and statues does not live up to its opportunities and fails to minister as it should to the wants of one part of our nature.

We hear much of republican simplicity, and it is sometimes argued that buildings of impressive proportions and lofty purpose are wasteful and contrary to that utilitarian spirit which is the foundation of our material progress. But the truth is that purity of line in buildings is not at all inconsistent with usefulness, and that an ugly structure may cost as much as one which has real value as a work of art. It is not the want of money, but the failure to appreciate the real worth of architectural beauty, that makes so many of our streets commonplace and featureless. We do not mean by this that our people, as a rule, lack good taste. It is only vulgarity and snobbishness which consider anything good enough for Americans. Our national, state and municipal authorities go on constructing public buildings which not only are lacking in ordinary comfort and convenience, but which have nothing in the way of stateliness or beauty to show for the vast sums that are every year expended upon them. And yet when by some happy chance some really meritorious building or monument or fountain is set up the plain people who are stigmatized as lacking the æsthetic sense at once recognize its value and look upon it with genuine satisfaction and pride, for they are quite as able to appreciate the beauties of a well-designed park or fountain or statue or building as any in the world.

One reason why we have no more good public structures lies in the self-reliant and self-sufficient feeling of men who are elected to office, and who assume, therefore, to decide upon questions of art with the same positiveness and assurance with which they decide matters of their own private business. So-called self-made men have too little respect for expert opinion in any direction. They consider themselves able to decide all serious questions, and questions of art they are apt to consider too trivial for any study. They seem to imagine that the artistic and the practical are in everlasting conflict, and they have not begun to learn the truth that the highest art in the laying out of a park or the construction of a building is simply the exaltation of its greatest practical value. The artistic view of a question is not something opposed to what is known as the common-sense view of the same matter. For example, the Report of the Fine Arts Federation on the site of the soldiers' and sailors' monument was a document full of hard, practical sense, and it set forth reasons for the conclusions reached that any man of ordinary cultivation could weigh. The fact is that the view of artists upon such a question is nothing but the view of the educated community, only the artists by their training are able to seize upon the real points at issue and present them in an orderly way for the

approval of the intelligent public. The artists and special lovers of art in any community are simply that part of the people who have thought the most about art matters, and what is the view of the artists to-day on a question of municipal decoration would be the view of every man of ordinary cultivation in the city if the same question was properly presented to him, and it will be the popular view in a year.

Bridge over the Kent at Levens Hall.

THE bridge illustrated on page 25 is a good example of the form of construction most often seen in the north of England and in Scotland. Built of the common serviceable stone of the neighborhood, these bridges look as if they had laughed at the elements for generations, and would continue their defiance for many a year to come. On the high road between Milnthorpe and Kendal this one crosses the Kent in the park of Levens Hall, where lovers of the curious may still see the topiary marvels created by the gardener to James II. In the home grounds the gently flowing river is bordered by tall grasses, the large leaves of the Coltsfoot and great tufts of purple Loosestrife, while in the deer park trees dip to the water as it saunters past. From the lawn in front of the house the little island, on which the pier rests, makes a pretty foreground to the bridge, which rises, gray and solid, above the waving tangle of flower and sedge.

Bridges of this sort would be just as appropriate here as in the old country, and would, of course, be more durable than the wooden constructions which are every year washed away by the dozen in the spring freshets. The initial cost, to be sure, would be greater, but in the long run the stone would prove more economical, since trifling repairs are needed, and these at comparatively long intervals. Here and there, in out-of-the-way parts of this country, stone bridges are still to be seen, but the structures which are now being built are almost without exception of wood or iron. If village improvement societies would turn their attention in this direction much could be done to restore streams, now defaced, to their original beauty. The simple lines and quiet color of this Ivy-draped bridge in Westmoreland are what make it satisfying to the eye and an added charm to the stream; it is made from the stone of the country, and the native plants grow about it as familiarly as though it were a boulder playfully deposited there by Nature in the ice age.

New York.

Beatrix Jones.

The Retail Prices of Cut Flowers.

IN one of the two articles on the New York Cut Flower Company which appeared in GARDEN AND FOREST during last November, it was stated that the retail price for cut flowers in this city seems unnecessarily high to Americans who have lived abroad, where they learn to consider choice flowers a necessity rather than a luxury, and examples were given showing the relative prices of roses and violets, which here are nearly twice as high as in southern Europe. By some persons this is attributed to the large profits of the commission houses, while others hold that the retail dealers receive the lion's share of the great advance in price over that received by the grower.

The retail florists of this city number about two hundred, not including a large class of street vendors known as the Greeks, and representative dealers give many reasons, which seem convincing, for the prevailing scale of prices. In the first place, it is necessary to keep so large a stock of many different kinds of flowers that the capital required is considerable. Not a few firms, founded twenty or more years ago, have a history of moderate, steady growth from very small beginnings, sometimes less than one hundred dollars having constituted the original capital. But the same conditions which have affected the jewelry, dry goods, house-furnishing and other lines of trade have revolutionized the florist's business, and now a very modest establishment

needs at least \$5,000 to begin with, while double that amount is necessary to open a tasteful and attractive store in a good location, and a first-class business in a fashionable locality cannot be successfully started without a much larger investment. Furnishings and decorations in a store are expensive necessities, which may easily take \$2,000 or more, besides the heavy outlay for horses and delivery wagons. A van, too, is a necessity, since these immense enclosed vehicles are heated and ventilated to insure the safety of tender and valuable stock, such as large decorative plants. Fancy baskets, silver bowls and artistic jardinières of many forms and all colors and shades are required in a first-class establishment, and one such house has in regular use 200 pedestals needed in the grouping of plants in decorations. While \$50.00 is a minimum daily investment for cut flowers, the largest stores handle 5,000 to 20,000 individual flowers, for which they pay from two cents to \$1.50 apiece.

Taking the year through, it is, perhaps, not too much to say that twenty-five per cent. of the stock bought is not sold, and is a total loss, and it is easily possible on many days to have half the stock represented in flowers aggravatingly removed from freshness. Roses, bright-colored and deliciously fragrant, which would furnish delightful home decoration for several days, are stored in the ice-box at the close of a day only to be just too widely blown for the next day's trade. At their best, roses and Bermuda lilies are the longest keepers, and may be successfully carried three days, while heliotrope withers and blackens in a day, and the welcome fragrance of violets becomes a death-like and offensive odor after from twelve to twenty-four hours, though their color is still clear and bright. The resentment against paying what seems exorbitant prices is, perhaps, directed more generally against violets than any other particular flower, their quiet unobtrusiveness making the price all the more startling. But these modest little flowers now cost the retail buyer \$2.00 a hundred, and it is a good business day that sees his stock of them exhausted, and anything short of this means actual loss. For example, four small bunches left over represent \$8.00 of lost capital. The critical selection of the customer leaves a dozen to twenty roses and carnations out of every hundred to be sold in a lower grade for less money, and a few lilies out of every twenty-five are sure to be bruised and, of course, made worthless whenever they are handled. All this signifies that one hundred per cent. advance in price means a much smaller profit than these figures imply. Indeed, the perishable nature of flowers makes them more uncertain than almost any article of commerce. Even the most delicate fruits and hot-house vegetables can be held over in cold storage and their appearance be preserved until they are to be eaten—that is, they do not need to be kept for a long time after they are sold, simply for appearance sake—while the duration of the beauty of flowers is their essential value.

One of the most important conditions for success is the judicious selection of stock as to variety and quantity. Twenty years ago Safrano, Bon Silene and the old white Lamarque roses constituted almost the entire variety of this class of flowers, whereas now of pink varieties alone the dealer is obliged to have at least half a dozen Tea roses and nearly as many Hybrids. Although customers do not know the names of the different roses, yet they know the distinctions of shade and form between Mrs. Pierpont Morgan, Belle Siebrecht, Madame Cusin and Bridesmaid, and insist on being precisely satisfied. If the desired variety is not on sale, telephone and telegraph are at once brought into requisition, with the result that these special flowers cost the dealer more than he receives for them. Cases like this are aggravated by the short notice now given to dealers. Formerly several days were allowed for the filling of a moderate-sized order, but now a florist must be equipped to complete the decorations for a sumptuous entertainment in a few hours. In the matter of color modern taste has come to be very exacting, since great

care is taken to select flowers of a tint which will be in effective harmony or contrast with the other decorations of a room or a table, or of a gown. Even in white the flowers must match the exact tone, whether ivory or cream or pearl, and samples of dress materials are often sent to the florists with orders. To meet these demands the larger stores are compelled to have a superintendent, skilled bouquet makers and buyers who command large salaries.

The cost of material given away nowadays would almost have paid the expenses of an ordinary flower store a quarter of a century ago. Boxes which cost fifty cents each, ribbons where cotton cord was formerly used, expensive lavender-colored tinfoil, fine papers of various textures, corsage pins, and the greens which are used for filling amount to a round sum in the course of the year. Twenty years ago a ball bouquet was made of *Bon Silene* roses and Ground Pine, and the regulation price of five dollars left a fair profit for the dealer. Now a bunch of choice loose flowers costs twenty-five dollars, because no culls can be used, and only perfect long straight-stemmed flowers. Where *Geranium* leaves were once acceptable for foliage, modern taste demands the use of expensive fronds of *Adiantum* and *Asparagus*. Then it should be remembered that the season in this city begins with the week of the Horse Show and ends with Easter, with many breaks caused by holiday visits to country places and to the south, so that whatever money is made in the year must be made within a comparatively few weeks. This necessitates for a part of the year long hours and hard work for many employees, with no holidays.

All this means high prices for the most fashionable flowers, and yet the business is making a steady and healthy growth. More flowers are sold every year, and more growing plants are used for decoration. As a general rule, too, the popular taste is becoming more refined, and not a few of the retail dealers are exerting a wholesome influence in this direction.

New York.

M. B. C.

Trees of Minor Importance for Western Planting.—I.

THE Kentucky Coffee Tree, *Gymnocladus Canadensis*, has not received the attention it deserves in ornamental planting in the United States. It is indigenous as far west as central Kansas, to my knowledge, and grows thriftily and with comparative ease even on dry upland. It is not difficult to handle in the nursery while young. The tree has in all stages of growth picturesqueness and charm. Its foliage is beautiful, and while it gives a distinct variety in the foliage-texture of any planting, it is not so conspicuous as to appear obtrusive, nor does it bring any note of disharmony to the composition. In winter, after the foliage is shed, the large, dark seed-pods persist, adding to the picturesqueness of the gray branches and making altogether such a piquant effect as an artist might long seek for. The tree is sound and healthy, and not subject to insect attacks, so that I am at a loss to understand why it is not more frequently used. Some twenty-year-old specimens recently examined in McPherson County, Kansas, have a height of twenty feet, and have been bearing seed for eight or ten years.

The Honey Locust, *Gleditschia triacanthos*, is native to pretty much the same western situations as the Coffee Tree, which it resembles in more points than one. Though the foliage is not so compoundly pinnate as in the Coffee Tree, it is much finer and gives an even more emphatic touch of shimmering tremulousness to the masses which it composes. This effect is much heightened by the glossy surface of the leaves, which reflect the sunlight at every movement, and this becomes more important in a country which has twice as much sunlight in a year as New York state. This tree thrives throughout Kansas and Oklahoma in almost all situations in which any other trees grow, though it is, perhaps, a trifle shy of the drier uplands. I have seen many handsome specimens in several western states. It is said to be attacked sometimes by borers, but I have never had evidence of serious trouble on this score.

The American Elm was omitted from my notes of western timber-trees in GARDEN AND FOREST, December 18th, 1895, because I have not seen it planted for timber. For ornament, and especially for streets, it is a great favorite in the west, though its popularity has, I think, been somewhat declining in recent years. The young trees are grievously worked by borers in many cases. I especially noted several hundred large nursery-grown trees along the streets in Norman, southern Oklahoma, which had been totally destroyed the first year, with hardly a single exception. The long, slender, exposed trunks of these trees, however, offered an unusually fine harbor for the insects. Lower-headed trees with cleaner bark should be chosen for planting, and it seems as if some other defensive measures might be adopted.

At Oklahoma City, Oklahoma, I also noted Tea's Hybrid Catalpa used as a street-tree. The trees had only recently been set from not very good stock, and so gave small opportunity for judgment; but, so far as my observations went, they helped to confirm a prejudice which I had already formed against all Catalpas for street-trees.

The American Ash has sometimes been used as a timber-tree in the west, and has, I think, been carefully tried in the well-known plantings at Farlington, Kansas. I have never seen it much used for any purpose, and the only really satisfactory record of it which I have ever made is taken from several trees which came up from seed as undergrowth in a planting of *Ailanthus*, Catalpas and Cottonwoods in a timber-claim in McPherson County, Kansas. In this situation they did well, and when examined a few months ago were good, straight trees of eighteen or twenty feet high. They are now twelve years old. I have once or twice seen them planted in solid blocks, without shade, in timber-claims, but I never saw them successful under such treatment. I remember also a close planting of Ash in blocks on the Kansas Agricultural College farm, and my impressions of their success as a forestry venture were not flattering; but for good reasons they had not come under such systematic and sympathetic treatment as might have developed a better showing. This Ash is also sometimes used as a street-tree, but nowhere with great success, so far as my observations have gone.

Maples have been extensively used in western towns as street-trees, the Silver Maple being in a large majority. In some places public squares have been planted with them, and the result is generally entirely satisfactory. All things considered, it is probably the best street-tree for the west, though it has its faults, to be sure. Some seasons it is quite defoliated by a lepidopterous larva, which adds a considerable unwelcomeness of its own to the unsightliness of the naked trees. But these ravages do not occur every year, and some of the people who, a few years ago, cut down fine large Maple-trees on this account were undoubtedly hasty.

Gleichenias.

WHEN well grown the *Gleichenias* form handsome specimen plants. They are among the most attractive of the Ferns cultivated in the cool fernery at Kew, where the conditions as to temperature, moisture, etc., appear to exactly afford their somewhat special requirements. This house is one of the most recently erected; it is built of light iron, with wood sashes, the panes of glass ten inches wide, the roof span-shaped, with a lantern ventilator, the position being from north to south. A central stage and two side stages, the latter a yard from the roof, formed of thick slate, resting on an iron frame and covered with small coke, accommodate a collection of all kinds of Ferns which require a minimum temperature in winter of from forty-five to fifty degrees. I describe the house because it is the first of those at Kew set apart for Ferns that has proved suitable for *Gleichenias*.

Three years ago a collection of species and varieties of *Gleichenia*, at that time only a few inches high and planted in four-inch pots, was obtained for this house. These plants are now each from three to four feet in diameter, their stem-like fronds interlacing and forming a thick bush of elegant green, prettily crimped pinnæ.

The treatment these plants have received is as follows: They are potted in a mixture of peat, silver sand and nodules of sandstone in shallow pots or pans. The soil is pressed firmly about the roots, and any straggling rhizomes pegged down close to the soil. Plenty of water is given at all times, and this is perhaps the chief essential in the cultivation of *Gleichenias*. If a plant has lost fronds, turned brown, or made stunted growth, it has proved to be due to insufficient watering. I have been told by travelers that *Gleichenias* generally grow in sunny, dry situations in countries where they are wild, but I know from experience that under cultivation they do not like bright sunshine, and they revel in moisture at the root.

Gleichenias are remarkable in the structure of their fronds, in which respect they resemble the *Lygodiums*, several species of *Davallia* and one of *Gymnogramme*. The true stem is a creeping rhizome from which spring the fronds, which have wiry stalks, generally dichotomously branched many times, and bearing numerous elegant, deeply cut, pinnatifid branches or pinnæ. These are what are usually looked upon as the fronds proper, the long wiry portion being popularly supposed to be stems. The sori are capsular, in cups formed by the usually reflexed edges of the ultimate divisions or teeth of the pinnæ; they contain few spores, which are matured on cultivated plants and are used for their propagation. Beginners are apt to collect and sow only the spore-cases after the spores have escaped, which they do at an early stage. The pinnæ should be collected when the capsules are green and plump, and kept in paper in a dry place till the capsules burst and release the spores. They should be sown in pots of very sandy peat and covered with a pane of glass. Although the wiry growths are really the stalks of the fronds, they may be used for the purpose of multiplication, as they frequently bear axillary buds. A stock of plants can be obtained by planting a specimen in a prepared bed of sandy peat and pegging down the fronds, especially fixing the apical fork close to or a little below the surface of the soil. Many Ferns have proliferous or bud-bearing fronds, the most familiar of all being the *Aspleniums* of the *bulbiferum* type.

Gleichenias may be grown into very large specimens. I have seen them fully six feet in diameter and as leafy and healthy as a well-grown *Asparagus plumosus*.

There are about thirty species of *Gleichenia* scattered widely over the tropics both of the Old and New World, extending into Chili, Australia, the Cape, etc. Some of the handsomest, especially of the truly tropical species, have not yet been introduced into cultivation, although many attempts have been made. The following are cultivated at Kew and in other gardens in England:

G. CIRCINATA.—Rhizomes covered with black-brown scales; stalks of fronds brown, clothed with gray wool; pinnæ (fronds) six to eighteen inches long, dull olive-green above, silvery below; the segments linear, one to three inches long, one-eighth of an inch wide; the teeth rounded, flat, or forming shallow cups in some of the varieties, of which there are five at Kew, viz., *Backhousiana Mendelii*, *semivestita* and *Spelunca*. These are all natives of Australia and New Zealand and have long been in cultivation.

G. DICARPA.—Rhizomes nearly glabrous; stalks brown, hairy only when young; pinnæ bluish green, the segments very narrow and divided into numerous very small rounded teeth, the margin of each of which is recurved and forms a small purse-like cavity, which is partly closed with fine rust-colored hairs. This character distinguishes *dicarpa* from all the other species. The varieties of it

grown here are *alpina*, *glauca* and *longipinnata*, all natives of Australia and New Zealand.

G. DICHOTOMA.—The stalks of this species are thin, somewhat zigzag, hairy when young, smooth and shining brown when old; they are dichotomously branched, each pair of pinnæ being subtended by a pair of smaller in the axil or fork, from which springs the continuing stalk. The pinnæ vary in length from six inches to a foot, and in width from one to six inches; they are not unlike the fronds of a *Nephrolepis*. This species is usually unsatisfactory under cultivation, but at Kew it grows well under the conditions above described. It is quite distinct from all other Ferns. It occurs in all tropical countries, and there are numerous forms of it.

G. FLABELLATA.—Rhizomes as thick as goose-quills, olive green, clothed with black hairs; stalks erect, smooth, dark brown, unbranched for some distance, bearing a cluster of repeatedly forked pinnæ about nine inches long, flabellately arranged, more or less parallel and gracefully arched; the teeth are half an inch long, shining dark green. There is a large specimen of this very striking Fern at Kew. It is a native of Australia and New Zealand, where it sometimes forms masses many feet through.

G. RUPESTRIS.—Stalks of fronds thin, wiry, glaucous when young, smooth; pinnæ as in *G. circinata*, but with thicker, rounder teeth, and always quite flat; they are glaucous green above, silvery below. Var. *gigantea* has the segments nearly a quarter of an inch wide and is a noble Fern; var. *glaucescens* is more distinctly glaucous than the type. Native of Australia.

Plant Notes.

LEUCOTHOË CATESBÆI.—Certainly few people can realize the winter beauty of this shrub or it would be more often seen in northern gardens. The flower-buds are developed in autumn in the axils of the persistent leaves of the year, and are formed like elongated pointed cones, about half an inch in length, with closely imbricated scales. As the weather grows cold the scales turn deep red, the same color suffusing in a slighter degree the ends of the zigzag stems and the upper leaves, and their petioles, vigorous young branches and their leaves being often as richly colored as the flower-buds. The lower leaves for the most part retain their brilliant lustrous green color, and the contrast between the upper and lower parts of the plant only adds to its beauty. *Leucothoë Catesbæi* is a shrub with recurving stems from three to six feet in length, persistent, tapering thick and leathery leaves, and short spike-like racemes of nodding waxy bell-shaped flowers. It is a common under-shrub in the region of the southern Alleghany Mountains, where, from Virginia to Georgia, it inhabits the moist banks of streams, usually growing in the shade of trees. It was one of the earliest of the Appalachian plants cultivated in Europe, and English gardeners soon learned its value. It has always been propagated in English nurseries, but in this country has remained comparatively rare in gardens. It flourishes in damp situations and in peat soil, growing equally well in the shade and in full sunlight and is beautiful throughout the year. When it is desirable to unite the margins of a plantation of evergreen trees or large shrubs with the ground, or to plant the shaded banks of a brook flowing through a rocky gorge, there is no better plant for the purpose than this Alleghany shrub, which possesses a constitution that enables it to bear uninjured the severe climate of New England. All the North American *Leucothoës*, of which half a dozen are distinguished by botanists, are first-rate garden plants; and they are all easy to cultivate, with the exception, perhaps, of the beautiful *Leucothoë Davisia*, which inhabits the high Sierra Nevada of California and has not yet been satisfactorily tested in our gardens, although it was introduced into England as long ago as 1853 by the collector Lobb. Like many other California plants, however, it is difficult to manage in the east, and probably will never become a popular garden plant here.

About Currants.

THE marked development in recent years of the interest in currants as a market fruit has naturally been accompanied by the introduction of many new varieties and some old varieties under new names. The newer candidates for favor include the Eclipse, North Star, Red Cross and Wilder of the red kinds, and Marvin's Seedling, Caywood's Seedling and White Versailles of the white kinds, and several other sorts. None of these have been fruited here long enough to determine their productiveness.

North Star, introduced from Minnesota, makes a vigorous upright or somewhat spreading growth. The color of the fruit is much like that of the Red Dutch; bunches medium length; fruit probably large under good cultivation, but varying from small to large. Red Cross, from seed of Cherry fertilized by White Grape, was originated by the originator of Brighton Grape. The fruit is medium to very large, milder-flavored and lighter in color and somewhat later in season than Cherry. Habit of bush, upright, vigorous. Eclipse is a good grower and bears bunches from two and a half to three inches long. The fruit varies from small to large; color good, somewhat lighter than that of Fay; flavor comparatively mild. Wilder, from seed of Versailles, originated about eighteen years ago with Mr. E. Y. Teas, Irvington, Indiana. It is a good grower, bearing fruit medium to very large, less uniform in size than Fay, and somewhat lighter in color. It appears to be worthy of extended trial as a late kind.

Among the red Currants that have been in full bearing at this station during the last three years, Cherry has been one of the most desirable of the large fruited kinds. Fay yields longer bunches and more uniformly large fruit than Cherry, but it does not make as satisfactory a bush, nor has it been as productive in this locality as the Cherry. Neither of these kinds will remain on the bushes in good condition for shipping as late as will Victoria, Prince Albert or Wilder. On account of its thin skin and abundance of fine-flavored juice, Cherry is liked at fruit-preserving establishments for making into jam, but it is necessary to evaporate away more of its juice in making jelly than it is with some other varieties. Fay and Prince Albert are especially liked for making into jelly, because of their large size, thin skin and rich pulp.

Prince Albert is a vigorous grower, more upright even than Red Dutch. When well grown the fruit will pass for large. Of all the varieties in full bearing here during the last three years it has given the highest average yield, and London Red, also known as Short-bunched Red, has taken second place. The London Red, like Cherry, has short clusters, with stem so short as to make it difficult to pick. The fruit varies from medium to large and is similar to Red Dutch in color and quality. One of the most valuable of the kinds that produce medium-sized fruit is Victoria, also known in Canada as Ruby Castle or Raby Castle. The bush is a very strong grower, upright and very productive. The cluster of well-formed buds at the end of the shoot, the bluish gray color of the buds and the rather pale green foliage are quite characteristic of this variety. The clusters are of good medium length. The fruit is late in coloring, has a bright red color, and will keep on the bushes in good condition later than either Cherry or Red Dutch.

The market demand for white currants is quite limited, and the number of new white varieties is not so great as the number of newly introduced red sorts. White Grape and White Dutch still remain the standard sorts. White Imperial has not yet fruited here. Caywood Seedling is a very productive white kind, with spreading or drooping branches. The fruit is large, attractive and of good quality. Marvin's Seedling is similar in color to White Grape, larger in size and rather more acid. White Versailles has long, well-formed clusters slightly darker in color than White Grape; berries larger, less juicy and about the same in acidity as White Grape.

How to Grow Peppers and Egg-plants.

THERE are few vegetables which so often disappoint growers by failing to produce fruit as Peppers and Egg-plants. It seems to be an easy matter to grow plants which by the last of August are large and vigorous, but in many cases only an occasional plant is productive. Conditions of soil, climate and culture might cause such failure, but I think it is most often the outcome of little-understood peculiarities of Solanaceous plants. The Tomato, Egg-plant and Pepper are annuals and natives of a tropical climate. The seed does not

start until the growing season, and then the plants have the advantage of a uniformly favorable degree of moisture and heat, in which they grow rapidly and steadily from the starting seedling to the ripening fruit. This is their normal habit of growth, and any interference with it is sure to result in less perfect development and fruitfulness. A temporary check, which would have no permanent influence on Peas, Beans or Lettuce, will materially lessen the fruitfulness of a Tomato, Pepper or Egg plant, even though it does not lessen its ultimate size and apparent vigor. I could give details of experiments which go to prove this fact, but readers will recall instances where a single volunteer Tomato-plant which sprang up after the started plants were set, and in the favorable weather grew steadily without check, was noticeably more productive, though no larger, than those that were transplanted. If individual plants of Egg-plant and Pepper are noted, those which have grown most steadily and been least checked in transplanting will prove the most productive plants. The practical lesson of these observations is that the utmost care should be taken in starting plants of this class to secure steady and unchecked growth.

Sowing the seed should be delayed until there is just time enough before setting the plants in the open ground for the seedlings with a moderate rate of growth to reach the size most desirable for handling and transplanting. Special care should be taken to so control light, heat and moisture as to secure the steady growth of the plants. To start the seed so early or grow the plants so rapidly as to be forced to hold them back or let them get soft and spindling through want of room is sure to result in a poor crop of fruit, no matter how promising the plants look in July. The ground should be well prepared and so fertilized as to give the plants a well-balanced food ration; and the plants set and the ground cultivated so as to avoid, as far as possible, the least check in the growth of the plants.

Freesias.

AMONG winter-blooming plants which furnish flowers for cutting few equal in usefulness or popularity these Cape bulbs. Within the last few years the price of flowering bulbs has been so much reduced that they are now sold at very low rates, and no one possessing a greenhouse can afford to be without them; we have seen very good pots and pans of them grown in windows where the temperature has not been too high. A great many house-plants are ruined by heat, and Freesias are impatient of high temperature until their flower-spikes show, when they will endure a little forcing. If opened in strong heat, however, the flowers lack the substance of those grown cooler, and they fade sooner.

For our earliest batch, from which we usually begin to cut flowers at Christmas, we plant our bulbs about the middle of August, using boxes four inches deep, well-drained with broken crocks or clam-shells, over which is placed a layer of sphagnum-moss. The compost used consists of equal parts of loam, leaf-mold and well-rotted cow-manure, with a good dash of sharp sand and some pulverized charcoal to keep the whole porous. A box twenty-four inches by twelve inches will carry fifty bulbs. These are covered two inches deep with the compost; after being boxed a good watering is given and the boxes are placed on a bed of ashes in a cold frame and covered with some strawy manure to prevent the drying out of the soil. As soon as the young shoots appear this covering is removed; the sashes are only used over the plants to throw off heavy rains, and, later in the season, to protect from frost; the more steadily the plants are kept growing the better will be the returns at flowering time.

We house these first lots early in October, and place the boxes on a shelf in a Carnation-house close up to the light. From the beginning of November until the flowers commence to open, stimulants are applied at each alternate watering. We find sulphate of ammonia and sheep-manure water the best liquid foods, and we use these almost as strong as for pot Chrysanthemums. Freesias, if well grown, should average from twelve to twenty inches in height when in bloom, with four to five side branches on each spike; the starved specimens too often seen average from six to nine inches in height, and are ruined by too much heat, being grown too far from the glass and in too poor compost.

By putting in a few boxes of bulbs each month from the middle of August to the middle of November a succession of bloom may be had from Christmas till Easter. We hold our late batches in a cold frame until Chrysanthemums are quite over. Freesias increase about three-fold each year, and home-grown bulbs, we find, produce much finer flowers than

the larger ones from California. After the flowers are cut we place the boxes under the benches and gradually withhold water. About the middle of July we shake the soil out and pick the bulbs out in two sizes; the smaller ones, like garden peas, are sown broadcast, rather thickly; these make fine flowering bulbs for the next season. For use in the conservatory, *Freesias* grown in pots or pans are very effective, their delicate odor and free-flowering properties making them indispensable. By sowing seed in pots or pans and thinning them out (as the seedlings cannot be successfully transplanted) good flowering bulbs may be had the second season, but bulbs of good quality are now so cheap that few go to the trouble of raising them in this way. *Freesia refracta alba* is the most largely grown and popular of the three sorts in commerce. *F. Leichtlinii*, with creamy yellow flowers, may be added; stray bulbs of it are usually to be seen mixed in with those of *F. refracta alba*.

Taunton, Mass.

W. N. Craig.

Oxalis versicolor.

THE trouble with most of the species and varieties of *Oxalis* lies in the fact that their flowers remain closed for a considerable portion of the day; especially is this the case in mid-winter, when some of them only open in clear sunny weather. Few of the species are very attractive unless they are in full flower. The species known as *O. versicolor*, however, is a notable exception to this rule, as the flower-buds and closed flowers are quite as attractive to many people as the fully opened ones. The petals, when closed, are so arranged that they overlap each other to a certain extent, the overlapping edges of the under surfaces being a reddish pink color, and the remaining part white and greenish yellow at the base, and this combination of color in the closed flower makes it very attractive. When expanded the flowers are about an inch in diameter, and upper surface of the corolla is pure white. This species is not of robust growth; the leaves, which are small and divided into three linear leaflets, do not spring directly from the bulb; long slender stalks are first produced, which form bunchy growths at the apex, from which spring an astonishingly large number of leaves and flowers. The plant is particularly well adapted for planting in baskets, as the branches hang over the sides. It begins flowering here about the middle of December, and continues for at least three months; this is in a house where the temperature is kept just high enough to prevent freezing. The pear-shaped bulbs are small, and in starting I set them singly in thumb-pots, using peat loam and sand in equal parts. When the growths are an inch or two high they are transferred to baskets lined with sphagnum-moss, when a richer soil is used, and in this they are planted rather closely.

Botanic Garden, Washington, D. C.

G. W. O.

Notes from Harvard Botanic Garden.

IN a greenhouse here, where the temperature ranges from forty to forty-five degrees, there is a showy group of plants of *Senecio Petasites* which invites special attention. This plant is an old inhabitant of gardens, having been grown for more than three-quarters of a century, but it is seldom seen now. It is of special value at this season for those who have large conservatories to be kept gay during the dull months of winter. The plants are seldom kept more than one year, but if large specimens are desired the old plants may be cut back late in spring, and when the weather is favorable in early summer they may be planted out in the garden. They need plenty of room, as the old branches soon break and make large handsome specimens. Cuttings struck in spring make the most useful plants for us. When the plants are through flowering one or two are kept for stock plants. They are cut back, and in a few weeks they make young shoots, which make the best cuttings when they are three or four inches long. It takes them about two weeks to make good roots in the cutting-bench. After they are well rooted they are put into three-inch pots, and in May they are planted out in the garden. They soon begin to grow, and about the first week of July they are cut back so as to make them branch. They generally make three or four stems, but those stems are never cut back during the remainder of the season. If extra-large panicles are wanted, the young plants should be grown to a single stem. Just before there is danger of frost the plants are lifted, and are large enough now for eight-inch pots. As they are gross feeders they need a rich compost, and before they blossom weak liquid-manure is very beneficial.

This *Senecio* is a stout, erect plant with round stems, which

attain a height of three or four feet or more. The stems are clothed with large circular leaves, which are cordate at the base and dark green above and paler beneath. The leaves are from six to twelve inches broad, and their petioles are nearly a foot long. The large terminal panicles measure a foot and a half in length and are developed in November, but the flowers do not open until the second week in December, or sometimes later. The flower-heads measure more than an inch across, and the color of the disk florets are brownish, and those of the ray are of a bright yellow. When the plants are in full bloom they are very attractive, for not only are the flowers showy, but they are also fragrant. It is a Mexican plant, and when first introduced was known as *Cimeraria Petasites*.

Half a dozen large plants of the showy *Cestrum elegans* are blooming freely now in pots. These plants make handsome objects when planted out in a bed or border in a cool greenhouse and trained to a pillar. In such a position, if properly treated, they blossom nearly all the year round. Two or three year old plants, grown in pots, we find most serviceable, as they branch more freely and are more graceful than younger plants. The season of blossoming of plants grown in pots is regulated by the time the plants are rested and pruned. When they are through flowering we find they do much better after a long rest. This rest is brought about by withholding water, and it helps to ripen the soft wood. In June they are pruned close to the old stem, leaving only one or two buds of the previous year's growth. They are then turned out of the pots, and after most of the exhausted soil is removed they are planted out in the garden. If syringed regularly they soon make young branches, and their naked and ragged stems are soon hid with green leaves. When they are taken up in the fall they need plenty of pot-room and good rich soil. They begin to blossom in December and continue for two or three months. The purplish red, tubular flowers are produced in dense terminal cymes on long, graceful branches a yard or more in length.

Eranthemum tuberculatum is a handsome species introduced from New Caledonia in 1863. At this time its pure white star-like flowers, which are about one inch across, are produced plentifully on the thick, bushy plants. They are about a foot high, branching freely into slender twigs which are thickly covered with small oval leaves. This *Eranthemum* is grown as a stove plant here, and after blossoming it is cut back and kept slightly dry for a short time. In spring it is potted in a rich open soil and the plants are placed afterward near the roof-glass, which induces them to make short, healthy growth. Cuttings made from the young growth root easily if given slight bottom heat, and they soon make nice little plants if given good treatment.

Botanic Garden, Harvard University.

R. Cameron.

Ardisia crenulata is one of the prettiest of all berried plants for winter decoration. The berries are vermilion-red, and one crop holds over until another is ripe, so that it is an available plant at all seasons. It is a shrub of very slow growth, taking four years to make a specimen a foot or eighteen inches high. This is the most useful size, since the plants afterward become leggy and need cutting down and restarting in fresh soil in slightly smaller pots. They are easily raised from seed, and usually enough self-sown seedlings are found under the benches. Ordinary greenhouse temperature is sufficient after the fruit is set, but during the blooming season a slightly higher temperature is advantageous in securing a good setting of berries. Good peaty soil and firm potting is essential, as the plants will remain in good condition for two or three years in the same pots. The plants are subject to scale as a pest, and it is only by frequent syringing with a decoction of tobacco-water and fir-tree oil or kerosene emulsion that they can be kept clean.

Wellesley, Mass.

T. D. H.

Reinwardtia trigyna.—This good old plant is now a blaze of beauty in the warm temperate house. It is rather remarkable that one so rarely meets with this plant either in private or commercial collections, yet it is just upon one hundred years since it was first discovered and sent to England. It is a sub-shrub, though it perhaps is best to take cuttings each year (unless large specimens are wanted) and throw away the old plants. The leaves are ovate, entire, and about one inch in length, alternately disposed on the branches. The flowers are of a rich golden yellow, about the size of a silver dollar, solitary in the axils of the leaves in the lower parts of the branches, but crowded at the upper ends of the branches. The petals are fugacious, which is the only drawback to the commercial

use of the flowers, but the large quantity of buds keeps the plants in bloom several weeks. It belongs to the family Linaceæ, and is also known under the name of *Linum trigynum*. It is interesting botanically in that it has three pistils, as its specific name implies, which is rather uncommon in dicotyledonous plants. Cuttings rooted in February and planted out during the summer in the open ground, kept watered during dry weather and pinched occasionally to keep them shapely, will make nice plants by fall, when they may be lifted and placed in a warm greenhouse, where they will repay the little trouble spent on them. It is a native of the mountains of the East Indies.

Northampton, Mass.

The Prospects for California's Orange Crop.

To the Editor of GARDEN AND FOREST:

Sir,—Unless some unexpected calamity should destroy the orange crop of California, the state will send to market this year the finest and largest crop of this fruit ever gathered here. The output is estimated at ten thousand car-loads, two thousand car-loads in excess of any previous year, and comprising three million boxes. At \$3.50 a box in the east, their value will be ten and a half million dollars, approximating the gold production of California for 1894, which was about thirteen million dollars.

Shipments of last season's oranges to the east continued until late in the summer. During the week ending May 9th, 224 car-loads left Riverside, the largest shipment ever sent from any one place during the same period. The first car-loads this year went from Porterville and Oroville, in the northern part of the state, a region which has been growing oranges for some years in but small quantities. It is evident, however, that the northern Citrus belt, of which Butte County is the centre, will prove a strong competitor for early shipments and high prices, with the larger and better-known orange-growing districts more than five hundred miles to the south. Riverside sent the third car-load of oranges east this year, and Redlands the fourth. These shipments were at least three weeks earlier than the first shipments of last year. The ruling price here has been \$2.50 a box. These early oranges answer for Christmas decorations, but they were not fully ripe and not really fit to eat. No California oranges are at their best before the first of February, and, as far as establishing a permanent demand is concerned, these early shipments do more harm than good.

A vigorous effort will be made this year to market the California fruit to the best advantage, and to market it all. For this purpose the Southern California Fruit Exchange endeavored to secure control of the entire crop. The growers are naturally anxious to make the most of the absence of Florida's competition, and the Fruit Exchange, which handled about half of the orange crop last year, argued that the best way was to form a combination of all the growers in southern California, and practically to control the markets. This exchange has a central executive board, composed of representatives from eight subordinate exchanges. Its plan is to have representatives in each distributing centre of the east to watch the markets, to see that they are all fully supplied and that none are overstocked. Orders are subject to the supervision of the executive board, and shipments are to be made on a pro rata basis. That is, if the market at any given time is estimated to demand, say, two per cent. of the total crop, each district forwards two per cent. of its crop. Provision is made for meeting undesirable foreign competition by cutting prices, the consequent loss to be prorated among all the exchanges. In brief, this is a daring plan to control the marketing of a perishable product, which is not uniform in quality, like oil or sugar or coal, and the market value of which has always been determined by a number of uncertain factors. The extension of this work through the year, so as to include the shipments of green and dried deciduous fruits, has also been contemplated.

As oranges are a luxury, there can be no arbitrary fixing of the price, but it was urged that systematic cooperation among growers would develop new markets and obtain a foothold among the old ones. The possibility of this was shown by the successful work of the exchange last year, after the Florida freeze, in forcing the California fruit upon the markets of New York, Philadelphia and Baltimore. The necessity of such cooperation was argued from the fact that the growing orchards of California will, in the near future, produce from 15,000 to 20,000 car-loads of fruit a

year, the consumption of which will demand an active representation in all the markets of the United States. This would amount to four and a half to six million boxes, the latter amount being the estimated Florida crop which was destroyed by frost last year. California expects competition from Florida as soon as the latter state can grow new orchards. Land in Florida is cheap, and the probabilities are that growers will set out new orchards and take their chances of the weather.

These facts are understood in California, and certainly made a strong argument for cooperation. The plan, however, failed of support. The friends of the exchange claim that they will ship this year about sixty per cent. of the entire crop of the state. Its opponents state that not more than forty per cent. will be handled by it. There are several principal reasons for the partial failure of this plan. The first is the competition between localities in southern California. The quality of the fruit grown here depends upon climate and soil, which vary to an extent that an eastern man can hardly understand. The principal orange-growing region of southern California is within a belt not more than one hundred miles in either direction, and within this territory there is a wide diversity of climate. The best oranges are grown in the interior, away from the fogs and dampness of the ocean, and at an altitude of from one thousand to fifteen hundred feet. The fruit reaches its perfection in the San Bernardino Valley, where the heat in summer is sometimes oppressive and where even the winter climate is very warm. Here are grown the fancy Navel oranges, which, in the absence of the best Florida oranges, will be the finest fruit of the kind that can be procured this year. These oranges are in demand wherever they are known, and many growers are unwilling to place them in any prorating or pooling arrangement with inferior fruit. Some of the younger orange-growing localities are in better position in this respect than the older ones, because they profited by the experience of the latter in regard to the varieties which they planted, with the result that the seedling and inferior varieties were almost entirely discarded.

A second consideration was that the exchange method practically does away with f. o. b. (free on board) sales. The price is determined by the executive board in the west and by the several agents at the principal distributing points in the east. The judgment of the latter is also final as to whether a car-load of fruit ordered for any particular market shall be forwarded to that market or not. These are distinctions which might work against the growers of the finest fruit. If the theoretical plans of the exchange could be carried perfectly into practice there might be no discrimination, but it is hard to convince the grower of the best fruit that he will not suffer from cooperation with growers of fruit of a less desirable quality. Probably not more than one-fourth of the oranges sent from California this year will be strictly fancy Navels. Many growers of Navel oranges believe that they can sell them to responsible dealers and can know before the car goes forward what the price is to be, an advantage which they are naturally unwilling to abandon.

In former years the orange growers of California have suffered greatly from the dishonesty of middlemen. Sometimes no returns whatever would be made on shipments and no attention would be paid to correspondence. Sometimes the broker would pocket the proceeds, if any, and draw upon the producer for the freight. The despair and exasperation of an orange grower who has produced his fruit upon land representing an investment of a thousand dollars an acre and shipped it to market two or three thousand miles, can be imagined under such circumstances. When complaints were made and the dealer could be found, there was always the excuse that the fruit was in bad order, and, as it had long since disappeared, there was no way of verifying or disproving his statements. Such extreme instances as these have been less frequent for the past two or three years than formerly; but it has been a common thing for a dealer to reject a car, after he had ordered it by telegraph, if he found, after making the contract, that he could do better as regards quality or price. The agents of the exchange will be on the ground to look after such matters as these. They will know whether fruit reported in bad order was really so, and dealers who violate their contracts will be blacklisted, on investigation, and thus be prevented from repeating fraudulent transactions. Moreover, reputable dealers will be protected from the competition of men who do not pay for their goods or do not carry out their contracts. The exchange will guarantee the quality of all the fruit which it sells, and this fact will necessitate a similar guarantee on the part of all other shippers.

California growers confidently believe that their oranges

will take precedence as regards quality over all importations from foreign countries. The results of the present season will be watched closely and will have an important bearing upon the future of an industry which represents millions of investment.

Redlands, Calif.

Wm. M. Tisdale.

Meetings of Societies.

THE twenty-first annual meeting of the New Jersey Horticultural Society was held in the State House in Trenton last week, and it was very successful in point of attendance, in the character of the discussions, and in the display of fruits. In the course of his report, the secretary, Mr. Henry L. Budd, stated that the fruit farmers of the state, although they had much to complain of, came out ahead of their brethren, the value of the apple crop alone being greater than that of the general field crops. The great importance of frequent tillage had been made more manifest during the year than ever before. In former years fruits have been so abundant without cultivation that it had come to be an accepted truth that orchards in sod-ground are as profitable as those which receive frequent tillage, but this year experience and observation both showed that every cultivated orchard in the state yielded better where the soil was stirred as often as once a week and not allowed to become compact, so that the moisture could rise to the surface and pass into the atmosphere by evaporation. Over a large part of the state no moisture fell for ninety days, and the value of frequent surface-tillage was evident, especially in the Corn fields. Under ordinary cultivation the crop did not reach more than fifteen bushels an acre, while seventy-five bushels an acre were often reported from neighboring fields where the surface had been frequently broken, so as to become a protecting mulch. The struggle with weeds had been largely responsible for teaching this truth, as not one farmer in ten would have tilled his land but for these vigorous schoolmasters.

Where the products of market-gardens and orchards and vineyards are marketed, and where it is necessary to haul fertilizers to insure crops, the secretary named good roads as an important element in success. When it costs fifteen cents a basket to haul truck over dirt roads and three cents on macadam roads the value of a smooth road is evident. But, besides this, good roads make it possible for the farmer to get to the market when the prices are good, instead of being compelled to wait in spring or after hard rains until the mud dries.

Professor Voorhis, Director of the Experiment Station, explained the experiments going on in regard to fruit and vegetables, and announced as an important part of the work in the near future a study of methods of forcing vegetables and fruit for the early market. The station had been making some statistics of the production of the various fruits for commercial purposes, with the following result for last year: Taking the state through there were 18,749 acres devoted to Peaches, 6,104 acres devoted to Apples, 3,700 acres devoted to Pears, 64 devoted to Cherries, 27 to Quinces and Plums. Of small fruits, 3,926 acres were in Strawberries, 2,847 acres in Blackberries, 1,052 acres in Raspberries, 839 acres in Grapes, 85 acres in Currants, 20 in Gooseberries, making a total of large and small fruits 37,423 acres, to which, perhaps, ten per cent. ought to be added to cover orchards and fruit gardens not reported. The number of fruit growers in the state was 3,058, so that the average acreage of each would be twelve and a quarter acres.

Mr. J. H. Hale, of South Glastonbury, Connecticut, who has had great success in raising peaches, said that he cultivated the ground in his orchard thoroughly and pruned the trees for form until they began to bear, after which he pruned them for fruit. After they had come out in bud he trimmed them, leaving the twigs that had budded. This was a great advantage when the winter had killed part of the buds. This practice sometimes left an ugly-shaped tree, but a very valuable one. After the peaches had formed he pulled off the diseased ones, then thinned out the others until they hung four inches apart. Next year he will thin more severely, so that the fruits will be six inches apart. He fertilized heavily with potash and bone and pulled up a tree, root and branch, at the very first appearance of yellows. He took the greatest pains in picking and handling his peaches to make sure that they were in the very best condition, so that every basket was exactly what it seemed to be, the bottom layer being as good as the top. He then advertised his method and sold his fruit on the reputation for honest packing he had made. He declared that he received fifty cents a basket more by so doing and he felt better by dealing honestly with the consumers.

Mr. Charles Parry thought it was impossible to exterminate the San José scale here in the east, but that we should try to introduce the natural enemies of this insect, as had been done in California. The difficulties in fighting this pest are due to its rapid increase and the difficulty of detecting it. The treatment of the trees with a wash of caustic potash in December and of whale-oil soap in February last year left only a few scales to escape, and he thought another treatment this year would probably finish the work. The trees made a fine growth the next summer, but because of the severe cutting back necessary three or four crops would be lost. The hydrocyanic method as used in California was considered too expensive, if anything else would possibly do, especially as it had to be repeated every fourth or fifth year. He considered the introduction of such predaceous insects as feed on these scales, or of their diseases, the only safety. Some parts of California which were at one time badly infested are now practically free. Of the fifteen hundred species of ladybirds known to science as helpful, one-half eat various scale insects. They will work where a man cannot.

Professor Smith did not consider the case so discouraging. He did not believe that ladybirds could do as much for us as for the Californians, because our damper climate was inimical to them. Then, too, the ladybirds have but one brood a year, thus giving the scales a chance to gain largely on them, both before and after their time. Even in California spraying is still practiced. The action of insecticides is quite different on the Atlantic and on the Pacific sides of the continent. Kerosene emulsion is good here, but comparatively useless in California, though lime and sulphur are effective there. The predaceous insects are worth importing on trial, though fewer of them will be likely to succeed here than in California. Keiffer Pears are only infested in large orchards, though where they are near other varieties they are not liable to be attacked. A good wash can be made of fish-oil, with plenty of caustic potash, the office of the oil being to hold the potash while it eats into the scale. He never knew scales to get from one orchard to another or to isolated trees by any ordinary methods, so he considered the spread of the trouble not likely to be rapid. At Egg Harbor City Apple-trees of four or five years' bearing were infested, but they had been frequently and thoroughly sprayed with Bordeaux mixture, and the coating of lime thus given had kept the scale in check.

Mr. Charles Black, of the Fruit Committee, reported that the Crosby peach was not handsome enough in appearance for this section, but it was good to have when no other tree bears. The Elberta was all that had been claimed for it—one of the best, hardy and vigorous. Lemon Free was reported as a promising late variety. In Strawberries the Cumberland was still valuable on heavy moist soils. Pearson's Seedling, not yet introduced, produced forty crates from a quarter of an acre by the 6th of June. It is good on upland as well as lowlands. The Mary was pronounced very good in Burlington County, but other growers pronounced it a failure the first year, while the second year it was fine, although a trifle soft. Among Potatoes the Carman No. 1 was said to be the best in yield of marketable tubers.

Mr. S. D. Willard thought the Columbus Gooseberry, introduced by Ellwanger & Barry, the most promising large American Gooseberry. It makes good wood, and the fruit is large, egg-shaped, white and free from mildew. The Triumph would not make wood for Mr. Willard in New York, but Mr. Baird said it grew strong in Monmouth County.

Recent Publications.

Thoughts from the Writings of Richard Jefferies. Selected by H. S. H. Waylen. Longmans, Green & Co., New York.

This is a beautiful little book with an artistic cover enclosing some one hundred and twenty-five pages of text in heavy-faced type, red initial letters and with broad margins, and somehow the reader feels that the works of Jefferies should never be printed in any other way. No one would think of putting the robust thoughts of Thorou in such a dress, but there is nothing robust in this anthology. Sometimes one sees a display of fierce energy, but even this seems more like the exhausting effort of delirium than the manifestation of quiet natural strength. Unfortunately, the genius of Jefferies is not displayed at its best in extracts like these, and the reader who is unfamiliar with his works will hardly get an adequate idea of his real merits. Those who know his writings will relish them because they

suggest the context and recall impressions which are left by entire essays. One closes the book with something of sadness, and, in fact, an hour with Jefferies never has the exhilaration of an outdoor walk, although no one describes what he sees more accurately, and few men ever had more of genuine poetic insight. He lacks, however, the serenity of real greatness, and, although it would be unfair to say that there is anything like querulousness in the tone of his writings, there is a certain discontent as of one who had made a failure in the battle of life and is not ready to accept the situation with patience or subordination.

Notes.

Diseases of Carnations is the subject of a bulletin which will be issued by the Indiana Experiment Station next month. As it is expensive, owing to elaborate illustrations, only a limited edition will be published, and, therefore, Carnation growers who desire to see it should send their names as soon as possible to C. S. Plumb, Director, Lafayette, Indiana.

A newspaper in Denver states that seventy-five acres of ground near that city are covered with glass for growing winter vegetables, such as Lettuce, Radishes, Onions, Spinach and Cucumbers. Car-loads of mixed vegetables, like celery, cauliflower, parsnips, etc., are sent every day to St. Louis, Kansas City and other points to the east.

Mr. Edson S. Bastin and Professor Henry Trimble begin in the January issue of *The American Journal of Pharmacy* a series of papers on the botany, histology, chemistry and economic properties of some of the important coniferous trees of North America. In the first paper, after a general account of the family, which is divided into two suborders, the Pinoideæ and the Taxaceæ, *Pinus Strobus*, of which the photograph of a branch is reproduced, is described, and the tannin contained in the leaves and bark is determined, 25.7 of tannin being found in the absolutely dried leaves, 9.37 in the dried bark of the stem, and 6.48 in the root bark.

There are a good many complaints about the careless and dishonest packing of fruits in this country, but it seems that growers beyond the sea are not altogether above criticism in this matter. In a paper on the fruit supply of Covent Garden, read before the Horticultural Club in London last month, Mr. George Monro said that he was informed by the proprietor of a large wholesale store in Manchester, where both English and American apples were on sale, that one thousand barrels of American fruit were sold against one hundred bushels of English fruit, and this was simply because the packing of the English apples could not be depended upon—there being no proper selection or grading in the English packages of fruit.

The Lemon growers of southern California think that the fertility of the soil of that state and its adaptability to the production of citrus fruits will enable them to compete with the product of southern Europe in spite of the low price of labor there and the small cost of freight from Mediterranean ports. It is not expected in Lemon-producing districts of Europe that a tree will fruit before the sixth or seventh year, and it will do well if it yields three boxes of fruit the tenth year. In California a Lemon-tree is expected to pay expenses the third year, and it should yield from five to ten boxes of fruit in the sixth year, while it is not an exceptional occurrence for trees ten years from planting to produce twenty-five or thirty boxes of fruit.

Rhubarb, forced in cellars, is already in our markets, a dozen small stalks selling for fifteen cents, and also young carrots, grown under glass on Long Island and in New Jersey. New okra is coming from Cuba, and parsley, Romain lettuce and kohl-rabi from Bermuda. Last week's Bermuda steamer brought twelve crates of onions, the first of the season, which sold at \$2.00 a crate, wholesale. Chervil, delicate and fresh-looking, from hot-houses on Staten Island, is selling in considerable quantities, as also tarragon, and spring lamb has made an active demand for mint and for peas. Besides peas from Florida, a considerable supply is received from California. These are well filled out and tender, in baskets holding a half-peck, and cost seventy-five cents.

The so-called Paradise nuts, known in English markets as the Sapucaia nuts, are rather more common in our fruit stores this winter than they formerly were, and sell for fifty cents or more a pound. These nuts are closely allied to the Brazil nuts, although they are superior in flavor and more wholesome. They are about two inches long or rather more, and half as thick through, with a corky shell furrowed lengthwise, and they are the true seeds of the large, urn-shaped woody fruit

of *Lecythis Zabucajo*. This pericarp is six inches across and half an inch thick. It is very hard, and has a lid which fits tightly at the top, and which, when the fruit is quite ripe, is easily lifted off, and this gives the general name of Monkey Pot to the several trees of this genus. These trees grow in the forests of Brazil, Guiana and Venezuela, where their great trunks are seventy-five or more feet high, carrying a broad head of glossy leaves. Sapucaia nuts keep for a long time, and some of those in the market here have been held for more than a year.

The florists' windows throughout the upper part of the city are now interesting and beautiful in their attractive displays of forced flowers. In a Fifth Avenue establishment flowers of the golden-banded Lily, *Lilium auratum*, make a rich show at this unseasonable time. Sprays of *Calanthes* bearing seven to fifteen flowers are occasionally seen, and cost \$1.00, and those of *Odontoglossum crispum* command \$1.50 to \$6.00. Other Orchids now offered are varieties of *Cypripedium insigne*, *Phalænopsis Schroederiana*, *P. amabilis* and *Cattleya Trianae*. A small group of *Cattleyas* in a large window bedded with *Adiantum cuneatum* edged with *Lycopodium*, was one of the most artistic and refreshing window arrangements last week. Small plants of Azaleas, extremely well flowered, made a nosegay effect in their dressing of white crêpe paper, and branches of Pussy Willow seemed to deny winter in the bright glossy brown bark and silvery catkins, while *Dracænas*, grouped among Palms and other green-foliaged plants, were hardly less showy and effective than flowering plants.

According to the *Northwest Magazine*, a great fruit fair was recently held at Spokane, Washington, and although the admission fee was fixed at the nominal sum of ten cents and it was necessary to construct a great building of timber and canvas, after all expenses had been paid the net profits amounted to \$1,000, which was turned over to the treasurer of the Bureau of Immigration, under whose direction the fair was held. There were 52,000 paid admissions, the visitors coming on cheap fares from all parts of Washington, Idaho, Oregon, Montana and British Columbia. The trains carried from one thousand to three thousand people every day, and the aggregate number of strangers entertained by the city often ran up to five thousand daily. Although the exhibition was open to all products of the soil, fruits were the principal objects of display, and there were tons of fresh fruits, dried fruits and canned fruits. Seventy varieties of apples were exhibited, not to speak of other green fruits, besides a profusion of cereals, grasses, flax, broom-corn, sugar-cane, melons, tobacco, hops and native wines, so that fifty thousand feet of floor-space under roof and canvas were occupied. When we consider that the fruit industry of this region is comparatively young, both the exhibition and the interest it excited were remarkable.

To make good the shortage of oranges in the United States, caused by the loss of the Florida crop, many remote countries are being drawn upon. Jamaica, Mexico, north and south California, Spain and Sicily have each contributed to our markets, and cases of oranges from the Holy Land have recently been put on sale in Chicago. This fruit is said to be light-colored, oval, carefully packed and in excellent condition. It was grown in the district between Jerusalem and Jaffa and sold for \$4.00 a case. Only meagre reports of the effects of the freezing weather in California on the last days of the year have gone out from that state. Conservative business men here who have much to lose by the failure of the California orange crop, and every reason to wish for heavy shipments of choice fruit, estimate that as much as eighty per cent. of the oranges in the Riverside district are frozen on the trees, while Redlands, Arlington Heights and other elevated sections suffered little injury. The intense cold continued during the nights of December 29th and 30th, the anniversary of the fatal freeze in Florida the year before. The thermometer is said to have registered as low as seventeen degrees, Fahrenheit, at Riverside, and since the trees were killed in Florida at fifteen degrees, the groves themselves may have suffered, and this would be a more serious matter than the loss of a single crop. Hardly ten per cent. of the crop had been marketed, prices for Navels here being \$4.25 to \$4.50 a box at wholesale. Some oranges frozen in transit during the same period of severe weather have brought but \$1.60 to \$1.80 here, and the depression of prices will continue for fruit now on the way and suspected of having suffered on the trees. In the event of serious injury in California the Mediterranean supply must now be the main dependence, and the quantity of oranges and lemons imported from Italy, Sicily and Spain last season, 2,222,044 boxes, is likely to be greatly increased.

Horticultural Education.

IN a recent number of this journal it was held that the study of horticulture and agriculture in their scientific aspects has a distinct value as a factor in furnishing exercise for certain powers of the mind. Every one admits that the natural sciences should have a place in the curriculum of colleges and schools as elements of wholesome intellectual development, if for no other reason; and, perhaps, no science furnishes better mental training and exercise than agriculture and horticulture when their principles are systematically studied. This does not imply that there should be no such a thing as direct technical training in horticulture and agriculture as arts, but the fact should be emphasized that the mental exercise and discipline furnished by horticultural education in its broad sense is equal, and perhaps superior, to that furnished by the study of any other science. No kind of mental application will be more effectual in forming habits of careful observation and comparison and in securing those orderly methods of thinking which are of the greatest use in the examination of many of the problems which confront us in our daily life.

In an article in a recent number of *Science* on Horticulture at Cornell, we are glad to see that this view is set forth with considerable fullness by Professor Bailey, who contends that horticulture as studied at that university is capable of adding much to the value of a course of liberal academic training. Professor Bailey illustrates the merits of horticulture as a science by showing some of its uses and applications in discussing the theory of evolution, which is perhaps now the most important conception with which the thinking world has to deal. In supporting the hypothesis of evolution, horticulture shows the development of life in actual operation. More than six thousand species of plants are cultivated, and most of these have been broken up into varied forms by the touch of man. Some species have produced thousands of distinct forms, and the methods of the production of many of them are on record. In place of arguments as to the probable influence of climate upon plants the horticulturist cites definite cases, so that there is no conjecture about the matter. Instead of speculating upon the transmission of acquired characters the horticulturist furnishes proofs of such transmission. Palæontology brings disjointed evidence in regard to the

influence of selection and probable changes from environment, while the horticulturist brings examples before our eyes to prove that he can modify and mould vegetation at his will. The horticulturist creates new species and shows you numbers of cultivated plants of which no one knows the original form, because the ones with which we are acquainted are so unlike the type that the two can never be connected. This is only a single line of inquiry, and other illustrations quite as striking can be given to show that there is an abundant field for scientific research and profound thought in horticultural science as such.

The value of agricultural colleges as training schools for those whose purpose it is to practice agriculture and horticulture is conceded, and there is no question that they have been very helpful in making expert farmers and gardeners, in increasing the products and profits of cultivation and in improving the conditions of rural life. But, aside from the strictly educational value of the broader way of studying the science of crops, it must be remembered that this scheme of instruction has also its immediate practical value. The student who masters principles is more thoroughly equipped than one who only learns rules. Of course, it requires a somewhat mature mind to grasp the scientific laws on which the practice of horticulture is based, but when once this is accomplished the student can make his own applications, and he is not only less liable to make mistakes than one who is generally ignorant of the principles upon which his practice is founded, but he will constantly be stimulated to use his mind rather than his hands, and to get that enthusiasm for rural life which is essential to the highest success. Horticultural and agricultural education, as distinct from mere training, is not always possible, but where the course covers several years this broader method is certainly preferable, and this not only because it insures better practice in the rural arts, but because, as a part of a general education, it makes more capable and self-reliant men and women.

In reference to the methods at Cornell, Professor Bailey says:

The teaching there aims not so much to make farmers as to educate farmers' sons and daughters. Its fundamental idea is to give those students who anticipate a rural life such a breadth of training as will put them in touch and sympathy with the traditions of education, with all the larger movements of the day, and enable them at the same time to understand the fundamental reasons of their own occupation. There is less attempt to apply this teaching upon the university farm than there is to instill the desire to master the underlying principles of horticulture. Teaching is done by class exercises and by laboratory work, as it is in other scientific and technical subjects at the present day. If the student hears a lecture on the rotation of crops he goes for a walk with the professor over the fields of the farm and the adjoining lands and there observes the good and bad points of farm management. If he hears a lecture upon Winter Tomatoes he also goes with the instructor or alone, or from day to day, and studies the Tomatoes as they grow under glass. Besides this, he has his mind opened by thinking upon economics, language, history and general science as much as upon some of the particular subjects with which he is to deal in a more intimate way. The student should be a citizen before he is a farmer.

Our great progress in the mechanic arts is due to the application of science to the various branches of manufacture in cheapening processes, making them more effectual and utilizing by-products. The arts of agriculture and horticulture have the same need of science, and advancement in either of them must be in the same direction. Unlike manufacturing industries, however, which are mainly carried on by large forces of men under a single directing head, the work of agriculture is scattered over thousands of farms. The number of men superintending these operations—that is, of men who must rely upon their own knowledge—are in much larger proportion to the mere laborers than are the skilled superintendents in the field of manufactures. For this reason there is no class of persons, taken as a whole, who stand in greater need of such an education as will enable them to conduct their work with

intelligence. The experiment stations are doing much for cultivators of the soil by publishing the results of scientific research and making experiments which are too costly for farmers to carry out. But the hope of agriculture in the future in this country must rest, after all, on a wider system of education. The rural industries will prosper just as the whole rural population becomes more enlightened and are enabled to bring to their daily work minds drilled and equipped for active thinking as well as muscles trained and strengthened for expert handiwork.

THE latest and forty-eighth volume of *The Garden* is dedicated to George Nicholson, curator of the Royal Gardens at Kew, for his work among trees and shrubs. In his dedication the editor takes occasion to state that "we do but express the general feeling of the horticultural world toward the important national establishment of which Mr. Nicholson is the distinguished practical head. We recognize with considerable pleasure the great improvement in the present cultivation and disposition of the collections at Kew compared with past times, an improvement due to the proper recognition of the general desire to see picturesque and artistic gardening in the nation's own garden as well as the purely botanical. We believe this has been accomplished without any loss on the botanical side; indeed, we learn that the collections are now much richer in species, as well as in botanical interest, than ever they were. Every gardener is grateful for this improvement at Kew which we owe to the present staff of which Mr. Nicholson is a distinguished member, having been appointed curator at the same time as Mr. T. Thiselton Dyer was appointed director on the retirement of Sir Joseph Hooker in 1886." In this country Mr. Nicholson is well known as editor of the useful *Dictionary of Gardening*. In 1893 he visited the United States as a judge in the Horticultural Department of the Chicago Exposition and made many friends here.

Early Experiments in Crossing Plants.

IN the reference to Thomas Andrew Knight and his work in GARDEN AND FOREST of December 25th, p. 512, a statement is made from which a wrong conclusion may be drawn. Professor Bailey is reported as saying: "He was the first man, so far as I know, who advised the use of cross-fertilization for the purpose of producing new varieties and for the purpose of improving existing ones. A similar work was taken up by Darwin." The emphasis may be on Knight's important work in experimenting with varieties which already existed rather than in the production of new varieties by the crossing of species. But the coupling of the name with that of Darwin seems to refer to cross-fertilization in general, for Darwin experimented both with species and varieties. Possibly a distinction is made between a hybrid, between different species and a cross between different varieties, but this is scarcely valid on the scientific side. Nägeli has said of it: "This distinction may sometimes serve a practical purpose, but is frequently confusing and deceptive, for it supposes a difference that is merely one of degree."* However this may be, Köhlreuter, an earlier experimenter than Knight, also used varieties as well as species in his extended investigations on cross-fertilization, and so anticipated Knight in this respect also. His object differed from Knight's, for it was to prove the sexual nature of plants, a question about which botanists were still contending. Like Darwin's experiments in cross-fertilizing plants to prove his theory of the origin of species, Köhlreuter's work was almost purely scientific in its aim, but he was a pioneer in what has proved of immense practical benefit. Some account of his earliest work, and that of Linnæus, along similar lines, may be of interest.

Köhlreuter was a Swabian, born at Sulz, on the Neckar, where he produced his first hybrid plant in 1760. In 1764

he was made Professor of Natural History in Carlsruhe, a chair which he held till his death in 1806. Detailed accounts of his earliest work were published at Leipsic at different times from 1761 to 1766.† The results of subsequent experiments appeared in the *Transactions of the Imperial Academy of Sciences of St. Petersburg*. Like the work of Conrad Sprengel on the agency of insects in fertilizing flowers—in which he was anticipated by Köhlreuter—published in 1793, his experiments for a time passed out of sight or attracted but slight attention. The revived interest in the subject from the labors of Knight and Herbert in England, Gaertner and Wiegman in Germany, Godron in France, not to mention others, called attention to them once more. Knight's efforts to improve fruits and vegetables, which began about 1787, were evidently made in ignorance of what Köhlreuter had done, and his discoveries were to that extent independent. So scholarly a man as the Rev. William Herbert, who did much splendid work in crossing plants, says that he began his investigations "ignorant of the experiments of Köhlreuter." He gave the first account of his investigations before the Horticultural Society of London in 1819.‡ Köhlreuter's work, being purely scientific in its character, did not enlist the coöperation of horticulturists like the later work of Knight and Herbert, which had, or was soon given, a practical bearing. Botanists, being mostly devoted to systematic botany, were indifferent or even opposed to such labors. This attitude of botanists and failure of horticulturists to see the bearings of such experiments on their art, may to some extent explain the temporary oblivion into which Köhlreuter's earlier work passed.

His first success was in crossing *Nicotiana paniculata* and *N. rustica*. From the seed produced other plants were raised. Various other experiments followed, sometimes with varieties of one species, more frequently by crossing different species. Though some of the conclusions he derived from his experiments have proved erroneous, partly because he mixed up certain a priori ideas with them, to him is largely due the credit of placing the theory of the sexuality of plants on a firm foundation. Little ground for doubt was left after his careful experimentation, conducted on the strictest scientific lines, and the sex of plants became a fact without dispute, though it had been broached as far back as the time of Aristotle. Köhlreuter claimed that this *Nicotiana* cross was the first one artificially produced to which absolute credit could be given. There was a bare possibility of their spontaneous production among plants in a wild state, but the antecedent probabilities were against it.

Prepossessions, based partly on such ideas, partly on the great infertility of hybrids and their tendency to revert to one of the parent species, especially when left under conditions to be fertilized by their pollen, hardly left Köhlreuter in a state of mind to do full justice to Linnæus, who was also investigating this subject. The great Swedish naturalist had a lively imagination and drew too much upon it, but every case of the crossing of plants he and his pupils discovered or artificially made cannot be disproved as easily as Köhlreuter and others have thought they might be, so he sets aside the claim of Linnæus to the production of a hybrid Goat's-beard in 1759, calling it but a half hybrid at the most.

In 1757 Linnæus found a *Tragopogon* in his garden, which he named *T. hybridus*. It sprang up in a bed where he had planted *T. pratensis* and *T. parvifolius*. Winter came on before the seed matured, and he was not able to test its power of reproduction. The next year he fertilized the plants artificially. He removed the pollen of *T. pratensis* by rubbing it off early in the morning, and a little later in the day brought pollen from *T. parvifolius* to

† Dr. Joseph Gottlieb Köhlreuter's *Vorläufige Nachricht von einigen das Geschlecht der Pflanzen betreffenden Versuchen und Beobachtungen*. (Reissued by Engelmann.) Leipsig, 1893.

‡ All the references in Herbert's book on the Anaryllidaceæ and its supplement (London, 1837) are to the acts of the St. Petersburg Academy, unless a doubtful allusion to "one concerning *Nicotiana*" is to those begun in 1761.

* *Botanische Mittheilungen*, vol. ii., p. 188 (note), in an essay on "Die Bastardbildung im Pflanzenreiche."

its stigmas. The heads were marked by a thread. Seeds were formed, which being sown germinated in the autumn and in the following year bore flowers, which were purple, with a yellow base. These also bore seed that matured. An account of the plant was given by Linnæus in a prize essay on the six plants sent to the Academy of Sciences of St. Petersburg in 1760.* It is mentioned in a later paper read at Upsala in 1762 by one of his pupils as being annually propagated by seed.† Focke, who has given us a convenient summary of what is known of hybrid plants, both spontaneous and artificially produced, calls this plant of Linnæus "the first hybrid intentionally produced for scientific purposes," and adds that the objections which have been brought against its hybrid character by Köhlreuter and others "are not sound, since they deal with plants of the second generation."‡ The seeds of the hybrid seem to have reverted to *T. pratensis*, which was one of the grounds of Köhlreuter's objections, and of his disbelief in the spontaneous production of crosses when the plants were left free to be pollenized by their parents. A spontaneous cross between these species has, however, been reported from the Danish islands of Laaland and Fünen, "the outer flowers brown-violet, the inner yellow."

A limitation is made in the above cases to crosses produced artificially for scientific purposes, for it can scarcely be disputed that Thomas Fairchild, the nurseryman and florist, of Hoxam, near London, had before 1719 artificially crossed *Dianthus caryophyllus* and *D. barbatus*. This has since been cultivated under the names of Fairchild's Sweet William, The Mule and *D. hybridus hort.* The authority given for this is Richard Bradley, an English writer on horticulture and husbandry of the first half of the last century. Hence the credit for the earliest authenticated cross intentionally made is due to a man engaged in the practical work of gardening.

The Box-Elder on the Plains.

I HAVE been interested in studying the problem of the distribution of native trees upon the Great Plains and their adaptation to the peculiar conditions which prevail over this great central region of the continent, and no tree has attracted my attention in this region more than the common Box-Elder, or Ash-leaved Maple, *Acer Negundo*. As it grows upon the Plains it is a stocky tree with a trunk ten or twelve inches in diameter and not more than six or eight feet in length, bearing a rounded bushy top, giving to the tree, as a whole, much of the appearance of a well-grown Apple-tree in an eastern orchard. It occurs along the streams in Nebraska from the Missouri River to the Rocky Mountains, and here and there in favored localities it has pushed away from the streams a mile or so. It appears to be perfectly hardy, and I am sure that I have never seen the slightest indication of injury from the greatest exposure to severe cold.

The Box-Elder has been used very freely by the settlers who took up "tree claims," and for many years, until the repeal of the timber-claim law, there were millions of these trees planted every year in the state of Nebraska alone. The young trees transplant easily and are readily handled, the per cent. of loss usually being very low. Then, again, it is a very simple matter to grow the trees from the seeds, which insures the low price of the young trees. A few years ago I visited a large establishment in southern Nebraska where from eight to ten millions of young Box-Elder trees were grown each year. The winged fruits were collected in the autumn and carefully protected in a great barn, and in the spring these were sown in drills, just as a farmer sows any of his crops. In a short time the little plants pushed through the soil and began to shoot upward. The fields of Box-Elder seedlings were cultivated from time to time, and when a few inches

high properly thinned to prevent overcrowding. The crop of trees required little more care than a crop of Corn, and not as much as a crop of Onions or Sugar Beets. Late in the autumn they were taken up by the aid of a special plow, gathered into bundles and stored away in damp, cool cellars, ready to be sent out in early spring. Few trees are as easily propagated and handled. In fact, one could very easily cover hundreds of acres with this tree by simply planting the seeds and caring for the young trees a few years.

The wood is light and easily cut and split, and makes good fuel. The tree might very profitably be grown for supplying fuel, its rapid growth giving it a special fitness for this purpose. Something, too, might be said for it as an ornamental tree. Its rather regular top and light green foliage, which is usually free from insects, make it desirable for the grounds near the house.

Charles E. Bessey.

What is the Forest Policy of European Nations?

WHENEVER we are about to advocate or inaugurate a new national policy it is wise to see what other nations are doing or have done in the same direction, even though we may not see proper to imitate them.

In regard to its public lands, the policy in the United States has been for the Government to get rid of them as quickly as possible, until in 1891 a new policy was feebly inaugurated with reference to forest-lands by giving the President power to set aside and reserve such areas as he saw fit. This policy has, however, not as yet been safely established, and arguments for upholding it and for securing further application are still in order.

In Europe the tendency at the end of last and beginning of this century had also been to divest the Government of this kind of property under the misapplication of the theories of Adam Smith and the doctrine of individual rights, urged to its most extreme consequences. France, during and after the Revolution, took the lead in this dismemberment of its forest property, selling during the years from 1791 to 1795 nearly one-half of its state forests and continuing to reduce the area until there remained in 1874 but one-fifth of the original holdings of the state. Many of the German principalities followed the same policy, selling off the forest-lands which had been preserved in the Government for centuries.

But during the last fifty years or so of this century a reaction set in; the fearful consequences of unrestricted exercise of individual ownership over this class of property had made it plain enough that the necessity of a change arising from communal interests had come, and now it can be stated that the policy is entirely reversed, that all European nations have the tendency, not only to hold their forest property in Government hands, but to extend it in area and in efficiency, and also to exercise stricter control over the use of private forest property wherever damage to communal interests might result thereby.

Instead of selling, most Governments now buy. There is, to be sure, also selling of Government forest property, but only for the purpose of making the Government forest property more efficient, of consolidating it and of making it serve to the best advantage the purposes of protection to agricultural interests. Thus, in Prussia, agricultural land under forest is exchanged or sold for non-agricultural land or devastated forest property, and servitudes resting on the state forest property from olden times are sometimes removed by cession of forest-lands, so that the bare statistics of the increase in the area of state forests do not tell the whole story.

In France, since 1870, no sales have been made, and by gradual acquisitions a small and steady increase of forest-land has taken place. The difference between the areas in 1872 and 1892 was over 300,000 acres, the state holdings representing now about ten per cent. of the total forest area, and in addition the state has spent in the neighborhood of

* *Amenitates Academicæ*, Gilibert ed., 1787-88, vol. 1., p. 212.

† *Ibid.*, p. 182.

‡ *Pflanzen Michlinga*, pp. 221, 430.

\$40,000,000 toward reforesting dunes and devastated mountain-sides, and in the budget for last year for its Forestry Department nearly \$1,000,000 of the \$2,500,000 appropriated for the department is set aside for such extension of forest area and improvement of the existing one. In addition, the private property is controlled entirely as regards clearing; that is to say, no clearing may be done without the sanction of the Government authorities.

In Prussia, which represents about two-thirds of Germany, the policy of selling also prevailed in the beginning of the century, but since 1831 a constant increase has taken place, the increase in the old provinces from 1831 to 1892 being but a small fraction, but in the entire monarchy from 1870 to 1892 it amounted to 280,000 acres. Here, especially, the apparent small increase is due to the fact that much land was exchanged or given to get rid of servitudes, obligations which were a charge on the forest property. For this purpose 125,000 acres were ceded, besides the payment of fully \$20,000,000 in money, all of which represents an increase in the efficiency of the remaining forest property. Altogether, between the years 1867 and 1895, over 22,000,000 marks were spent in increasing the forest area, and the budget for 1895-96 contains an item of 2,000,000 marks for the purpose of acquisition. In addition it is of interest to note that during the last twenty-five years the conservative management has resulted in increasing the stock of wood in the state forests by over 25 per cent., in spite of the fact that the annual cut has increased by 40 per cent., while the receipts have increased by 50 per cent., although the expenditures, and especially the salaries of the forest officials, have been increased during the same time. The net income was of the gross receipts—in 1830, 61 per cent.; in 1870, 52 per cent., and in 1893, 47 per cent. The control of private forest property in Prussia is, perhaps, least developed in the German states, the necessity for such control being probably less on account of the situation of the larger part in the plains country, and also because the large holdings of the great proprietors were less liable to dismemberment or mismanagement. The belongings of the communities, however, are under the same control as in France, and legislation looking toward greater control of private property wherever communal interests are involved is in preparation.

In other German states we may note an increase of 4 per cent. in the state forest area for Bavaria between the years 1873 and 1890—an increase of over 3 per cent., by purchase, for the state forests of Württemberg, the one state in Germany where clearing is also absolutely controlled by the state authority. A small increase is notable in Baden and Saxony, so that we see Germany, as a whole, is increasing its state forest property.

In Austria the selling craze lasted until about 1872, and now the state is the only great purchaser, buying, besides minor lots, in 1886, 60,000 acres; in 1888, over 230,000 acres, and in 1891, 210,000 acres in single purchases.

Italy, to be sure, has been too poor to enlarge its state property, but the laws of 1877 and 1890, which provide for reforestation of denuded mountain lands with financial assistance to the communities from the Government exchequer, exhibit the conservative tendency of the Government and its recognition of the fact that a strong communal interest attaches to this kind of property.

Even Russia, though probably the least-developed of the European countries, and largely in the pioneering stage, holds on to its Government possessions, provides for their rational administration and extends the same where this is desirable. In the extreme north, where more than one-half of the country is still covered with woody growth, no forest policy, probably, is carried out. In the central states and Baltic provinces, representing one-quarter of the total area, where the percentage of forest land sinks below 30 down to 17 per cent., a conservative forest management of the Government forests after the pattern of Prussia is established; and in the prairie country on the southern third of the empire large amounts of money are

spent by the Government in planting forests or assisting private owners to do the same. Russia, therefore, does not sell any of its real timber-lands, excepting where communities do not own their timber, and, therefore, the state property is liable to depredations, when the Government tries to obviate the difficulty by making the community owner. In addition a very elaborate law exists for the purpose of preventing mismanagement, which places the approval of working plans, of making clearings, etc., in the hands of a specially constituted committee for each department, and the Government itself must secure the approval of this democratic committee for its operations.

Finally, while England has not any forest area worth speaking of, for India, at least, the same policy of conservation and of increasing Government control is notable. Her Indian forest policy was inaugurated about 1873. From 1882 to 1892 the reserve forests were increased from 46,213 to 59,743 square miles, and the total forest area under the control of the Government from 71,972 to 114,966 square miles. Strong efforts are being made to place the entire forest under the direct control of the Government.

We see, then, that these nations, having learned from sad experience, reversed in time their policy and act upon their knowledge that forest property is best preserved in the strong hands of Government, which is permanent, as the forest cover in the mountain must be to secure favorable agricultural conditions. Must the United States learn also from her own experience, or can the lesson be learned from the experience of others?

Forestry Division, Washington, D. C.

Plant Notes.

Stuartia Pseudo-Camellia.

THE genus *Stuartia*, a member of the Tea or *Camellia* family, named in honor of John Stuart, Marquis of Bute, is distinguished by its deciduous membranaceous oblong-ovate serrulate leaves, large solitary axillary flowers with five or six sepals and five or six obovate crenulate white petals, and by its five-celled pods with one or two seeds in each cell. The genus is confined to eastern Asia, and to eastern America, where there are two shrubby species; one of these, *Stuartia Virginica*, grows only in the coast region of the southern states and bears the largest and most beautiful flowers of any member of the genus which is now known; the other, *Stuartia pentagyna*, is common on the lower slopes of the southern Appalachian Mountains, where it sometimes grows in great profusion, especially in eastern Tennessee. In Japan and China there are two or three species of *Stuartia*. Only one of these, however, *Stuartia Pseudo-Camellia*, is a common plant in Japan; the others are either confined to the southern islands or are extremely rare, and neither of them is found in our gardens. Little is known of *Stuartia* in China beyond the fact that one of the species of southern Japan extends to the mainland, where it is not improbable that other members of the genus will be found.

Stuartia Pseudo-Camellia (see illustration on page 35) is a tree upward of fifty feet in height, with a trunk sometimes two feet in diameter, and in the mountain forests of central Japan, where it is abundant, is always a conspicuous object, owing to the smooth, bright red bark, which peels off in great thin flakes like that of the Crape Myrtle (*Lagerstrœmia*), and gives the tree its name of *Saru-suberi*, or *Monkey Slider*. The handsome dark green leaves, which insects do not mutilate yet in our gardens, and the large delicate flowers, whose beauty is heightened by the contrast between the purple stamens and the white petals, need no special description, for, in general appearance, they resemble those of our native species.

Thirty years ago *Stuartia Pseudo-Camellia* was sent to the United States by the late Thomas Hogg. It was propagated with other Japanese plants in the Parsons' Nursery, at Flushing, Long Island, and flowered several times in the neighborhood of this city some years before its flowers

unfolded in Europe, where it is now rightly considered one of the most attractive garden shrubs.

In Japan *Stuartia Pseudo-Camellia* grows freely up to elevations of three thousand feet above the level of the sea, and in the United States is perfectly hardy as far north as

but once established they go on improving for many years, and are among the most beautiful and desirable of shrubs.

PYRUS CORONARIA.—Few small trees are more desirable than the Crab-apples from Japan and Siberia, which we

Fig. 4.—*Stuartia Pseudo-Camellia*.—See page 34.

eastern Massachusetts, the specimen from which our illustration is made having been produced in the Arnold Arboretum. *Stuartias* can be raised from seed and by layers, which, however, take some time to produce roots. They require deep rich soil, delighting in a compost of peat and loam; they grow slowly and do not begin to flower early,

have often commended in these columns. But our native Fragrant Crab, as it is sometimes called, ought not to be neglected, especially when parks or large grounds are to be planted. The beauty of this tree was appreciated by the early settlers in this country, and the Swedish traveler, Kalm, notes that in Pennsylvania and New Jersey single

trees of this species were even then often planted near farm-houses on account of "the fine smells which their flowers afford." It has been a favorite garden tree in Europe for more than a century, and our European correspondents have commended it as having few rivals among ornamental Pears and Apples, although of late years it seems to have been somewhat neglected. When at its best in the lower Ohio valley and in the states west of the Mississippi River it is a bushy tree sometimes thirty feet high, with a trunk more than a foot through, breaking into stout spreading branches eight or ten feet above the ground. Usually it grows smaller, and sometimes is little more than a shrub with stiff contorted branches. Its small size and attractive habit give it a value for wood borders, shrubberies and even for small gardens. Its pale pink or rose-colored flowers appear ten or twelve days after the petals have fallen from other Apples. They are nearly two inches across when fully expanded and have a delightful odor. The waxy, translucent fruits, which are from an inch to an inch and a half in diameter, hang gracefully on long stems and remain on the branches until after the leaves have dropped in autumn, when their greenish orange color, flushed with scarlet as they ripen, and their delicious fragrance make the tree quite as ornamental as it is in June.

BEGONIA EVANSIANA.—This plant, often called *Begonia discolor*, is a native of China and Japan. It is much the hardiest of all the *Begonias* so far as known, and we have often commended it for this quality as well as for its beauty. The plants, of course, die down root and branch every year with the first frost, but the bulblets, which form plentifully at the bases of the leaf and flower-stems, will have fallen to the ground; these sprout just as soon as warm weather commences the next year, and soon develop into blooming plants. Mr. Oliver writes that this *Begonia* has become naturalized in the Botanic Garden at Washington, not in one place only, but in several, for over thirty years. It seems to like positions for hibernating which are not affected in the least by sunshine. On the north side of a house, close to the wall, it comes up abundantly every year—in fact, far too abundantly, for many of the plants have to be pulled up to give the remainder a chance to develop. The bulblets do not receive any protection whatever in the way of mulching; they are invariably left to take care of themselves. The rock-garden is another spot where this *Begonia* is at home; those bulblets which fall on the shady side of the rocks survive the winter with ease, while those which are exposed to the sun, owing, perhaps, to successive freezings and thawings, are killed. After the plants are up a certain height a little decayed manure thrown over the roots accelerates the growth of the plants and produces a heavy crop of flowers. Some interesting experiments have been made at the Washington Gardens with this plant, where new colonies have been started with bulblets from plants growing out-of-doors, and also from those which have been grown for years in a hot-house. While it is an easy matter to start a new colony in a suitable place with plants or bulblets grown outside, it is difficult to get a plant from indoors to perpetuate itself in the open air. The plants from the hothouse form bulblets enough, but in winter they require protecting by dry leaves or some similar covering for a season or two.

Cultural Department.

Winter Work among Insects Injurious to Fruits.

MR. M. V. SLINGERLAND, of Cornell University, makes some timely observations on this subject in the current number of *The American Agriculturist*, the principal points of which are here reproduced:

The burning of fallen leaves and other rubbish in or near fruit plantations of any kind will prevent many insect pests from obtaining winter shelter near their food-plants, and those pests already in hibernation will be killed. Many of our worst

insect pests, as the plum curculio, thus hibernate in rubbish. It is a good practice to scrape off the rough bark from the trunks and larger branches of fruit-trees, for many caterpillars of the codling moth (then in their little cocoons of silk), the hibernating adults of the pear psylla, and the hibernating eggs under the scales of the oyster-shell bark-louse and the scurfy bark-louse will be dislodged or killed. A coating of white-wash or some similar wash will tend to keep the bark clean, thus rendering it less attractive as a hibernating place for insects.

If fruit-trees are pruned at any time during their dormant period, the prunings should always be burned. These prunings will often bear the wintering eggs of the different kinds of plant-lice (as the apple and cherry aphides and the hop aphid, whose eggs are laid on Plum-trees) that appear in such great numbers on the trees in the spring and summer. The half-grown caterpillars of the cigar-case-bearer are also then snugly tucked away in their little curved cases attached to the bark of the twigs, and many would thus perish on the prunings. This insect has recently come to be a serious Apple pest in western New York.

Trees infested with the oyster-shell bark-louse, the scurfy bark-louse, the San José scale or any other scale insect should be thoroughly washed with whale-oil soap in a solution of one or two pounds to a gallon of water. It should be remembered that the wash must come in contact with the insects to kill them. With this wash, or with a strong kerosene emulsion, many of the adults of that dreaded pest, the pear psylla, then in hibernation in sheltered places on the bark, can be killed.

The New York Plum-scale, which has recently caused great destruction in western New York Plum orchards, can be fought to the best advantage only when the trees are dormant, as the scales are then young and tender and lie exposed on the bark. Badly infested trees should receive a thorough spraying with kerosene emulsion (Hubbard-Riley formula diluted four times) in the fall, in the winter if possible, and another very thorough application early in the spring before the buds swell.

The eggs of several insect pests can be collected and destroyed during the winter, thus greatly reducing the numbers of the pest the next season. The eggs of the Apple-tree tent caterpillar are glued together in a large, conspicuous mass, which usually encircles a twig; it is a short job to look over a tree and remove these egg masses. The eggs of the white-marked tussock-moth form a very conspicuous large, white, froth-like mass on the bark of the trees, or on near-by fences or buildings; this is the insect that is ravaging the shade-trees in several of our large cities. It was nearly exterminated in Rochester by offering prizes to the school children for collecting the eggs; the children collected millions of the frothy egg masses. The eggs of the four-lined leaf-bug, a serious Currant pest in some localities, are laid in slits cut in the shoots near the tips; the white ends of the eggs project out of the slit, and one can thus quite readily determine the infested tips and cut them off. The long ragged scars or slits often found in Raspberry-canes, or in the twigs of fruit-trees, are the work of the snowy tree-cricket, done in laying its eggs; this is the only damage done by the insect. The infested canes or branches are readily seen, and should be removed. When the eggs of any of these insects have been collected, they should always be burned. If left on the ground they will hatch as readily there as on the tree or bush, and the young will easily find their way to their food.

Currant-bushes and Raspberry-canes are often infested with borers; two kinds, a beetle and a moth, work in currants. Usually the infested shoots can be quickly detected in the spring when growth begins, and all such should be removed and burned at once, thus destroying the developing insect life they contain. The hydrocyanic acid gas treatment, so extensively used in California, will probably never come into general use among New York fruit growers. It is too expensive, and most of our insect pests can be effectively combated by other means with less labor and expense. There is scarcely any question about its efficiency against all insect life, especially scale insects; we have been unable to find a living San José scale on trees treated with the gas. It is the most efficient and practicable method for our nurserymen to use in fumigating their stock to prevent the distribution of the San José scale, the pear psylla, the bud-moth and other serious pests. There is no longer any doubt that some New York nurserymen are sending out these insects on their stock; and the time may soon come when they will be compelled to resort to fumigation with the gas to protect their trade, and the matter is worthy the careful attention of nurserymen throughout the country.

Cultivation of the Tomato.

THE Tomato is an annual, a native of tropical America, and under normal conditions completes its cycle of life in from one hundred and fifty to two hundred days. For the first ninety to one hundred and twenty days the plant gains at a constantly increasing rate in size and vigor, acquiring a sort of momentum of growth, and then commences to mature its fruit, expending more and more of its strength in this way until the plant becomes exhausted and dies. The preliminary accumulation of vital energy is essential to perfect fruitfulness, and if it is not established or is lost through a check in growth the plant will endeavor to develop it by extending the growing period into that in which under normal conditions its undivided energy would be expended in the production of fruit. A temperature of about seventy degrees in full sunlight is essential to the best development of the plant during the growing period, and one ten degrees higher is most favorable for the maturing of the fruit, and the plant will not thrive if either the air or soil is much colder. As in its native home favorable conditions of heat and moisture are during the growing season very constant, we are not surprised to find that the plant has little ability to endure unfavorable conditions. In a temperature of forty-five degrees or less, either of the soil or air, the plant not only will not grow, but will lose vigor and vital energy, the injury being proportioned to the duration rather than the degree of cold, although a freezing temperature for an hour will kill it.

In the latitude of Detroit the average temperature at noon is not as high as seventy degrees until about June 1st, and it is only during August and September that the average noon temperature reaches eighty degrees. It is thus evident that in order to secure a perfect development of the Tomato in this latitude we must extend the season artificially, and the only practical way to do this is to start the young plants under glass. If we sow the seed about April 10th, supply the necessary conditions of light, air and heat to secure a natural, healthy and vigorous growth, the seedlings will be as large as it is practicable to transplant by June 1st, which is as early as favorable conditions of soil and air can be expected, and if we then set out the plants without seriously checking their growth they will reach their full size and acquire the vital energy necessary to the production of a maximum crop of fruit by July 20th or August 1st—as soon, that is, as favorable weather for the ripening of the fruit can be expected. The common practice is to plant the seed much earlier, often as early as March 1st; this gives ninety days before the conditions are such as to make it safe to set the plants in the open ground, and if the plants grow naturally they would reach their full size and be far too large for transplanting without most serious check. On the other hand, to grow the plants so slowly that at the end of ninety days they are still of a size suitable for transplanting, is to fail to develop any of that momentum of growth which is essential to perfect fruitfulness. Such plants can never in our climate give a maximum crop of fruit, though they may reach full size.

It seems, then, that a careful consideration of the character of the plant and the climatic conditions we have to meet will lead to the adoption of the following as the best method of adjusting them: Sow the seed between April 1st and 10th in boxes of light, loose soil, kept at a temperature of about sixty degrees and moderately moist. As soon as the plants have started true leaves, transplant into small pots or other boxes; if in boxes, they should contain three to five inches in depth of light rich soil, and the plants should be set four inches apart each way. If pots are used, the plants should be repotted into larger ones often enough to prevent their becoming pot-bound. A day temperature of sixty to seventy-five degrees should be maintained, with the soil and air moderately but constantly moist. Above all, an abundance of light and air must be provided, a necessity which makes a special hotbed, or a well-protected cold-frame where the soil has been well warmed up, a better place to grow plants than a greenhouse. In the mean time the ground where the plants are to be set should be thoroughly prepared by first a deep cultivation, then an evenly spread dressing of well-rotted manure, which should be well worked in. Plowing or spading and cultivating should follow, and after an interval of a few days another cultivation as deep as possible, and the land should again be cultivated just before setting the plants. The purpose of this is to form a deep bed of well-warmed and friable soil in which the finely divided fertilizer shall be well mixed, and which will retain as much as possible of the spring rains. This thorough preparation of the soil is the prime secret of successful Tomato culture, and it is much cheaper and better to do the necessary deep cultivation before the plants are set. In this latitude the

danger of cold storms is rarely over, and the soil is rarely warm enough to warrant the setting of plants before June 1st, and where the ground is well prepared and the plants well grown there is no advantage in putting them out till the conditions are favorable for rapid growth.

Give the plants but little water, barely enough to prevent wilting, for four or five days before, and a liberal watering two or three hours before setting. In putting out the plants be careful to save as many of the roots as possible and to get them into the ground in a natural position without being kinked or crowded together, and, if it is practicable to do so, soak the ground about the plant after setting, but if this is done care should be taken to draw some dry earth over the wet soil, so as to prevent its baking and cracking. A few days after the plants are set stir the surface soil with a hoe or rake, and repeat this every few days as long as the size of the plants will permit. If the preparation of the ground has been thorough there will be no need of deeper cultivation, which would do more harm than good. If a smaller quantity of extra-fine fruit is preferred to a larger yield of that which is simply good, it will be better to stake or trellis the plants. For this purpose we have found nothing better than four two-inch square stakes, about six feet long, driven into the ground in a square of about sixteen inches around the plants. From four to six branches are allowed to grow up within the space enclosed (the others being removed as they appear), and are held therein by strings around the stakes, kept in place by occasional tacks. We think, however, that, except in very heavy and wet soils, more satisfactory results will be secured from unpruned plants which are allowed to rest on the ground.

Will W. Tracy.

Winter-flowering Begonias.

BEGONIA, Dr. Nacthingale, is a garden hybrid, evidently closely related to *B. nitida*. Like that plant, it is deliciously fragrant. Its habit is better than the type, being less angular. The panicles and also the individual flowers are larger and of a clear bright rose-color. It is very floriferous, never at any time being out of bloom.

After two years I have succeeded in growing well-flowered plants of the distinct and beautiful hybrid known as *Gloire de Sceaux*. A figure of it appears on page 185, vol. vii., of GARDEN AND FOREST, which, as stated in the accompanying description, does not do it justice. It is a neatly growing bushy plant, about a foot and a half high, well furnished with nearly orbicular, deep bronzy green leaves. The flowers appear near the ends of the branches in short scape-like panicles, and, unlike most of the shrubby kinds, the male flowers are the largest, showiest and most persistent. The flowers are clear pink, sepals and petals rounded, and nearly equal in size. This is the only characteristic of the pollen parent, *Begonia Socotrana*, visible. In foliage and general habit it resembles its seed parent, *B. subpeltata*. We grow it in good rich loam with plenty of drainage and in a shady position in a greenhouse at an intermediate temperature.

Begonia Haageana is a very interesting and beautiful species, evidently related to *B. Scharffiana*. It makes a handsome specimen plant, whether in bloom or not. The leaves are light bronzy green, irregularly ovate, tapering and covered on both sides with a rather bristly pubescence of reddish brown hairs. It flowers sparingly all the year round in large rambling paniced cymes of light pink flowers. Both the sepals and petals in both the male and female flowers are covered on the outer surface with brownish hairs, a character not common among *Begonias*. Outside this type the only other kind I remember with this peculiarity is the well-known *B. metallica*.

Begonia Credneri is another of these hairy kinds. The whole plant is stouter, with a more deeply bronzed tint. The leaves are rounder and more bluntly pointed. The inflorescence is quite erect; the flowers nearly white, and almost covered on the outside of the sepals and petals, and the ovary with bright red hairs. It is quite as handsome a plant as *B. Haageana*, but not so free in growth.

Paul Bruant, a short-jointed, erect-growing, bushy kind, with irregularly cordate, deeply cut and wavy deep green leaves, is one of the best I know of, for window decoration. The flowers occur in large drooping panicles, reddish pink in color. Only the female flowers are persistent, and with large red-winged ovaries make a very pretty effect. I have known a plant to remain well in bloom for six weeks in an ordinary house window.

When Mr. Veitch, of London, was here a year ago, he was surprised to see large, well-flowered specimens of one of their recent hybrids, *President Carnot*. It is a robust-growing hybrid, and had been a small plant the spring previously.

Planted out for the summer, with unrestricted root-room, it had made strong canes four feet long and very stout, without blooming, having been used for tropical effect, for which it is extremely well adapted. It lifted well, ripened the stout wood it had made and bloomed profusely all winter long. This year I thought to make neater specimens by growing them in pots, but results prove the plants have not the stamina for a good show of bloom. The paniced cymes are very large, drooping from near the ends of the branches, and if the branches be long, as when the plants are grown out-of-doors, they have a somewhat leggy appearance. These branches root easily any time during the summer, develop the panicles which show in the bud state when the cuttings are taken, and make neat little specimens which can be planted out the succeeding summer. The individual flowers are very large. The whole flower, including the large winged ovaries, are bright coral-red, from which we may probably trace its parentage, on one side, to the old *B. (rubra) corallina*.

Ferdinand de Lesseps is another of these large hybrids into which the blood of the bronzy leaved *Begonia olbia* has been some way infused. This is evident in the short, almost hidden cymes, and in the reddish bronze under-surface and margined leaves. This, also, is better for a season out-of-doors, needing age and well-ripened growth to bloom well.

T. D. Hatfield.

Siegesbeckia orientalis.—Last June we received from the Royal Botanic Gardens, Buitenzorg, Java, a large number of packages of seeds, principally natives of that island. I sowed the greater portion as soon as they arrived, and have been much interested in watching their developments. The above-named plant was in the collection, and though by no means ornamental, it is interesting botanically. My first impression of the plant when it began to flower was a miserable weed. It is an annual, and belongs to *Compositæ*. The leaves are cordate, with coarsely serrated margins, four inches long by two inches wide. The flowers are small and yellow, and rather inconspicuous, but the flower-heads have, in addition to the scales with which *Compositæ* are surrounded, five spreading, rather long, involucre scales, which are covered with glandular hairs, each having a drop of viscid fluid at the tip. These hairs catch insects, apparently with the same ease as *Droseras*, as there are numbers of small insects caught on the plants we have here. Whether these insects are of any use to the plant after being caught is a problem for botanical students to solve. I do not know of any insectivorous *Compositæ*, and possibly the viscid glandular hairs are for a protection for the flowers from small insects, yet from their spreading position and the smallness of their number this is hardly probable. Many plants have sticky hairs on the stems and flower-stalks, to prevent ants and other insects climbing and stealing the nectar; as, for instance, *Browallias*, *Cupheas*, *Primulas*, *Plumbagos*, etc., but I do not remember ever seeing them hold insects, as this plant does. *S. orientalis* is by no means a rare plant, as it is largely distributed through the tropics, under the name of *S. droseroides*, apparently from the resemblance of its involucre scales to the leaves of *Drosera*. It is well worthy of a place in botanical collections, and I find it does best in the warm temperate house.

Northampton, Mass.

Edward J. Canning.

Cytisus racemosus.—This is a common greenhouse shrub, and one of few plants with yellow flowers which are available to any extent for winter and spring decorations. It can be had in bloom from January onwards. By regularly pruning into bushy shape, plants may be grown for many years and make large specimens. This is practiced only in private places; for commercial use new stock is annually raised. Cuttings are taken from half-ripened wood and put in pots filled with sandy peat, or in a cool propagating-bed to callous. Afterward, a bottom-heat of sixty-five degrees, Fahrenheit, will induce new roots, and the cuttings should be ready for potting off in two or three weeks. They should be grown continuously in small pots for the first season, as it is almost impossible to lift plants which have not previously formed a ball of earth. Small plants rooted last spring and grown to a single stem in four and five inch pots are perfect pyramids from one to two and a half feet high, showing bloom for nearly the entire length of the stem.

Wellesley, Mass.

T. D. H.

Cælogyne cristata.—Next to *Cattleya Trianae*, this is the most useful Orchid of the midwinter season. The abundance of its snowy flowers, its dwarf habit and dark glossy foliage make it truly beautiful at this season. The flowers, which measure

about four inches across, are produced in loose racemes resting on the foliage. Except for the rich golden-yellow fringes inside the lip, the color is pure white. The bracteate peduncle springs from the base of an oblong, shining, bright green pseudo-bulb of a walnut's size. The pseudo-bulbs are formed on creeping stems, and bear one or two long strap-shaped leaves of a dark green color. A cool well-ventilated house in a northern position is best in summer, and during the flowering season the plants should be kept in the coolest part of the greenhouse. While growing they need frequent syringing and watering and occasional fertilizing with weak liquid-manure.

Correspondence.

The Pepper-tree for House Culture.

To the Editor of GARDEN AND FOREST :

Sir,—Your recent article on the Pepper-tree leads me to add that it is readily grown from seed and makes a pleasing window plant. I have a plant now over five feet high, with the characteristic drooping branches. Daily showering seems to induce floriferousness. It has thus far never borne fruit. It is peculiarly free from all insects save the scale, which seems to have a special liking for it. I have tried in vain to discover why the apparently spontaneous movement of the leaves in water is at times so much more marked than at others, and suspect your statement that "in wet weather the leaves emit a pungent odor," has given me the clew.

Meetings of Societies.

Horticulture in Pennsylvania.

THE thirty-seventh annual meeting of the Pennsylvania Horticultural Society was held in West Chester last week. In the interesting report of the Fruit Committee it was said that in the south-eastern counties of the state the fruit crop was unusually abundant, being in many sections the heaviest known, while in the greater part of the state there was a slender crop, owing to late spring frosts and a dry summer. In the north-eastern part of the state the Pear blight was more destructive than it has been for twenty years. Peaches only yielded from one-tenth to a quarter of a crop; Cherries in the south-east gave a small crop, Early Richmond, Montmorenci and Napoleon Biggareau being the best varieties. Of blackberries there were practically none, and but few raspberries and strawberries. It was reported also that the San José scale, which seems to have established itself securely in the east, had already been found in half a dozen different parts of the state.

The subirrigation of Strawberries was discussed in a paper by Mr. Martin Brinser, of Middletown, who stated that there were two ways of practicing this. One was by supplying water through tiles laid underground, and the other by subsoiling, so as to hold the rain-water. This last method is quite satisfactory where there is a compact soil beneath. Deeper plowing makes a deeper reservoir, which holds more of the winter and early rains. After plowing deeply the land can be subsoiled so as to loosen the soil to a point sixteen inches below the surface. In this way Mr. Brinser had produced excellent crops of cherries during the last dry year. In addition to the subsoiling, Mr. Brinser used frequent shallow culture, which furnished a dust mulch, so that during the dry weather moisture could always be found an inch below the surface. Mr. Ingraham, of West Chester, said that he had tried subsoiling several rows of Strawberries at the foot of a hill, and the beneficial results were plain. Mr. H. M. Engle argued that while some lands were aided by this practice, he had found that in loamy open subsoils not much benefit was derived. Mr. H. D. Van Deman, formerly Pomologist for the United States Government, thought that subsoiling was one of the very best practicable methods of storing up water for crops. A layer of finely pulverized soil resembles a sponge, and if it were three inches thick it would hold half as much as one six inches deep, and one one-third as much as one nine inches deep. Subsoiling has the practical effect of under-draining—that is, it makes a wet soil drier and makes a dry soil wetter. The deeper a hard soil is loosened up the more moisture it will hold, and plants require all they can get in this latitude. The object is to hold the winter rains in a reservoir rather than to allow them to run off. Professor Heiges told of some scions he had received from Oregon with their buds all started. He grafted them and then planted them in ground from which the surface soil was

thrown off, and the trench was then deeply spaded. After planting his trees he had the surface soil thrown back, and, in spite of the dry weather, ninety-five per cent. lived, and he believes that he would not have saved one-quarter of them if he had planted without such careful preparation.

Mr. Calvin Cooper, in speaking of fertilizers, urged farmers to secure their own nitrogen with the help of leguminous plants, in doing which they will be able to get some potash besides. Another member claimed that on the cyanite grasslands about West Chester commercial fertilizers gave no appreciable returns, while on the lighter soils farther south he had a farm on which he used four hundred pounds of complete fertilizers to the acre, and nothing else. He had continued this practice for ten years, sold everything off his land and yet his crops were increasing. Mr. Van Deman thought we did not sufficiently consider the fertilizing value of tillage, since this practice liberated the plant-food in the soil. He thought that millions of dollars were wasted every year in the purchase of commercial fertilizers. It was best for farmers to buy a high grade of muriate of potash, as it contains the least foreign matter, and either bone or dissolved South Carolina rock for phosphoric acid and then try to get nitrogen by trapping it from the air and soil water with leguminous plants. When we can catch nitrogen so readily we ought not to buy such an expensive material for orchard purposes. Some soils have enough potash, but it does not leach out if more is applied. An excess of nitrogenous plant-food makes a leafy, succulent growth, and some Peach growers in Delaware, who have plowed under heavy crops of Crimson Clover, have found that there was enough nitrogen in this green manure to hurt their trees. It is their practice now to cut the Clover and turn under the roots, which contain all the nitrates necessary. Potash and phosphoric acid are the two elements most needed in orchards. In a subsequent paper, Mr. Van Deman said that potash, phosphoric acid and nitrogen were of no use unless they were dissolved, and they could not be dissolved without water. Sap is plant-food dissolved in water; then nature mulches with leaves and the like to hold the water. As fruit growers cannot follow nature's way they should mulch by tillage. Plant deep, make a basin to hold water in and cultivate to keep it there. In speaking of irrigation, he said that a one-inch pipe with six-feet head ought to irrigate an acre. Mr. H. M. Engle, of Marietta, said that an inch pipe with eighty pounds head had supplied a quarter of an acre and they paid eighteen cents for a hundred gallons of water. Some of his crops paid for this expenditure, and others did not.

The pruning of orchards was the subject of an address by Mr. Calvin Cooper, who stated that he had set out an orchard thirty-four years ago, forcing its growth while young, and now his trees are overgrown and declining when they should be in their prime. Fourteen years ago he set out another orchard on comparatively poor ground, used no fertilizers and pruned the trees freely. He starts the tree with three branches and a leader and allows branches above, but leaves an open top. The best sprayer he could find three years ago would not reach the top of these large trees. Two years ago he cut off from ten to fourteen feet from the top of each and thinned them out, and now he gets good fruit. He uses an Excelsior sprayer, making three applications of Bordeaux mixture and Paris green and occasionally some clear copper sulphate before the buds swell, if the scab was bad the year before. Varieties that do not grow upright he prunes so that the last bud is on the lower side of the limb, while those which tend to spread have the last bud on the upper side. When pruning is done in winter the bark is bruised less than at other seasons, and it will not hurt the tree if the wood is slightly frozen, but it is better to prune at some time when the tree is entirely dormant. Mr. Gabriel Heieter, of Lancaster, pushes his trees as hard as he can all the time, then puts in a crop to check growth and throw them into bearing, and afterward feeds again. He thought that Apples must bear a crop every year if they are to be profitable. This means strong feeding and the control of insects and fungi, so that the leaves will be kept on the tree to make apples mature later and thus keep better. The finest fruit grows on young trees or on the young wood of old trees. On a rich soil a young tree will bear two or three crops in succession, and then, as the fruit-buds begin to crowd, it will bear only on alternate years. An annual bearer has its fruit-spurs separate. The top should always be kept young by going about the tree with long pruning-shears and taking out old spurs. A vigorous tree will be less liable to danger from frost than weaker ones.

The last afternoon was devoted to the subject of orchard planting, in which Professor Bailey made the principal address and answered many questions. In his opinion the hope of old

orchards is to plant new ones. His advice was to make the land rich and deep to hold moisture, although he thought that subsoiling would be of only temporary value. We never have rain enough in a summer to grow crops, and hence the need of tile draining, subsoiling and the use of deep-rooted plants to break into the subsoil as much as possible. The ground should be plowed in the fall, or some other device should be used for catching the winter rain. Clayey lands after hoed crops often run together and puddle if they are fall-plowed. For fertilizers Clover was advised for nitrogen, and two hundred to four hundred pounds of high-grade sulphate of potash and about the same of bone should be used every two or three years. Four-fifths of the orchards planted never amount to anything from lack of care, and this makes the field a more profitable one for those who give proper attention to selecting varieties and growing them properly. In his own orchard he is taking pains to work his trees over with scions from individual trees that are known to be doing well, and he will spray at least twice, once just before and again just after blossoming time.

The Minnesota Forestry Association.

THE annual meeting of this vigorous organization was held in Minneapolis last week, and, among other important matters discussed, was a proposition submitted by J. M. Cross, Esq., to the purpose that the state shall receive donations of stump-lands from lumbermen on the condition that they and their heirs shall receive one-third of the proceeds for one hundred years, after which they will revert to the state. One-third of the proceeds is to go to the state for the care of the land, and the remaining one-third to whatever institutions the donor may indicate. This proposition received much approval, and was submitted to a committee for action. The value of these stump-lands was a subject of much discussion. Most of them in the state are burned over and the seeds and seedlings destroyed. They should be taken in hand at once after they are cut.

Prairie forestry was another subject which commanded much attention. The failure of the Cottonwood for general planting was noticed, and the Ash and Bur Oak were spoken of most favorably, and after them the Hackberry.

The instruction in forestry at the University was shown to be more considerable than was generally supposed, since, under other names, it covered most of the branches of the subjects which are studied in Europe. Prairie forestry now receives the most attention, and the students have the actual care of a plantation of twenty acres. The care of natural forests has not received much attention, since, as yet, there has been no demand for skilled foresters. Experiments in caring for natural woodlands were strongly recommended, so as to secure data from which a policy could be formed. It was said that estimates could be made from observation in the woods we already have which would furnish facts or principles which could be used in constructing a system for the preservation of forests, and especially for their protection against fire.

Attention was called by D. R. McGinnis, of the St. Paul Commercial Club, to the fact that the water-supply of interior continental regions is diminishing the world over, and that the people of Minnesota had reason to use intelligence in preventing such droughts as threatened the interior of this continent.

A summary of the year's work seemed to show a substantial gain, especially in the improved management of the state lands and the establishment of a system of protection against fire. Other good work is under way, with a promise of favorable results.

Recent Publications.

Down the Lane and Back. By Uncle Matt. T. Nelson & Sons, London and New York.

This little book is a talk with children about a few of the weeds and wild flowers which one would naturally find along a country roadside in England. The illustrations are admirable, and the text is so instructive that we think it is a mistake that some one has not modified it so that it will suit an American wayside as well as an English one. This is the first book of a series, each devoted to a ramble, and their character can be seen from such taking titles as *Through the Copse, A Stroll in the Marsh, Across the Common and Around a Corn-field.* After all, many of the flowers described have made themselves as much at home

in America as they are in England. Here are Nightshade, Buttercup, Dandelion, Mallow, Bindweed, Marsh Marigold, Meadow-Sweet, Plantain, Harebell and Silver-Weed running wild—either the identical ones figured, or such near relatives that the picture of one will answer for both—while the Corn Bluebottle, Ragged Robin, Wild Hyacinth and many more can be found domesticated in country gardens, so that the little books can be used to a considerable extent as manuals for young botanists even on this continent.

Notes.

It is estimated that in Ventura County, California, alone 15,000 tons of Lima beans and 7,500 of other beans are raised annually.

We learn from *Le Petit Republicain de l'Aube*, published at Troyes, France, that Monsieur Charles Baltet received the Prix Montyor for his book, *L'Horticulture dans les Cinq parties du Monde*, from the Société Académique of that city at its meeting held on the 18th of December last.

The latest results of comparative experiments with bone meal and other phosphatic fertilizers seem to show that the superior value hitherto given to the undissolved bone is due to the nitrogen which it contains and not to the phosphoric acid. As a phosphatic fertilizer bone meal gives no better results than the mineral phosphate.

In an address recently delivered in Munich, Dr. Baur, Rector of the Ludwig-Maximilian University, mentioned that sixty per cent. of the wood now yielded by the state forests of the kingdom of Saxony is used in the manufacture of paper pulp. In other European districts there is likewise a great and growing demand for timber for this purpose. And the extent of the demand in this country may be divined from the fact that pulp mills have been built at seven places in the single county of Penobscot, in Maine, and that the daily product of three of these mills constitutes a train-load of paper pulp, usually consisting of eighteen or twenty car-loads.

Dr. D. T. MacDougal has taken pains to verify the results of former experiments, which show that the leaves and stems of adult plants of *Cypripedium spectabile* and *C. pubescens* exert a poisonous influence on the human skin. Later tests with both these plants and *C. parviflorum* establish the fact beyond doubt that all three of these species are poisonous. The irritant action is found to be due to a secretion of the glandular hairs. On account of the extremely small quantity of this secretion its exact chemical nature has not yet been ascertained, but it was found soluble in alcohol and gave the reaction of an oily substance. The irritant action of the plants increased with their development and reached a maximum effect during the formation of the seed capsules.

A memorial has been addressed to Congress by the legislative assembly of Arizona, asking that the lands covered by the famous "petrified forest" should be reserved as a public park. They form an area about twelve miles square and lie in the heart of the Apache country. But, despite the remoteness of the spot, curious tourists have already wrought much damage to the singular and beautiful petrifications, commercial enterprise has been active in the exportation of specimens, and even the residents of the country who do not try to make money out of the "forest" seem also to be active in willful depredations. It is reported that, not long ago, a cow-boy rode his horse over the most remarkable petrified trunk, which forms a natural bridge above a ravine, in the mischievous hope that he might thus break it down. There are no settlers upon this tract of land, and therefore its reservation would not injure or even inconvenience any one, while it would preserve an array of natural curiosities which are unique of their kind and as interesting to the lover of the picturesque as to the scientific student.

For many years the boxes in which plug tobacco was packed in the United States were made of Sycamore lumber (*Platanus*), which, owing to its properties of great strength and freedom from all odor, made it the favorite wood for this purpose. It is now stated by *Hardwood*, however, that there is not enough Sycamore lumber manufactured in the United States to supply twenty-five per cent. of the plug tobacco boxes used annually, and that Gumwood, *Liquidambar*, is going to be the popular wood for this purpose, if it is not so already. Formerly the plugs were pressed by powerful machinery directly into the boxes, which therefore had to be made of some strong wood.

Most manufacturers now, however, have iron or steel moulds into which the plugs are pressed into a body of exactly the size of the wooden boxes in which they are marketed. This plan allows the use of lighter boxes without cleats or corner-pieces; and many of these light boxes are now made from three thin layers of Gumwood, the middle layer being placed transversely to the other two and the whole solidly glued together under great pressure. Gum boxes made in this way are said to be substantial and durable. Rock maple and black birch are also used in some factories for tobacco boxes, but probably not to any great extent.

We have often spoken with regret of the wanton destruction of song-birds in this country, not only because their beauty and melody are a delight to all who live in the country, but because they are such important auxiliaries in the war against insects injurious to vegetation. This wholesale butchery is by no means confined to our own country. A recent number of the *Fortnightly Review* states that forty thousand larks daily come into the London markets, where poulterers sell them by the bushel. Besides those sold for table purposes, there are thousands killed for their feathers, their wings, when dyed so as to counterfeit tropical birds, being worn for ornaments. Large numbers are also trapped to let fly at shooting-matches, and many more are sold to be confined, not as household pets, but by gamblers, who, strangely enough, keep them and bet on their powers of song, although how such matches are decided one can hardly understand. All this makes agriculture and horticulture more difficult in England, where, under any circumstances, it is none too prosperous. But what seems surprising to Americans is that public sentiment in England will allow the extermination of a songster which seems to be such a favorite and holds so high a place in the poetical literature of the language.

A few boxes of grape-fruit from southern Florida and, perhaps, fifty barrels from Jamaica made up last week's supply for this city. The Jamaica output is nearly exhausted; much of this fruit now coming is of hybrid origin, and other, no less inferior, is gathered from old and neglected trees. This small thick-skinned fruit sold for \$5.00 a barrel, while large specimens, with the fine quality of skin known in the trade as silky, readily brought \$7.00 to \$8.00 a barrel at wholesale, and the choicest from Florida commanded \$10.00 a box. On Monday of this week a dozen barrels from Jamaica were eagerly bought up on the dock at \$12.37 each, and owing to the scarcity and prevailing high prices so small a lot as two boxes was included in a large shipment of citrus fruits received from California on the same day. Grape-fruit has been known in this city only about twenty years, and so little was it appreciated fifteen years ago that some of each lot from the Bahamas was reshipped to England, where the prices, \$7.00 to \$8.00 a barrel, were double those obtained here for a very limited quantity. During the last five years the demand has increased rapidly, and each of the past few years has seen the supply doubled, until this season of scarcity due to the freezing of the trees in Florida last year.

In the recently published report of the Dean of Barnard College, in this city, which covers the year 1895, we read: "In view of the importance of her work, the responsibility she carries, and the learning and ability that enable her to bear it, the title of Professor of Botany has this year been conferred upon Dr. Gregory, with the approval of the President of Columbia College. Her department is doing its full share of university work, besides containing successful classes of special students and undergraduates. It has this year four candidates for the higher degrees and five for the Barnard Certificate. Its exhibit at the exposition of the Academy of Natural Sciences attracted much favorable attention. The department is one which has been of interest and usefulness to the community. But, though its progress is gratifying, it is also expensive. Professor Gregory reports that it is impossible to carry out our plans in regard to advanced work with our present equipment. A much-needed course in plant physiology, for instance, calls for materials and apparatus which are not at our command." The state of things which the Dean thus makes plain seems to offer a good opportunity for practical benevolence to some person of botanical tastes who is likewise interested in the higher education of women. Certainly there is no pursuit in which certain qualities which have always been considered characteristically feminine ought to make themselves felt to better advantage than in the higher branches of botanical research. We mean those qualities of patience, perseverance, careful attention to details, preciseness in observation and delicacy in manipulation which this branch of science conspicuously demands.

The Shrubbery in Winter.

IN another column a correspondent calls attention to some winter effects in the wild shrubbery which interested him, and, perhaps, it is worth while to repeat what we have often said—that when home-grounds are planted there are many cases where more attention should be given to their winter aspect. Where a house is occupied in summer only, the principal aim should be to make it attractive at that season. There are many trees and shrubs which are conspicuously beautiful in spring and autumn, and, of course, there are places where the selection of species and varieties should be made with special reference to these seasons. But where a country house is occupied in winter it can readily be seen that in some part of the grounds commanded by the windows of rooms appropriated for winter use provision should be made for the prospect at this season. In the middle of this century it was not uncommon to have a glade or lawn in such a position bounded by Spruces, Firs, Hemlocks, Pines and other conifers with such broad-leaved evergreens as Kalmias, Rhododendrons, American Hollies, and some herbaceous plants with persistent foliage, like Yuccas, for example, and the whole brightened by a few shrubs with colored fruit, like the Carolina Rose, Black Alder, Cockspur Thorn, Snowberry and Bittersweet. Such an arrangement has some merits, although the idea that this green foliage brought in a touch of summer when January was at its bleakest was rather fanciful. Any effort to produce summer scenery in winter must be a failure, as, indeed, it ought to be, for what is desirable at a particular season in the landscape is an effect which will harmonize with the prevalent tone of that season, rather than one which conflicts with it. As a matter of fact, however, there is no hint of summer in the winter aspect of evergreens. In freezing weather their darkened foliage only emphasizes the strength of the cold, and the particular human interest they have at this season is their hospitable suggestion of shelter against the driving winds. Whatever is especially home-like and companionable or genial in their winter appearance is not that they remind one of summer verdure, but that they are sturdy enough not only to brave the wildest weather, but to give us some protection against its blasts.

Following the fashion imported from the mother country, coniferous trees were too exclusively planted in the early years of the century, and we can all remember country houses which were half-smothered in summer under the gloom of their heavy foliage. Perhaps the reaction against this has been too decided, and some of these trees which are beautiful at all seasons are too much neglected. Nevertheless, there is an abundance of beauty and variety to be found in deciduous trees and shrubs at this season, and in any scheme of planting for winter effect in this climate they should have the largest place. Most trees have a beauty in winter which is quite as distinct and individual as it is in any other season. Indeed, this is the best time for studying the peculiar structure or framework of a tree—that is, for noting how its branches diverge and the manner in which they break into spray. The special characteristics of a particular species, whether of dignity or grace, are shown as well when the trees are stripped of their summer garments as at any other time, and never until the leaves are gone can we mark the peculiar beauty of the different figures made by the interlacing branchlets against the sky. There is no need to speak of the endless varieties in the shade and texture of the bark, both of trunk and limb and spray, and it is well known that the richest colors in a winter landscape are those of the warm browns of a distant wood. The colors of the small twigs are especially varied, too, and the tinted mist which hovers over a shrubbery a few hundred feet away is collected from the mingled colors of the bark on the smaller branches.

This brings us to a point in planting shrubbery for winter effect which we wish here to insist upon. In former articles we have given lists of various shrubs which are ornamented with brightly colored fruit until midwinter, but we have not so often named those whose bark lends a pleasing color to the short days of the year. The glossy green branchlets of the Kerrias, the golden bark of the Willows which warms into still brighter yellow with the approach of spring, the ashen gray of some of the Viburnums and the scarlet twigs of the Dogwoods make pictures of unflinching beauty, either against the glittering snow or the brown earth. Taking the Cornels alone one is surprised to find the variety of form and color they display at this season. Our common Red Osier, *Cornus stolonifera*, with its broad leaves, pale flowers and bluish white fruit, is ornamental all summer. Its leaves turn purple and yellow in autumn, and now its purple-red branches sustain its beauty in mid-winter. There is a variety of the plant, too, with golden-yellow bark, specimens of which have been exhibited by Mr. Warren Manning at the Massachusetts Horticultural Society, and it is distinct and striking. *Cornus alba*, the common European Red Osier, which is often sold by nurserymen as *Cornus sanguinea*, is another bright-barked plant. It is a variable shrub, and one strain, which is called *alba Sibirica*, has stems of almost vermilion. *Cornus circinata*, too, one of our native species which is found on wooded hillsides, in addition to its beautiful flowers and light blue fruit, has red and yellow stems which are sometimes finely mottled, while *Cornus candidissima* has an ashen gray bark of a singularly soft texture. Certainly a group of these Cornels properly arranged gives a pleasing stretch of varied color, and with judicious selections from other families, by harmonious contrasts, a most interesting feature can be added to our winter landscapes.

The San José Scale in New Jersey.

IN our report of the late meeting of the New Jersey State Horticultural Society, brief mention was made of a paper on the San José scale by Mr. Charles R. Parry, in which he described its destructive nature, the spread it had made in the state of New Jersey, and asserted, from his own observation and from information obtained during his visit in California, that certain natural enemies were controlling it in that state, and that the growers had ceased to regard

it as a pest to be dreaded, largely because of these natural enemies. These enemies, certain ladybirds imported from Australia against the fluted scale, Mr. Parry had tried unsuccessfully to introduce into New Jersey, and he argued that the best hope for the control of this destructive pest in that state lay in securing a supply of them. The paper brought out some discussion, and it was held by some of the most careful observers that differences of climate would prevent the ladybirds from being as effective here as they are in California. Since this meeting we understand that a flying visit through the infested regions has been made by the Entomologist of the New Jersey Experiment Station, who has discovered that Mr. Parry's assertions concerning the spread of the scale were unfortunately too well justified. In many orchards where the presence of the scale had not been previously suspected it was unpleasantly conspicuous, and one case was discovered where the insects had been carried for nearly, if not quite, a mile in a straight line, probably by the agency of birds. In the course of an address before the New Jersey State Board of Agriculture, held at Trenton January 14th, Professor Smith called attention to these facts and to the danger threatening the fruit industry of the state. So much alive were the farmers to the importance of the subject-matter that, after some discussion concerning the probability of a successful importation, a resolution was adopted, asking the Legislature of New Jersey for an appropriation of one thousand dollars for the purpose of importing into the state of New Jersey such of the predaceous or parasitic insects as might be found feeding upon the scale in California or elsewhere. The resolution was unanimously adopted, and was at once referred to the legislative committee and will be pushed as soon as the Legislature reconvenes. There is no doubt as to the importance of the matter, and there is no doubt that the state of New Jersey owes it to so important an industry as that of fruit-growing to offer it every possible measure of protection. The sum asked for is ridiculously small compared with the possible benefits, and there seems to be at least a fair chance of success. Of all the Atlantic fruit states New Jersey is worst infested and has most to lose, while offering unusual facilities, from its numerous closely set orchards, for the spread of the scale.

Perhaps it is worth stating that the late Dr. C. V. Riley, by whose advice the predaceous insects that so completely destroyed the Cottony Cushion scale were introduced into California, after visiting that state early in 1895, argued at a meeting of the Entomological Society of Washington that an attempt should be made to import the coccinellids from the Pacific to the Atlantic coast. The opinion of so conservative a man ought to have some weight in a question like this, and we think that there is sufficient probability of success to justify the experiment.

Self-reliance in Farming.

IN a recent editorial article in this journal it is said that one advantage of a broad education in agriculture is that it makes more self-reliant men, and I am prompted to add a few observations on this subject. For many years the farmer has been scolded on every hand for following the ways of his father and grandfather in managing his farm. This steady rain of advice, urging him to turn from the accustomed ways of his fathers, was freely offered even before there was sufficient knowledge of a true science of agriculture to give the advice any specific merit. If the farmer must take up new ways, it was not too much to ask that these new ways be defined and described. But, for the most part, no adequate method of revolution was proposed, although it was easy to see that there was reason enough for a change. Under the circumstances, the farmer, of course, did little or nothing. He felt that little could be gained by jumping from the frying-pan when the chances were that he would land in the fire. He accepted the advice as good on general principles, but he saw no way of paying mortgages with it.

Now all has changed. With the advent of the experiment stations and the Babel of new teaching, there are methods and to spare for the improving of farming. The farmer will be scolded no longer. He will convert himself to the new ideas forthwith, and he will ask for advice and help in every emergency; for, were not the stations and the agricultural colleges made for his benefit? But, really, the great danger now is that the farmer will lose something of his accustomed balance and self-reliance, and desire a doctor from an experiment station whenever a strange bug or a perverse soil perplexes him.

Every experiment station is burdened with questions which it cannot answer, and never can answer. They are local questions—questions which do not have to do with principles, but with the particular matters which pertain to the one farm or to the personality of the farmer. The commonest question of this type is, "What varieties shall I plant?" Now, this question no one can answer for another. It is purely a local and personal question. For myself, I invariably refuse to advise. I am willing to say that I know some varieties which please me, and to name them, but I cannot advise any one else to plant them. The question really shows that the questioner has not yet mastered and adopted the fundamental principle of the modern teaching, which is that every man must manage his farm as seems best for his particular conditions and aspirations. If he asks what varieties of apples he shall plant for drying, or what he shall plant for the foreign markets, then a more direct answer can be given him; and the questioner has arrived at the point of observing that successful farming is not copying after others, but is the working out of a local problem.

All this is equivalent to saying that the experiment station and the agricultural college do not exist for the purpose of managing everybody's or anybody's farm. More than ever before, the farmer must collect opinions and evidence, then weigh them and choose. The stations should enunciate principles—illustrating them by concrete examples—rather than lay down rules.

L. H. Bailey.

Trees of Minor Importance for Western Planting.—II.

THE Russian Mulberry was brought to America in great numbers by the Mennonites, who, during the decade following 1870, settled in large colonies in Marion, McPherson and Harvey counties, Kansas. By them it was introduced to their American neighbors, and was quite extensively planted in that vicinity. Many of these planters seem to have expected too much of it, for it has evidently declined in favor in recent years. As grown in this section, it is notably polymorphous in fruit, foliage and form of the head. Varieties appear bearing pure white fruits, and others deep black ones. Occasionally a tree of the black-fruited sort appears to be wonderfully productive. I have seen the fruit sold in the market, bringing six to ten cents a quart, but the demand is not great, and the bargain is a poor one for both buyer and seller. The fruit cooked with gooseberries or other very acid amendments is palatable, and in the absence of blackberries and raspberries is not altogether to be despised.

Throughout central Kansas and eastern Oklahoma *Morus rubra* is native to the streams, and though not common, wild or cultivated, makes a good tree. In the scattered instances where I have seen it planted it gives a uniformly vigorous growth, with clear straight trunk, symmetrical top and dark rich foliage. It seems to me that it should have had a more extensive trial in timber plantings.

The western limit of the Sycamore, *Platanus occidentalis*, runs through Salina, Marion and Winfield, Kansas, and Guthrie, Oklahoma. East of this line it is neither abundant nor uncommon along streams, and within its natural territory is sometimes used as a shade tree or for streets. It seems to be well adapted to street-planting. The best planted specimens I have seen are at Manhattan, Kansas, where one tree in particular, standing by itself and having

a remarkably straight and symmetrical form, has always met my warmest admiration.

The Hackberry is indigenous over as great a longitude as almost any western tree, yet it has very seldom been planted. I know of no plantings from which any judgment of its value might be formed.

University of Vermont.

F. A. Waugh.

Water against Frost.

OF course there is no way of protecting plants or crops from injury when the temperature falls several degrees below the freezing point, but for light frosts the practice of burning any material that will form a dense smoke has been found useful in vineyards by forming a canopy over the field, which prevents the escape of heat by radiation from the ground. Protection by water is, however, more practicable than protection by fire, and we condense the following notes from an article by Professor Kedzie, of the Michigan Agricultural College, which appeared originally in the bulletin of the Michigan State Weather Service:

The vapor of water in the atmosphere may control excessive changes of atmosphere in two ways: (1) By condensing into water, it liberates enough heat to raise through one degree the temperature of a thousand times the amount of water condensed, and hence it arrests the fall of temperature by giving out heat. In this way the beneficent dew becomes a warming-pan for chilling fields. (2) Vapor of water in the air as well as clouds prevents the escape of heat by radiation from the soil, and the consequent cooling of the air by night. But for the vapor of water in the air we should have a frost every night in the year. Professor Tyndall says that the removal for one summer-night of the aqueous vapor which covers England would bring about the destruction of every plant which a freezing temperature could kill.

If the farmer is forewarned of the approach of a slow frost he may do something to avert the calamity. The old plan of a tub of water under a fruit-tree with a rope reaching from the tub into the branches may serve a useful purpose. The evaporation from the water in the tub and of the water carried up through the rope may spread a water blanket about the tree. Of course, such an appliance, while of some use in a small garden, would be futile on the farm. The shallow cultivation of hoed crops draws by capillary action upon the reservoir of water in the subsoil and keeps the surface soil in a condition which prevents the rapid distribution of soil moisture, and in this way saves the fields from frost by a covering as impalpable as air, but as effectual as eider-down. One night the Indian Corn in Michigan was almost entirely killed by frost, but a few fields on the banks of rivers and the borders of lakes were spared. In these fields the Corn-stalks next morning were dripping with dew. There had been but one-eighth of an inch of rain in two weeks, but evaporation from river or lake had moistened the air and staved off the frost. If the air over the whole state had been as moist as it was along the rivers a heavy dew would have fallen everywhere, and the corn crops would have been saved. Beds of Coleus and other tender plants which have been thoroughly wet down with cold water in the evening have escaped frost in October when other plants near by were killed, and grapes have been saved by drenching the vines with water. Strawberries and Grapes in blossom may be saved in the same way if a good supply of water and a sprinkling hose are available when there is threatening frost. Even after severe frosts grapes have been saved by thorough drenching with water early in the morning.

Mr. E. P. Powell says that the best preventive against frost is a thorough spraying with water during the evening and night. By this means the danger from a fall of two or three degrees can be averted, and this will often save a whole crop.

Foreign Correspondence.

The English Fruit Market.

ONE of the leading salesmen of Covent Garden Market, Mr. G. Munro, lately dealt with the subject of the fruit-supply of England in a paper read before the Horticultural Club. It is difficult to arrive at even an approximate estimate of the annual consumption of fruit in the United Kingdom, but as the bulk of what is placed upon the market passes through Covent Garden, Mr. Munro is in a

position to gauge the supply with some approach to accuracy.

There are between seven and eight hundred porters employed day and night in Covent Garden Market in unloading and delivering English produce, and one hundred and fifty on the average employed on the foreign supply. Many English growers, and not a few among the foreigners who send fruit to England, find it advantageous to consign their produce direct to large centres all over the country, such as Manchester, Leeds, Glasgow and Edinburgh. Mr. Munro stated that the English are becoming much larger fruit-eaters than they were, the demand having increased to such an extent that the principal growers find it more profitable to become specialists. "The grower who sends the largest quantity of a good article regularly, makes a large connection for his goods, large consignments often selling to better advantage than small ones, though the quality of the latter may be equally good."

Where the foreign grower competes with the English in supplying the same kind of fruit he generally succeeds for the following reasons: 1. He packs his fruit carefully and honestly and never fails to grade it. 2. He grows only sorts that are sure to sell, and in such quantities that he can keep up a regular and continuous supply. This is shown in regard to apples, which are rarely a profitable crop with the English grower, notwithstanding the suitability of our climate for this fruit and the fact that English apples are far better in quality than any foreign. "I was in a large wholesale store in Manchester this autumn where they had English and American apples side by side, and on asking the quantity of each sold I was informed about three thousand bushels of American against one hundred bushels of English, and simply because the packing of the latter could not be depended upon."

Apples are imported into England nearly all the year round, commencing in April from Tasmania, followed by supplies from France, Italy and Germany, and in winter from the United States, Canada and Nova Scotia. American apples are better in flavor than those from Tasmania, and, as a rule, they sell at prices which would scarcely remunerate the English grower. Mr. Munro does not deal with the question of cost in producing, nor yet with the relative uncertainty of the seasons in England.

Pears are imported chiefly from France, Italy and California, the latter arriving in excellent condition and being of good flavor. About a thousand cases weekly of Californian pears, chiefly Easter Beurré, arrive in December, and about six times that quantity in September. Strawberries, currants and cherries are imported in enormous quantities from France and Spain. Plums, such as the Green Gage, are received from Italy, France and Germany for a period extending over about three months before the English crop is ripe, as many as ten to fifteen thousand flats being often sold daily in Covent Garden alone. Thus, the English consumer gets a surfeit of these fruits by the time the home supply is ready.

Pineapples are received in shiploads from the Azores, and although the prices they realize are much lower than they used to be, the supply is steadily increasing. The cost of producing pineapples in England is so great that an English-grown pineapple is a novelty in the market. Pineapples are also received from Africa and Florida.

Bananas are sold in increasing quantities annually, the quality of the fruit being superior to what it was before, now that choice sorts are grown and greater care taken in the transport. There are much better sorts known even than the best of those grown by exporters now, and if only growers will take trouble to secure these the demand for this most delectable of fruits will increase greatly. The ordinary banana of the fruiterer is mawkish and poor in flavor compared with the fruit of such varieties as Ran-Kela, Champa and Pisang Rastalei. Mr. Munro stated that the bananas received in London and Liverpool in November last, from the Canary Islands alone, numbered nearly thirty-seven thousand bunches.

Peaches and nectarines grown in England, if of good quality, find a ready sale, and suffer nothing from the competition of foreign supplies, which are either of inferior sorts, unripe, or too much damaged to find much favor. Expert growers of these fruits contrive to maintain a supply from April to November by cultivating a variety of sorts under different temperatures. Mr. Munro says there were often a thousand boxes of English-grown peaches and nectarines disposed of daily last year in Covent Garden. I have tasted here peaches from California which compared favorably with the English-grown fruit.

Grapes are in greater demand than ever. Enormous quantities are imported from the Cape, Spain, etc., yet cultivators in this country find this fruit a profitable investment, the acreage of glass devoted to it being largely increased every year. I am told that good grapes grown under glass in England pay at one shilling per pound. The varieties cultivated are chiefly Alicante, Black Hamburg and Gros Colman. About one thousand tons of English-grown grapes are now annually marketed in this country, and nearly twice that quantity are received from the Channel Islands, where grape-culture has become a staple industry. Even Belgium sends forced grapes to the English market, about two hundred tons being received from that country last year, a prohibitive duty practically closing the Paris market to them.

Cucumbers at one time were largely imported from the Continent, but now English growers supply the Continental markets as well as their own. Mr. Munro estimates the supply of this fruit from March to the end of July at about fifty thousand per day.

The increase in the consumption of Tomatoes in England within the last ten years has been phenomenal. They are a certain source of profit to the beginner with limited capital, being easily grown and marketed and readily sold. The quantity of house-grown fruit that passed through Covent Garden Market alone from March to November is estimated at two thousand tons, and this is probably only a tithe of what is marketed throughout the country. I know a market grower in the provinces who cannot sell apples and pears at any price, while his tomatoes offered direct to the same consumers sold readily at sixpence per pound, the price asked for six pounds of apples. My friend proposes to leave the supply of apples and pears to the foreigners, and to devote himself entirely to tomatoes and cucumbers.

New or Little-known Plants.

Chrysanthemum, Mayflower.

THIS plant was raised in 1892 from seed of Fascination by Mr. John N. May, of Summit, New Jersey, and it was exhibited for the first time in the autumn of 1893, but it received comparatively little notice on account of the fact that it was rather too early for the great exhibitions. It was distributed in the spring of 1894, and at the autumn exhibitions that year it took prizes wherever it was shown, while the flowers sent to market by Mr. May brought higher prices than those of any other variety. The plants had a remarkable sale last spring, and in the autumn the flowers took the leading prizes in most of the great cities of the United States wherever white varieties were in competition. It is a first-rate flower for commercial purposes, and ranked last year in our leading markets as the best of its season. It is a sturdy grower, with large handsome leaves and remarkably stout stems, carrying erectly massive, though not coarse, blooms of a pure white color and of firm texture. It has the light and somewhat fluffy appearance of many Japanese incurved varieties, and the florets are wavy-twisted, the lower ones being reflexed (see fig. 5, page 45). It was at its best this year during the last week of October and a few days into November, though, with careful management, Mr. May thinks it can be carried well into the

middle of the latter month. Last year the largest flowers measured eight to nine inches through and from twenty-two to twenty-five inches over from the lower petals on one side to the same point on the other.

Cultural Department.

Lily Blight.

THE Lily blight, which has not troubled plants in this locality to any extent for a number of years, was noticed here last season on a good many species. It seems to attack *Lilium candidum* first, and spreads from it on to the other early sorts. I have noticed the blight on the fall growth of the leaves of *L. candidum*, and have wondered if it did not winter on these and spread in spring from them. It was noticed as late as December, after cold weather had set in. Of course, one's opinions formed from a single year's experience may not be correct, but, from what I have seen, I am led to believe that a timely and thorough application of the Bordeaux mixture will overcome it to a great extent, if not entirely. I was surprised to note that our native Lilies were among the first to be troubled. *L. Canadense*, *L. superbum* and *L. Philadelphicum* were troubled, but it did not apparently injure their bulbs. It may be that, though the mixture was applied to these after the disease had made considerable progress, it prevented its descending to the bulbs. *L. Humboldtii* and *L. croceum* bulbs seemed to suffer more than any others noticed. *L. Parryi* was cut down by it, but the bulbs were left apparently sound. *L. giganteum* and *L. cordifolium* both were injured. A bed of the two or three varieties of *L. speciosum*, which had come up very early and had been nipped by the late spring's frost, were cut back by the disease, while other lots of this same Lily were not touched. The bulbs of *L. speciosum* were not apparently injured, except that they did not make any growth. The blight had made a good foothold before I was prepared to apply the remedy, and on this account I believe that if I had taken it in season very little damage would have been done. It had gone so far that the flower-buds of *L. Leichtlini* began to droop and they seemed past help. I was surprised to see these recover after the first application and develop good-sized blooms. A friend who had been troubled with the disease, in another state, had advised me to cut down at once all stalks that had been affected. I did so with every plant of *L. croceum*, and they were injured in the bulbs the most of any. I believe if I had not cut them down, but had used the mixture on them, I would have saved all of the bulbs. I noticed that some species could be entirely cut to the ground with the blight and still no apparent damage was sustained by their bulbs. Others, like *L. Humboldtii* and *L. croceum*, would be affected. A bed of *L. Nepalense* had been planted very late, the bulbs having been brought that same year from Burma. As soon as these began to form leaves of any size they were attacked by the blight. I applied the remedy several times very thoroughly, and saved nearly all. They gave very fine blooms and were the last Lilies to flower, some buds opening after the leaves had frozen turning dark.

I think the best time to apply the remedy is before it shows itself, or immediately after. It will not do to wait long after the first spots are noticed. The mixture should be applied in a fine spray to the upper surface of the leaves and also to the stalks, so as to completely cover them. I found that the mixture was more effectual when used soon after it was prepared. To facilitate the application of the mixture I prefer to have my Lilies in rows, two or three abreast, and the rows far enough apart to admit a narrow cultivator. In beds it is almost impossible to touch all of the leaves and stems in the centre of the bed with the mixture. Of the Tiger Lilies, the variety called *Splendens* seemed free, or nearly so, while both the common Tiger Lily and the double Tiger Lily were affected.

The blight was noticed more or less on about every species I had, but on some of them it was very light. I noticed that *L. Henryi* seemed least affected, although it was near plants of *L. candidum*. This species, if it will stand cold weather, is one of the surest to succeed. Young Lilies, too small to bloom, were soon cut back. The blight seems to prefer their more tender leaves. A lot of small *L. Canadense* cut back in this way very early in the season were transplanted and the bulbs seemed to be perfectly sound. Young bulbs of *L. Wallacei* were affected, and when these were reset many had to be discarded. These had been entirely killed down to the ground before the mixture was applied.

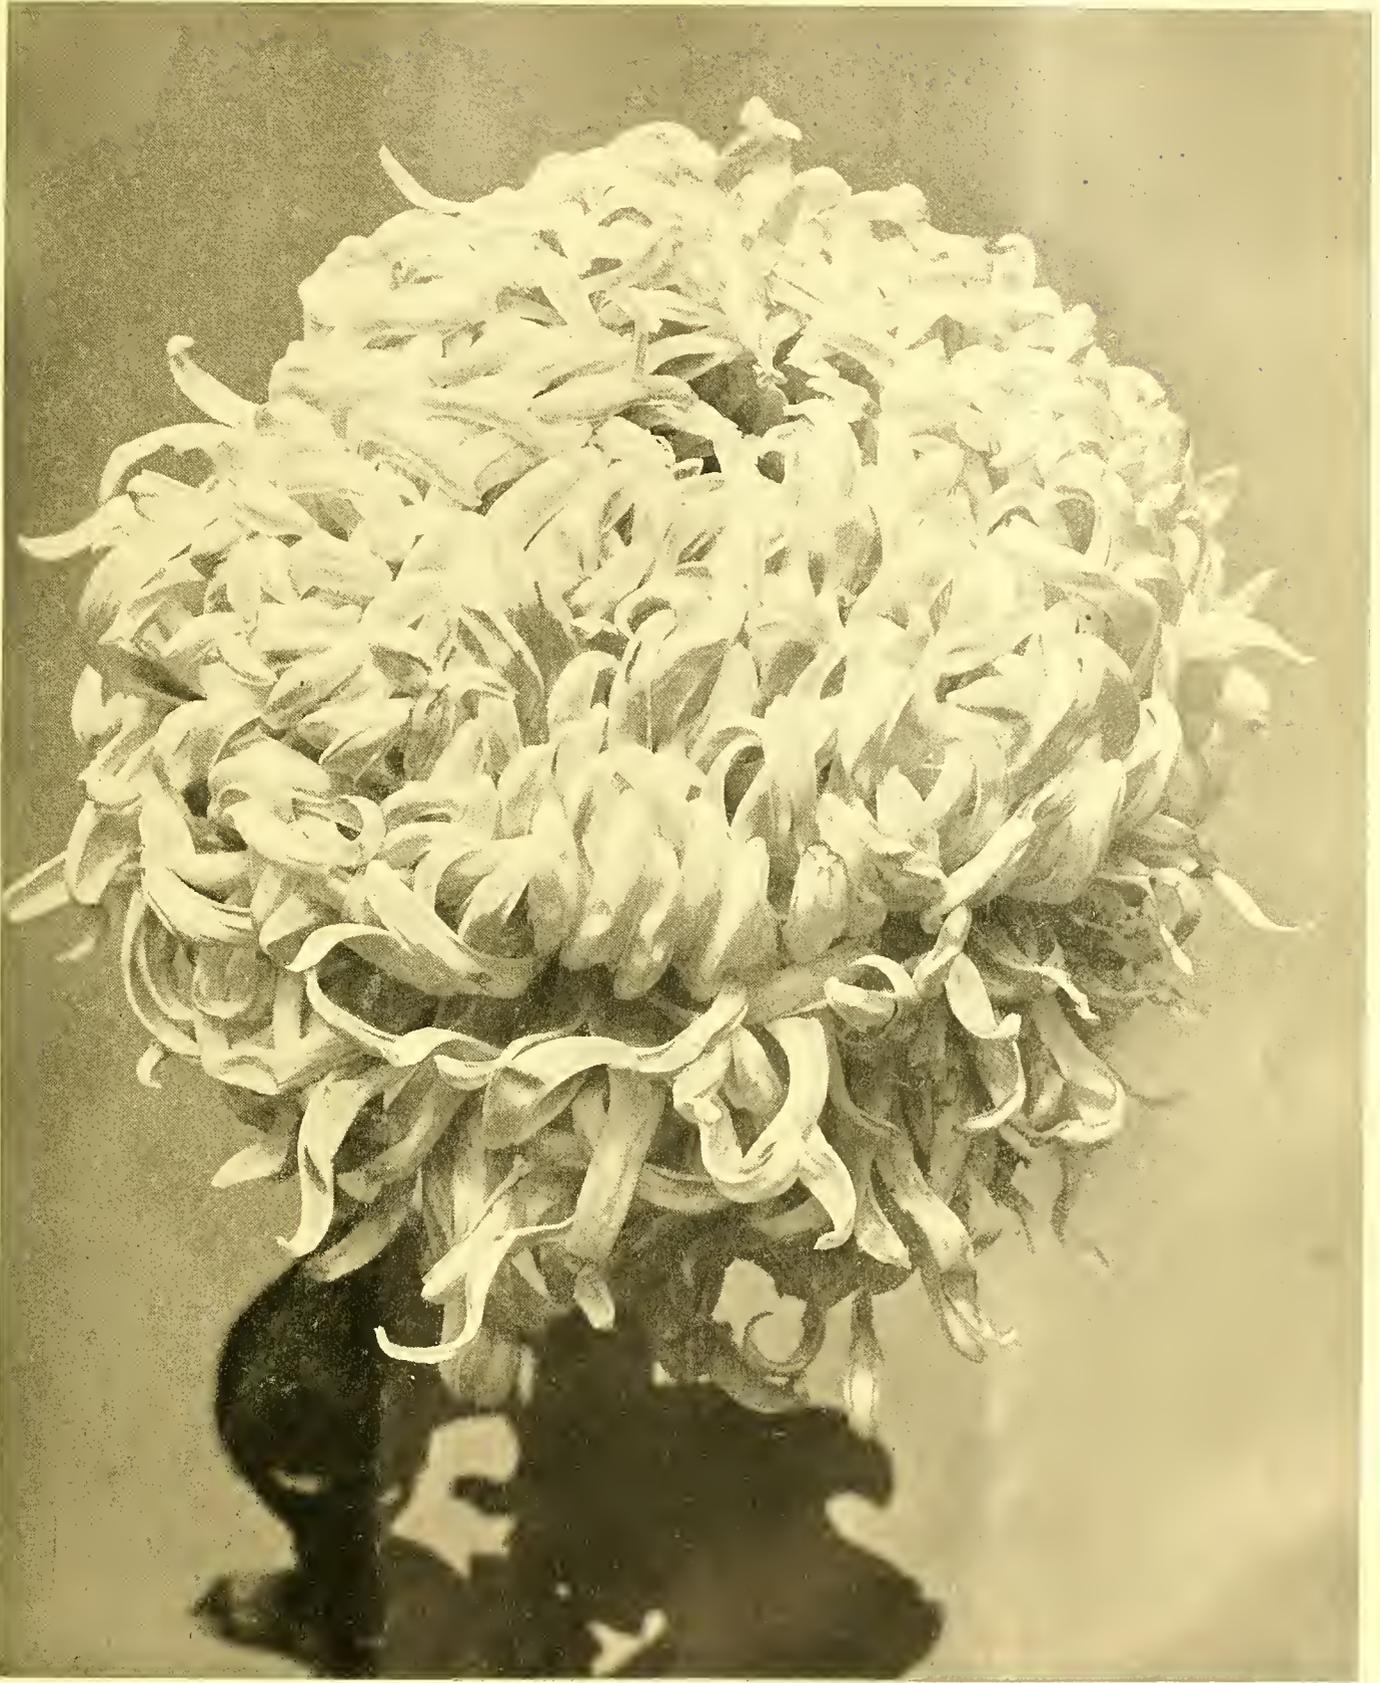

Fig. 5—Chrysanthemum, Mayflower.—See page 44.

The Lily blight is not new to this town. It was noticed here by Pringle fully fifteen years ago. It seems to come and go like the Potato blight, which it closely resembles in many ways. A part of last season was quite favorable to the development of both in this section.

Charlotte, Vt.

Cultural Notes on Orchids.

THE close observer of this class of plants, whether a cultivator or a plant physiologist, cannot fail to remark that there are certain periods of rest and activity that are well marked by the plant itself. Sometimes these periods do not conform to our seasons, but, for the most part, the plants adapt

themselves to the changed conditions under which they are placed, and respond to a rational system of treatment. It often puzzles the grower to know what to do with a plant that has apparently made its growth for the season early in the fall months and then makes another start, the later growth having to finish up during our winter months under adverse conditions as to light and air, the two most potent factors after warmth and moisture. This is frequently the case with newly established plants which have not quite adapted themselves to the changed seasons. Sometimes it occurs in the case of well-grown plants that have been in a collection, perhaps, for years. We have come to the conclusion that to try and retard this tendency by keeping the plants overdry at the roots is to cripple seriously latent energies; to place them in a warmer temperature with more moisture to encourage this growth results in throwing the whole mechanism of the plant out of gear. We have found it best to ignore the fact that anything abnormal is going on and to let nature rectify its own error, if error it be. Often this seems to be merely a safety valve for the escape of a superabundance of vigor, for, excepting the newly established plants, this peculiarity is confined to plants that are the most robust.

European cultivators, to whom we have been indebted hitherto for our works of reference on this subject, have laid great stress on the ripening up of growths by withholding moisture, but, aside from the fact that this system is not practicable here, owing to the greater amount of sun we get and the much larger amount of artificial heat required to maintain the proper temperature for the plants. All these conditions tend to exhaust the store of moisture, which in the case of a *Cattleya* bulb, whether old or new, averages over ninety per cent. Aside from these facts, the most advanced cultivators in Europe are beginning to see the fallacy of this system and to teach a more rational treatment.

It is also easily seen by the interested student that there are times when a plant is putting forth new efforts in the way of a bunch of young live roots from the base of the last-made growth. Often this is by way of fortifying itself for the crowning effort of producing flowers, and sometimes of recuperation afterward. In either case it will be found good practice to take advantage of these signs and to give any encouragement possible, such as new material and a larger pot if this is deemed necessary, remembering that decayed inert matter about epiphytal Orchids is death to roots, whether young or old. Care should be taken to remove every particle of decay by directing a jet of water on the mass before placing in new material. It would have been considered bad treatment by the authors of the reference-books to repot a *Cattleya* at the approach of the dull winter months, but it will be found here in practice that any day of the year is a good time, provided the plant shows signs of renewed activity at the roots, a sure index that will never betray either the plant or the cultivator.

Cypripediums are to be regarded more as terrestrial plants. They will take water freely all the year, and may be repotted at almost any time. This is a good time, as the roots are, for the most part, dormant, or have but few growing tips, and these are not so easily injured as the brittle white roots of the epiphytes. If a *Cypripedium* holds tenaciously to the pot in which it is, as is often the case with older plants of *C. insigne* and its hybrids, it is well to soak the roots in water the day before potting, and, if it is necessary, to break the pot to liberate the roots. The broken parts will easily separate when charged with moisture, and this is true of *Cattleyas* and other genera. It is not economical to spare the pot when the contents represent, possibly, as many dollars as the pot does cents. For such Orchids as require a quantity of water at all seasons it is safe to use sphagnum-moss liberally in the potting material. *Cypripediums* and *Odontoglossums* belong to this class. *Dendrobiums*, we find, do well in moss alone, for it can be easily washed out each year and new living moss added, but for *Cattleyas* we have for several years used no moss, and only the best grade of *Osmunda*-root. The moss, we find, only hastens the decay of the fibre, and when the latter is used alone there is no danger from overwatering, and the compost is well aerated at all times, a condition favorable to the development of good live roots, apparently the basis of vigor and success.

Much can be done to render the atmosphere agreeable to the occupants of our plant houses besides the ordinary applications of moisture on the paths. An occasional damping down with some liquid stimulant is desirable, and we have found that a minute proportion of sulphate of ammonia in the water has a beneficial effect, giving a healthy green color to the foliage. A quantity of Oak leaves brought in twice a year

and placed under the centre benches helps to give off ammonia. These should be well treated with air-slacked lime to prevent snails and other insects from coming forth, but I am told that the lime would help to impoverish the supply of carbonic acid gas, and in this way not be a benefit, although liberating the ammonia contained in the decaying leaves. Fresh air, as often as available, is one of the chief essentials to keeping a healthy atmosphere. This is not easy when the temperature is far below the freezing point outdoors, but a system of ventilators near the heating pipes makes it easy to warm the air as it comes into the house. Even in hot weather this is the better way to change the air in preference to opening wide the top ventilators and letting out all of the carefully balanced moisture-laden atmosphere we have been at so much trouble to prepare. Greenhouses are seldom constructed with openings in the brick-work for ventilation, but this is most essential for successful culture and should be more insisted upon than it is. Water also that is taken from the supply-pipes direct is far too cold in winter for spraying or watering. Here it averages forty-five degrees in the winter months, and it is not well to use it for spraying a house at from seventy to eighty degrees. We have in part overcome this difficulty by placing on the warmest flow-pipes a cylinder holding sixty gallons, and taking the water from this to the warm houses. The water is let in at the base of the cylinder and out at the top, and in this way we secure a supply of tepid water adequate to our needs at all times when fire heat is used.

White scale is the worst enemy the Orchid grower has to contend with; it comes on the plants as they are received from the woods, and increases at a rapid rate, but a fine jet of water, as from the Stott sprayer, will, if used with a good force, effectually rid the plants of this pest, and without the least injury to them.

In successful plant-culture it is the trifles that tell. Sometimes they are inappreciable to the cultivator himself and a puzzle to others, but more often they are wholly at the will of the careful student who avails himself of the signs given by the plants themselves. A system that is haphazard is likely to give results that correspond.

South Lancaster, Mass.

E. O. Orpet.

Greenhouse Notes.

WHILE the common practice of banking flowering and foliage plants in the conservatory for effect may be agreeable from one point of observation, and may be excused when following architectural lines, it is more advisable generally to show as much as possible the individual character of the plants. Lately I have seen some very fine trained standard plants effectively used in this way. One of these, *Adhatoda cydonicefolia*, I found in the greenhouses belonging to Mrs. Pauline Durant, of Wellesley. This elegant rafter-plant, allied to the *Justicias*, and belonging to the *Acanthaceæ*, was introduced from Brazil in 1855. It is naturally of straggling growth, and in forming a standard one stout stem had been carried upward six feet and attached to a strong support. From a head made the branches diverged in all directions, arching outward and downward, some of them reaching the ground, forming a perfect pyramid. Nothing more beautiful than this plant in flower can be imagined, with bunches of large labiate pink-colored flowers borne on the tips of the branches. It is an easy plant to grow, propagating freely from cuttings in an ordinary propagating-bed, or they may be put in pots of half light loam and sand and stood in a warm shady corner of the greenhouse. Although usually recommended the treatment accorded tropical plants, they will grow well out-of-doors in summer, and will bloom quite freely in December in a greenhouse of intermediate temperature.

Streptosolon Jamesoni is another plant which by careful training can be grown into a handsome standard. It grows rapidly when young, and training must begin as soon as the plant is a few inches high, since it branches freely and would soon be out of hand for training purposes. At Mr. H. H. Hunnewell's place at Wellesley there is now a beautiful specimen in bloom, with a clear stem of about four feet, and above this an unevenly globular head of the same diameter. Some branches are longer than others, and some drooping, with just enough variation in length to offset an otherwise formally trimmed appearance. The flowers are borne in loose terminal corymbs at the ends of the branches; they are narrowly campanulate, with an irregularly rotate limb of brilliant orange-color. A second crop of flowers follows closely on the first, from laterals developed while the first crop is open, and with a little trimming away of dead flowers the plant remains fairly effective during the remainder of the winter. The best results are obtained by continuous pot-culture. Those we have

planted out have grown too rampantly, and have been with difficulty established in pots when taken up in the autumn.

All who have seen *Richardia Elliottiana* are captivated by its beauty. In habit it more nearly resembles *R. albo-maculata*, and in the manner of its growth our common *Arisæma*, blooming in early summer and afterward going to rest. It increases very slowly, the bulbs developing eyes only when two or three years old, and these are with difficulty established when removed. It is an expensive plant and likely to remain so until some more successful way can be found of propagating it. A silver medal was awarded Mr. Joseph Tailby, of Wellesley, by the Massachusetts Horticultural Society, before whom he exhibited two years ago. The plant bloomed also about the same time with Mr. Robinson, at Mrs. Ames' gardens, North Easton, Massachusetts. Both plants have borne seed. Examination of the spadix of the common *Calla* shows the male and female flowers distinctly divided. They are apparently so in *R. Elliottiana*, but closer examination shows additional stamens scattered, or masses of anthers, which are apparently sessile among the female flowers, and these are the only ones in which the pollen is ripe at the same time as the stigmas, all the upper staminate part of the spadix having shed its pollen long before, as in the common *Calla*. This would seem to be a natural provision for self-fertilization, and accounts for the fecundity of the species, as the plants which have borne seed must have been self-fertilizing, as only one plant bloomed at one place at a time.

Mr. Tailby has tried pollination with the "little green" *Calla*, and also with the common *Arisæma*. Seedlings, so far, show only the characters of the female parents. I think it is unlikely that so wide a cross should be productive of any other result.

John Brown's Grave.

To the Editor of GARDEN AND FOREST :

Sir,—Every student of American history must be glad to know that on the 10th of January the Adirondack farm which holds the grave of John Brown was transferred to the possession of the state of New York, to be kept in perpetuity as a public park. And every one who has visited the farm itself must rejoice that John Brown chanced to be buried in so beautiful a place. Chance, however, is hardly the right word to employ in this connection. It is well known that John Brown was not born in this place, but chose it as his residence, fixed upon the exact spot for his future grave and transported from Connecticut to this spot the tombstone upon which the names of some of his forefathers were cut.

This now historic farm lies within the limits of the village called North Elba, in Essex County, about three miles from the village of Lake Placid. But while the latter has become a popular summer resort, with several large hotels, North Elba is hardly more than a village in name. It contains only a few houses, and one may easily drive through it without suspecting that he has reached a place which claims a personal identity. Then, to reach the Brown farmhouse one must turn southward from the highway and follow a narrow, winding and somewhat rising road through a thick tract of woodland for the space of, perhaps, half a mile. Suddenly the forest ceases and one emerges upon a wide and beautiful plateau largely surrounded by impenetrable-looking woods, beyond which to the north are glimpses of stately mountains, while toward the south the ground slopes away, affording a more extended panorama of hills and far-off noble peaks.

Had this approach been carefully planned it could not have been more beautiful or more dramatically impressive. Level green areas as large as the one contained by the Brown farm are rare in this elevated part of the mountain country, and rarely are the painful signs of man's forest depredations so wholly shut out from view. It seems like a fertile, hidden oasis in a land where tangled forests alternate with mournful, fire-swept, barren tracts and with little farmsteads which seem almost as unproductive and are almost as ugly. Within this lovely circle of woods all looks luxuriant and complete, and all is absolutely peaceful; and in the centre of it, close to the farmhouse, rises the singular, isolated, large-rounded boulder which John Brown selected as his tombstone.

Nothing is cut upon this boulder, under the shadow of which he now lies, except his name and the date of his death, in plain large letters. Close to it stands the small old stone which he brought from Connecticut. Blossoming Roses and

other shrubs twine about them, and the little plot thus formed is surrounded by a simple rustic paling. There is no attempt at "art" and none at ornamentation, except such as Mother Nature could contribute; therefore the effect of the spot is as beautiful as it is impressive, and it is to be hoped that, now it has become a public possession, nothing will be done to "improve" any part of the farm. It should remain as it is—as John Brown saw it and as his family left it. The cottage should be placed in charge of a guardian, of course, but no gardener should be let loose upon the land; and, I think, if a landscape-artist were asked for his advice he would decide that nothing, or very little indeed, should be done to it.

The farm comprises 244 acres, and in the year 1870 was purchased by a number of public-spirited persons in order that it might be preserved from destruction. Miss Kate Field started the subscription for this purpose, and has since been active in urging the transfer of the place into official keeping. Since 1870 a fund has accumulated from the rental of the house and land; and, the newspapers of the moment assert, this fund is to be used "in the erection of a monument on the farm to John Brown's memory." Had I not read these words I should not have been so strongly prompted to write about the place just here and now. But just here and now it should be very plainly said that no money could be expended in a worse way than in building a monument of any possible kind in the beautiful and characteristic spot which I have tried to describe. Its charm, its individuality, its impressiveness, spring from its purely and simply rural character. To build anything ambitious in such a scene, in the vicinity of John Brown's humble little low-browed wooden house, would be an artistic sin of the deepest dye. There would be no excuse for such an act even if the grave were wholly unmarked. Were this the case, only a stone of small size and of the simplest possible sort should be erected. But John Brown already has a monument which he selected himself, and which, in its simple appropriateness to the character of the site and to the character of the man himself, has a greater beauty, dignity and significance than anything that mortal hands could make. No man in America needs, near the place where his body lies, another monument as little as does John Brown. If there is money lying idle, and if it ought to be used to commemorate his name, let a monument be built, but not on the Adirondack farm; anywhere else, but not within sight of John Brown's grave.

M. G. Van Rensselaer.

Our Native Plants in Winter.

To the Editor of GARDEN AND FOREST :

Sir,—The beauty and value of some of our native shrubs, as regards their winter aspects, impressed me more strongly than ever during a stroll along the banks of a stream and through a forest one warm sunny afternoon in last December. The ground was bare, save where it was carpeted with fallen leaves, *Hepaticas* and evergreen Ferns. Here and there stood groups of *Sumach*, *Rhus glabra*, making crimson spots in the landscape. In cultivation this is a desirable shrub, for, though its autumn effects are sufficient to command a place for it in every garden, it is beautiful through the summer also. The smooth glossy leaves show white beneath when upturned in the breeze, and during the latter half of the season its effectiveness is enhanced by the crimson cone-shaped fruit, which is carried late into the winter and long after the leaves have fallen.

The *Barberry*, too, *Berberis vulgaris*, thrives luxuriantly in New England, where it is now well established as a wild shrub. The abundance of this species growing beside the path, with its bright scarlet berries, frost-bitten, it is true, but still clinging to the spiny branches, lent a certain brightness and cheer to the surrounding landscape which were fairly exhilarating. Along the banks of the stream *Choke Cherry* bushes were covered with dense tangles of *Greenbriar*, *Smilax rotundifolia*. The prickly and vivid green stems were so closely interwoven as to form an impenetrable screen even in winter after the leaves had fallen, and the blue-black berries clustered against it helped, by contrast, to make it ornamental. The *Bitter-sweet*, *Celastrus scandens*, grew there, too, and of all the native shrubby climbing plants none is more attractive when the orange-colored pods open and disclose the bright scarlet seeds.

We are fortunate in having plants that remain beautiful when vegetation is taking its winter rest, and I wonder why they are left outside in the planting of home-grounds, and foreign shrubs introduced which are less beautiful, and often useful for summer effects only.

Experiment Station, New Haven, Conn.

W. E. Britton.

Meetings of Societies.

Nebraska State Horticultural Society.

THE prevalent financial depression and seasons of drought, instead of discouraging horticultural enterprise, has in Nebraska seemed to quicken it, and the twenty-seventh annual meeting of the State Horticultural Society was more largely attended and enthusiastic than any of its predecessors. The deficiency in rainfall of the last three years, not before equaled in severity for forty years, has served to emphasize the importance of better culture, so that every grower is on the alert to adopt the best possible methods.

IRRIGATION.

Mr. Lute Wilcox, of Colorado, gave a practical talk on methods of irrigation, illustrated by charts, which served to make his statements very clear. To show the importance of his subject he stated that Colorado has \$100,000,000 invested in its irrigation plants. The average grade of irrigation-canals is two feet a mile. Sometimes it falls as low as eighteen inches, and in case there is much silt in the water it may need to be as much as three feet. The ditch-walker carries the key to the public gate and governs the amount of water that each land-owner can have, and laws are very stringent against any attempt to steal it. From one-fourth to one-third of the water is lost by evaporation, so that it is most important to carry the water the least possible distance to the point where it is to be applied. The furrows for distributing the water have a fall of one inch in from 66 to 100 feet. In ordinary work these are not closer than forty feet apart, and in some cases several hundred feet. Grades in the land are overcome by means of check-dams. Water must never be put on land unless there is an opportunity to drain it away; otherwise the land will become over-wet and worthless. The furrow system is the most practical, and is especially adapted to fruit-culture. In orchard work two furrows are generally used between each row of trees, the furrows passing along under the tips of the branches. What is known as a lath-funnel is inserted in the lateral to supply each space between rows. This is made by nailing four laths together so as to leave an opening about one-half by one inch. This supplies the water just about fast enough, so that it requires little or no attention. A slowly running stream well managed does best work, and with a stream of this size the ground will be sufficiently watered in from five to twenty hours. This will not need to be repeated oftener than once in three weeks. Rows for irrigation should not be over 300 feet long. The furrows are made with a one-horse shovel-plow. If water is applied to one side of the tree only it will cause the tree to lean toward that side. To determine whether the land needs water, take up a sample of the soil five or six inches below the surface; if this will ball in the hand no water should be applied. One thousand barrels of water at each application is sufficient for an acre. In young orchards it is sometimes customary to run four furrows between each row of trees instead of two. Cultivation is just as essential as irrigation, and can no more be dispensed with in irrigated than in unirrigated sections. Special tools have been devised for orchard cultivation which will pack the lower layers of soil just as little as possible. The aim is always to get the water to soak four or five feet into the soil. For this reason it is important that the land should be thoroughly subsoiled before planting unless the subsoil is so open as not to require it. Water should never be applied to trees when in bloom. The most important time to irrigate orchards is when the buds are forming for the next year's crop. In eastern Colorado this occurs in August. No further watering is given until just as the trees go into winter quarters, or just before the ground freezes. This year the Colorado people are irrigating in January. Water should never be allowed to come in contact with the trunk of the trees, and for this reason the flooding system is not well adapted to orchard work. The greatest enemy to irrigation is the evaporation caused by the rays of the sun. This entails much additional labor in the matter of cultivation. It requires two men to irrigate and care for fifteen acres of orchard during the season.

Subirrigation is too costly for any ordinary crops, and in orchard work the roots are sure to fill up the tiles. A machine is in use which makes and lays a continuous tile in position beneath the ground at the least possible cost, but even then the cost is \$400 per acre. The equivalent of seven inches in depth over the entire surface of the land is considered a satisfactory amount to apply at one time in Colorado, and three

applications usually suffice for the growing season. The water used in winter is in addition to this. Potato growers, however, are now coming to give nine or ten irrigations. If possible to avoid it, no water is applied until the tubers begin to form, but thereafter it is given every ten days. If is very injurious to let Potatoes stand for two or three weeks and then apply water again, as that induces a second growth.

In the discussion following this paper it was stated that one million acres can be irrigated in Nebraska from canals now under construction, and probably one million acres more from canals proposed. The point was also made that with the greater rainfall and diminished evaporation in Nebraska much less water would be required for the same area than in Colorado.

THE CONSERVATION OF SOIL MOISTURES.

Professor T. L. Lyon, of the State University, said that this is a subject of paramount import west of the Missouri River; it is estimated that fifty per cent. of the rainfall of the eastern states is lost by running away on the surface and by percolation, while in Nebraska only about ten per cent. is lost in the same way. The primary cause of droughts in this region is not insufficient rainfall, but excessive evaporation. Nebraska soil contains a large proportion of silt and comparatively little clay. The finer the particles the closer they will pack, hence the result is that the lower layers of our soil are exceedingly compact. A loose soil will allow water to sink into it much more rapidly, and will also retain this water much better, than a compact soil. From these facts it is easy to see the value of subsoiling as a means of retaining moisture. Its value, however, depends upon the condition of the subsoil. It is beneficial when the subsoil is compact, but may be useless or even injurious when the subsoil is open and sandy. The work should preferably be done in the fall rather than in the spring, in order to retain to the fullest extent whatever moisture falls during the winter and early spring months. Next in importance to subsoiling should be ranked fall plowing, as this accomplishes the same object, though in a less degree. Failing in this the earlier in the spring the work can be done the better. Thorough and frequent cultivation during the summer is most important. The same qualities of soil which make the subsoil compact also make it a good carrier of water by means of capillarity. The layer of loose soil formed by cultivation simply acts as a mulch or blanket to prevent evaporation. This point was illustrated by lighting two lamps, in one of which the wick had been cut apart and a piece of hemp sewed between to break up the capillarity. In this case the blaze quickly died out. For the same reason it is advantageous to plow stubble land as soon as the grain is off. This not only aids in conserving moisture, but the land is then in better condition to plow than later on.

SUNSHINE AND CLOUDINESS IN RELATION TO CROPS.

In a paper on this subject by Professor G. D. Swezey, of the State University, it was stated that May is the cloudiest month in Nebraska and September the clearest. Taking the length of the day into consideration, it is found that the greatest amount of sunshine is found in July, which in turn is followed by August and September respectively. Not very much is known regarding the intensity of sunlight here, but it is known to be greater than in more humid regions. With normal rainfall the conditions for the growth of crops are almost ideal, since the greatest amount of sunshine occurs when the crops are ripening their fruits. The evaporation of this region is excessive, however, and partly by reason of the large amount and greater intensity of the sunlight.

STRAWBERRIES AND IRRIGATION.

This was the subject of a paper by Mr. J. W. Stevenson, who uses windmills with one and a quarter inch pipe laid on the surface of the ground, and finds the results very satisfactory. Pieces of rubber hose prove useful for connecting the pipe. This allows more freedom in laying pipes, and they can be easily taken apart and carried by one man from place to place as required. He thinks the windmill the cheapest power for lifting water, but it is liable to fail in the time when most needed, hence it is desirable to supplement the windmill with steam or horse power if necessary. He finds it a simple matter by means of wires and proper adjustments to attach a windmill to a pump in a well several hundred feet away. He believes heartily in subsoiling, and uses a tree-digger for this purpose, preferring it to the ordinary subsoil-plow. The land should then be thoroughly saturated with water during the fall or winter. When irrigating in warm weather it is necessary to cultivate the following day in order to prevent the ground

from baking. No harm results from the direct application of cold water as pumped from the ground, as he uses no reservoir and applies the water directly as pumped.

The Western New York Horticultural Society.—I.

FOR fifty years fruit-growing has been one of the leading industries of western New York, and the annual sessions of the Horticultural Society at Rochester are largely devoted to orchards, vineyards and small fruits. The long experience of the members of this society and the efficiency of its officers make its gatherings the most important convention of fruit growers held in this country. The meeting of last week was no exception to the general rule. More than five hundred members were registered as present; the exhibition of fruits and of implements designed to facilitate fruit-culture was large and varied, and the addresses, as usual, had a genuine practical value. The large hall was filled at every session, and well-known horticulturists were present from Michigan, Ohio, Connecticut, Maine, Virginia, Canada and the Hudson River Valley. Mr. W. C. Barry was elected president for the next year; Wing R. Smith, of Syracuse, vice-president; S. D. Willard, of Geneva, second vice-president, and John Hall, of Rochester, secretary and treasurer.

THE PRESIDENT'S ADDRESS.

President Barry, in speaking of the increased usefulness of this society, took occasion to commend the professors of agriculture and horticulture in Cornell University and in the experiment stations, who have helped materially not only by their presence, but by carefully prepared papers, to make the sessions of the society profitable. He also acknowledged the debt which the fruit growers of the present owe to the pioneers who founded this society and who had sufficient enterprise to collect different fruit plants from abroad, and by testing different varieties and experimenting in methods of culture had left an invaluable body of experience. The dry weather of the past year, which injured all crops, and especially small fruits, has impressed growers more than ever with the necessity of providing for a permanent water-supply, and it is generally felt that every care must be taken to save the rainfall. Underdraining, deep plowing, hillside reservoirs, wind-power, should all be tried, and every other method of securing that moisture which is absolutely essential to the production of crops. In reference to the marketing of fruit, Mr. Barry considered it a mistake to sell and ship it at the time of gathering. In many cases this is unavoidable, because growers have no place to store their fruits and therefore dispose of them hastily and often unprofitably. Ordinary farm buildings cannot be successfully used. It is advisable on every fruit farm to have a structure, even if a temporary one, which is suited for storing fruits. If these can be held back for a month, or even a fortnight, until the rush to market is over, good prices can usually be realized, and very often the increase in price thus secured will, in one season, nearly or quite pay for the building. This building may be of moderate size at first, and can be enlarged as necessity requires. Well-equipped houses for retarding the ripening of fruits and for cold storage are expensive, both to build and to maintain, but in any section where fruit-growing is carried on largely a company can be formed and a building constructed for common use, but for ordinary cold storage for single farms one can be built at small cost, and when once used it will be considered indispensable.

In regard to the fertilization of orchards, Dr. Van Slyke was quoted to the effect that farm-yard manures need to be supplemented with fertilizers containing phosphoric acid and potash to make a proper food for orchards. With every ton of stable manure it is well to mix from fifty to one hundred pounds of acid phosphate and from twenty to fifty pounds of crude muriate or sulphate of potash. Unleached wood-ashes, ground bone and potash salts are better than stable manure. A peck or half a bushel of ashes to a bearing tree, with three or four pounds of ground bone, is what is needed. Two pounds of potash salts can be substituted for the ashes. When unleached ashes of known purity can be bought at home they are worth buying if they do not cost too much. But all the potash and phosphoric acid they contain can be had much cheaper than by paying \$10.00 a ton for ashes. Muriate of potash and bone meal cost two and a half cents a pound, and 150 pounds of it will furnish as much phosphoric acid as a ton of ashes,

and both together will not cost half as much as ashes ordinarily do. Mineral manures can be handled quickly and at little expense. In short, few people realize how much it costs to distribute such a bulky fertilizer as barn-yard manure. Orchards which have outlived their usefulness should be cut up into firewood and not allowed to occupy valuable ground and breed destructive fungi and insects. In their place new orchards should be planted on ground perfectly prepared and well planted with a proper selection of trees. We have now remedies and preventives which enable us to keep in check insects or diseases which threatened the destruction of orchards and vineyards a few years ago. Spraying has become almost as common as cultivation, and we should test every new help, even to the importation of natural parasites, to help us in our war against insects.

Among the members of the society who have died during the year, and to whom Mr. Barry paid special tribute, were the venerable John J. Thomas, first president of the society, who died in his eighty-fifth year—a modest, capable man and a trusted authority, eminent in the practice and in the literature of the art of horticulture; Charles E. Cook, one of the largest fruit growers in the region of western New York and the inventor of a fruit-gatherer which is widely used; the brothers Moulson, old nurserymen, of Rochester, both of whom had passed their fourscore years; the brothers Thomas and Edwin Smith, of Geneva, who for forty years have been eminent as nurserymen and fruit farmers, and Ethel C. Sherman, who had been for many years secretary of the Horticultural Society of Wyoming County.

THE COST OF A POUND OF GRAPES.

Mr. John W. Spencer, in speaking on this question, said, in part:

The Chautauqua grape belt, in the Lake Erie valley, is about fifty miles long, hemmed in on the south side by a ridge of precipitous hills, and the breadth of the valley available for fruit-culture varies from three to five miles. Through the centre of the valley runs a zone of gravel once the beach of the lake when it discharged into the Mississippi Valley through the gap where Chicago now stands. Between this beach-level and the present shore of the lake there is a belt of clay, and on the hillside a zone of glacial till. The gravelly land was once the highest-priced and bore better crops of grain, the clay was the best grass land and the hillside was a sheep pasture covered with mulleins and briars. At first the gravel was thought the most eligible for grapes, but now vineyards are found on the clay and the glacial drift, on which latter place the grapes are as good in quality and sometimes yield as much in quantity. The cost of the various processes in cultivation, such as cutting the curls, stripping brush from the wires, stretching wires, tying, tillage, etc., from spring up till the time of harvest, is about \$9.00 an acre. How much a nine-pound basket costs depends on the man and his soil. In vineyards where there are no missing vines, and all are thrifty and even, an acre will yield a thousand baskets, and often twelve hundred, but the average grape grower of the region does well if he gets five hundred baskets, and the careless vine dresser gets all he deserves if he has two hundred and fifty. With five hundred baskets to the acre each one will cost one and eight-tenths cents. But this nine dollars which has been expended since early spring does not take the grapes to the freight-car, and, indeed, it pays for only one-quarter of the journey. The cost of baskets, handling, picking, packing, attendance in various ways and hauling is yet to be met, so that harvesting the grapes cost \$27.00 more an acre, making a total of \$36.00. In 1894 grapes were 11¼ cents a basket at the car door, or \$58.75 an acre, which left \$22.75 of profit. Out of this must be taken the taxes, interest, wear of implements, posts, crates and sometimes fertilizers, which, of course, vary in individual instances.

Fruit-growing is every year becoming more and more a profession which combines skill and science, and the man who is best paid is he who raises the most difficult products. Fifty men are competent to produce crops where there is one competent to raise mushrooms, but mushrooms bring fifty times as much a pound as grapes. The exceptionally skilled horticulturist can find a better business than growing grapes. The man who raises five hundred baskets to the acre pays twice as much for cultivating the same product as the man who raises a thousand, but the difference is only \$9.00 an acre. Superior skill only tells in raising a crop. Large yields do not cheapen the cost of harvesting and transporting. Superior fruit does not bring superior prices under cooperative selling, as is done in Chautauqua. The straggling bunches of the careless man are dumped into the same cars with those of the most skilled grow-

ers, the car-load is sold as a whole, and the pay is made pro rata according to the number of baskets, so that coöperative shipping has disadvantages as well as advantages, and it is the skilled grower who suffers—that is, he does not reap the full reward of his superior knowledge.

Notes.

Since October 1st, 792,431 barrels of domestic potatoes have been offered in the markets of this city, 296,031 barrels in excess of the supply a year ago. During the past week there were received 30,934 barrels of the home crop, besides small shipments from Europe, Bermuda and the West Indies.

The first Florida strawberries of the season may be had at \$1.00 to \$1.25 for a quart box. The only Tangerine oranges now available are tiny specimens from California, and these cost the excessive sum of \$10.00 a box, wholesale. The few Mandarins offered are from Italy, and thirty-four half-boxes of this fruit from Sorrento, landed on Monday, sold for \$5.50 on the dock.

Another part of the important *Flora of Nebraska*, edited by members of the Botanical Seminary of the University of Nebraska, already noticed in these pages, has been issued. It is part 21 of the whole work, and is devoted to the Rosales, the author being Mr. Axel Rydberg. In this group are treated Rosaceæ, Cæsalpiniaceæ, Mimosaceæ and Papilionaceæ, these three families being formed from the Leguminosæ as limited by Bentham, the Saxifragaceæ, Crassulaceæ, Hamamelidaceæ and Grossulariaceæ. The editorial committee of this important work, Professor Charles E. Bessey, Roscoe Pound and F. E. Clements, announce that part 8, devoted to the Fungi Imperfecti, is approaching completion.

Formerly Cuban and domestic cigar boxes were all made from the wood of the Spanish Cedar, a species of West Indian Cedrella, but now the demand for boxes to hold cheap domestic cigars is so great in this country that other woods, stained to resemble Spanish Cedar, are largely used for the purpose. The wood of the Tulip Poplar, Liriodendron, is considered the best of the North American woods for this purpose, although chestnut, butternut, elm, basswood and cottonwood have been tried. Cigar boxes are also now very largely made in the United States with veneers of Spanish Cedar cut in thicknesses of from eighty to one hundred and twenty sheets to one inch and mounted on cheap American woods like cottonwood or basswood.

A report of the importations of bananas into the United States during 1895, issued by Bennett, Walsh & Co., of this city, shows that 186 cargoes of this fruit have been landed. Jamaica furnished more than any other country, 4,108,620 bunches coming from that island. Bocas del Toro, a port of the United States of Colombia, and Bluefields, each sent out more than 2,000,000 bunches, and a like total came from Belize, Livingston and Honduras, and also from Banos and Cabanes, with nearly as many from Port Limon. These, with importations from minor ports, amount to 16,722,127 bunches. Of this grand total 5,088,119 bunches arrived in New Orleans, 4,548,572 in New York; Mobile comes third with 2,449,618, followed by Philadelphia with 2,026,780, Boston 1,637,802, Baltimore with less than a million, and Charleston with only 41,000 bunches.

Well-blanchéd celery from California sells at \$1.10 for a bunch of a dozen stalks; that from Rochester brings \$1.00 a dozen, and, while less white and showy, is considered of higher quality. Small heads of cauliflower from California cost thirty to sixty cents each, and larger heads from France bring seventy-five cents. Brussels sprouts from the latter country sell for twenty-five cents a pound, and artichokes for the same price each. New string beans, beets and egg-plants come from Florida, besides tomatoes. The latter sell for twenty cents a pound, the price, also, of California tomatoes, the hot-house product, bringing thirty-five cents. Peppers, from Cuba, cost forty cents a dozen. Other vegetables now in season in our markets are celeriac, new leeks and onions, Spanish onions, sweet potatoes, Savoy and Danish cabbage, the green Hubbard and yellow squashes. Tender blades of sorrel and dandelion, grown under glass on Long Island, are in considerable demand, and sell, respectively, for fifteen and twenty-five cents a quart.

Currants are grown successfully at the Geneva Experiment Station on a southern slope with soil of rather a heavy clayey loam and a clay subsoil. This is well drained by lines of tiles

two rods apart. The bushes are set four feet apart in the rows, and the rows are from six to seven feet apart. A forkful or two of stable manure is thrown around each bush in autumn and turned under, but not deeply, in spring. The ground is cultivated two or three inches deep near the plants, and rather deeper midway of the rows at the first cultivation, after which, by shallow tillage, the surface is kept stirred and free from weeds until August. In fall the five-year-old canes are cut away with the broken branches with all those that droop to the ground, and all but one or two new shoots of one season's growth. No unvarying rule can be followed in pruning, but it is thought that generally a cane reaches its greatest productiveness during its fourth or fifth season. If a cane still appears vigorous after its fifth year's growth and well filled with buds it is allowed to remain longer. Under this treatment the bushes make enough wood and yield abundantly.

The council of the New Mexico Agricultural Experiment Station has passed a series of resolutions which have been sent to the stations of the different states, relating to the injury done by the introduction of scale and other insects from the West Indies and Central America into the southern states. After setting forth the fact that some of these insects may live over a large portion of this continent, as does the West Indian *Diaspis Amygdali*, which is now attacking Peach-trees as far north as Washington, and that experience in California has proved it possible to prevent by inspection the introduction of many pernicious insects, it is recommended that quarantine officers be appointed by the agricultural experiment stations of the several states, and paid out of the funds of these states, to be stationed at Key West, Mobile, New Orleans, Galveston and other ports, to examine plants introduced, to destroy those found infested and to issue a certificate for those which have been passed. It is also recommended that a skilled entomologist be appointed by the Department of Agriculture to travel in Mexico, Central America and the West Indies, make collections of injurious insects, investigate their habits and transmit his collection, with report, to the National Museum.

A writer in the *Scottish Geographical Magazine*, speaking of Formosa, states that the clearing of the forests of Camphor-trees there is going on at a very rapid rate. Many of the trees are cut up for making camphor; others are sawn into planks and knees for the building of boats. For over thirty years there has been a constant demand for camphor, and yet the Chinese Government has done nothing to prevent the reckless waste of these forests, and has taken no steps for the replanting of the tracts which are useless for cultivation. It is said that in the mountains of the interior Camphor-trees are still abundant, and there is no immediate fear that the supply will run short; but the increased demand for camphor in these days of smokeless powder will hasten the destruction of the trees, and it is therefore to be hoped that under the administration of the Japanese Government, which as a result of the war with China has come into possession of this territory, care will be taken to insure a future supply by planting these waste lands. The trees grow very rapidly and reach a height of forty feet in twenty years, and probably trees which are fifty years old will be large enough for all the ordinary purposes to which the timber is applied. To secure the camphor, distilleries of mud bricks some ten or twelve feet long, six feet wide and four feet high, are built on the hillsides, with five to ten fire-holes a foot apart and the same distance above the ground in each. An earthen pot full of water is placed over each fire-hole, and above it a tube a foot in diameter passes through the structure appearing above it. The tube is capped by a large inverted jar with a packing of damp hemp between the jar and the cylindrical tube, which is filled with chips of wood, about the size of the little finger, resting on the perforated lid covering the jar of water, so that when the steam rises it passes up to the inverted jar or condenser, absorbing the resinous material from the wood on its way. While the distillation is going on an essential oil is produced and is found mixed with the water on the inside of the jar. When the jar is removed the beady drops solidify, and crude camphor, crystallized like newly formed snow, is detached by the hand, placed in baskets lined with Plantain leaves and sent away to the nearest town for sale.

Publisher's Note.

A portion of the issue of GARDEN AND FOREST last week was printed on paper of a different color from that ordinarily used. Subscribers who return such copies will be furnished with others printed on our regular paper.

Plane Trees.

LONG before Xerxes encircled the Plane-tree of Lycia with a band of gold to mark his admiration for its beauty the peoples of the east venerated these trees for their massive trunks and wide umbrageous crowns of beautiful and cheerful foliage. The Persians, and after them the Greeks, formed their groves and shaded their dwellings with Plane-trees, which were the first shade-trees planted by the inhabitants of the valleys of north-western India. The Romans, who shared with the Greeks their admiration for the Plane-tree, carried it to Europe and planted it in all the southern countries which they overran. This Plane-tree of the east is *Platanus orientalis*, and its native land extends from the Grecian islands and peninsula to Afghanistan and Cashmere. The Oriental Plane is one of the noblest of trees, and fabulous stories are told of the great age, the enormous trunks and the far-spreading branches of some old specimens. Such stories are, perhaps, somewhat exaggerated, although large Plane-trees still exist in eastern Europe. A portrait of one of these old trees, now standing in the court of the Janissaries in the old Seraglio, in Constantinople, was published in our third volume, and gives an idea of the size this tree attains and the massiveness it preserves, even in very old age. The Oriental Plane is still the favorite shade-tree of southern Europe, where for two centuries, at least, it has been planted in the streets and squares of modern cities. It was brought to this country not very long ago, probably, and thrives in all the middle states, where it has proved itself an excellent street-tree; and it supports even the climate of New England.

In the flora of the Old World there is a single member of the genus *Platanus*, or Plane-tree, and North America now contains the others, only four or five in number, although the genus was once more widely distributed and richer in species, and during the tertiary period of the world's existence grew in Greenland and Arctic America, and then spreading southward inhabited central Europe and midcontinental North America, regions where no Plane-trees now occur. The entire absence of these trees from the flora of eastern Asia is an anomaly in plant geography

which is not easy to explain, for tertiary plants of circum-polar distribution which have survived to the present time, like *Platanus*, are generally found in the existing floras of eastern America and eastern Asia, and it is exceptional to find one of these genera represented only in North America and Europe.

There are strong points of resemblance in all the trees of this genus; the structure of their flowers and fruits is practically identical; they all grow to a very large size, with enormous stems covered below with dark scaly bark, and above and on the branches with smooth, thin, light gray or greenish bark separating easily in great thin scales, which, in falling, expose large irregular surfaces of the pale yellow, whitish or greenish inner bark: they all produce the same peculiar leaf-buds enclosed in summer in cavities of the enlarged bases of the leaf-stalks, and their lobed leaves are all of ample size and of the same color and texture; the wood of all the Plane-trees is hard, heavy, light red-brown, and contains broad and very conspicuous medullary rays, which make it attractive as a furniture wood and for the interior finish of houses; and it is only by the shape of the leaves and by the amount and character of the pubescence which clothes their lower surface that the different species can be distinguished.

Of the Plane-trees of the New World three species grow within the territory of the United States and two exclusively in Mexico. Of the Mexican species one is a little-known and rather problematical tree of the south; the other, *Populus Mexicana*, inhabits Nuevo Leon and the states to the south of it. This tree is frequently planted in the plazas of the cities of north-eastern Mexico, and is perhaps the handsomest of all Plane-trees, the under surface of the mature leaves being clothed with a thick coat of snowy-white tomentum which, as they flutter in the wind, makes a beautiful contrast with the dark, rich green of their upper surface. This tree, although it has been long known to botanists, seems to have escaped the attention of the horticulturists of southern Europe, where it may be expected to flourish and become an ornamental tree of the first class.

Of the species of the United States the most widely distributed, the largest and the best-known is *Platanus occidentalis* of the east. Although not the tallest deciduous-leaved tree of the United States, perhaps, it is the most massive of them all, and the largest tree which grows on the continent east of the California Sierra Nevada. On the rich bottom-lands of the basin of the lower Ohio River the Plane-tree sometimes attains the height of one hundred and seventy feet, and forms a trunk ten or eleven feet in diameter above its much-swollen base. Trunks of this size are usually hollow from old age, and such great trees, which were common when the Mississippi Valley was first settled by white men, are now rare; and each year sees their numbers decrease. In the second volume of this journal the portraits of two of these trees growing on the bottoms near the junction of the White River with the Wabash were published, and on page 55 of the present issue will be found that of another tree in the same region made from a photograph for which we are indebted to Dr. Jacob Schneck, of Mount Carmel, Illinois, the centre of the richest and one of the most interesting tree regions of this country.

Platanus occidentalis is one of the common inhabitants of the borders of streams and lakes and of rich bottom-lands, and is distributed from southern Maine to the northern shores of Lake Ontario and to eastern Nebraska, and southward to Florida and western Texas. It is occasionally cultivated in the eastern states and in Europe, although as a planted tree it is much less common than the Old World Plane, which is a more desirable street and park tree here, as our native species suffers more seriously from a fungus which every spring destroys the young leaves in the seaboard states, causing them to turn brown and wither, as if the trees had been scorched by fire. This pest is so serious that the trees are often stunted and deformed

in their efforts to produce new crops of leaves to replace those killed by the fungus, and the planting of the western Plane cannot be recommended. The wood of this tree is now used in very large quantities in the United States in making furniture and in finishing houses. Formerly it was almost the only material used in the manufacture of the boxes made for packing tobacco, but the demand for wood for this purpose has become so great that that of other trees is now often substituted for plane-wood in the manufacture of tobacco cases.

The second of the North American Plane-trees, *Platanus racemosa*, inhabits the banks of streams in California, where it is distributed from the valley of the lower Sacramento River southward through the interior valleys and coast ranges of the state, and finds its most southern home on San Pedro Martir, a high mountain half-way down the peninsula of Lower California, where several other California trees have retained a foothold. It is one of the largest and most beautiful of the deciduous-leaved trees of California, and is very common on river-banks in the neighborhood of the coast from Monterey to San Diego, growing often to the height of more than a hundred feet and forming a trunk eight or nine feet through and sometimes erect and free of branches for half its height, but more often divided near the ground into several secondary stems which are erect or inclining, or often prostrate, for twenty or thirty feet at the base, and then turn upward toward the sky.

The third species of the United States, *Platanus Wrightii*, bears the name of the indefatigable botanical collector, Charles Wright, who discovered it nearly fifty years ago in southern Arizona when he was connected with the survey undertaken to establish the boundary between the United States and Mexico. It inhabits the banks of streams in the cañons of the mountain ranges which stretch along our south-western boundary from the Rio Grande to the Colorado, and, like most of the trees of these mountains, belongs to the flora of northern Mexico rather than to that of the United States. As it appears in the sombre cañons of these sun-baked mountains *Platanus Wrightii*, which frequently attains the height of eighty feet and makes a trunk four or five feet through, is a splendid object, rising high above the Walnuts, Willows and Alders with which it grows, and spreading far its great limbs, clothed in pale sea-green bark. From other Plane-trees it differs in this coloring of the juvenile bark and in the shape of the leaves, which are divided by narrow sinuses, sometimes nearly to the centre, into from three to seven, but usually into five, elongated, acute lobes, and are often deeply cordate by the downward projection of the two lower lobes. The Arizona Plane-tree is the largest deciduous-leaved tree in the mountain forests of the south-west and one of the most distinct and beautiful trees of the genus.

Forest Lands in Massachusetts.

THE town of Washington, Massachusetts, is located at the highest point on the Boston and Albany Railroad. About Washington, as a centre, a large area of land is given up to second-growth timber, and a view from the top of one of the higher summits of the mountain range extending north or south from the railway will disclose a large territory growing up to forests. Last summer I made a carriage-drive over a considerable section of Berkshire County, where this timber-land could be readily seen. Numerous observations were also taken from high points not ordinarily visited. Among these was Becket Mountain, 2,194 feet above the sea-level, from which a view is secured extending from the Catskills on the west to the Holyoke range on the east.

A person unfamiliar with this region would be surprised at the amount of land now occupied by growing timber. Leaving out of consideration the immediate vicinity of the towns, and a few rural homes about Lenox and Stockbridge, clearings are the exceptions, and not the rule. Driving east or south from Lee extensive forest tracts are

found. The country is rapidly becoming reforested. These lands have a very low valuation. During the past year Pittsfield and New York parties have been purchasing extensively in Washington, so that already it is claimed that one syndicate controls some 5,000 or more acres, for which four dollars an acre have been paid. This land, it is understood, is to be fenced, and, rumor has it, will be kept as a game preserve. The people occupying this region, so far as I have been able to learn, have no faith in the future prospects of the forests as a source of revenue. Hardwood, delivered, brings three dollars a cord in the local market, and this price hardly pays the hauling over poor roads. The supply of saw-logs is quite limited; tan bark is comparatively scarce, and the railroads get their ties cheaper elsewhere. The country is now rapidly growing up to forests more extensively than ever in recent years.

Nevertheless, I believe that the timber resources of these New England hills will have a significant value in the future. The sources of timber-supply of the country are becoming more and more restricted. Michigan, Minnesota and Wisconsin no longer have extensive areas of timber. The big timber-fields adjacent to the good shipping points are becoming scarce. In Massachusetts and New England are many small forests twenty to thirty years old that are producing promising crops of timber for the future. Within ten or twenty years they will begin to yield a revenue from timber-supply, without taking cordwood into account, and such lands as these ought to be safe investments for the farmer and for the future.

And this suggests a field for investigation for the agricultural colleges in the several New England states. As an example, would it not be desirable and appropriate for the Massachusetts Agricultural College to secure a block of, say, one hundred or more acres of cheap land in second-growth timber, and use it as a permanent field for systematic forestry? Many problems of a practical nature could here be investigated that cannot be considered on the high-priced land where the college stands. Here could be maintained a summer school of forestry, where, for two or three months, students might repair to study under conditions at present unavailable in New England, if not in the United States. The summer school is now accomplishing work in many directions, but the first summer school in forestry is yet to be created.

A block of such timber-land might be made a great source of instruction and benefit to the farmers of Massachusetts, and the practicability of timber-culture in the state could have a fair trial. The farmer needs to be educated as to the possibilities of these rough hills for forest purposes. He has neither the time nor the money nor the training which would enable him to make these investigations for himself, and the state can well afford to help him and set the example if this will encourage the study and practice of scientific forestry by the people.

In the mean time the timber reserves of the state are growing, and some day their value as a source of income will become manifest.

NEW ORCHIDS.—The productions of the hybridist are the only noteworthy recent additions to garden Orchids, and there are only few of these that call for special mention. *Cypripedium* Miss M. Ames, a hybrid between *C. Curtisii* and *C. concolor*, raised by Messrs. F. Sander & Co., is remarkable in form and in the yellowish green wax-like flowers tinged with rose. The pouch is pinched laterally, as in *C. concolor*. Another Sanderian hybrid, named Said Lloyd, raised from *C. Godefroyæ* and *C. venustum*, has yellow and pale brown flowers, heavily blotched with chocolate-brown; is sufficiently distinct to find favor with

collectors of hybrid *Cypripediums*. Another hybrid addition to this genus is a cross between *C. callosum* and *C. Druryi*, raised at St. Albans and named *A. R. Smith*. It has large yellow and dull brown flowers, which are not as attractive as the characters of the parents would lead one to expect. *Oncidium Wheatleyanum*, although not new, is a rare plant in English collections. It was shown in flower this week by Sir Trevor Lawrence. I should call it a form of *O. varicosum*, with a large blotch of red-brown at the base of the deeply lobed labellum.

DENDROBIUM JOHNSONÆ.—A well-flowered example of this Australian *Dendrobium* was among the plants exhibited at the Drill Hall this week by Messrs. F. Sander & Co. It is a distinct species, but disappointing horticulturally, the segments of the flowers being too narrow and the pose of the inflorescence wanting that grace and fullness which characterize the pick of the Australian members of this genus. The flowers are smaller than those shown in published figures of this species.

VANDA CHARLESWORTHII.—Baron Schröder exhibited a plant of this rare *Vanda* last Tuesday. It is supposed to be a natural hybrid between *V. cœrulea* and *V. Bensoni*, and was described by Mr. Rolfe in *The Orchid Review* last year, page 323. The flowers are two and a half inches across, nearly white, veined and marbled with rose-purple, the sepals and petals resembling those of *V. cœrulea* in texture and form, while the lip is like that of *V. Bensoni*. The leaves are narrower than those of *V. cœrulea* and the scapes are erect, the plant exhibited having two scapes, with an aggregate of seven flowers.

CYPRIPEDIUM MASTERSIANUM.—This hitherto rare species was imported probably from Borneo to Kew nearly twenty years ago, and was described by Reichenbach in 1879 from materials supplied by Messrs. Veitch & Sons, and named in compliment to Dr. Masters, F. R. S., the distinguished editor of *The Gardeners' Chronicle*. It has broad leaves about a foot long, deep green with paler tessellations, and erect scapes fifteen inches high, each bearing a large flower, probably the largest in the genus. The dorsal sepal is orbicular, bright green, with a broad margin of white and a fringed edge; the petals are horizontal, spatulate, nearly two inches long, dull red, with black-purple warts near the base and along the upper margin; the pouch is very large and inflated and is colored reddish brown, shaded with green and spotted with purple. Messrs. Sander & Co. have succeeded in rediscovering and importing a large quantity of plants of this species and offered 5,000 plants of it for sale by auction recently. The plants were in excellent condition and realized fair prices.

PRIMULA SINENSIS.—A special feature of the last meeting of the Royal Horticultural Society was a large collection of the forms of *Primula Sinensis*, exhibited by Messrs. H. Cannell & Sons, Swanley, who have long held a foremost place among the trade growers and breeders of this useful winter-flowering greenhouse plant. Seven large houses are filled with it in all its best forms, about ten thousand plants being grown annually for seeds. The best white variety is one called *White Perfection*, which has short-stalked large heads of flowers, each one and a half inches across, conspicuously imbricated, the segments wavy and crisp-edged. Equally beautiful and large in flower is a carmine-pink variety called *Cannell's Pink*. These two varieties come true from seed and are very floriferous. They have, however, one fault, from a purely decorative point of view, a fault common to nearly all the improved strains of this *Primula*—namely, the flower-stalks are too short, and, consequently, the plants have a squat, stubby look even at their best. Messrs. Cannell are, however, alive to this defect, and for several years now they have aimed at producing a race with looser, taller trusses. They have made considerable progress in this direction, their *Pyramidalis* strain, bred from a loose, tall-stalked variety known as *White Lady*, crossed with the short-stalked, large-flowered forms, being a decided improvement. Twenty years ago long-stalked *Primulas* were discarded as weedy

and lacking finish, but Messrs. Cannell were fortunate in securing this *White Lady* variety, which had been kept for years in the famous garden of Sir George Macleay, at Pendell Court, and with its aid they are rectifying the mistakes, or, at any rate, are going back to strains ignored or repudiated by recent breeders. These fine varieties come true from seeds, a remarkable fact, but one about which there can be no question. A new variety called *Cannell's Gem*, with rich carnation-pink flowers, of which a few plants in flower were shown by Messrs. Cannell, is certain to be popular on account of its color. It has yet to be tested as a seed-bearer, as sometimes a beautiful variety is practically barren when fertilized with its own pollen. *Swanley Blue* is a deep mauve-flowered variety, which is the nearest approach to a true blue Chinese *Primrose* so far produced.

Hybridizing Nymphæas.

IT is generally supposed that *Nymphæas* are difficult to hybridize, an opinion based on the numerous failures to cross some of the species. Most of these attempts, however, have been made with species which are not closely related to each other; for instance, the pollen of *N. cœrulea* has been tried on flowers of *N. odorata* or *N. alba*, and pollen of *N. Devonensis* or *N. rubra* on some white-flowering hardy kind. It is difficult to imagine a cross between the species mentioned above, because their habits of growth are so widely different.

For several years I have experimented in hybridizing some of the kinds with satisfactory results, but my successes have been scored when the seed parent and pollen parent were closely related. To show how easily *Nymphæas* are hybridized one has only to take a plant of the white-flowered *N. gracilis* and flower it in company with any of the Zanzibar section. The result will be that, without any other interference than that effected by the wasp-like insects which infest the blooms, it is next to impossible to get seed that will come true. The seedlings will show foliage almost similar to that of *N. gracilis*, but the flowers will be either light or dark purple, instead of white, and in shape pretty nearly intermediate between the Zanzibar varieties and *N. gracilis*. Again, if the true dark purple-flowered *N. Zanzibarensis* be isolated from the lighter-flowered form called *azurea* and from all others related to it, many of the seedlings raised from it will have flowers every bit as deep in color as those of the parent, whereas if seedlings be raised from a plant which has grown in company with its lighter-flowered forms those seedlings will have flowers of an intermediate color.

In the night-blooming section all the kinds are easily crossed, and any one having the facilities, who will spend a half hour or so over a bloom, can have hybrids of his own raising. Take, for instance, the well-known *Nymphæa Lotus*, which, so far as my experience has shown, sets and ripens more seed than any other of the night-bloomers, unless it be its variety *dentata*. As the seed parent I prefer *N. Lotus* to *N. dentata*, as its flowers are of such a graceful outline. When crossed with *N. Sturtevantii*, for example, they preserve the cup-shaped form and make a splendid bloom. The ideal cross between these two well-known kinds is seen in the hybrid which has been named *Smithiana*. In form the flower partly resembles each parent, being larger than that of *N. Lotus*, the seed parent, and a trifle smaller than that of *N. Sturtevantii*. The color is not intermediate between them, however, but is a delicate blush.

I have never been able to gather seed from *N. Sturtevantii*, although I have watched it every season since it was sent out. The pollen grains from its flowers are efficacious enough on other flowers. *N. Smithiana*, too, has not set any seed so far. The first season's flowers of this hybrid were rather disappointing, being quite small; this was partly due to a great profusion of growths from the little tuber which was set out along with the plant. All of this section, by the way, ought to be planted without tubers, as they are then more apt to concentrate their energy in one crown and produce very much larger flowers.

The large white-flowered *Nymphæa dentata* sets seed every time when properly fertilized with pollen from *N. Devonensis* or *N. rubra*. Every intervening shade between the white and deep red may be obtained, such as is seen in the hybrids

named O'Marana, delicatissima and Deaniana. The hybrid with very dark flowers named Columbiana is a puzzle to me, as it is a cross between the kind with very dark-colored leaves which goes under the name of *N. rubra* and *N. dentata*, the first-named being the seed parent. One would suppose that a hybrid between these two well-known kinds would have flowers of a light red or pink color, but the flowers of Columbiana are darker than either of the forms of *N. rubra* or *N. Devonensis*. Another peculiarity which the plant possesses is that the flowers are much smaller than those of either of the parents.

In order to make sure of success in hybridizing *Nymphæas* one or two little details should never be neglected. The first thing to do is to make ready for each flower a wire screen in the shape of a hood, the mesh to be small enough to keep out the smallest insects; this screen ought to be large enough to completely envelop the flower when it is fully expanded; it should be attached on one side to a stout stick, and merely placed over the flower by thrusting the end of the stick into the soil in which the plant is growing, taking care that the bottom of the screen is beneath the water, but before this is necessary the flower which is selected for seeding must be prepared carefully, and this is the most important part of the work. Begin just before the flowers expand in the evening, select a flower which is about to open for the first time, open the petals gently and remove every vestige of the stamens; this can be done perfectly with the thumb and forefinger. At this period of the flower's existence the pollen is unripe and there is not the least possibility of any of it getting on to the rayed stigma of the flower. After the operation is completed place the hood over the flower and let it remain till next morning. At the same time another hood should be placed over the flower selected as the pollen parent, taking care that it also is about to open for the first time; this will remove any possibility of insects visiting it and mixing pollen from other flowers with its own. Now, during the forenoon of the next day, just before the Lilies are about to close, examine the pollen-bearing flower, and if, as is likely to be the case, the pollen is ripe, shake it over the one from which the stamens were removed, and, as a further means of insuring success, nip off a few of the stamens and place them in the centre of the impregnated flower; next draw three or four of the inner petals together by their tips and join them by a pin, replace the hood, and if the flower sets any seeds at all it is reasonably certain that they cannot produce anything else than hybrid seedlings.

Botanic Garden, Washington, D. C.

G. W. Oliver.

Orchid Notes.

CALANTHE VEITCHII is one of our most useful winter-flowering Orchids, and even small collections should not be without this showy plant. For the past month it has made a good show of flowers here, and they will last for several weeks yet. Our plants are grown in five-inch pots, with one pseudo-bulb in each pot. As the plants are without leaves when they blossom, we find it easier to arrange them when they are in small pots among other foliage plants, which make a good groundwork for them. There are three dozen plants in bloom now; they have flower-spikes a yard or more long. When the plants have finished flowering water is entirely withheld, and they are kept on a dry shelf which is near the glass roof, where they get an abundance of light, so as to harden and mature the pseudo-bulbs better. The repotting is done in March, when the young growth is about an inch long and just as the young roots start to grow. The plants are turned out of the pots and all the exhausted soil removed from the roots. The dead roots are cut back to within an inch of the pseudo-bulb, and this short piece of root which is left helps to keep the plants in place until they make new roots. Good drainage is very essential, and the pots are almost half-filled with broken crocks. Over the drainage is placed a layer of fern-root to prevent any clogging. When potting the plants the pots are filled up moderately firm to within an inch of the top. The plant is then placed on the top of the soil, and about half an inch more of compost is added, so as just to cover the base of the bulb. If the plants are not perfectly firm then they are tied to a small stake, which keeps them in position until the roots take hold of the new compost. A place where they get plenty of light suits them best after they are potted, and they are, therefore, placed on a shelf near the glass in the stove. After potting they need very little water for several weeks. If too much moisture is given at this stage the young growth turns black. When the plants have made good roots and fairly sized leaves they need an abundance of water. About July, the

young bulbs begin to form, when weak liquid-manure can be given twice a week until the pseudo-bulbs begin to lose their leaves and the flowers begin to open. When the plants are in bloom they only need enough water to keep the flowers in good condition.

This beautiful hybrid was raised by Mr. Dominy at Veitch's Exeter nursery in 1856. It was obtained by crossing *Calanthe rosea*, then known as *Limatodes rosea*, with the pollen of *Calanthe vestita*. It flowered for the first time in 1859. The pseudo-bulbs are flask-shaped, six or seven inches long, and the leaves are large, plaited and light green in color. The long graceful spikes have rich, bright rose-colored, white-throated flowers two inches across.

Calanthe vestita is a handsome species that has been cultivated for nearly half a century. Although it is not quite as showy as the above hybrid, it is well worth growing and makes a good display at this season. It has roundish pseudo-bulbs with broadly lanceolate acuminate leaves, which are about a foot and a half long. The flowers are produced in long nodding hairy spikes. They are milky white, with a yellow blotch on the lip in front of the column, and they measure about two inches across. This Orchid was first discovered by Dr. Wallich, an Indian botanist, in 1826, but was not introduced to cultivation until 1848. Then it was collected in Moulmein by Dr. Kane and sent to England.

Calanthe vestita rubro oculata is a handsome free-flowering variety also in bloom. It has large delicate white flowers with a blotch of rich crimson in the centre.

Dendrobium Linawianum is a mass of handsome flowers. It has upright, deeply furrowed stems, which are a foot or more high and are swollen at the internodes. The young stems have oblong, obtuse leaves, which are about three inches long. The very beautiful flowers are produced in pairs from the joints on the two-year-old stems. The flowers measure more than two inches across, and the sepals and petals are oblong, acute, white at the base, and are of a rosy purple color in the upper half. The lip is ovate, reflexed, being of a bright crimson-purple and has a crimson spot on each side of the disk. This plant is grown in a basket, and when it requires rebasketing it is done in spring after it has flowered. It thrives in a mixture of fern-root, sphagnum and lumps of charcoal. During the summer months it is grown in the stove, hung up near the roof, where it gets plenty of light, heat and moisture. When it has finished its growth for the season, which is about September, it is removed to a cooler house, where it gets plenty of light and air, so as to ripen its pseudo-bulbs. It needs very little water during the early part of winter, when it is resting, just enough to keep it from shriveling. When it shows flowers it is taken into a warmer greenhouse, where it is watered carefully until all the flowers are developed. They last in good condition for about three weeks.

The sweet-scented *Dendrobium aureum* is also flowering now. Although it is not quite as showy as some other species of this genus, it is quite distinct and useful. Its flowers are produced in twos or threes from the nodes of the two-year-old stems. They measure about two inches across, the sepals and petals being a cream color. The lip is large and reflexed, velvety above, buff-yellow, streaked with dull red, and the column is orange-red. The flowers, before they perish, change their color to a deep golden yellow. During spring and summer the plant is grown in a hot, moist house, and in the fall it is removed to a cooler one. In winter it is kept dry and hung in a place where it can get all the sunlight it needs. It grows best in baskets in a mixture of fern-root and sphagnum. This *Dendrobium* is East Indian, and is said to have a wider distribution than any other species of this genus. It has been collected in eastern Assam, on the Khasia Hills, in Nepal, the Madras Presidency, southern province of Ceylon, in Moulmein and in the Philippine Islands.

Dendrobium Ainsworthii is a beautiful hybrid between *D. aureum* and *D. nobile*. It was raised in the collection of the late Dr. Ainsworth, Manchester, England, and flowered for the first time in 1874. It makes a useful winter-flowering plant, and its fragrant flowers are very pleasing now. They are produced on the mature pseudo-bulbs and measure more than two inches across. The sepals and petals are white, with a slight tinge of rose. The lip is white, with a large central blotch of an amaranth color.

Another hybrid with the same parents as the above, but raised by Veitch, of Chelsea, is *D. splendidissimum*, which is also in bloom. The flowers of this hybrid are larger than those of the preceding, and more glossy. The sepals and petals are white and tipped with rosy mauve. The lip is white with a slight touch of yellow in it, and a rich deep purple blotch in the centre.

Botanic Garden, Harvard University.

R. Cameron.

Forcing Hybrid Perpetual Roses.

ONE of the most important points in selecting hybrid Perpetual Roses for forcing is to procure such plants as are budded well down on the stock; plants budded high invariably become exhausted much sooner than those budded lower, when subjected to the trying ordeal of forcing year after year. The time to introduce the plants into heat must be regulated with reference to the time the flowers are wanted; about fourteen weeks is generally required from start to finish. It is necessary that the plants be first subjected to a thorough freezing to insure their breaking away freely. Pruning is also important, and in no case should the young shoots be left too long, about three good eyes being sufficient.

are growing freely, and especially after the flower-buds are set, frequent applications of liquid-manure will be found helpful, and the odor from the manure will assist in keeping down red spider and help to darken and strengthen the foliage. After blooming, repotting or top-dressing should be seen to, according to the requirements, and the same careful treatment continued, every encouragement being given to the plants until the growths have been matured. They may then be hardened off gradually, and toward the beginning of June they should be placed out-of-doors, the pots being plunged to the rims in ashes. The most suitable forcing varieties are Ulrich Brunner, Paul Neron, Magna Charta, Baroness Rothschild and Earl of Dufferin. The last two varieties are somewhat subject to mildew, and should be placed in the warmest end of the house.

Tarrytown, N. Y.

William Scott.

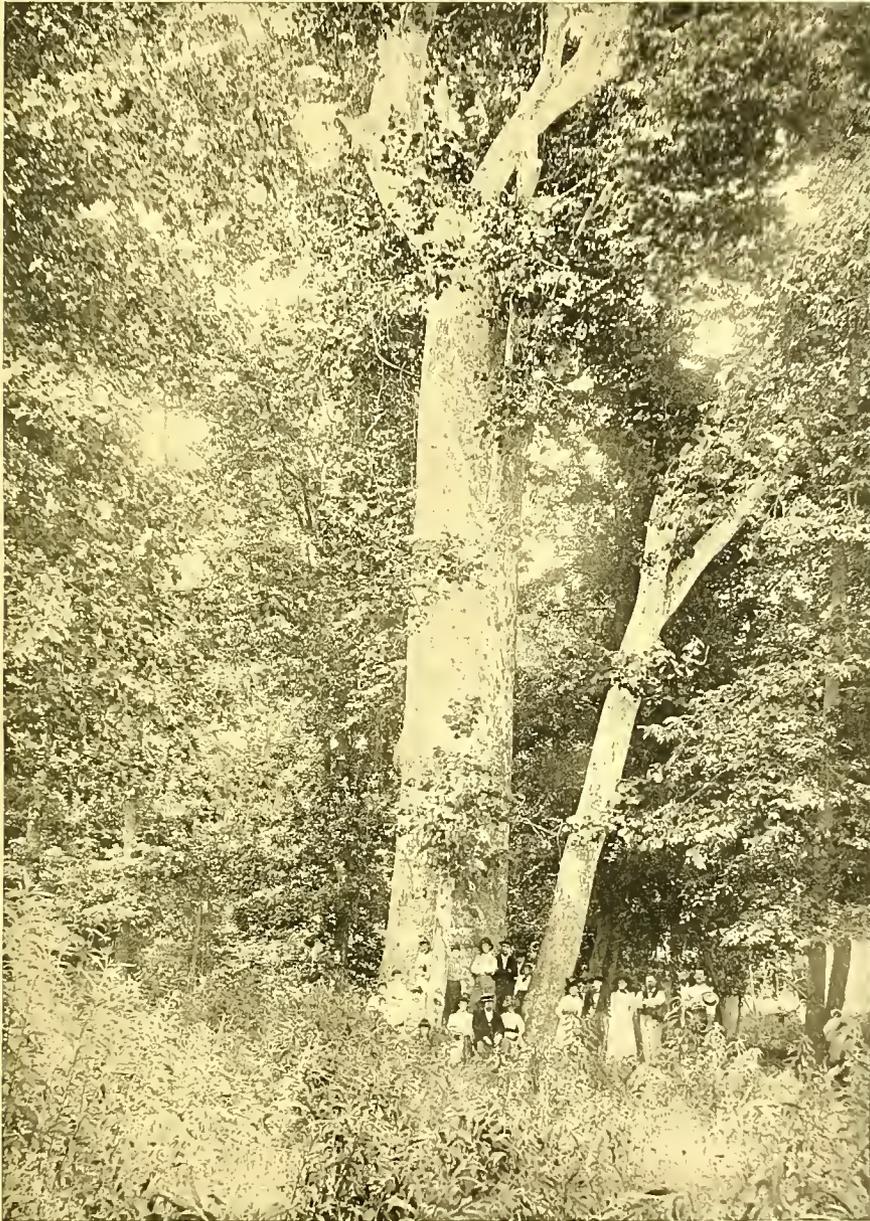

Fig. 6.—The Western Plane, *Platanus occidentalis*.—See page 51.

A night temperature of forty-five degrees will be quite sufficient for the plants at first, increasing to fifty degrees as growth advances and until the buds are well formed. After this time sixty degrees will do them no harm so long as the atmosphere of the house is not kept too dry. The first growth is probably the most critical in the whole process, as during that time there is greatest danger from stagnation. If water is applied too freely before the plants have had time to produce fresh roots the result will be a sickly stunted growth in place of the desired strong, vigorous break. We find light syringing twice daily and the maintenance of a moist atmosphere all that is required for the first three or four weeks. When the plants

Carnation Notes.

THE propagation of cuttings for plants for next winter can be begun now. We have already inserted cuttings of one or two slender growers like Lizzie McGowan, as it is well to start these early to have strong plants in the fall. Our main batch of Carnation cuttings will be inserted during February, although we find that such easily propagated kinds as Daybreak, William Scott and Tidal Wave make sufficiently large plants if not put in until March. If the sand in the propagating bench has been already used for other cuttings it should be removed and fresh material supplied, with which more satisfactory results will be obtained. At the bottom of our bench we put a layer of clinkers and coarse cinders; over this is placed a layer of sphagnum moss, and some three inches of sharp sand is ample for all propagating purposes. This should be pressed down firmly and watered with a rose can before the cuttings are inserted. From four to five weeks generally elapse before the young plants are ready to box off, and with careful attention at least ninety per cent. of the cuttings should take root. The percentage lessens somewhat later in the season. We find a bottom-heat of about sixty degrees about right. Care must be taken not to allow cuttings to wilt before being put in the bench, and to protect them from the sun's rays until rooted. Neglect of these simple precautions is the cause of many failures. Too much stress cannot be laid on taking cuttings from the strongest and healthiest plants, those produced on the flower-stems being the best. If plants are weak or diseased it is far better to buy stock from a reliable florist who makes a specialty of Carnations than to run the risk of perpetuating disease, with consequent disappointment.

We have recently boxed off our cuttings rooted for outdoor summer-blooming, and we keep them on a shelf close to the glass. In about six weeks these will be potted off singly into three-inch pots, or a size larger if the plants are extra-strong. In this latitude it is risky to plant out until the middle of May. By that time, with judicious topping and careful attention, the stock will be of good size. Only a

limited number of sorts flower satisfactorily out-of-doors. Mrs. Fisher is still the best all-round variety, and with us is a mass of bloom and buds from July to November. Other kinds which have proved a success are William Scott, F. Mangold, Daybreak and one or two unnamed scarlet seedlings.

If plants on the benches have not yet been cleaned it is well to get this work done before the spring rush commences. That the plants yield better returns after being cleaned any one can testify who has tried it, yet many growers continue to leave the diseased, decaying and dead leaves on their plants the season through. Such foliage on Violets, Roses or Chrysanthemums is more noticeable than on Carnations, but the health

of the plants demands its removal from all these. Cleaning Carnations takes considerable time, but it can be done when other work is not pressing, and its benefits will be seen as the flowering season progresses. Where rust has obtained a foothold too much vigilance cannot be exercised. Every affected leaf should be picked off and the plants dusted with lime. Some growers think its spread is checked, but we are still awaiting a cure for it here. I think that keeping the plants picked clean, having proper atmospheric conditions, and paying attention to temperature and ventilation does as much to check the disease as any remedy I have seen tried. A number of prominent Carnation growers advertise their stock as being absolutely free from rust, and I believe there are men in the trade who do their utmost to send out perfectly clean plants, yet for the last year or two novelties have been sent out at high prices after being well boomed, which have turned out to be rusted beyond redemption. It is both an injury to the sender out and the buyer to place such stock on the market. Introducers of new varieties should state explicitly whether or not their introductions have taken disease or not, and no kind should be sent out, however good, if not clean. The American Carnation Society, at its forthcoming exhibition in New York, which promises to eclipse anything of the kind ever held, requires that plants must be shown as well as cut flowers of all novelties entered for certificates. This is a move in the right direction, and the inspection of the stock once or twice during the season by a committee of competent judges is better still. This will have the effect to lessen the number of novelties put on the market yearly and to improve their quality.

At this time of the year burst calyces and slender flower-stems, consequent on sunless weather, are very common, and clear, bright weather and freer ventilation are needed to check these defects. The benches now require rather more frequent waterings, and slightly stronger stimulants are given. With heavy firing red spider is apt to get a foothold on the plants which the heat from the hot-water pipes strikes most strongly. Syringing with a good pressure on bright mornings is the best preventive. We give our plants a night temperature as near fifty degrees as possible, with a drop to forty-five degrees on very cold nights. The top ventilators are opened a little each day when the temperature has risen over sixty degrees. Disbudding is now practiced by most florists and gardeners, and the larger blooms and stouter stems are proofs of its merits.

The interest of prominent Carnation growers is at present centred on the New York show and convention, and a number of promising novelties which will be staged there. It will be interesting to note how last year's seedlings—a number of which were certificated—appear this year. Among whites Storm King was one of the most admired last year at Boston. In this locality it does not appear to be much of a success and compares unfavorably with Alaska, which is good almost everywhere and proves itself to be the finest novelty of last season's introduction. It has a better stem than Lizzie McGowan and a better formed flower, and is likely to lead the latter popular variety by another season. Bride of Erlscourt has been thrown out nearly everywhere, being badly diseased. Bridesmaid, which some growers claim is a serious rival to William Scott, will never, I think, attain half the popularity of the last-named sort. It has not averaged more than one flower to the plant up to this time, and other growers near-by report the same thing. Rose Queen blooms more freely than Bridesmaid, but is of a less pleasing color; it has a good stem, but the calyx bursts badly and the plants take rust. Peachblow is too flimsy for a market flower. Della Fox, similar in color to the well-known Daybreak, will be largely grown about Boston another year. Those qualified to speak predict well for Myers & Santman's seedling. Maud Dean, one of Mr. John N. May's varieties, is also likely to be in considerable demand next spring. Daybreak has a sprawling habit of growth, and a novelty as free blooming, identical in color, and like William Scott in habit, would, no doubt, supersede it. Among dark pink shades Tidal Wave is still hard to beat when well grown. Lena Saling, a little paler in color, to be sent out this spring, and another of Mr. May's certificated kinds, is a promising sort. Meteor, sent out by Mr. C. W. Ward, although it has not proved nearly so floriferous as F. Mangold, is now yielding us a few very handsome flowers of a rich crimson-scarlet color. The plant is a clean and vigorous grower. There is a good opening for a new scarlet Carnation, as no kind now grown is altogether satisfactory. Hector is still the best we have here. With a stem like Mr. Hill's Jubilee, it would be an ideal scarlet. Portia, Emily Pierson and E. G. Hill all lack size. The Stuart is not useful in this locality; it has a grand stem, but the flower comes streaky, and it is only semi-double. Eldorado, yellow,

raised by Mr. Shel mire, looks very well with Mr. Nicholson, of Framingham, Massachusetts. It has a large, well-formed flower, but rather weak stem. Among variegated sorts the contest seems to lie between Helen Keller and Minnie Cook. Those who are growing both seem to prefer Mr. Chitty's variety. Helen Keller is fine when grown as Mr. Edwin Lonsdale grows it. A few plants we have are doing well this year, but most of the florists say a large proportion of flowers fade before opening, and there are few perfect ones.

Correspondence.

California Oranges and the Frost.

To the Editor of GARDEN AND FOREST :

Sir,—The exaggerated and conflicting reports which have gone east in reference to the freeze of December 29–30 in southern California are partly explained by the fact that only recently has the full extent of the damage done become apparent. Growers, dealers and newspaper correspondents are naturally unwilling to make definite statements until sufficient time has elapsed for the full effects of the frost to show both upon the trees and the fruit.

It is now apparent that the Riverside crop is practically ruined. Riverside is the oldest orange-growing section in southern California, and the largest producer. Her crop this year was estimated at 3,400 carloads, out of a total of 10,000 for the state. The estimates of the loss have been placed at from 50 to 90 per cent. It is unquestionably much nearer the latter figure than the former, and the frost was so general that probably not fifty carloads of absolutely uninjured fruit could be picked from that now remaining on the trees. Much of it has fallen to the ground as a result of rain. Some of the young orchards are apparently dead, and the leaves are falling from the trees in many of the older ones. The proportion of trees actually killed will be very small, but in many orchards the trees have been so badly injured that the yield for a year or two will be greatly decreased.

Next to Riverside, Ontario and Pomona suffered most. In these districts the young trees are somewhat injured, and frost which would produce such a visible effect upon the trees must have frozen many of the oranges. But probably not more than fifteen per cent. of the oranges in these localities have been injured, and this would amount to only a few score carloads. None of the trees have been killed, and the damage will not materially affect their production another year.

Allowing for the fruit shipped east before the frost, which was something over 400 carloads, and the highest reasonable estimate of the frozen fruit, there are still left in southern California from 5,000 to 6,000 carloads of oranges which are uninjured, and which include a large proportion of the very finest fruit. It may be difficult for the eastern man to understand how orchards within a few miles of those frozen escaped entirely, and I will state some facts about topography and climatic conditions which may help to explain it.

The orange-growing sections of southern California lie principally in a series of valleys extending from Los Angeles seventy miles eastward to Redlands. These valleys vary in width from two miles to twenty. They are bounded on the north, south and east by mountain ranges. They are traversed on the north by the Santa Fé Railroad, and on the south by the Southern Pacific. It is up-grade all the way from Los Angeles to Redlands, the most easterly town, 1,300 feet above the sea. The only other orange-growing sections are Orange County, immediately south of Los Angeles, and portions of San Diego County, a hundred and fifty miles still farther south. The relative importance of these sections may be seen from the following estimate of their respective crops for this year: Los Angeles County, 3,750 carloads; Riverside, 3,400; San Bernardino, 1,700; Orange, 800; San Diego, 180.

Frost in southern California always depends upon purely local conditions; it is never the edge of a cold wave from the north, as was the case in Florida a year ago. The mountains and deserts to the north and east prevent this. It occurs usually during the longest nights of the year, and is a result of the rapid cooling of the earth after sundown and rapid radiation of the earth's heat through a rarified atmosphere. This cooling process begins soon after nightfall and continues until sunrise, the cold growing greater as the night advances, and being greatest just before sunrise. There is greater liability to frost in dry seasons than in wet, because radiation is more rapid through a dry atmosphere than through one which is charged with moisture. Low-lying lands suffer most, because the coldest currents of air settle closest to the ground, while

the warmer currents linger longest on the higher slopes, and also because the lower lands do not receive the rays of the morning sun as quickly as the higher altitudes. This item of the sunrise is an important one where the frost is a constantly increasing factor for destruction through the night, and where the amount of damage is largely dependent upon the length of time that the cold endures. Trees and fruit which would perhaps withstand cold for three hours would be ruined should the same degree of cold continue for six or eight hours.

These facts were fully illustrated in the recent freeze. This season has been very dry. Only a slender thread of snow rests on the highest mountains, where usually their slopes are covered halfway to their bases. The total rainfall up to the night of the frost had been less than two inches. The air was dry and heavily charged with electricity, and the frost occurred at a time when the days had been for weeks unseasonably warm. The frost was preceded by a high, dry wind, which swept the air of every particle of moisture. This wind died away before night. The cold set in soon after night-fall, and continued until sunrise. The lowest point reached by the thermometer, at Riverside, was 17 degrees; the lowest at Redlands, fourteen miles distant, but on higher ground, was 26 degrees. This difference of eight or nine degrees made the difference between the destruction of the crop at Riverside and its escape uninjured at Redlands. Most of the other sections of San Bernardino County which grow oranges are, like Redlands, on high ground, being the warm, sunny slopes of the foothills. They escaped, except in a very few of the lowest and most exposed localities, in which there was damage, so slight, however, as to be practically of no importance whatever. In Los Angeles and Orange Counties there was frost, but not enough to injure the oranges to any great extent. These sections are nearer the coast, and the air is not so dry as in the interior. The location of Pomona is in the middle of a wide plain, and is therefore more like that of Riverside than some of the other localities, and the district suffered accordingly. The United States weather observer at Los Angeles had the following to say about the frost at Pomona in his report for January 7th: "The temperature, December 30th last, at sunrise, ranged from 23 to 27 degrees, which was no doubt correct, as the flowers and vegetation showed the fact. There were but few oranges or lemons injured by the frost; many orchards suffered none at all, and the tender growth of lemon trees and lemon blossoms were untouched. Very young citrus trees were damaged in some places, but old trees none worthy of note." This report was, perhaps, as accurate as could be made at the time, but later observations have shown that the damage was greater than at first estimated. It will be noted that the temperature was lower than at Redlands, though higher than at Riverside.

Admitting that the crop of Riverside County is practically destroyed, we still have nearly all the crop of Los Angeles County, or, approximately, 3,000 car-loads. The crops of Orange and San Diego Counties, originally about 1,000 car-loads, have not been hurt by the frost; but the bulk of these are grown near the coast, and are not as fine as those grown in the interior. They are frequently infested with scale, and have to be washed. They are much more acid than the interior orange, and lack the rich, burnished color which the hot winds from the desert give the latter. They are also much slower in ripening, and for this reason most of the crop is still upon the trees in these localities. In San Diego County some oranges are grown in the sheltered valleys back from the coast, and are of excellent quality, but the coast-grown product is a sour fruit, of a light, almost lemon, color, and full of "rag." However, the whole product of this county, 180 carloads, is too small to be of much importance at present. In San Bernardino County there are about 1,000 carloads left, nearly all of which are the very choicest fruit that California produces. The original estimate of the best portion of this county was: Highlands, 200 carloads; Redlands and Crafton, 700, and Colton Terrace, 100. Of these about 350 cars have gone forward, most of it as early fruit, at a high price. There was no damage whatever in these districts by frost. This makes about 5,000 carloads of fruit left unharmed. Much of the fruit still upon the trees at Riverside will be sold, and the amount will be anywhere from 300 to 1,000 carloads.

The early shipments of oranges were, in the opinion of many, a blunder. The best of the fruit was immature, and could not possibly give the consumer a favorable notion of the California orange. The action of growers and shippers after the freeze was still more injudicious, if not actually dishonest. A demand was made upon all the outside districts for packers, and frozen oranges were rushed out of Riverside

at the rate of fifty carloads a day. A few shipments were also made from Pomona. False and contradictory reports were sent out through the associated press and other agencies, which confused the eastern buyer. It is also alleged that frozen oranges were packed under the brands of localities where no damage had been done. The Southern California Fruit Exchange, which was organized ostensibly to protect the growers, did its share toward demoralizing the market by injudicious shipments. This hasty and ill-advised action is to be regretted, as it has caused a loss of reputation greater, perhaps, in the end, than the million dollars or more actually lost in the value of frozen fruit.

The fruit most badly frozen is now upon the ground, abandoned as worthless. One packer at Riverside threw away, last Thursday, twelve carloads, for which he had paid \$7,000. The loss will come heavily upon some of the packers who had bought early, and took their chances of a frost. Badly frozen oranges rot and fall to the ground after a few days, especially if there is rain. Fruit that is frost-bitten, but not frozen, will remain upon the tree. The juices evaporate through the skin, and the pulp becomes dry and tasteless. Sometimes the flavor is injured, although there is no apparent change in the appearance of the orange. The remainder of the fruit forwarded from Riverside this year will doubtless be open to suspicions of these undesirable changes, but this will be only a small proportion of the total still remaining for shipment.

It is absurd to compare this partial disaster with the destruction of the Florida orange groves a year ago. Riverside has about 7,000 acres of bearing groves, and if all of them had been destroyed, instead of the possible five or ten per cent. that have been destroyed and the twenty or thirty per cent. that have been injured, the loss would have been balanced by the new groves coming into bearing in other localities.

There has been heavy loss at Riverside three years during the past six, and the frost of this year seems to indicate that the location has not justified the heavy plantings made there. Experience now shows that the higher lands are best adapted to citrus culture. It also shows that California is only upon the northern edge of the true citrus belt. The sheltered, sunny, foothill lands have never lost a crop through frost, but to come within six or eight degrees of loss every year is not a pleasant experience for the grower who anticipates a return of from \$300 to \$600 an acre from his orchard. If the market recovers, as it should, from the demoralizing effects of the frost, the best groves will pay very handsomely this year, and will be as good a hard-times investment as any one could wish.

Redlands, Calif.

Wm. M. Tisdale.

Notes from Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—Mr. Watson's remarks upon the Cherimoyer (page 14) lead me to say that this fruit is successfully grown here in some localities. Along the foothills on the northern side of the beautiful Cabuenga valley, near Los Angeles, quite a number of trees have been planted. From the garden of Mr. Jacob Miller I have had specimens quite four inches in diameter. A more delicious fruit I have never tasted. In flavor I would compare it to a combination of the pineapple and the strawberry. The flesh of those produced here is creamy white. It ripens here during March, April and May, and good specimens retail at twenty cents each. In this same garden (Mr. Miller's) are growing a number of uncommon trees and plants. A Coffee-bush, some eight feet high, produces annually a profusion of fragrant flowers and ripe berries. A good-sized Carob-tree bears pods regularly. There is also a grand specimen of *Plumieria alba* (Frangipani), four or five feet high and as much in diameter, which blooms abundantly during late summer and autumn, filling the garden with fragrance.

The belated rains have at last arrived, and the landscape is fast assuming the greenness of spring-time. The farmers are now shipping from this favored locality green peas, string beans, tomatoes and ripe strawberries, and in the water garden *Aponogeton distachyon* is flowering freely.

Los Angeles, Calif.

Edmund D. Startevant.

Irrigation in Horticulture.

To the Editor of GARDEN AND FOREST:

Sir,—In your report of the meeting of our Horticultural Association at West Chester, Pennsylvania, on irrigation, I am reported as saying that we paid eighteen cents for a hundred gallons of water; the figures should have been fifteen cents for a thousand gallons. When I said that a one-inch pipe with eighty pounds pressure will irrigate a quarter of an acre, I

meant that such a pipe running a day would answer for one application. As the subject of irrigation has become of unusual interest, permit me to add some of our experience. We have used water to a considerable extent for two seasons past, and are satisfied that it pays on some crops even when bought by the gallon. The past summer we used not less than 125,000 gallons on Potatoes, Cabbage, Cauliflower, Celery, Horseradish, Sweet Corn and Strawberries.

The first consideration is not only will it help the crops, but will it justify the expense, and when we pay for water by the gallon the expense rises as rapidly as the water flows from the pipe. Where the water can be pumped or collected by damming a stream, the increased use does not increase the cost, and if the first cost is not too high irrigation would be profitable in very many cases. There are few summers without one dry spell at least, and when this is not too long it will pay to irrigate many crops even at the price we are paying, but in a continuous drought, such as that of the past season, the expense will be too great, except, perhaps, on a few fancy crops, such as Strawberries, Celery and Cauliflower.

Subirrigation is the best method for field crops, but for market gardening a full supply of water is needed on most crops. Crops that require only a short season cannot wait long for rain and then reach perfection.

H. M. Engle.

Meetings of Societies.

Nebraska State Horticultural Society.—II.

HORTICULTURE IN EASTERN NEBRASKA.

A CAREFUL discussion of the comparative advantages of fruit-growing here and in other sections was presented by E. T. Hartley. Mr. Hartley has given special attention to the advantages of the Colorado fruit-growing sections during the past season, and has come to the conclusion that the prospects of eastern Nebraska are as good as those of Colorado. There is a great deal of booming in the matter of fruit-growing as well as in other lines. We are inclined to make too much of our successes and too little of our failures, to report the returns from exceptional trees, unusual prices, etc. Reaction is the inevitable result of such a course. He has no desire to ignore the disadvantages of Nebraska, but believes that when both advantages and disadvantages are carefully compared we shall find a balance in our favor. Nebraska has seen forty years of prosperity, and it is unlikely that its whole character will now change. It is only a matter of common observation that other states have seen similar periods of depression from time to time. Moreover, orchardists have suffered less than other classes during this time. While Corn has in countless instances failed to produce any crop whatever, orchards which have been well cared for have given fair, and in some cases heavy, returns. It is also a significant fact that while corn is now selling at fifteen or sixteen cents a bushel, apples are bringing from \$2.50 to \$3.00 per barrel at wholesale. When we consider carefully the cost of drainage, the disadvantage of working among stumps and stones, the cost of irrigation, the backward civilization and other disadvantages which must be encountered in the different sections of the country, we see that our own location is not so unfavorable after all. There are many drawbacks to irrigation—first, the cost of the water-right and fees, then the increased cost of cultivation, together with numerous annoyances that an outsider never dreams of. Mr. Wilcox stated that it requires two men to irrigate and care for ten acres of orchard, while in Mr. Hartley's orchard two men and one team will care for one hundred acres. He can cultivate the whole of his orchard while the men who use irrigation are plowing out the furrows to apply the water. Then these furrows must be gone over with a hoe to correct irregularities, remove clods, etc., and this may take more time than to make the furrows in the first place. The short rows which irrigation demands increase the cost of cultivation materially. Even if a crop can be secured every year by means of irrigation, it is not likely to prove as profitable as the same amount of labor applied to more land, but with a crop only every other year. Transportation is just as important as production. In this matter the Colorado growers work under a very serious disadvantage. In fact, Mr. Hartley presented figures, gathered on the ground, which seem to show that after the crop is all grown and ripe upon the tree at Grand Junction it then costs over two dollars a barrel to gather, pack, ship and market it in Denver or Pueblo. Mr. Hartley found that at Grand Junction he must pay twenty cents a dozen for peaches grown there, while in Denver the same peaches were selling at two dozen for fifteen cents. This year has demonstrated the ability to

produce fruit in eastern Nebraska in spite of drought. Moreover, with the small fruits, which yield a large return from a small amount of ground, it is possible to profitably lift water by means of windmills to help out the rainfall. This cannot prove profitable for ordinary farm crops, for there is too little margin in the possible product of an acre. The loss of water by seepage and evaporation is too great also, even if reservoirs are employed, to make the undertaking feasible, except for those crops in which the market value is high. Hard winds, cold waves and frosts have been much more injurious than drought even during these recent dry years. Many orchards have proved an unexpected blessing to their owners during these trying years.

E. M. Pollard, of Nehawka, gave results of work and statistics to show that orcharding in Nebraska had proved a profitable venture with them thus far. They make a specialty of apples and cider. The cider is heated to about 150 degrees, Fahrenheit, by steam and run into heated barrels while still hot. By this means the cider is kept sweet, provided only that the package is completely air-tight. They also employ vinegar generators, by which they can secure first-class vinegar from fermented cider in thirty-six hours. They find it very difficult to compete against the cheaper corn vinegar, which is nearly everywhere sold as cider vinegar. From the best statistics which he could get he finds that the average price to the grower of apples in Nebraska during the last seven years has ranged from \$1.50 to \$3.00 per barrel. They now set eighty trees to the acre, but with only forty trees to the acre, at an average price of fifty cents per bushel, the returns would be twice as great as can be realized from corn, even if the yield should be but one bushel a tree, while it ought to be five bushels. He deprecates the continued planting of the Ben Davis Apple. In the better family trade, which they aim to supply, he finds it difficult to dispose of this variety, and in their newer plantings it is discarded altogether. Many of the Apples of good quality which succeed in the east fail here, but the Swaar does well.

ARE THE BIRDS FRIENDS OF THE HORTICULTURIST?

This was the question discussed by Professor Bruner, of the State University, and he made a strong plea for these feathered inhabitants of our fields and gardens. Seventy-five per cent. of the food of birds consists of insects. Moreover, when we consider their ability to withstand cold and their powers of endurance, it is apparent that they must require much fuel to maintain the bodily functions, and consequently must be hard eaters. There are fifty more species of birds found in Nebraska than are reported from any other state except Texas. There are undoubtedly more than 75,000,000 birds in Nebraska for half the year. These, upon the most conservative estimate, destroy thousands of bushels of insects. The winter birds subsist largely upon weed seeds, thus causing marked depreciation in the spread of these nuisances. Numerous figures were quoted showing the contents found in the stomachs of different birds when examined for that purpose. The quail is one of the best friends of the farmer and horticulturist, for it destroys millions of chinch bugs. The flicker also eats chinch bugs. Professor Bruner believes that the unusual destruction of fruits caused by birds within the past few years has been primarily owing to their lack of water. Upon this point, however, many of the growers did not agree with him.

The Western New York Horticultural Society.—II.

THE INVISIBLE FRIENDS AND FOES OF THE FARMER.

ON this subject Professor Roberts said:

The soil teems with invisible plants or low vegetable organisms which prepare it for higher growths by making available the combined nitrogen in the soil. These invisible plants need a certain amount of air, moisture and warmth for development and growth. They are ever at work breaking down the crude material and transforming it into plant-food, and the fruit grower, like other cultivators, must learn that, like higher vegetables, these flourish best when their home is warm, mellow, dark and moist. Since there are from three to six thousand pounds of potential nitrogen in the first foot of an acre of fairly fertile soil the advantage of multiplying these nitrifying organisms is apparent. The cultivation of the soil unlocks this vast storehouse of food and puts it into circulation. Proper cultivation not only promotes the process of nitrification, but it makes available phosphoric acid and potash, so that these considerations point to a short rotation, frequent plowing, partial soiling and the use of leguminous plants whose roots gather free nitrogen from the air. The objects of cultivation are primarily and chiefly not to make the soil porous

so that the roots of plants can enter it easily, but to promote the invisible vegetable growth and chemical action of the soil which, while holding on to the water as minutely divided, will allow flowing water to pass downward into the subsoil. Water is nature's universal carrier, and it transports all nutrients into and out of the circulation of vegetables in growth. It not only lifts up tons of solid matter through the stems and trunks of trees and smaller plants, but it breaks rock and levels hills and transports them to the sea. Nearly all the moisture used by plants is brought to them by the silent forces of capillarity, and if the soil is in proper physical condition moisture flows upward to the roots of vegetation from the reservoirs in the subsoil as certainly as it runs downward by gravitation.

This is the underlying principle of successful husbandry—an ample reservoir for stored moisture to tide plants over critical periods held by capillarity in well-prepared soils which contain no free water. Under-drainage and deep tillage furnishes this reservoir, and two or three inches of surface soil tilled until it is loose, light and porous prevents the water from evaporating and passing off into the air, so that it is retained in the soil where it must be drawn up through the roots of the plants.

MISTAKES IN ARRANGING HOME GROUNDS.

In speaking of this subject, Mr. W. W. Parce, of Rochester, mentioned the disposition to plant something or to build something everywhere—fences and hedges where none were needed, flower-beds and fountains or a statue to occupy the centre of a lawn which should be open turf. Another error is the mania for making grounds look artificial, formal terracing where nature's way would answer better, rows of trees and shrubs instead of natural groups, trees and shrubs trimmed into unnatural shapes. In many grounds, such trees as Kilmarnock Willows, White Birches, variegated Altheas, Purple-leaved Plums, Irish Junipers and Smoke-trees and a few other trees of singular form, made up the collection, with a Geranium bed, and one of Coleus, and a dozen Rose bushes, each of a different shape. If a man were to dress himself in articles of such staring contrast he would be arrested. In this locality most of the trees and shrubs are deciduous, and there are none with variegated foliage except for a week or two in the autumn. This suggests the use of similar plants in natural grouping, and although it is not desirable to turn a dooryard into a primitive wildwood state, it is true that those places which are treated in what is known as a natural manner are most attractive. Highly colored plants and flowers should be kept out of the foreground, where peaceful scenery and restful forms are needed. To produce these quiet, homelike effects, groups and single specimens of trees and shrubs which are not of such pronounced types as to catch the eye by their peculiarities, should be used, for of these last we will grow weary on long acquaintance.

EVAPORATED FRUITS IN WAYNE COUNTY.

Mr. B. J. Case regretted that large quantities of cheap and worthless apples, half-ripe, badly pared, not thoroughly cured, and treated with too much brimstone were sent out as evaporated apples. This year dealers have returned load after load when they have not been up to standard. Fruit like this can be delivered at the station for from five to seven cents a pound, but it is not fit to eat. In 1893 heavy storms blew down thousands of apples that were hardly fit to feed to hogs, and these were all evaporated. Fifty car-loads of this stuff were marketed in Wayne County. It is no wonder, therefore, that good apples were cheap in 1894 and that they did not bring good prices in 1895. When consumers have received this unpalatable and unwholesome product once they refuse apples the next time. We can learn much from fruit growers in California in this matter, where everything is done neatly and only ripe fruit is used. To hold our market we must keep a uniform product, pare more cleanly and dry more thoroughly, so that the product will keep. They are learning, however, in Wayne County, and first-rate evaporated apples are now sure to bring good prices, and so are first-rate raspberries, of which a million pounds are produced in this county. Berries are stored by packing in a dry barrel and kept in a cold place. Apples, to hold their color, must be packed in boxes and put in cold storage by the first of May. A load of apples well dried in 1891 and put in storage in February, 1892, is now as good as it ever was. Good work is done by evaporating apparatus of all grades and sizes, but the upright-flue system seems the most thorough, and the hot kiln the cheapest. There are no apples evaporated in this state which will grade "fancy" in Boston. Some will in New York and Chicago. One-sixth of the Wayne County product will grade "fancy" in Boston, and five-eighths "prime." Of the prime there are two grades—

one dried on wood and the other on wire. On account of the German law prohibiting the importation of wire-dried fruit, wood-dried apples bring a higher price when Germany is buying freely.

THE EXPERIMENT STATIONS AND FRUIT-GROWING.

On this subject Mr. W. D. Barnes said, in part, that the prime work of the stations should be scientific—that is, they should investigate principles, but they should also make practical tests in matters which involve too much expense for the individual fruit grower. For example, they should try different methods of irrigation and ascertain what kinds of fruits are most benefited by it. Of course, we must look to the stations to find whether the San José scale and other insects are liable to be a continuous and growing pest here, and, if so, how they are to be suppressed. The stations, too, might well try to find some substance which will stick to a glossy surface so that it can be used as a vehicle for fungicides and insecticides. But, however good the stations' work, the growers will get no benefit from it unless they read the station literature. It should, therefore, be the duty of every one to interest his neighbors to send their names to be put on the mailing list. At every institute names should be gathered not only of farmers, but of the special lines in which they are interested, so that each one will receive just the literature that he needs.

American Forestry Association.

THE characteristic feature of the annual session of the American Forestry Association at Washington, last week, was the hearty coöperation of several leading public men, especially of the chairmen of the Public Lands Committees of the Senate and of House of Representatives, the ex-chairman of the House Public Lands Committee, and now leader of the minority, and the Secretary of Agriculture. Secretary Morton presided at a largely attended evening meeting, which was addressed by Senator Dubois and Representatives Lacey and McRae. The Secretary has long been known as an enthusiastic advocate of rational forest management, and his opening remarks pointed out from a statistical point of view the folly of depleting our forest resource and the evil consequences to agriculture. It was to be expected, however, that the founder of Arbor Day, which is Mr. Morton's distinction, would enter heartily into a movement for the preservation of the national forest domain, but more notable and significant were the emphatic utterances of Senator Dubois, in whose state of Idaho much of the best of public timber-lands remain, which are looked upon by the people as their rightful property, to be used at will. Mr. Dubois displayed a familiarity with the forest conditions of his state hardly to be expected from one who had not made the subject a special study. He explained the causes of the failure of the timber agents to protect the forests on the public domain, and expressed his earnest hope for the early passage of some such comprehensive legislation as is proposed in the bill introduced by Senator Teller (S. 914).

Congressman Lacey discussed in a delightful way the destruction and repair of our natural resources, and the audience was fascinated by his wit and his poetic pictures of the rich woods and running brooks, once so abundant, and now rapidly disappearing. As a means of repairing our natural forest resources he considered Government action indispensable. He argued that the Government alone can hold tracts either long enough or large enough to effect the great climatic purposes involved in the preservation of the forest cover. The laws providing for timber reservations were a great step in this direction, but it was also necessary to provide for their use. A thorough system of cutting this timber rationally ought to be provided under which the wants of the people might be satisfied. But this should be done with such system as to preserve them as a whole.

Congressman McRae, who was chairman of the Public Lands Committee in the last House, and is a member of the committee at present, spoke of the proposed legislation for an administration of the forest reservations. H. R. 119, which, being reintroduced by him with the same number, goes by the name of the McRae bill, although not ideally the best, contains such features of administration as it would be possible to get passed at present, when improvements might be made afterward from time to time. This bill was actually passed both in the Senate and the House of the last Congress, but failed by unavoidable accident to go to conference committee and to become a law. He expressed the belief that at the present session its passage might be effected.

The Forestry Association is to be congratulated on having secured from three legislators of such prominence emphatic

expressions of sympathy with their purposes, and the country at large will join in the hope that their expectations of successful legislation may be realized during the present session.

From the report of the Executive Committee it was learned that the membership of the association had rapidly grown to over 600, and it now feels strong enough to support a regular monthly or bimonthly publication, and steps to establish such a publication are presently to be taken by the Executive Committee as well as to secure an affiliation with the various state organizations.

Notes.

According to official statistics the importations of lemons into the United States during the past ten years amount to \$38,500,680.

In the February bulletin of the well-known Thayer Fruit Farms, it is stated that after the land is put into high cultivation the actual cost of bringing an acre of Blackberries or Raspberries, well set and with no missing hills, to a good bearing age, is from \$125 to \$150.

Fruits are usually considered luxuries, but Mr. G. C. Snow, of Penn Yan, New York, presented many analyses to the horticultural meeting at Rochester to show that at present prices more heat-producing and life-sustaining power could be bought for the same money in the shape of fruits than of most other articles of diet.

Professor Massey sends us a photograph of some flowering plants of the Chinese Narcissus from bulbs grown in water. The specimens are very well grown and seem to dispose of the objection that bulbs grown in North Carolina will not flower in water. Professor Massey writes that he has Dutch Hyacinths in bloom under glass, Trumpet Narcissi and Frezias, from home-grown bulbs, which are quite as good as any imported ones.

In a recent lecture, Professor Goodale stated that one who wishes to see the showy plants of the tropics at their best ought not to go to the jungle or forest where they are widely scattered and in many instances crowded out of proportion and not in the best health. Under the care of an intelligent gardener all their caprices are humored and they thrive better than they do where they have to shift for themselves. In a stove like that of Mr. Hunnewell, at Wellesley, Massachusetts, and in similar places, where the treasures of the torrid zone are gathered together from the entire circuit of the globe, these plants have a brilliancy of bloom and a perfection of form which are rarely seen in their natural abode.

Oranges have been in light demand for several weeks past, due to the unsound condition of the last of the Jamaica crop and to the injury by frost to the California fruit. Valencia oranges have been selling at a loss recently, but a cargo which arrived in sound condition early last week realized satisfactory prices, and sold for \$4.00 to \$4.62 a box in wholesale lots. On Saturday, however, practically as good oranges from Spain brought only \$1.50 a box. Lemons, too, are selling at low prices, Messina, Palermo and Malaga furnishing the main supplies. Bananas share in this depressed condition, and the highest grade of fruit from Port Limon commands but \$1.15 a bunch at wholesale, while smaller bunches sell for forty cents each.

Mr. Smith Hawley, of Luddington, Michigan, in a lecture before the Horticultural Society of that state, said that the picture so often seen in agricultural papers of a man standing on a wagon and throwing spray into Apple-trees as he was drawn along is a delusion. To do thorough work one must go all about a tree and throw spray upon it from every direction. When this work is properly done the trees will retain their foliage until the snow falls; it will be bright, healthy and in good working order long after unsprayed trees are bare. As a result, trees will produce much fruit on off years, and the fruit, because properly ripened, will keep better than that grown on trees weakened by the attacks of fungi and insects.

A class of advanced students who are fitting themselves to be professional horticulturists meet once a week at the residence of Professor Bailey, in Ithaca, New York, for the purpose of an informal discussion of current horticultural topics or matters of history and criticism. There are about a dozen of these students, who are most of them Bachelors of Arts or Bachelors of Science, graduated from different agricultural colleges or universities, and they together constitute a class of mature and trained men such as probably have never before been brought together in this country for the express study of higher horticulture. The topic last week was The Lindleys—

their times and work. Other topics have been The Downings; Jethro Tull and the Tillage of Land; The Commanding Factors in New York Pomology.

The recent subscription of \$10,000 to the endowment of the New York Botanical Garden by Mrs. Esther Hermann increases the fund to \$260,000, besides \$5,000 worth of plants contributed by Mr. James A. Pitcher. Some 250 species of trees and shrubs, besides those already in Bronx Park, where the Garden is to be located, have now been placed in a temporary nursery, and the construction of roads and erection of buildings may be begun during the present season. The Finance Committee of the Board of Managers will be glad to receive subscriptions from any one who wishes to follow Mrs. Hermann's generous example. All persons intending to contribute can communicate with Mr. James A. Scrymser, chairman of the Finance Committee, 107 East Twenty-first Street, or with Mr. J. Pierpont Morgan, Treasurer, 23 Wall Street, New York. Inquiries as to the scope and progress of the enterprise will be answered by the Secretary, Professor N. L. Britton, 41 East Forty-ninth Street, this city.

The St. Louis *Lumberman* says that there is no wood which equals the Cypress in value, of which so large a proportion of the total supply still standing is put into market every year. The president of the association predicts that in ten years there will be but seven mills cutting Cypress in Louisiana, in twenty years but four, and in twenty-five years none. This means that within ten years from sixty to seventy-five per cent. of the Cypress will be cut and sold, and that probably half of all the Cypress now standing will have been marketed before the end of the century, and yet the production is now only about two billion feet, say, one-thirtieth that of White Pine, the wood with which it mainly competes. Cypress belongs to the finer class of woods, and it certainly seems short-sighted to sell it for less money than it must soon be worth. It is not abundant, nor is it rapidly reproduced, and it is practically certain that when the present supply is used up that will be the last of cypress lumber as a commercial product.

Mr. Rydberg prints in the third volume of the *Contributions from the United States National Herbarium* an interesting paper on the flora of the sand-hills of Nebraska, a region extending from the ninety-eighth to the one hundred and third degree of west longitude and from the Niobrara River on the north to the North Platte River on the south-west. This is a region of shifting surface and of sandy soil, which is carried away by the wind when it is not held down by the roots of plants or otherwise protected. Some attempts at agriculture have been made in this region, but a farmer, after breaking his field, may find it transformed into a deep hollow and its soil deposited miles away, perhaps, in a great drift which serves as the foundation for one of the hills which are the characteristic feature of the region. Probably once covered by a forest of Pines, the only trees of the region now are Willows and Poplars, confined to the river-bottoms, the largest part of its flora being composed of grasses, sedges and low leguminous plants. A Thistle, the *Cnicus Hookerianus* variety, of Gray, is elevated by Mr. Rydberg to specific rank as *Carduus Plattensis*, a plate accompanying his description.

In a bulletin issued by the Chemical Division of the Experiment Station of Minnesota on the composition, digestibility and food value of potatoes, a cross-section of a tuber is given, in which the relative amount of water and other compounds is graphically illustrated. Three-fourths of the potato is water. One-fifth of it is starch, with limited quantities of fat, fibre, ash, malic acid and pectose or jellies. Only two and a half per cent. of protein occurs, and only about half of this is digestible. It is noted that early varieties of potatoes contain less starch and a larger proportion of protein, because the protein or nitrogenous compounds are formed in the early part of the growth of the tuber, while the starch is added at a later stage. For starch-making the medium-sized and later varieties are preferable, but in excessively large potatoes the jellies and other substances replace the starch. A large part of the limited quantity of albumen in potatoes is often lost in cooking; since when they are placed in cold water to boil much of this material will be extracted while the water is warming up, and, therefore, most of the vegetable albumen is lost. If the tubers are placed directly in boiling water the albumen is coagulated and retained. Peeled potatoes, when placed in cold water and boiled, lose four-fifths of their albumen. Potatoes not peeled, and started in hot water, lose only one-fiftieth. This means that when a bushel of potatoes are improperly boiled as much protein is lost as is contained in two pounds of beefsteak.

A German View of the Value of the Forest.

WE recently attempted to answer in a general way the question, "What is Forestry?" To give some idea of the importance of this science to the people at large we now quote some passages from an address delivered by Dr. Franz Baur, in November last, on the occasion of his inauguration as Rector of the Ludwig-Maximilian University in Munich.

This address was a discussion of the peculiar place held by the forest in national life, or, as Dr. Baur expressed it, "in the housekeeping of a nation." In the course of it he showed that forest preservation has not only a strictly economical, but also a social-political and ethical side. "At the time," he said, "of the despotic rule of Napoleon I., near the beginning of this century, Germany lay economically exhausted, and through the pressure of necessity the axe was used more vigorously against German forests than in normal times. It was then that E. M. Arndt, who loved his fatherland above all else, exclaimed, 'Now, in many lands, the axe which is laid against the tree is laid against the people itself.' Evidently, in using these words, he thought less of a decrease in the revenues from the forests than of a lasting injury to the character of the German people through persistent forest destruction. And, in a similar spirit, W. von Riehl wrote these significant words: 'Hew down the forests and you will ruin our historic burgher society. By destroying the contrast between field and forest you will take from the German people its principle of life. Man does not live by bread alone. Even if we should need wood no more, we should need the woods. Even if we should no longer require the dried products of the forest to warm our bodies, we should still require the living forest to warm our souls.' The truth of these words grows ever clearer with the rapid development of our industrial life. Already in our great factory towns there live millions of people who exhaust themselves during the week in crowded, and often unwholesome, workrooms, and on Sundays and holidays seek indispensable recuperation for mind and body in the fresh green forest."

This, according to Dr. Baur, is one peculiarity of the forest among the economical treasures of a nation—the fact that it has a spiritual, an ethical, as well as a purely

economical, importance. And from this he deduces the truth that the management of public forests should not be regarded in a narrowly business-like way, as a mere matter of present capital and present interest. The forests of a nation should be looked upon as a great national trust. They should be so controlled that, while the present generation is enabled to draw from them as large a revenue as possible, at least as large and varied a revenue should be secured to future generations. "The dissatisfied directors of our forest finances," he adds, "who always consider the present profit they yield too small, would be in better spirits if they more clearly realized this radical peculiarity of the forestry question." It is true that forests may be made to yield a satisfactory revenue, but since they mature slowly, instead of giving an annual crop, like wheat or barley, they cannot, like many other sources of national wealth, be regarded solely from the money-making standpoint, and, still less, can they lend themselves to the modern wish to secure immediate returns upon invested capital, and to meet, with speculative rapidity, the changing needs and tastes of a community.

After briefly surveying the past history of European forests, during the long periods when no official care was taken of them, and during the more recent periods when a right realization of what this care ought to be, in extent and in kind, he explained that there are still European countries, like Spain and Denmark, where the need for scientific forestry is not yet appreciated; and of the United States he said: "Even in the primeval forests of North America, once believed to be inexhaustible, irreparable damage has already been wrought. Eager for quick profits, the great lumber syndicates of that continent still continue the work of destruction; yet, even there, the necessity for some thought for the future has been recognized, and millions of acres have been set apart as forest reservations—that is, even in this comparatively new country, it has come to be a recognized fact, as it is in the Old World, that if the wounds inflicted on the forest through lack of forethought are to be healed, the cure must be worked by the state rather than by rich private landholders. Even the popular assemblies of most of the German states are no longer willing that their forests should be at the mercy of private interests."

Dr. Baur adds, that in addition to lumber, fuel and other staple products, the forests produce vast quantities of berries, fruits, flowers, mushrooms, mosses, basket-material and materials for decoration, the value of which cannot be accurately computed, although it certainly amounts to millions of marks annually, and hundreds of poor families in Germany, who would otherwise be destitute, depend upon these products for a livelihood.

The unique value, however, of forest-lands as sources of refreshment, enjoyment and inspiration for the souls of men is something which should always be insisted on. If one imagines Heidelberg, for instance, denuded of its forests, or Baden-Baden or Carlsbad, one can understand the importance of forest surroundings to an urban community. Nor are economic interests ignored even when this point of view is taken. Were these cities denuded of their forest environment the multitudes of travelers who now frequent them and bring gold to the hands of their inhabitants would conspicuously diminish.

No government, says Dr. Baur, in conclusion, can administer a forest as it may administer a factory, where it writes over the door, "No admittance except upon business." To do this would be to destroy the value of the forests as a possession of the people. Their portals must be thrown wide open, not only to the architect, the painter, the musician and the poet, not only to the scientific student and the seeker after health, but to the public at large. And in this country one needs to add, the public at large as well as the government must be taught to realize that, while the forests should be utilized by all they should be injured by none, for they are the property, not of this generation only, but of generations yet to be born.

A Botanical Journey in Texas.—I.

DURING the month of May copious and almost continuous rains fell throughout most of Texas, and from Louisiana to Mexico all farm crops were growing luxuriantly and all nature was rejoicing, when, on the second day of June, I started to make a long and tortuous botanical trip from San Antonio to El Paso, a distance of over six hundred miles. Western Texas was at its best, the trees and plants dressed in full holiday attire, with new shoots longer and more drooping than they are in drier seasons, leaves greener, flowers larger and handsomer.

Lovers of nature must have noticed the beauty of all forest scenery in the full growing time of the trees, when the varying tints of green in the newer leaves mingle with the deeper hue of those that are fully developed, and no such lover would soon tire of contemplating a grove of Yellow Locust in June and after a drenching rain has washed their leaves.

Botanizing from the windows of swiftly moving railway cars is too careless observation for the purposes of science, except in regard to well-known and conspicuous species, which, of course, may be recognized. As far west as San Antonio occurs the French Mulberry (*Callicarpa*), the Box-Elder, which will be found at intervals as far as the mountain cañons of central New Mexico and southern Colorado, and the Honey Locust which about San Antonio is either native or naturalized. Wild China or Soap-berry, *Sapindus*, in full blossom, is common in woods throughout our entire journey.

After we cross Medina River the ripe crimson fruit of *Rhus microphylla* renders that shrub conspicuous and adds variety and beauty to the forest scenery. Travelers who have been over this route in times of long-continued droughts are now surprised to see in the clearing of every ranchman and small farmer luxuriant fields of rank tall Corn and other grains growing in a region which they had thought to be only a dreary waste. A stop for a day at Sabinal gave me an opportunity to botanize along the river and among the hills. Sabinal signifies a Cypress grove, and the Cypress-trees grow along the river. Some individual trees are three to four feet in diameter. Most of them, however, like the Buttonball-trees of Kansas, have outlived their usefulness. Yet there are thrifty and vigorous trees here, which, left to themselves, will long preserve the significance of the name of the river and that of the little village near by.

Going from Sabinal we soon reach the valley of the Leona and of the near-by Nueces River. The valleys of those rivers are the lowest of any river valleys between the San Antonio and the Rio Grande Rivers. Irrigated farming there is already begun, and, doubtless, will be carried on to still greater success. Near Nueces River large Tree Acacias appear. That river, too, is about the eastern limit of Willow Catalpa, *Chilopsis*, which we shall see at different points far up into New Mexico. So *Fallugia*, with a still more northern range, grows southward to the Nueces.

A wide, deep and swiftly flowing current of water fills the river-bed, where two years ago I walked for miles without seeing a drop of water, and where on the dry sands I collected *Fallugia*, the small-fruited Walnut, other shrubs and many rare smaller plants. The country here assumes a more rough and mountainous aspect. The shrubs are sturdier in their growth and the flora generally is changing. The almost ubiquitous Mesquit is nearly everywhere and heavily loaded with young fruit. Because the Mesquit sometimes grows on the most barren hills it must not be supposed that the species does not recognize better opportunities when they present themselves. Those individuals now so forlorn, or, at least, their ancestors, have seen better days. In such localities they simply persist from a time when, perhaps, different climatic conditions prevailed here, or before a nomadic husbandry had made their homes a practical desert. Indiscriminate general grazing will make any country a desert.

No station on the Southern Pacific Railway, so easily accessible as Spofford, gives botanical tourists opportunity to find *Acacia tortuosa*. It grows a few rods above the station on the right-hand side of the road as one goes up. The flower-clusters of this species are very like those of *A. Farnesiana*, but its generic habit and its long Mesquit-like pods lead to its easy identification. It is hardly fair treatment of a peculiar and handsome shrub to call this species, as some botanists do, Mexican, as it is by nativity and residence a United States species. If the tourist can stop off a day at Spofford he will have time to visit Las Moras River, where he may find the remarkable semi-tropical white Water-lily, and the largest of our species of *Castalia*, *C. ampla*. I found it in the waters of that river, just in the rear of Fort Clark, and in full blossom on the twenty-second day of January, 1893, which, so far as I am informed, is the first time that the species has been identified as growing in Texas, or in North America, outside of Mexico. And if the tourist be curious in the so-called small things of science, he may chance to find in the same locality pods of the beautiful Red Bean, *Sophora secundiflora*, containing eight beans. The pods are sometimes fitted to hold only a single bean.

My stop at Del Rio was opportune to inspect the early summer flora, as I had already the late summer flora of that region. The Yellow Water-lily (*Nymphæa*), so common in the waters of San Filipe River, at Del Rio, varies somewhat from the more eastern forms of that species. The tabs of its leaves are produced, and end in an acumination giving to the leaves an elliptical outline. San Filipe River is about the southern limit of *Eysenhardtia orthocarpa*, with its upright fruit, as indicated by its name, while the pods of its southern congener, *E. amorphoides*, are reflexed. Nogal, *Juglans rupestris*, is very common along the river, where it sometimes grows into a large tree. Its fruit is small, but two or three times as large as that of the shrubby form.

From beyond the Sabinal to beyond the Pecos, at least, the honey-yielding shrub of western Texas, which Mexicans call Huajillo, and botanists know as *Pithecolobium*, grows in great abundance. The groves of this species in flowering time are the favorite pastures of the bees, and at other times they are hardly less pastures for domestic animals, which largely subsist upon its leaves and fruit. Meanwhile the species finds time to manufacture in large quantities a strong and pleasant perfume. This species, *Acacia Farnesiana*, one or two other native Acacias and two or three species of *Mimosa* yield from their flowers such an abundance of strongly fragrant volatile oil that it might be profitable for perfumers to utilize them.

Both species of *Siphonoglossa* near Del Rio were in blossom at the time of my visit. They are curiously made and good-looking plants. Near them were growing *Krameria canescens*, another *Krameria* and a handsome shrubby *Lippia* producing its flowering stems in whorls around the main axis. *Xanthima Texanum*, a handsome yellow-flowered composite, is common throughout central and western Texas, extending northward to southern Kansas. *Chrysopsis villosa* is an inhabitant of most of the region of the plains. It is a variant species. Several of its forms have been exalted to named varieties, an honor of which no one of them is really worthy.

Trichocoronis Wrightii, a western composite with variously cut leaves and rayless white flowers, is a plant of devious ways of living. It floats in the river, producing rootlets at the nodes of its stems. In shallow waters it roots in the soft bottoms. Where no water is to be found it grows equally well in the rich limon. The species probably located at Del Rio on account of the perennial waters of the San Filipe. The handsome *Centaurea Americana* of Arkansas and the Indian Territory extends through Texas to Mexico, and the small-growing Virginian Thistle bears it company all the way. *Cuscuta squamata*, one of the Love vines, grows abundantly on the alkaline soils of

western Texas. It lives generally upon composite, and more rarely upon Malvaceous plants. *Helianthus ciliosa* is its favorite host, which it sometimes kills.

Ephedra pedunculata, a slender-growing species, too weak to stand alone, ascends as high as any of its congeners by associating with stronger friendly plants and rising with them. It is found at various stations along our way. *Apodanthera undulata*, an important member of the Squash family, inhabits western Texas and extends into New Mexico, with its large leaves, white flowers and ribbed fruit. The very handsome shrubby little *Dalea*, *D. formosa*, is seen at various points along our route and high up on Mount Franklin, at El Paso. *Hoffmannseggia drepanocarpa* is a Texan of long and respectable standing in good plant society. It is also common at Las Cruces, New Mexico, on the high mesa between the town and "Little Mountain." Fine specimens, and of larger growth than I have elsewhere seen, were growing near Albuquerque.

La Junta, Colo.

E. A. Plank.

Distribution of the White Cedar in New Jersey.

IN the peculiar climate and soil of the coast plain of New Jersey the White Cedar, *Cupressus thyoides*, a very valuable soft wood, finds a suitable environment. These trees produce many seeds even while very young, and these are widely disseminated by the wind. The trees grow with great rapidity, and there are extensive neglected areas where it can be profitably cultivated; and yet White Cedar is becoming scarce, owing to the demand for its timber, and no attempt is made to prevent its extermination. Less desirable species, which are fit only for fuel, have been and are still allowed to usurp its place. In the northern part of the state it grows in a very few isolated localities. Botanists have found it near the southern end of Greenwood Lake, swamp at Kingsland, New Durham and Secaucus swamps, meadows near Newark, Bergen Point and South Amboy (see *Catalogue of Plants*, Part 1., vol. ii., Final Report of State Geologist of New Jersey). But there is another station about a mile from High Point, and the posts and rustic work of the inn there are made from white cedar cut in this swamp. One is surprised to find a typical isolated swamp of White Cedar in a very thrifty condition growing in a little valley near the New York state line and fifteen hundred feet above sea-level. Other plants, such as the Pitcher-plant, *Sphagnum*, etc., which are common in the swamps of the southern part of New Jersey, are growing with the Cedar.

May's Landing, N. J.

John Gifford.

Foreign Correspondence.

Mr. Chamberlain's Garden.

THE eminent statesman who is now Her Majesty's Minister for the Colonies, the Right Honorable Joseph Chamberlain, has for many years taken a keen interest in Orchids, as well as in gardening generally, and his garden at King's Heath, near Birmingham, has long been famous for the collection of plants it contains, Mr. Chamberlain being as keen an amateur gardener as any in England. He knows his plants well and watches their growth and behavior with all the zest of a cultivator; indeed, I was informed by his Orchid grower, Mr. Burberry, that he almost daily inspects the collection and discusses the details of its management with the same thoroughness as he exhibits in his more serious work. Mr. Chamberlain's only recreation is his garden. Only a few weeks ago he wrote to Kew an account of some interesting observations he had made on hybrid Orchids with a view of ascertaining the prepotency of their respective parents, and this at a time when matters of state requiring the most delicate handling were under consideration. Mr. Chamberlain takes an interest in Kew, and it is partly due to his desire that Kew should be well equipped, that the completion of the large

temperate house has been undertaken at a cost of about twelve thousand pounds.

Highbury, the residence of Mr. Chamberlain, stands on an eminence looking south over the open country. The garden is not large, only about fifteen acres, but it is laid out with great taste in what is known as the natural style. Hollies, Rhododendrons and Conifers are its main features. Surrounding the garden stretch about a hundred acres of meadow-land so planted with trees as to form an important adjunct to it. The farming of this land is the hobby of Mr. Austin Chamberlain, M.P., who lives with his father at Highbury. Another son, Neville, manages an extensive estate in the Bahamas, devoted chiefly to the cultivation of Sisal.

The houses at Highbury are grouped about the residence, most of them being connected with it by a glass corridor some hundred and fifty feet long, one end of which opens into the conservatory, and this again into the drawing-room. The conservatory contains a rockery, cascade, fountain, etc., and is tastefully planted with Palms, Tree Ferns and Bamboos, with other plants intermixed. A large specimen of *Anthurium Chamberlainii* is a striking object in this house. Introduced accidentally from no one knows where, this grand Aroid flowered for the first time at Highbury about twelve years ago, when it was named by Dr. Masters and figured in *The Gardeners' Chronicle*. The only other example of this species is at Kew, where it flowers frequently and is now ripening seeds. The Highbury plant now has a stem as thick as a man's wrist and three feet high, bearing about a dozen enormous sagittate leaves. This plant also is ripening seeds. In one of the houses there is a batch of plants which are the outcome of crossing *A. Chamberlainii* with *A. Andreanum*; the flowering of this cross is looked forward to with considerable interest.

The corridor is draped with a selection of greenhouse climbers, and planted along one side with ornamental foliage and flowering plants. A large mass of *Hedychium Gardnerianum* filled a circular bed in the conservatory and looked particularly attractive in January, with its rich green, glossy leaves and spikes of fruit colored orange and scarlet, and more effective even than the flowers. Cultivators unacquainted with this character in *Hedychiums* sacrifice their winter value by cutting off the spikes as soon as the flowers fade.

A dozen houses open at right angles from the corridor, each containing some special kind of plant. There are also several houses behind these again, and a large lean-to range, recently built, is filled partly with *Dendrobiums* and other sun-loving Orchids, and partly with fruit-trees. Zonal *Pelargoniums* are favorites with Mr. Chamberlain, a house being filled with the best varieties to flower in winter. *Primula Sinensis* is well grown in Birmingham, several nurserymen there being famed for its cultivation. A house is devoted to it and to *Cinerarias* at Highbury. Winter-flowering *Begonias* are also a special feature there, especially the hybrids from *B. Socotrana*.

The Orchids are the principal attraction, about a dozen houses being filled with them. Mr. Chamberlain does not apparently care for *Cypripediums*, the only species I noticed there being *C. Chamberlainianum*, of which a plant bore a scape one and a half feet long with sixteen flowers, or, rather, that was the total number borne, this species being disappointing in its habit of developing only one, or at most two, flowers at a time. A house filled with *Cattleyas* in good health, and another with *Laelias*, chiefly forms of *L. anceps*, were remarked. The latter were represented by big specimens of the white varieties, that named *Sanderiana* by one plant with seventeen scapes bearing from three to five open flowers each; a second specimen, just over, had borne nineteen scapes with an aggregate of seventy-three flowers. The rare variety *Dawsoni* was in flower, and Chamberlain's variety, equally rare, was in good condition. The white varieties of *L. anceps* are not damaged by fog to the same extent as the type. *Dendrobiums* are favorites at Highbury, and many rare

species are represented there. *D. glomeratum*, a recent introduction, had slender pseudo-bulbs two feet long bearing clusters of flowers one and a half inches wide, remarkable for their small infolded labellum and rich glistening mauve-crimson color. *D. cymbridioides*, with the habit of *Cœlogyne* and slender racemes of pale yellow flowers, lined with red-brown on the lip, was in flower. I have not seen this plant elsewhere. A very fine example of *D. Falconeri* was suspended in the corridor, where it hangs all the year, and grows and blooms freely. Hybrid *Dendrobiums* of many kinds, not yet flowered, and, from their parentage, likely to be useful additions, were noted in one of the warm houses. A similar number of unflowered hybrid *Cattleyas* and *Lælias* occupied a shelf in the *Cattleya*-house. *Dendrobium nobile nobilissimum*, with a dozen pseudo-bulbs, each a yard long and as thick as a man's thumb; grand examples of *D. Wardianum*, *D. crassinode*, the rare *D. Lowianum* and such popular hybrids as *splendidissimum*, *Cassiope*, etc., were noted either in flower or in bud.

Miltonia vexillaria and *M. Roezlii* are exceptionally well grown at Highbury, and in the same house with the latter I noticed a good example of the miffy *Phajus tuberculatus*. A house filled with forms of *Cattleya gigas* and *Cœlogyne cristata*; another with good varieties of *Odontoglossum crispum* and allies, and another with *Masdevallias* revealed careful and skilled management.

Cool Orchids generally are well represented at Highbury, and in the middle of January the display of bloom was rich and varied. *Odontoglossum coronarium* is grown there astonishingly well in a cold house on a turf of fibrous peat resting on a wood-raft and placed close to the roof glass in a shaded position. Here it has formed a mass two feet through of healthy pseudo-bulbs and leaves, and a short time ago it bore seven strong spikes of flowers. *Epidendrum vitellinum* is also an exceptional plant under Mr. Burberry's care. *Odontoglossum citrosimum*, *O. Cervantesii*, *Oncidium macranthum*, *O. Leopoldii*, *O. Andersonianum* and many others were remarkable either for their flowers or healthy vigorous growth.

Mexican Orchids are well grown, the secret of success being, no doubt, the light houses in which they are accommodated and which are never shaded. A house partly filled with *Phalænopsis* was a source of anxiety to Mr. Burberry, who finds what many others have found in the continued cultivation of this genus, namely, that the plants are apt to go wrong without any apparent cause.

Tea Roses and Carnations are largely grown under glass, these being the favorite flowers of Mrs. Chamberlain.

A novel feature of the houses at Highbury is the possession of electric light, which is so fixed that at night by touching a button Mr. Chamberlain can transform his houses into a veritable fairyland, which can be inspected by his guests with comfort and without any risk of catching cold.

London.

W. Watson.

New or Little-known Plants.

Rhododendron mucronulatum.

THIS deciduous-leaved shrub, raised in the Arnold Arboretum from seed gathered on the mountains near Pekin, and sent in 1883 by Dr. Bretschneider, at that time surgeon of the Russian Embassy in the Chinese capital, is closely related to the Siberian and Manchurian *Rhododendron Dauricum*, although, for garden purposes at least, it will, perhaps, be well to consider it distinct. In American gardens it is now a robust shrub from three to four feet in height, with slender stems, and branches clothed during their first year with smooth, rather light yellow bark. The leaves, which do not unfold until after the flowers have begun to fade, are oblong, gradually narrowed to both ends, and mucronate at the apex, very finely serrate, thin and firm, dark green above, pale and pubescent below, from two to two and a half inches long, about an inch wide and short-stalked, turning in the autumn, before fall-

ing, bright scarlet. The flowers are broadly campanulate, about an inch across, and light clear rose-color, with broad rounded corolla lobes, and are produced in two to four-flowered clusters; they appear in eastern Massachusetts during the last week in April, before those of any other plant of this class, and at a time when comparatively few other shrubs are in bloom. Their brilliancy and cheerfulness and the splendid color the leaves assume late in the autumn make this little *Rhododendron*, which is very hardy, a most desirable inhabitant of northern gardens.

Rhododendron mucronulatum * (see illustration on page 65 of this issue), which the Russian botanist Maximowicz, who made a special study of these plants, considered merely a geographical variety of *Rhododendron Dauricum*, inhabits south-eastern Siberia, Russian Manchuria and northern China.

C. S. S.

Plant Notes.

BEGONIA SOCOTRANA.—Plants that produce abundant crops of flowers in northern gardens during the short sunless days of November and December are not very numerous, and every addition to their number is eagerly welcomed by gardeners. Last year we spoke of the value of the winter-blooming tuberous-rooted *Begonia Socotrana*, and the sight of a house in December filled with plants of this *Begonia* in the neighborhood of Boston has served to confirm the good opinion of it we have already expressed. The bulbs begin to grow and are potted in July, and the first flowers appear at the very end of October and continue to open for six or seven weeks, the plants being well covered until after Christmas. The flowers are large, of a beautiful clear pink color, borne in ample open clusters and raised well above the large bright green, lustrous, peltate leaves. Flowering plants stand well in conservatories, and are admirably suited for the decoration of dinner-tables; and cut flowers remain in good condition for nearly a week in the temperature of an ordinary living-room. *B. Socotrana* is so easy to cultivate, and increases so rapidly by the development of new tubers, giving such large results for a small outlay, that it will probably become a popular florist plant as soon as it is better known and its value for late autumn and early winter decoration is understood.

ULMUS RACEMOSA.—The American Elm, or White Elm, as it is sometimes called, has so long been a favorite tree for ornamental planting and has been used so universally along country roads and city streets, by lonely farm cottages as well as in urban parks and the grounds about stately villas, that our other native Elms have been quite overlooked. There is an excuse for excluding the Slippery Elm from public grounds and streets because it is difficult to save it from the predatory small boy, whose appetite is tempted by its fragrant and mucilaginous inner bark. Nevertheless, this tree transplants easily, grows rapidly into a beautiful shape, and is worth a place in any private collection. The beautiful Cedar Elm, *Ulmus crassifolia*, ranges too far south for our climate, although in Texas it is one of the most graceful of our forest-trees. The Wahoo, too, *U. elata*, another attractive tree, is also doubtfully hardy north of Washington, but there is little excuse for neglecting to plant the Cork Elm, *U. racemosa*, also locally called the Hickory Elm and Rock Elm. It is a useful tree with hard close-grained wood that polishes well and is valuable for every purpose where strength, toughness and flexibility are required, so that it is well worth planting as a timber-tree. But it is also attractive as a shade-tree for its distinct and handsome appearance. At its best it is a hundred feet high, with a trunk three feet through, a narrow rounded head, and leaves which are deep green and glossy above, paler and covered with a soft pubescence below. In autumn these turn to a clear bright yellow. It does not grow as rapidly as the White Elm, but it is a vigorous thrifty tree, and

* *Rhododendron mucronulatum*, Turczaninow, *Bull. Soc. Nat. Mosc.*, x., 155 (1837); *Fl. Baicalensi-Daurica*, ii., 208.—De Candolle, *Prodr.*, vii., pt. ii., 327. *Rhododendron Dauricum*, β *mucronulatum*, Maximowicz, *Mém. Acad. Sci. St. Pétersbourg*, sér. 7, xvi., 43 (*Rhododendrie Asie Orientalis*).

certainly does not deserve the utter neglect with which it has been treated. The tree has acquired its common name from the broad, irregular corky wings with which the stiff branchlets are usually furnished.

Cultural Department.

Amaryllis.

UPON looking over the stock of mature bulbs of Amaryllis at this time I find that many need encouragement as the flower-spikes are just showing up. It is sometimes desirable

until warm weather this early start will give the bulbs a long season of growth, and the foliage will be sufficiently matured on the arrival of frost in autumn to allow that the pots be put on their sides under the stages, or in some convenient place in the greenhouse of no special value for other plants. If the pots are stood on an earthen bottom after the leaves have died off it will be found that very little water will be needed during winter, as the pots will absorb enough moisture from the earth to keep the roots from becoming too dry. Amaryllis of the hybrid section, such as are generally grown, are almost truly deciduous; but a few roots are sure to remain in a living state, and the more there are the better will be the start made from this time on. The effort the plant is required to make in

Fig. 7.—*Rhododendron mucronulatum*.—See page 64.

to have them come on in succession, and in this case it is best not to repot all the bulbs now, but only those that are most advanced, starting the others later as they require. We have found, however, that it is not well to retard Amaryllis-bulbs to any great extent beyond their natural flowering time. Last year the display would have been of little value to us before May, and an attempt was made to keep them for this time, but the spikes received a check, and were not nearly so fine as if encouraged to come on steadily from the time they were potted. Indeed, many did not develop beyond the bud-stage. On the other hand, if started now and kept in moderate warmth

producing the large flowers is considerable, as may be easily seen by the shrunken condition of the bulbs that were plump and fat before starting to grow, and it takes them all summer to recuperate and lay a foundation for the following year.

At potting-time it will be found that there are a number of young offsets clustered around the parent bulb. It is preferable to keep to a single bulb in a six or seven inch pot after the flowering size and strength has been attained, and these offsets may be planted around the edge of other pots to grow on separately. If space is limited, later on in early summer they may be planted out in the open ground, where they will make

a good growth if carefully protected from frost, to which they are most susceptible both in spring and fall. Flowering-size bulbs may be planted in pots of large size, several in a pot, but I am of opinion that for decorative purposes they are more serviceable when dotted in among a groundwork of green, owing to their scant foliage. A setting of *Adiantum cuneatum* is especially useful for this purpose. Another reason why pots of a small size are to be preferred is because of the ease with which these can be stored in winter. They will stand on a very narrow margin next the walks under the benches, not too near the heating pipes. It will have much to do with the popularity of *Amaryllis* when it is realized how easy it is to store the pots when the benches are crowded with other occupants.

For potting material we use a good sound loam made rich with the addition of bone ground moderately fine. Bone-meal should not be used, this being apt to close the pores of the soil and prevent proper aëration, a most important point in the culture of all pot plants. To assist aëration we use coarse sand and charcoal dust, and if the loam is naturally heavy or retentive some leaf-mold or material from an old Mushroom bed to lighten it. *Amaryllis* have thick succulent roots and like a rich, free-rooting soil.

It is also desirable to place the pots where the soil contained in them will be at least as warm or a little warmer than the temperature of the structure in which they are. To accomplish this the great English growers place them in a gentle bottom-heat of some fermenting material until the flowers are developed. But this is not necessary if the pots are placed on a bench over the heating pipes, and some non-conducting material, as sand, put between the pots. A part of a propagating bench is as good a position as one could desire. The roots will start and grow without any check, and sometimes the quantity of bloom is doubled by this means.

Thrips are the one enemy to be avoided in *Amaryllis* culture, and their work is shown by the under sides of the foliage turning red in spots. A wash with any approved insecticide will banish them if followed up once or twice at intervals of a few days. No shade is needed at any time, except to prolong their beauty when the flowers expand, the *Amaryllis* being a native of south Africa and a sun-loving plant.

This is a good time to sow seeds of a good strain. These have a peculiar black envelope like tissue-paper. The germ is small in comparison with the envelope, and the whole is easily lost from overwatering before germination takes place. To avoid loss, the seeds should be pressed into the soil on edge when sowing them, covered lightly with very sandy soil and placed in a temperature of seventy degrees, Fahrenheit, until they are well up. Seedlings will be found to keep their foliage during winter until the flowering stage has been reached; this varies from two to three years. As soon as the plants are strong enough to bloom the leaves will die off each year in autumn. Young bulbs must, therefore, be given encouragement during winter and summer from their infancy until they show signs of maturity, and after that they must have an annual rest of four to five months. There are evergreen species of *Amaryllis* in cultivation that have been derived partly from *A. aulica*, which is evergreen, and from a packet of seed it is often noted that some plants are obtained whose leaves never die down. These are the exceptions, and must be treated accordingly, as an attempt to dry off the foliage will most likely result in no bloom the following year.

South Lancaster, Mass.

Showy Acanthads.

PERISTROPHE SPECIOSA, introduced from the East Indies about seventy years ago as *Justicia speciosa*, was for some time a favorite winter-flowering plant; but like many others cultivated then it is now seldom seen. When well grown it is a pleasing subject for an intermediate house in the winter months. Many good Acanthads are neglected because they are almost useless for cutting purposes, their flowers being fugacious. It is unfortunate that many persons like plants only for their usefulness for cutting, especially as not a few of our most showy flowers have short lives. Although the flowers of this plant do not last long when cut, they are produced plentifully on the plants for several weeks. *Peristrophe speciosa* is an erect plant, branching freely, and its stem and branches are thickly clad with opposite, ovate, acuminate, pale green leaves. The flowers are about one inch long, and the twisted tube is a pale purplish color, while the two elliptic oblong lips are a rich carmine-purple. One-year-old plants give the most satisfaction, as they are more neat and compact than older ones. The tips of the young branches make good cuttings, and if rooted

in April and planted out in the garden in May they make large plants by the end of August, when they should be taken up.

Another Acanthad that deserves special notice at this time is *Strobilanthes anisophyllus*. It is a handsome, graceful and very floriferous plant; in fact, every twig and branch is loaded with flowers. The graceful branches, about one foot and a half long, have opposite unequal, lanceolate, acuminate leaves. Its flowers are of a pleasing lavender color. The showy part is the corolla, which is more than one inch long and about three-fourths of an inch wide at the mouth. It was introduced from Sylhet in 1823 and was known under the generic name *Goldfussia*. Another species which flowers at this time, *S. isophyllus*, makes a compact little bush, but is not so graceful as *S. anisophyllus*. The stems and branches are more erect, and its leaves equal or nearly so. Its flowers are lavender color and about the same size as those of *S. anisophyllus*. Both are easy plants to grow. Cuttings of the young growth made in March root easily with a little bottom-heat. When well rooted they should be put into small pots, giving another shift into larger pots as needed. As soon as the weather is warm they should be planted out in the garden, where they grow vigorously if given plenty of water. To get nice bushy plants the young points of the branches must be cut back regularly until the last week in July. They may be taken up about the last week in August, when they will be large enough for six-inch pots. They thrive in a compost of good loam, mixed with a small quantity of dried cow-manure and some leaf-mold and sand, and flower well in a temperature ranging from fifty-five to sixty degrees.

Botanic Garden, Harvard University.

R. Cameron.

A Few Momordicas.

THIS genus, which contains some twenty-six species of annual, or, in a few cases, perennial climbers, is distinguished by the neat appearance of the foliage, small yellowish flowers, the male peduncles of which bear a bract. The fruit is usually bright-colored and fleshy, bursting open when ripe.

Momordica balsamina, the Balsam Apple, has deeply and much lacinated palmate leaves of a dark green color and short, smooth orange-colored fruit. This species is often confounded with *M. Charantia*, the common Balsam Pear, the leaves of which are palmate like the other, but the lobes are rounded and not deeply sharp-pointed. The fruit is yellow, elongated and covered with many angled tubercles. The fruit preserved in spirits is commonly used as a vulnerary. Another species which we had here last summer was *M. Martinenseum*. I can find no record of such a name. The flowers are whitish; leaves a little like those of *M. Charantia*, and fruit resembling that of *M. balsamina* in shape, but paler in color. The seeds were in a collection sent from the West Indies to the University six or seven years ago and had been in the museum since.

The *Momordicas* are easy of culture, and the seeds, if placed in the ground where they are to grow, after danger from frost is past, will quickly spring up. Given a few strings or wires to run upon, and left to themselves, they will quickly form a nice screen, and, what is more important, will retain their dark green elegant foliage until pretty late in summer, even after all other cucurbitaceous climbers are withered.

Allied to *Momordica* is the genus *Luffa*, which has no bract on the male peduncle and has a long cylindrical fruit or pepo, which at length becomes dry and fibrous within. They are climbers somewhat coarse in appearance, having large leaves and yellow flowers. The chief interest in these plants lies in the fibrous fruit which often attains a length of two feet or more. As it ripens, the outer skin becomes dark and dry; then a little circular lid at the tip opens and gives the elliptical black seeds a chance to drop out. The skeleton of the fruit can be used as a wash-cloth, whence the common name of Wash-cloth Gourd. Prepared by softening and bleaching it is sold in drug stores for use in the bath-room. There are many species known, but *L. Ægyptiaca* is the most common form. They are easily grown, though, like the rest of the family, they do best in a very rich open soil.

Botanic Garden, Univ. of Pa.

Alex. MacElwee.

Notes from Santa Barbara.

Tecoma Smithii.—Plants of this shrubby hybrid, raised from seed received about a year ago from its originator, Mr. Edward Smith, of Adelaide, South Australia, are in bloom now, and, for the sake of variety at least, will prove a welcome addition to our flowering shrubs. It must be confessed, however, that both the parents of this plant—namely, *Tecoma velutina*, with yellow flowers, and *T. Capensis*, with scarlet flowers—have

more intrinsic ornamental value than this new intermediate form, which partakes of the characters of both.

Berberis pruinosa.—This recent introduction from Tibet, through the French missionaries, proves to be a neat and attractive little shrub, the new growth, the underside of the leaves and the abundant berries being all pure white and the flowers sulphur-yellow. Here it flourishes in full sunshine, as does its antarctic congener, *Berberis Darwinii*, from southern Chile and Fuegia. A fine bush of the latter, literally covered with its rich orange blossoms, is just making a suggestive contrast with the numberless bunches of the crimson-flowered tropical *Passiflora princeps*, which covers an extensive trellis close by.

Polygonum elegans.—This is a half-shrubby Buckwheat, growing about two feet high and twice as much across, with nearly leafless wiry stems and myriads of small white flowers. It makes a first-rate plant for the rockery or the herbaceous border, besides being useful for cut flowers. It is a native of Mount Gargano, in southern Italy, and will prove satisfactory, even if grown in pots.

Tagetes lacera.—This is one of a large number of new plants lately discovered by Mr. Brandegee in the extreme south of the peninsula of California. It makes a pretty compact bush, four to five feet high, well furnished to the base with finely cut metallic-green foliage, having the peculiar smell of other Marigolds, and bears a profusion of yellow flowers, mostly produced in winter. Small plants can be well bloomed in pots.

Pittosporum phylliræoides.—This is a striking species from the desert regions of Australia and quite distinct in habit from all others with which we are familiar. It resembles an evergreen Weeping Willow, with yellowish, rather small solitary flowers in the axils of the leaves, succeeded by far more conspicuous yellow elliptical fruits.

Santa Barbara, Calif.

F. Francheschi.

Crassula quadrifida.—This plant is now in full bloom in the succulent house, and is one of the best of the species. The leaves are thick and leathery, ovate spatulate in form, at first sessile, afterward forming a short petiole, and arranged decussately on the stems. The flowers are borne in terminal panicles; the under sides are bright pink and the upper a very light pink. The parts of the flower are all in fours. The individual flowers do not exceed half an inch in diameter, but the quantity produced makes it a very attractive plant. It is, moreover, well adapted for a hanging basket, as the lower branches droop gracefully round the pot in which it is growing. It is also an excellent window-plant, as the leaves are of good texture, well able to withstand a dry atmosphere and at the same time it requires but little water.

Cotyledon gibbiflora.—This plant is now in full bloom in the same house and is better known under the name of *Echeveria metallica*. The fleshy leaves are about six inches long by two wide, arranged alternately round the top of a short thickened stem, and of a metallic color. The flower-stalks, which are some two feet in height, grow from the axils of the lower leaves and are clothed with small leaves alternately disposed. The flowers of this plant are singularly beautiful, and are what are termed perfect flowers, all the parts being present. The calyx is composed of five spreading sepals, much the same color as the leaves. The corolla is of a rich salmon, and composed of five upright petals. There are ten stamens and five pistils.

Perhaps it may be added, in this connection, that one of the best ways of drying succulent plants for herbariums is to dip the specimen in very hot water, when it may be pressed with as much ease as any ordinary plant, and the flowers will retain their color.

Northampton, Mass.

Edward J. Canning.

The Pleiones.—This group of very dwarf, large-flowered Orchids is now generally included under the genus *Cælogyne*. The plants, although quite beautiful, are seldom seen in this country, but deserve to be grown even in choice collections. They are natives of Assam, Nepal and Sikkim, and plants with shriveled pseudo-bulbs close to the ground and deciduous foliage of a membranous texture. The flowers are produced in great abundance, but are almost sessile and solitary white or rose-colored, with or without yellow veins in the lip. Some are exceedingly showy, others are chiefly of botanical interest. All flower freely under cultivation—almost resembling certain varieties of *Crocus* when seen at a distance. The flowers appear before the leaf, or, in other words, during the period of rest, which occurs at different times for different species. Most common is *Pleione lagenaria*. The sepals and

petals of this species are of a rosy lilac, the lip being pure white, with yellow and crimson bars and veins. The leaf is solitary, membranous and plaited, springing from a peculiar wrinkled, bottle-shaped pseudo-bulb. *P. humilis* is another common kind, with flowers smaller than those of the first-named species, almost white, with the lip marked with brown and crimson or yellow. The flowers are numerous and appear late in fall. *P. maculata* is one of the finest of all, with pure white sepals and petals and lip barred with crimson and yellow. The flowers appear late in fall. *P. Hookeriana* is one of the smallest of the section, very dwarf, with rose-colored flowers produced in spring, at the same time as the leaves. *P. Wallichiana* has large, sweet-scented flowers of a bright rose-color. All the species do best in shallow pans, in equal parts chopped peat, sphagnum and silver sand and an addition of well-decayed cow-manure. A cool, airy position is most suitable to them. During the growing season an abundance of water should be given, and then gradually withheld as the young bulbs have reached a normal size. The plants should then be allowed to rest until the buds begin to appear.

Newark, N. J.

Correspondence.

Old Stone Bridges in Pennsylvania.

To the Editor of GARDEN AND FOREST:

Sir,—Your picture of an English stone bridge again reminds me that such bridges are numerous in south-eastern Pennsylvania—one over the Pickering Creek, just above where it empties into the Schuylkill River, in Schuylkill township, Chester County, forming part of the old highway to Philadelphia, along which the armies of Washington and Howe encamped and marched in the autumn of 1777. Valley Forge is two miles below. There are stone bridges, some of them with several arches, over the Perkiomen, the Manatawney, the Brandywine and other streams in south-eastern Pennsylvania. The one over the Perkiomen, in Montgomery County, built in the last century, partly with money raised by a lottery, is the subject of these appreciative lines which I find in "The Perkiomen Region":

The bridge of old-time masonry, intact,
Untouched by passing flood or rising tide,
A monument unshaken, stanch, compact,
Standing so firm and strong, to pick our pride,
Asks us, who builds to-day, with conscience pure,
The sterling structures that shall still endure?

But, besides the poetess, the county commissioners and judges of Chester and Bucks Counties have lately been drawing a comparison between the durability of the old stone bridges and the new and ugly iron bridges. This investigation shows that the iron structures cost for repairs, painting, etc., every year, more than the stone bridges have cost in half a century.

Philadelphia, Pa.

Isaac R. Pennyacker.

Training Tomatoes.

To the Editor of GARDEN AND FOREST:

Sir,—Referring to the Tomato-trellis described on page 37, I would say that for several seasons I have used wire netting in my garden for training Tomatoes in preference to stakes and strings. Netting three feet wide, securely tacked to strong stakes set at intervals of three and a half or four feet apart was formerly used, but greater width is desirable. This forms a perpendicular trellis about four feet high, as the wire should be placed ten or twelve inches from the ground. Stakes two by four inches are heavy enough if braced the first season, although I have used three-inch hard-hack fence-posts. A light strip of wood may be run across the top for straying the upper edge of the wire, but this is not essential unless heavy blankets are to be used for protection against light frosts in autumn. Raffia, once used for tying the vines to the wire, will never be superseded by strings; it is always soft, pliable and strong, never stretching in wet weather or slipping if properly tied.

This method of training Tomatoes admits air on all sides and does not interrupt the sun's rays. The fruit ripens evenly, is easily picked and readily protected on cold nights.

An ideal trellis of this sort was developed in a neighbor's garden the past season. Ten-foot stakes and netting two feet wide were used. But the growth of the *Ponderosa* is phenomenal, and two other strips of netting were added, with a space of a few inches between them. The result was a handsome screen fully eight feet high, thickly decorated with crimson fruits. The aspirations of the vines, however, were

unsatisfied, and a foot more of netting would have been covered. The expense of such an arrangement is light, and the profit and pleasure arising from clean well-ripened fruit is satisfactory in every way.

Habits of Ferns.

To the Editor of GARDEN AND FOREST :

Sir,—Regarding the habits of *Aspidium aristichoides* (see page 18), I think that an examination with an ordinary lens will show that the fronds become prostrate through the decay of the tissue at a point not far above the ground. To my mind, these fronds are not "protecting themselves from snow," but anticipating death, in order to give way to the new fronds next spring. They are always when prostrate entirely limp at this point just above the surface.

A specimen at present in our window was taken from the forest in November last. The matured outer fronds are prostrate, but the younger inner ones are as perfectly erect as ever. At the time this plant was dug most of its neighbors had perfected the size of their fronds, and were then wholly prostrate. The specimen in question was selected because of its evidently less mature, and still erect, fronds. It is much admired by visitors, few of whom know that it is one of our native Ferns.

Meetings of Societies.

The Western New York Horticultural Society.—III.

WILL IT PAY TO PLANT MORE APPLE ORCHARDS ?

Mr. Willard thought that apple-growing was still too much neglected. Orchards once profitable are now decaying; many are practically worthless, and in western New York there are not enough young trees planted to take their places. The acreage of other fruits is increasing, but the one kind of fruit which a young farmer should plant, because he will be sure in later life to reap the benefit of such an outlay, is the Apple. The scab is the worst foe of Apple orchards, and the great need is scab-proof varieties. The old Baldwin is one of the kinds which are the worst affected. If badly attacked one season the effects will continue the next year. The disease can be held in check by spraying, and the trees should be strengthened by strong feeding. Varieties known to be almost scab-proof should be selected, such as Duchess of Oldenburg, Sutton's Beauty and Hubbardston. Sutton's Beauty is the best variety we have, and will be free from scab in seasons when the Baldwin is ruined. Mr. Willard had one tree with Longfield and Baldwin grafted on the same root. Longfield bore good fruit and smooth, when the Baldwin apples were worthless. Mr. Morris, of Ontario, said that Canadian apples sold better in the market than the United States apples, not because of freedom from scab, but because they were packed better. Mr. Woolverton said that the Government of Ontario sent three different teams of men to show fruit-growers how to spray. They did the work well—sprayed in thirty different places six times—and it was a very helpful experiment. He found the Cranberry Pippin not superior in quality as a winter apple, but scab-proof. It commands a good price in Liverpool and Glasgow, and has been shipped, when carefully selected and wrapped in tissue-paper, to New South Wales. The Baldwins did not stand the journey as well as the Cranberry Pippins, which were considered the best apples there. Mr. Fowler said that while the Ben Davis was not found in fancy-fruit stores, the pie-bakers bought it by the carload. With many people the Cranberry Pippin was no better than Ben Davis. The Wealthy is apt to overbear, but, if thinned out, is an excellent apple, and is practically scab-proof. In Chicago the Ben Davis brings \$2.50, while Snow apples brought out from cold storage sold for \$6. Mr. Van Deman said that the Mississippi Valley, from Ohio to Kansas, was the true home of the Ben Davis, and that the season was not long enough for it in New York or Ontario. He spoke of the York Imperial as a good business apple. Stark is not high enough in color, and is astringent in quality. What the market demands is a rich, bright apple. York Imperial is far better in quality than the Ben Davis. The best fruit of this variety is grown in Pennsylvania, and it stands high in Liverpool markets. Mr. Hale thought that there was no better outlook for fruit-planting than winter apples of high quality and bright color. It would pay in New England. He proposed next spring to plant Sutton's Beauty, feed it well, thin the fruit, and then watch and spray.

THE CULTIVATION OF THE DEWBERRY.

According to Mr. J. A. Wilcox, the growing of this fruit began about twenty years ago, but not until within a dozen

years has any attention been given to it in a large way. Of about a dozen varieties the best for this region is the Lucretia, and often where it is said to have failed the roots planted were not true to name or the plants have received improper care. Mr. Wilcox had increased his plantation from year to year, and with continued satisfaction, and only regretted that he did not do so more rapidly. This Dewberry was found in West Virginia by a Mr. Williams, of Miami County. Some plants were sent to his father and five to Mr. Alwell, in Illinois. These last grew and matured, and from them all the stock has come. Dewberries do well on gravel, clay, loam and sandy loam. They ripen the earliest on gravel, but the loam is the best in dry seasons. They should not be planted where the roots will heave or where the snow will blow off. They need all the sunshine they can get and, therefore, should never be planted under trees, although wind-breaks help them. They can be transplanted with the green shoots started, if three or four inches of the roots are kept, and they should be set about three inches deep, with the soil compactly pressed about the roots, in rows six feet apart, with the plants three feet apart in the row. The plants should be kept clean and the surface loose by frequent cultivation, and a growth of from three to six feet may be expected the first year. Plants increase from the tips, which often will color at the ends when they are ready to root. These tips should be covered to encourage rooting. They will be ready for this covering at different times, so the field should be gone over two or three times to get them all. If covered too soon the tip will keep growing and not root, and the covering will need to be repeated. When the buds start in the spring plants should be pruned, and all the wood that has been winter-killed should be taken out. Three canes three feet long, or, as the bushes get older, five or six canes may be left. A wire trellis, preferably three wires, the lower one being three feet from the ground should be used, and the vines well spread on the wires. The berries should be picked every other day as soon as they are well formed and colored, and they will not turn red if left in the sun after packing as blackberries do. Cultivation after harvesting is not advised, nor is it advised while the plants are in blossom, but the special merits of the Dewberry are its large size and early ripening. Last year the fruit was fit to market on the 30th of June, which was earlier than usual and some two weeks ahead of blackberries. The berries average twelve cents a quart, and the vines yield 2,000 quarts an acre, or under heavy fertilization 3,000 quarts. The demerits of the fruit are that it is not quite as good as the best blackberries, and the plants are not perfectly hardy. It is safest to protect even old plants, and it requires more skill to grow them than it does the bush berries. So far the plants are comparatively free from disease, the most serious one being an insect which bores at the base of the stalks.

THE BUSINESS OF FRUIT-SELLING.

Mr. J. H. Hale, of Connecticut, said that the marketing of fruit begins properly with selecting the right varieties and planting them properly. For complete success the fruit grower must go to the wholesale market, to the retail market, and, if possible, to the consumer, to learn just exactly what is wanted. In this way the grower can, to a certain extent, educate the market, which is also a good thing, but he must understand primarily what the people want. The more time a grower spends in the market the better is the form in which his goods will be placed. A fine appearance opens the consumer's pocket-book, and then quality keeps it open. To make a real success one must have a genuine affection for his fruit. He must believe in it, and he must impress this belief on his package. After he has done all this he must go to the dealer and tell him what he proposes to do and impress this sincere intention upon him. The commission man must be made his partner, and the grower should only take as a partner a man who honestly loves his business, takes an interest in it for its own sake and for his reputation sake, as well as for mere money. The grower should induce the marketman to come and look at his orchards, even if he has to pay his fare. Then he can say, "I know this fruit, I know how it is picked, I saw it packed and taken care of," and he will receive more for it than if his interest was not thus aroused. To catch the eye the fruit must come as near to maturity as possible to get its proper color, and it will then hold the consumer, too, as its finest flavor is only developed in these last hours. The rule should be: Pick quickly, store promptly in a cool place, cure carefully, pack honestly, and use such packages as the market demands, as, for example, baskets for Philadelphia, boxes for Chicago, etc. Honesty is the best policy; well-graded fruit will sell for forty per cent. more than ungraded fruit from the same locality. The Chautauqua grape shippers lose much in

losing their individuality. An established reputation is worth a good deal. Certain growers habitually receive twenty-five per cent. more for the same fruit than their neighbors because the dealers know their grades. The use of printers' ink pays. Buyers ought to know what growers have to sell. There is a growing demand for the very best. Mr. Hale's own first-grade peaches sell the easiest, and they bring \$2.50 a basket; the third grade sells the slowest, and for these he only gets seventy-five cents, and sometimes only fifty. This year his Georgia orchard came into bearing. He had a man in each large city who devoted his entire time to placing his peaches during their short season. He never ships to more than one man in any place. These chosen men were enterprising; they had informed retailers of what was coming, so that the crop was picked, packed and railroaded as rapidly as possible to a market already waiting for the product. Mr. Hale attributes whatever success he has made largely to methods of marketing. There is certainly not enough profit in the fruit business to let this practical end of it run itself.

PEACH-GROWING—This industry is profitable in western New York, if conducted on strictly business principles. Peaches have the advantage of coming into bearing earlier than Apples. The fruits should always be thinned, so that they remain from six to eight inches apart on the branches. The trees will grow on almost any soil, if the cultivation is adapted to it, but, according to Mr. Hale, a light loam is an ideal Peach soil, except for Crawford's Late. The fourth-year trees on light land are twice the size of those on clay. Perfect drainage is essential, and thorough cultivation. The Crawford is the most tender type of Peaches, while Elberta is one of the hardiest, ranking with Mountain Rose and Stump. Mr. Hale thins when the peaches are about the size of a walnut. He prunes to a single stem at planting, with three main branches shortened in to six inches or more, and cuts away the limbs which interfere. He wants low-headed, well-branched trees shortened back every year about a half of the growth. He prunes for form, but does not prune until the buds are swollen, so that he can be sure to cut away dead wood. In this way he often gets badly formed trees, but they bear fruit. The distance from the ground to the first branch is from fifteen to twenty-four inches.

Peninsula Horticultural Society.

THE ninth annual meeting of the Peninsula Horticultural Society was held in Denton, Maryland, a fortnight ago.

The Fruit Committee reported the Tennessee Strawberry as one of the most promising. It is as early as Meek and produced well the past season. Greenville is one of the most desirable for ordinary growers. Timbrell and Marshall have not met expectations. Brandywine, on the lower part of the peninsula, shows a tendency to rust; Lady Thompson lacks productiveness, but is highly praised by many who have fruited it; Bubach is the most extensively grown. The Strawberry weevil, *Anthonomus signatus*, seriously injured the perfect flowering varieties in the vicinity of Denton the past season. The best preventive is the single-crop system and burning over the fields soon after the berries are picked.

The Blackcap Raspberries have not proved a profitable crop, and the early red varieties have almost entirely superseded them. The Miller is largely planted and has proved productive and a good shipper. Loudon is promising. Marion is a stout grower. The Wilson Blackberry has been partially discarded for a few years, but is now coming to the front again and has been quite largely planted. Maxwell and Eldorado are on trial; the latter, though producing fine crops of large berries, may prove too late in ripening. Lincoln is worthy of a trial.

Many Peach orchards failed the past season on account of the destruction of the blossoms by a fungus which was aided by the moist condition of the atmosphere. Yet the reports show that from two-thirds to three-fourths of a crop brought remunerative prices. Elberta has proved one of the most desirable varieties. The Committee on Peaches reported that the area of young orchards is on the increase in western Maryland. While the last season's crop was below the average in yield, satisfactory prices were secured by the growers, and the money was received as soon as the fruit was loaded into the cars.

Plums and Apples have been largely planted during the year. The Japanese varieties of Plums give the best satisfaction; Abundance, Burbank and Ogon being most extensively planted. An acre and three-fourths of land near Smyrna, Delaware, which was planted five years ago with one hundred and fifty Abundance, ten Kelsey and ten Ogon trees, between the rows of which were 1,200 Currant-bushes, netted the owner \$650 during the past season.

A marked feature of the meeting was the display of fruit from Delaware and Maryland. There were 250 plates of apples exhibited, comprising ninety varieties, several varieties of pears, chestnuts, walnuts and filberts. A striking contrast was shown between the apples from trees sprayed during the season and from those not sprayed, the fruit from the former being much fairer and of better color than that from the unsprayed trees.

The San José scale appears to have gained a foothold in numerous localities in Maryland, and vigorous measures will be necessary to prevent extensive damages to the fruit interests of the state in future. Mr. R. S. Emory, of Chestertown, has been making a vigorous fight the past year to exterminate it in portions of his Pear orchards, which have become badly infested. He stated that whale-oil soap, manufactured from oil containing its original impurities, had proved effectual in destroying the scales. He used two and a half pounds of the soap to one gallon of hot water, and sprayed the hot mixture on the trees after the leaves had fallen. Mr. Emory has one block of almost 300 Pear-trees, planted in the fall of 1888, which were found to be nearly covered with the scale in the fall of 1894. Since that time he has repeatedly treated them with various insecticides, such as kerosene emulsion, whale-oil soap, etc. At this time the hot mixture of whale-oil soap appears to have been effectual in freeing the trees from the scale. The Delaware Experiment Station officials reported that 116 suspected orchards in Delaware had been visited and the trees examined during the past season. The San José scale was found in thirteen localities in the state. The infested trees, in nearly every instance, were at once destroyed, and others have been treated with insecticides under the supervision of the station entomologist. The society urges the passage of laws that will prove effectual in preventing the spread of injurious insects and fungal diseases, and, whenever practicable, to exterminate the same.

Mr. J. J. Rosa, of Milford, Delaware, a successful grower of Sweet-potatoes, gave an interesting talk on his method of cultivation. The Big Stem Jersey variety gives the best satisfaction. The plants are grown by the use of bottom-heat, and from a bed ten by forty feet he took more than ten hundred thousand plants. The potatoes are stored soon after digging, and kept at a uniform temperature of sixty degrees. The yield in 1894 was 650 baskets of marketable tubers from an acre and 200 baskets of culls. The baskets held five-eighths of a bushel each. The receipts from four and a half acres of Sweet-potatoes in 1894 were \$433; in 1895 the crop from the same land was sold for \$650.

Mr. H. E. Van Deman, ex-United States Pomologist, was re-elected President; Mr. W. Webb, Secretary and Treasurer. The next annual meeting will be held in Milford, Delaware.

Delaware Agricultural Experiment Station.

M. H. Beckwith.

Recent Publications.

Number 6 of the third volume of the *Contributions from the United States National Herbarium* is devoted to a list of plants collected by Mr. Frederick Funston on the shores of Yakutat Bay, in Alaska, and prepared by Dr. F. V. Coville, of the Department of Agriculture. One hundred and sixty-eight species are included in the list, to which is prefixed Mr. Funston's interesting Field Report, from which it appears that *Picea Sitchensis*, the Tide-water Spruce, is the common tree of the region, growing to a height of seventy feet and extending from the level of the sea to an altitude of 2,200 feet on the slopes of Mount Tebenkof. This tree plays an important part in the economy of the Alaska Indians; with it they construct their houses and canoes: it is used in the manufacture of oil-crates, bows, arrows and other implements, and the small roots, boiled and split, are employed in basket-weaving. The Hemlock, *Tsuga Mertensiana*, is found scattered through the forest of Spruces with about the same vertical range as that tree, although it is much less abundant and of smaller size. The third conifer found by Mr. Funston in this region was a single individual of the Sitka Cypress, *Chamaecyparis Nootkatensis*. The common deciduous-leaved tree is the Red Alder, *Alnus Oregona*, which Mr. Funston noticed in great quantities in the forest region, especially on the edges of open glades, along the banks of streams and on the mountain sides, where it ascends to higher elevations than the Spruce, extending up Mount Tebenkof eight hundred feet

higher than the Spruce and Hemlock, or to about three thousand feet, growing on these high slopes in jungles so dense as to be almost impenetrable, and constituting one of the most serious obstacles to mountain climbing.

A Blueberry, *Vaccinium ovalifolium*, a shrub four feet in height, forms a large part of the forest undergrowth near the coast. The dark purple berries, rather larger than peas, are collected in great quantities by the Indians, who use them fresh and preserve them for winter, drying the fresh berries by artificial heat. In September, immediately after the close of the fishing season, nearly all the women and children devote themselves to collecting and drying blueberries for winter. The fruit of *Rubus spectabilis*, the well-known Salmon berry of the north-west coast, ripens in August and is also an important article of food among the natives. This fruit is usually crushed in a wooden bowl and eaten with sea-oil, and is not preserved for winter use.

Notes.

Mr. James A. Pettigrew, late Superintendent of Parks in Milwaukee, has been appointed Superintendent of Parks in Brooklyn, in place of Rudolph Ulrich, who has resigned his position, the resignation dating from the first of March.

The Botanic Garden of the University of Pennsylvania is hardly more than a year old, and consisted originally of six acres of very rough land. Already a little lake takes the place of what was a gravel pit; there are bog and aquatic gardens, a rock garden, a bulb garden, an iris garden, an herbaceous garden and a great many trees and shrubs, so that more than three thousand species are already represented. Professor J. H. Mactarlane is Director, and Alexander MacElwee the head-gardener.

The herbarium of the late John H. Redfield, of Philadelphia, which is extremely rich in Ferns from all parts of the world and in North American plants generally, containing all the sets made during the last fifty years in the western and south-western parts of the country, is to be sold by the Philadelphia Academy of Sciences, to which it was bequeathed under Mr. Redfield's will. The money derived from its sale, as well as that lately obtained from the sale of his botanical library, will form the nucleus of a Redfield fund of \$20,000 his friends hope to raise for the benefit of the Botanical Department of the Academy, which Mr. Redfield served faithfully for many years as curator.

East River Park is one of the comparatively new pleasure-grounds of this city which includes two blocks on the river, in one of the densely inhabited districts of the city between Eighty-fourth and Eighty-sixth Streets. A correspondent of *The Sun* of this city writes to say that just as soon as the improvement of the land was begun and the place grew in attractiveness the character of the neighborhood at once changed for the better, the houses became neater, cleanliness was more general, there was less dissipation, for the people now sit in the park instead of in the saloons. Altogether the change wrought in a congested neighborhood is reported as remarkable, and it furnishes a strong argument for providing more open spaces in the tenement-house districts.

Not long ago Mr. J. L. Normand, of Marksville, Louisiana, sent to this office what he considered the fruit of *Benincasa cerifera*, but which seems to be the fruit of *Sicana odorifera*, a Brazilian cucurbitaceous plant. This fruit is about a foot long, three inches in diameter, with rounded ends, of a deep crimson color and delightfully fragrant. In its natural state it does not appear to be at all edible, but Mr. Normand has made some preserved preparations which he considers worth something. *Benincasa cerifera*, the so-called White Gourd of India, is more nearly spherical, greenish in color, covered with a waxy bloom, and is used while green in making curries. If seeds of this *Sicana* are started early in pots and the plants set in rich soil after all danger of frost is over, they make a large growth in a single season. One of Mr. Normand's plants climbed, it is said, to the top of a good-sized dead tree and produced two hundred fruits, which weighed from four to six pounds each.

A few Florida oranges are included in the stock of the best fruit stores, and cost \$1.00 each. A limited quantity of Navel oranges from that state recently secured by the old retail fruit house of W. & C. Smith, on lower Broadway, is selling for from seventy-five cents to \$2.00 a dozen. Previous to the freeze in Florida a year ago last December

\$4.00 a box for grape-fruit was a high price in the wholesale markets of this city, but in view of the unusual scarcity as much as \$18.00 a box is now asked, and retail dealers are forced to sell this fruit at \$6.00 a dozen. The experiment is being made of introducing some bitter oranges from the Bahamas, to take the place of grape-fruit, the initial importation last week selling at \$2.00 a box. Selected pineapples from Havana cost fifty cents each at retail, and large smooth Cayenne pineapples from Florida, beautifully colored and with luxuriant tops, command double this price. Showy Lady-apples from Missouri bring twenty cents a dozen. Long Island Newtown pippins, mottled and brightly colored, and the green and russet Albemarle pippin from Virginia cost sixty cents a dozen for selected fruits. Pint boxes of small but well-colored strawberries from Florida cost fifty cents. The first Charleston strawberries were seen here last week.

Besides celery from this state and New Jersey, this vegetable is now supplied by some of the middle western states and California. The latter state is also sending tomatoes, the principal field-grown supplies coming from Key West, Florida, and Cuba. Smooth, even-sized and beautifully colored tomatoes from Pennsylvania hot-houses cost thirty-five cents a pound. Lettuce is coming from Louisiana in small lots, the dependence being on Florida, South Carolina and Virginia. Egg-plants, beets and string-beans also come from Florida, and new peas from the same state cost \$1.00 a half-peck. The first Florida cabbage of the season has been forwarded, but is not yet fully grown. The regular winter supply of, home-grown cabbage is nearly exhausted, and that imported from Denmark now constitutes the main supply. Norfolk is sending kale and spinach, and Bermuda is contributing a variety of new crop vegetables, as potatoes, onions, carrots and beets. Asparagus from Charleston brings \$2.50 a bunch; a dozen long shoots from pear-by hot-houses, and enough of a luxury to be held together by narrow ribbon, cost \$1.00, and the less crisp and fresh product from western glass houses may be had for sixty cents. Large mushroom of uniform size and even color from Long Island forcing-houses are offered at \$1.00 a pound, some hardly less attractive costing sixty to seventy-five cents.

Beds of many colored Tulips and other gay bulbous flowers, which made gardens of the florists' windows a few weeks ago, have given way to other suggestions of approaching spring, as branches of Pussy Willow thickly set with downy catkins, and of Forsythia, the golden bells in luxuriant flowering on the nearly leafless stems. Small plants of Heaths continue to be a conspicuous offering, although many of the best plants are still in the greenhouses of cultivators and will not be seen in city stores until the Easter season. The window exhibits of florists are more than a display of stock, and in the best establishments are both tasteful and artistic. A crowded window of thickly placed plants, without reference to arrangement or color, is rare enough to impress this fact. Groups of *Cinerarias* are likely to make exasperating masses of color, but a few of these plants in the window of a store on Fifth Avenue appeared to really pleasing advantage, the bouquet-like mass of flowers set in the immense leaves. Pink and white Azaleas are among the best-flowered and most beautiful plants now seen, and *Cytisus racemosus* and the more delicate flowers and foliage of *Acacia dealbata* give the touch of yellow which seems necessary in a collection. In one window the moss-draped trunk and branches of a tree constitute the main attraction, with Orchids growing from the bark and openings, an owl and hornet's nest being added for more realistic effect. In another a great vase of Bride roses was easily the most attractive object in a collection of cut flowers, and large deep buds, the edges of the outer petals beautifully recurved, made a richer show in their ivory whiteness than any of the more brilliantly colored flowers. An exceptional stem of this particularly well-grown lot measured four feet, the average being more than two feet in length. Marie Louise violets, in bunches of fifty blossoms, command \$1.50. Tiny spikes of a dwarf *mignonette*, very attractive in their neat form, cost thirty-five cents a dozen, and great spikes of the same flower measuring nearly a foot in length cost fifty cents each. The brightest and showiest bits of color are made by neat little buds of Papa Gontier roses, which sell for the reasonable price of a dollar a dozen. Sprays of white and purple lilac are included in the best offerings of cut flowers. An original effect with the charm of simplicity is a window measuring, perhaps, seven by eighteen feet, the margin framed with a wire foundation fifteen inches wide, hidden with smilax and dotted with Bridesmaid roses. A mass of well-grouped Palms set back some six feet furnish the satisfying picture for this beautiful frame.

The Surroundings of Statues and Monuments.

WE have often said that in this country the placing of outdoor statues and monuments is not properly considered. Such works cannot have their most effective exposure nor can they increase the attractiveness of their surroundings, unless they are artistically adapted to the special character and the special arrangement of neighboring objects. The effect of its environment upon the work of art, and the effect of the work upon its environment should be considered with equal care. And this care can be rightly bestowed only if the site is selected before the monument is designed. At the very least, the general character of the probable site should be thoroughly well understood in advance.

The folly of disregarding these plain truths has recently been shown by the attempt to secure a monumental statue of General Sherman for the city of Washington. Exceptionally fine sites for monuments of all kinds exist in that city; and from all accounts the models recently put on exhibition are interesting and varied in character. Yet the first thought excited in the minds of all who have examined these models seems to have been the difficulty of deciding between them, for the reason that no one had any idea where the accepted design would eventually be placed.

One of the newspapers of the city remarked that with this thought, as it inevitably arose, came "a feeling of injustice, not to the artists personally, for they all share alike in the disadvantage, but to their art itself, in asking for competitive designs without any indication of the kind of location the proposed monument is to occupy. It will readily be seen how a design of superior excellence in itself may fail of success because not so well suited to certain finally chosen surroundings as another of less merit; also that every artist was placed in a trying dilemma, whether to try to adapt his work in a blind sort of way to all possible surroundings at the sacrifice of artistic completeness and strength, or to design with a view to an imagined combined effect of statue and environment at the risk of being thrown out for want of these conditions."

Some of the competitive designs were elaborate constructions with terraces, balustrades or parapet-walls. Others showed the chief equestrian figure upon a highly wrought pedestal adorned by subordinate figures or groups; and others presented this figure in isolation upon a simple pedestal. The mere fact that, among the designs of the last-named class, the pedestals varied conspicuously in height, complicated judgment upon the intrinsic merits of the works by bringing in the question of appropriate placing. And, of course, the more elaborate the compositions were, and the more dominant their architectural elements, the greater became the importance of the matter of placing and environment.

Four of these varied compositions were eventually selected from the many. But just here an evil only too common in American practice once more has obtruded itself; that is, the decision of the distinguished sculptors who had been selected as experts to pronounce upon the merits of the models was not fully accepted by the representatives of the Army of the Tennessee, the donors of the statue. Only one of the four models which has received the honor of published preference, and the author of which has been admitted to the final competitions, was among the four which the expert jury pronounced the best. After such a bad beginning, the Committee of the Army of the Tennessee has now to decide upon the site it prefers, and to obtain official permission to use it. It is stated that this choice will be made before the four prize-takers begin to elaborate their ideas for the final competition. But it is already too late to utilize the fine artistic opportunity to the full. The committee must be confused in its selection of a site by the varying character of the four models for which it has shown its preference; and when the site is chosen more than one of the competitors will be forced to alter his idea conspicuously, or, perhaps, to recast it into a composition of an entirely different kind. This fact is made plain when we say that one of the chosen designs shows a very tall pedestal, surmounted by an equestrian statue, adorned with large reliefs and surrounded by allegorical figures, all raised upon an elaborate architectural base, while another shows a much lower pedestal with an exedra behind it; that is to say, one of these two monuments should be equally conspicuous from all points of view, while the other should be so set that the front view would be much more important than any other.

The proper method of procedure in a case like this would have been to choose a site at the very outset, after consulting with the experts who were to judge the models in regard to the general character which would be desirable for the monument itself. Thus, an intelligent choice among varying sites could have been made, and, on the other hand, the artist would have had a definite, or, at least, general idea to work upon. Or, still better, in a city where monumental sites are so fine and so diverse as they are in Washington, two or three sites of different sorts might have been chosen, with the understanding that it was open to each competitor to decide for which one he would prepare his design, and that his design would then be judged upon its intrinsic merits, as adapted to that special situation and no other. Thus the danger of possible loss through the checking of some fine idea by too narrow a limitation of opportunity would have been avoided, and yet the sculptors would not have been obliged to adapt their work "in a blind sort of way to all possible surroundings at the sacrifice of artistic completeness and strength," or else "to design with a view to an imagined combined effect of statue and environment" which it might prove impossible to realize in fact.

When it comes to a decision between the merits of works offered in competition, as little as possible should lie in the scale besides the intrinsic excellence of the respective models. And this state of things can be brought about only if the competitors have in advance a clear idea with regard to the special site, or, at least, the special kind of site for which their work is desired.

Rate of Growth of the Long-leaf Pine.

THE rate of growth of the Long-leaf Pine, *Pinus palustris*, given in the accompanying table, is based upon the measurements of sixty-five trees from various stations within its range. The measurements of the individual trees were extended enough to enable the Division of Forestry, with a sufficient number of properly selected trees, say, from 400 to 500 of a species, to make a complete investigation regarding its growth and progressive development. But while the biological laws of this species cannot be determined until a greater number of trees is examined, the rate of growth may be more or less clearly demonstrated by the analysis of the individuals already measured.

HEIGHT GROWTH.—The growth in height of Long-leaf Pine is comparatively slow for the first four or five years (about three or four inches); for the next two or three years the height growth has not been fully investigated, though it is also said to be slow. The most rapid stage of height growth begins with the seventh or eighth year, and continues to the 30th or 35th year, and amounts to from 16 to 17 inches annually. A tree 30 or 35 years old is from 37 to 44 feet high. From the 30th to the 50th year the annual growth in height begins to lessen, and is not more than 12 inches. A tree 50 years old is from 56 to 60 feet high. From the 50th to the 80th year the height growth rapidly decreases to about six inches annually, and grows less and less up to the age of from 90 to 100 years, when the tree reaches its full height growth—that is, from 76 to 80 feet. That Long-leaf Pine actually reaches about its full height in from 90 to 100 years is easily learned from the measurements of old trees which in from 225 to 300 years reach a total height not exceeding 108 to 118 feet.

DIAMETER GROWTH.—The diameter accretion of Long-leaf Pine is rapid for the first 30 years, when its trunk thickens by 1.6 inches (bark excluded) for each decade. For the next 50 years there is noticed a slight decrease in the diameter accretion, and for each decade only 1.4 inch is produced. A tree 80 years old at breast-height is 13 inches in diameter, including bark; this decrease of diameter accretion continues with age, being 1.2 inches for each decade between 80 and 100 years, 0.9 of an inch between 100 and 120, and 0.8 of an inch between 120 and 140 years. From the 140th year the diameter accretion falls very rapidly, its increase not exceeding 0.3 to 0.4 of an inch for each of the successive decades.

While the diameter accretion decreases with age—that is, while the rings become narrower from the centre of the tree to its periphery—the areas formed by them on the cross-sections, excluding the 20 central rings, are almost equal for the third, fourth, fifth and sixth decades. With the seventh decade, though, there is an increase of the areas, compared with those of the previous years; that increase is almost the same for the successive decades up to 140 years inclusive. Thus, dividing the time of the diameter growth into two periods, the areas of every 10 rings on the cross-section are almost equal within the limits of each period. It will be readily understood that each ring must be thinner with the increase of diameter.

MASS ACCRETION.—Speaking of mass accretion, it will be more convenient to consider separately the annual increase of the volume of a tree and that for certain periods. We distinguish two kinds of annual accretion: one, an average annual increase of the mass, produced for the total age of tree, which can be easily obtained by dividing the volume of the tree by its age. The other, called current accretion, is simply the increase of volume of a tree for a given year of its age.

From the table given below it will be seen that both current and average annual accretions, being scarcely perceptible for the first years, become gradually larger and larger till they reach their maximum point, and, remaining at those points for a couple of years, begin to decrease first gradually and slowly, then rapidly. It will be seen, also, that while the current accretion, passing its culmination

point, becomes smaller and smaller, the average annual accretion still increases, approaching the maximum and becomes almost equal to the current accretion when the tree is between 160 and 170 years of age. The age of a tree, when its average annual accretion becomes equal to the current accretion, is equal to that of the maximum point of the average annual accretion. The same is true with regard to all species.* The difference will be only in the age at which different species reach the stage of maximum growth. It depends a great deal upon the conditions under which the species is growing—that is, soil, moisture, climatic and forestry conditions. Thus the correlation between the current and average annual accretion is of great economical value, for it determines the time when a species reaches the stage of its maximum growth. The rotation for Long-leaf Pine, should it depend on the stage of maximum growth, would lie between 160 and 170 years.

RATE OF GROWTH OF THE LONG-LEAF PINE.
(Published in advance by permission of the Division of Forestry.)

Age.	Diameter with bark (breast-high).			Volume.	Periodical accretion.							
	Length of timber with upper diameter of five inches.	Height of tree.	Tree.		Log.	Decade.	Periodical accretion.				Average annual accretion.	Current accretion.
							Diameter.	Height.	Area of cross-section.	Volume.		
	Ins.	Feet.	Feet.	Cubic feet.	Cubic feet.	Ins.	Feet.	Sq're feet.	Cubic feet.	Cub. feet.	Cub. feet.	
10	2.1		9	0.12		1st	1.4	9	0.01	0.12	0.01	0.01
20	3.8		23	1.20		2d	1.8	14	0.04	1.08	0.06	0.11
30	5.5		37	3.35		3d	1.6	14	0.07	2.15	0.11	0.21
40	7.0	16	48	7.06	5.61	4th	1.2	11	0.08	3.71	0.18	0.37
50	8.1	24	56	10.75	9.30	5th	1.2	8	0.08	3.69	0.21	0.37
60	9.6	34	62	15.26	13.99	6th	1.4	6	0.12	4.51	0.25	0.45
70	11.5	44	67	24.16	23.11	7th	1.6	5	0.17	8.90	0.35	0.89
80	13.0	52	72	33.18	32.27	8th	1.6	5	0.19	9.02	0.41	0.90
90	14.5	56	76	43.57	42.66	9th	1.2	4	0.16	10.39	0.48	1.04
100	16.0	60	80	55.85	54.94	10th	1.2	4	0.17	12.28	0.56	1.23
120	18.0	65	87	76.87	75.87	11th	1.8	7	0.30	21.02	0.64	1.05
140	19.5	72	93	96.44	95.49	12th						
						13th	1.6	6	0.29	19.62	0.69	0.98
						14th						
160	20.5	80	98	112.3	111.5	15th	0.8	5	0.16	15.86	0.70	0.79
						16th						
180	21.3	85	103	122.0	121.2	17th	0.7	5	0.12	10.7	0.67	0.53
						18th						

But in fixing the rotation there ought to be taken into consideration the so-called stage of maximum value—that is, the stage when a cubic foot in the tree has its greatest value. For instance, one cubic foot in a tree 160 years old is worth \$0.05; the same cubic foot in the same tree when it is 180 years old will be worth \$0.07. With age the tree increases not only its mass, but also the value of the mass laid up previously, because the boards made from the oldest tree, being of a larger size, will bring a larger price. For Long-leaf Pine under the conditions of its present growth a rotation of 200 years is suggested as being the most economical that can be adopted.

In the table is shown the increase of volume for every ten years; we call it periodical accretion. A close examination of the figures given will give an idea as to the rate of volume growth of Long-leaf Pine.

Quite different would be the case under forestry management. In our records of tree measurements there are two whose environments in the forest are the same as those that would take place under management. Tree No. 314 (see table below), fifty-three years old, is from a moderately dense forest, the crowns of the trees being equally closed from all sides, thus forming a favorable roof-cover for that age. A Long-leaf Pine up to 90 to 100 years—that is, when it has reached its full height—being surrounded by neighbors of the same age—is competing with them for

* A mathematical proof of this law is given by Eger in *Allg. Forst und Jagdzeitung* for 1842, p. 175. Another, by means of calculus, is found there for 1870, p. 482.

light, and thus striving to increase its height growth, to be the first in stretching out its crown and to be the first in attaining the end of its biological destination to bear seeds. The trees are increasing their height vigorously, the trunks are regular in shape, clear of limbs, straight, and their diameter is not decreased so rapidly in proportion to the height. The forester will maintain the full cover in order to get all the advantages of the serviceable struggle among the individuals until they reach their full height. Then he should break the roof cover to give perfect freedom to the crowns, and to get all the light possible, which will increase the width of the annual ring, and thus the volume of tree. Tree No. 309, 140 years old, and tree No. 19, 149 years old, have perfectly free crowns and stand, as the record states, in the open forest. That would be exactly the condition under which they would be placed in a properly managed forest.

The following are the measurements of these trees :

No.	Age.	Diam.	Height.		Volume.		Accretion.	
			Tree.	Log.	Tree.	Log.	Average Annual.	Current.
314	53	12.5	60	35	19.96	17.84	0.37	0.42
309	149	25.5	102	86	142.18	141.13	0.99	2.40
19	160	25.5	111	83	176.96	170.23	1.11	2.12

Comparing these figures with those given in the table it will be seen that while Long-leaf Pine, under its present conditions, is not of much value when it is fifty years old, producing only four cubic feet in a log twenty-four feet long and eight inches in diameter; the same Pine, properly situated, would produce four times as much in a log thirty-five feet long with twelve and one-half inches in diameter. Not only would it grow well, giving an average annual accretion of 0.37, instead of 0.21 cubic feet, but it also promises to be thrifty in the future, for the current accretion is 0.42 instead of 0.37. The difference in the rate of growth will be more appreciated when compared at the age of 140 to 160 years. While a tree in a dense forest forms a log of 67 to 82 cubic feet, in the open forest the tree produces 148 to 177 cubic feet in a log of a larger size; while the 140-year-old tree, with deficiency of light, increases its volume for the next twenty years 16 cubic feet; the same tree with plenty of light in eleven years gives an increase of 36 to 37 cubic feet. This shows plainly that Long-leaf Pine in its rate of growth is very sensitive to light conditions. That Long-leaf Pine is a light-needing species may be also shown by the measurements of trees growing under shade and cover of neighboring trees. In the tree records there are such trees noted 70 to 120 years old with a total volume not exceeding 4 to 8 cubic feet.

It is left to the reader to draw his own conclusions as to what would be the profit to the southern states should the Long-leaf Pine be placed under forestry management in that section.

Washington, D. C.

A. K. Mlodziansky.

A Botanical Journey in Texas.—II.

CONTINUING our journey up the Rio Grande, late in the afternoon we reached Shumla, a railway station about three miles beyond the Pecos River, but much nearer the Rio Grande. Early in the morning of the next day, equipped for a botanical ramble, I visited the Pecos River, a long stream extending from its junction with the Rio Grande through Texas and nearly across New Mexico. In years of rain it is a large stream. The railway bridge across the river at this point is a marvel of engineering science, being the highest bridge in North America. Its extreme length is twenty-one hundred and eighty feet, and it is three hundred and twenty-one feet high. The river here is very narrow, as is the bottom of the cañon through which it flows, and the bridge practically spans the entire valley. The extreme height of the bridge is so great that it appears too light and airy to support even its own weight, much

less the weight of the heavily loaded trains that cross it. A narrow winding path leads down the left bank of the cañon to the river, and it is only when the visitor reaches the bottom of the cañon that he realizes the great height and magnitude of the bridge.

The vicinity of Shumla proved a good locality for botanizing. The bluffs adjoining the Pecos are, perhaps, as much as any portion of western Texas, a favorite haunt of the Resurrection Plant, Bird's Nest, or, as Mexicans call it, Siempre vive, the *Selaginella lepidophylla* of botanists. Individual plants everywhere on the bluffs crowd their neighbors and car-loads of them could now be gathered, and, perhaps, have been gathered here. This species is remarkable for the plan that it has devised to save itself from dying of thirst. Its broad lacinate leaves, which in wet times are completely spread and prostrate, as dry weather comes on coil themselves so tightly that their upper faces remain fresh and green, while their lower faces become faded and dry, giving to the plant the appearance of a rounded dead mass of vegetation, something like a small bird's nest. The plant is not dead, but sleeping, and when the rains come, or when immersed in water, it quickly revives and opens its green surfaces to air and sun. The plant roots deeply in the crevices of rocks, so that it requires the use of a trowel, or several vigorous kicks from a stout shoe, to loosen its hold.

Sotol, *Dasyliion Texanum*, the great native forage plant of this region, is common on the high mesas and mountain sides. It becomes five to eight or more feet tall, with two or three feet of the upper portion of its stems covered with greenish liliaceous flowers. Domestic animals could hardly subsist here without this provision for their wants by nature. They eat, in the winter, the cabbage-like head which this plant forms in the late summer to protect the growth and inflorescence of the coming year. *Agave heteracantha*, the *Lechuguilla* of Mexicans, is common from Devil River to New Mexico. Its thick and radical leaves are serrated with ugly curved spines. There are several species of *Agave* growing in western Texas and in New Mexico, more species, probably, than have been allowed. They differ principally in the arrangement and color of their flowers and in the size and form of their fruits. There appear to be two species with bright yellow flowers. The genus needs a thorough revision by a master workman, but only after a year or more of careful collection and study of the species as found in Texas, Mexico and New Mexico. The common Century Plant grows naturally in the lower Rio Grande region of Texas, though I have never seen it credited to that state.

The most conspicuous and, perhaps, the most remarkable shrub growing upon the mesas of western Texas is *St. Jacob's Staff*, *Candle Wood*, *Ocotillo*, *Fouquieria splendens*. It is a tall shrub, more nearly related to *Tamarix Gallica* than to any other native or naturalized shrub of Texas. It usually branches from the base or near it. The stems are strict and thickly armed from the base to the summit with pairs of strong spines, from whose axils fascicles of thick roundish leaves proceed. The structure of the stems is largely cellular, but the outer portion of them is woody, dense and hard. The bases of the spines appear to arise in the cellular part, leaving the wood full of holes in their decay, apparently upon the plan on which *Opuntia frutescens* forms its wood. The bright scarlet flowers are borne in long terminal racemes. When in full bloom it is certainly one of the most attractive of Texas shrubs. Though I have seen thousands of individuals of the species, yet none of them were "almost leafless," as we are told that all of them are. Perhaps they may become so later in the season. Mexicans use the stems of this shrub for fence palings. They sometimes grow and make a living fence. The species is common from Devil River to New Mexico.

It may be said in commendation of the plants of this arid region of the country that they appear to have carefully studied the conditions under which they live, and have well

learned the art of self-preservation; and they have not only lived, but also have found time to make their flowers attractive by their beauty, and often fragrance. *Selaginella rupestris* grows on damp rocks near the river. It is over most of Texas and common in some of its numerous forms. Close by the bridge I found a fine *Lucæna*. It was already in fruit, with long pods nearly grown. Low species of *Dalea* are common on the hillsides, and *Hoffmannseggias* make pleasant company for them. There are more and handsomer species of those genera of the Pea family along this route than I have met before. Later in the day a visit was made to the near-by Rio Grande. The cañon of that river here is deep and narrow—its walls of rocks so rough and precipitous that a descent to the river was impracticable. But the rains had brought nearly all the vegetation into growth that is ever seen here, and rare and peculiar plants invited an examination of their varied attractions. Ferns were abundant on the shaded sides of the great rocks; the species were about equally divided between *Cheilanthes* and *Pellæa*. A form of small Oak with sinuate spinose leaves was common in the ravines. The crowning glory of the hills from Nueces River to the Pecos in the early days of June is *Leucophyllum Texanum*. It is now in full flower, and its great profusion of light purple bloom literally gives to the hills their own hue.

The Pecan-tree is said to grow upon the upper waters of Devil River, which is its most western Texas limit. In order to keep up its popularity the Pecan has developed a new and valuable variety with a very thin shell. It would seem that in this variety Nature had exhausted her powers in nut-making. The variety is known as Paper-shelled Pecan.

Pin Clover, *Erodium cicutarum*, a forage plant of some renown, is rarely to be seen in Texas. Here it has to shirk for itself, no attention being paid to it as a cultivated plant, so it is very slow in getting a foothold. *Xanthium spinosum*, a Clotbur, armed with cruel spines, is liable to become a great nuisance throughout the entire central portion of the United States. As yet it is very rare in Texas, but if it is allowed to gain a hold on farms it will have no successful rival unless it be the Russian Thistle, *Salsola*; and a man or a beast of good sense would prefer to walk through a field of Russian Thistles rather than through a field of spiny Clotburs.

Machaeranthera tanacetifolia is not uncommon in the region which we are traversing. It is now a handsome low-growing Aster with Tansy-like leaves and typically purple flowers. A form with white flowers is frequent. One with rose-colored flowers is rarer. Along Big Creek, near Hays City, Kansas, I found a station where Nature herself had massed the three colors into a miniature parterre of great beauty. The species is sometimes seen under cultivation in gardens, and there are few handsomer native composites.

Nothing of value has been added to botanical knowledge or classification by subordinating the genus *Machaeranthera* or the genus *Diplopappus* to the Aster, a genus already large and unwieldy. The species of either of the degraded genera are less liable to be confounded with species of Aster than are species of *Erigeron* and of a half dozen other genera which, as well as they, might suffer. A plant already located, without great reason for a change, should be allowed to remain in its place, though it might as well have been placed elsewhere. That which in science is established should not without great cause be changed, and only then upon the verdict of a competent jury after a fair trial of each case upon its merits.

Several species of Wild Flax (*Linum*) grow in western Texas, and the cultivated plant is becoming established along most of the railways of the state. From its associations with the dawning of our civilizations we all are to see the venerable old species everywhere. The cultivation of Flax and the manufacture of linen from the tough fibres of its bark began in prehistoric times. Linen was doubt-

less the first plant product used, next to Fig-leaves, for apparel by the human race.

Gaillardia suavis is sometimes to be seen in western Texas, though commoner farther eastward. Here it usually furnishes its flowers with insignificant rays, and wears a very different general habit from the rayless forms of the species as seen in Kansas.

Before leaving Del Rio, apricots, peaches, plums and green corn of roasting size were on sale in that city, all raised on irrigated lands.

La Junta, Colo.

Plant Notes.

Clematis paniculata.

WE have already published a figure of this plant (vol. iii., p. 621), as well as the reproduction of a photograph showing a plant four years old from seed (vol. v., p. 91), but no apology is needed for the accompanying illustration of a plant on the grounds of Henry S. Hunnewell, Esq., Wellesley, Massachusetts. This beautiful climber was discovered in Japan about 120 years ago by Thunberg, and it is said to have been introduced a hundred years ago into European gardens. It was probably first sent to this country by Thomas Hogg, and was established in the Parsons' nurseries, at Flushing, thirty years ago. It was so rarely seen in cultivation that it was practically unknown until 1889, when mention of it was first made in this journal. Why it was not more rapidly disseminated can hardly be understood, except that sometimes its seed fails to ripen in the autumn, and, in any event, it germinates slowly. When planted in the spring the great proportion of it does not come up until the second year, a habit which it has in common with many other species of this family. It grows rapidly, however, when once started and makes strong plants, so that it remains a matter of surprise that so little was known of it until it was discovered how readily the plant can be grafted on our native *Clematis Virginiana*, and still better on *C. stans*. It ought to be said that the root-stock is only needed to sustain the plant in its infancy, for the base of the graft should always be set beneath the soil, where it will soon throw out strong thick roots of its own to supersede the parent root. Time is in this way saved by grafting, although, when well-ripened seed is sown in autumn in a box and wintered in a cold frame, the plants will appear the following spring and will bloom at two years old.

We have already described this *Clematis* so often that little needs to be said about it, and, indeed, it has now become so common that almost every one who takes any interest in garden plants is familiar with its character. It is perfectly hardy, although part of it is killed back every winter, and, indeed, it grows more strongly and is better furnished at the base when cut back hard every spring. Shoots starting from the ground when the roots are in deep rich soil will often grow twenty feet in a single season. In this respect the plant resembles *Clematis flammula*. It differs from *C. flammula*, however, in having comparatively large leathery leaves and in producing flowers in long axillary panicles. The individual flowers are an inch or more across and carried in such wild luxuriance that the foliage is entirely covered during the first half of the month of September in this latitude. The flowers are followed by heads of fruits which turn to a clear red, each one with a long silvery tail, so that these feathery tufts seem to hover over the leaves, which persist all through autumn, usually as green as they are in midsummer, but sometimes changing to copper-color and afterward to a dull bronze. The flowers have a distinct fragrance, which is likened by some to that of Hawthorn and by others to that of Hyacinth. Altogether, this vigorous, floriferous and long-lived Asiatic climber is one of the very best for porches or screens, while in parks, large grounds and along roadsides it might well be used, like our own Virgin's Bower, to clamber over shrubbery and drape them with its long stems covered with myriads of white star-shaped flowers.

Fig. 8.—*Clematis paniculata* in a Massachusetts Garden.—See page 74.

IPOMŒA BRIGGSII.—This species has been in full flower for several weeks in one of the conservatories of the Botanical Garden in Washington. As grown there Mr. Oliver describes it as very showy, resembling somewhat the well-known *Ipomœa Horsfallia*. It has a more profuse growth, however, than that species and bears double cymes of flowers in the axils of the leaves. The color of the flower is unlike that of any other known species of *Ipomœa*. It is described as a rich magenta-crimson, but the color varies in depth in different parts of the corolla and in different flowers. The tube is about two inches in length, and this expands to a diameter of two inches. The Washington plant is growing in a ten-inch pot, and, judging from the number of open flowers and buds, it is wonderfully floriferous, each leaf on the strong shoots having a cluster of flowers springing from its axil. If it will grow and flower outside as satisfactorily as it does inside it will be a valuable addition to our list of summer-flowering vines.

Cultural Department.

Notes on Begonias.

BEGONIA PHYLLOMANIACA is, perhaps, the most interesting species in the genus. The striking peculiarity of this plant is that it produces from its stems and petioles innumerable viviparous buds or young growths, which make young plants, if taken off and inserted in sand. It is an upright-growing plant, with succulent, hairy, green stems; eight or nine inches is about the length of the leaves and they are of a light green color. In shape they are obliquely cordate, attenuated, slightly lacinated and fringed. The pale rose flowers, which are produced in axillary cymes, rise slightly above the foliage. They measure about one inch across, are not very showy, but make a pleasing contrast at this time with the green foliage. It comes from Brazil and does best here when grown in a cool greenhouse during the summer months, and in the winter it thrives in a temperature ranging from fifty-five to sixty degrees, Fahrenheit.

Begonia Verschaffeltiana is a splendid winter-flowering plant and is now a mass of flowers. It is a large, strong grower and needs rich soil to develop its large cymes of flowers. In a deep, roomy pan we place three or four plants, which make an effective display while in bloom. In early summer they are turned out of the pans, the exhausted soil removed from the roots, and each plant or stem is then planted separately in the garden. By fall they make large healthy plants, and when the nights begin to cool they are lifted and put back into pans again. When replanted in the pans three or four plants about the same size should be selected, so that they will grow together evenly. If the plants get leggy they can be cut right below the thick head of leaves and inserted in sand in the propagating bed, where they make roots in a short time. This *Begonia* is a hybrid between *B. corolinæfolia* and *B. manicata*. It has large succulent stems clad with large ovate acutely lobed leaves, which have long green petioles. The flowers are in large showy cymes and raised well above the foliage on long stout peduncles.

The flowers of *Begonia sanguinea* are not showy, but it has handsome leaves and makes a good foliage plant when treated properly. It has erect red stems which are slightly woody at the base and are well covered with leaves from four to six inches long and sometimes longer. They are subpeltate, obliquely cordate, succulent, shining bright green above and deep red below. The plant is in bloom now and the red peduncles are nearly a foot long, carrying small white flowers produced in branching cymes. Young shoots are easily rooted in spring, and if they are potted on during the summer as they require it, by early winter they will make handsome plants. They are grown in the greenhouse during the summer as they make better foliage. If they are planted in the garden care should be taken when lifting them in the fall that the leaves are not torn, as this disfigures the plants.

Begonia peltata is a handsome foliage plant, introduced from Brazil in 1815. What makes the plant so distinct and easily recognized is that its stems, leaves and petioles are completely covered with a soft silvery tomentum. It makes a good stove foliage plant and has a very uncommon silvery color. When well grown it has large peltate, ovate acuminate, thick and fleshy leaves nearly a foot long. The small white flowers are produced at this season in cymes on tall erect peduncles. It

is not as free-growing as many *Begonias*, but with careful cultivation it can be grown into a handsome specimen.

Botanic Garden, Harvard University.

R. Cameron.

Dipladenias.

EACH recurring season reminds us of the value of these Brazilian climbing plants for the greenhouse, and there is a possibility of their soon becoming much used for planting outdoors in summer, since there is every reason to believe that they will be as well adapted for this purpose as for indoor use. Full sunshine is indispensable and rain will not injure the blooms, and in a warm position, with light soil, they will be sure to succeed. We have a batch of seedlings from seed saved last year, and as some of the plants have already bloomed we look forward to seeing them all flower during the coming season. Seeds are not often produced in this genus, but I have personal knowledge of three instances where it has been secured and plants raised from it. It is also an easy matter to propagate *Dipladenias* from cuttings of one or two joints each, made from well-ripened growth. When rooted they must not be potted in material that will become impacted. We use nothing but fern-root fibre to grow them in. With this it is impossible to overwater the plants, and it holds enough moisture in suspension to satisfy their needs. We use maure-water when the plants are in active growth and bloom. Loam in the soil has been the cause of more failures than anything else. It is necessary to grow the plants in full sunshine, even in the hottest summer months, and plenty of water should be used to spray with, as insects are liable to increase rapidly if they once get a foothold. It used to be considered indispensable to keep *Dipladenias* in a warm house at all seasons, especially when at rest in winter; the temperature of the Rose-house in summer for daytime, and fifty degrees, Fahrenheit, during night in winter, is best suited to them. It is difficult to imagine a prettier sight than a low span-roofed house with the roof covered with *Dipladenias*. The sprays of bright pink flowers shade off to crimson as they get older, the same sprays blooming continually from May until November. The growth of *Dipladenias* is not so rampant as is that of most tropical climbers, and is easily kept within reasonable limits. Last summer *Roses* were grown successfully in the benches underneath, and there are positions in every greenhouse where these plants would do well. We grow *D. prolusa*, *D. amabilis* and *D. Brearleyana*, all of which are good, the latter the richest-colored and largest-flowered of all. We cut the plants back at the close of the blooming period each winter, when they go to rest naturally, and keep them drier until they show signs of starting again at about this time. They are then repotted in pots or pans a size larger. At potting time it will be seen that these plants have large tuberous roots, not unlike *Dahlia* roots in shape, but more woody. These are the reservoirs of vitality and are easily injured, but if handled carefully there need be no check to the plants. Water should be applied with great care until active growth begins in the warm spring months. When the plants are grown in full exposure to the sun in an unshaded house, the pots containing the plants ought to be shaded by a layer of moss or other non-conducting material to prevent injury to the roots from the heat. We also put a layer of moss on the surface of the potting material in hot weather to show the condition as to moisture, and find this beneficial.

South Lancaster, Mass.

E. O. Orpet.

Notes on Geraniums.

IT may safely be said that the common *Geranium*, hybrids of *Pelargonium zonale* and other species, is the most popular exotic plant under cultivation. Through all the changes in popular fancy and through all the ridicule heaped upon bedding plants in general, the *Geranium* almost alone has been spared. Few plants have so many good qualities and are in so many ways fitted for the amateur and the novice. *Geraniums* are almost entirely free from disease and are very seldom troubled with insect pests. With common garden-soil, sunshine during the middle of the day and the temperature of an ordinary living-room, one can hardly fail to have them bloom all winter long, and, in fact, they are the brightest of window-plants everywhere. The only practicable danger is the tendency to overwater during the earlier winter months. It is safer always to err on the side of too little than too much.

Wherever bedding plants are used they are indispensable, and usually most effective when planted in masses, and scarcely less so when the free-blooming green-leaved varieties are edged with the variegated forms. They rarely com-

bine well with other plants, and are generally seen at their worst when associated with *Coleus*. I call to mind, however, an effective bed at Kew, where *Verbena venusta*, one of the erect-growing, purple-flowered species, had been planted among the silver-leaved *Geraniums*.

The types are scarcely recognizable in the many superb varieties we now see. One of the parents, *Pelargonium inquinans*, a species of erect habit, zoneless leaves and compact umbels of short, round-petaled, scarlet flowers, is more nearly exemplified in the variety known as General Grant than in any other cultivated variety I know. *P. zonale* is the other species, and this is characterized by shorter-jointed growth, more diverse habit and less compact umbels of longer-petaled pinkish flowers. It is probable that other species have entered into the parentage of the many florists' varieties, and even so, it is hard to see how so many fine crimson and salmon-colored varieties could have originated.

Geraniums flower freely when given generous treatment, and, however grown, are attractive in appearance. They are not now grown into specimen plants so generally as they used to be. Many years ago it was customary to accord them a year's special treatment, and many old gardeners do this now. During this time they were not allowed to bloom. Plants intended for specimens are grown from cuttings taken in the autumn. During the next year they are tied out, stopped and otherwise trained into the desired form. A good foundation of short, well-ripened growth is made during the summer, and for the winter the plants are rested in a cool house on shelves near the glass. With the lengthening days of spring it would almost be impossible to keep them from blooming if this were desired. The immense quantity of flowers such plants will produce is surprising to people unfamiliar with this treatment. A gorgeous setting of these well-trained specimens is always an attractive feature in the floral display in the tent near Mr. H. H. Hunnewell's residence at Wellesley, Massachusetts, during the early spring months.

Ivy-leaved *Geraniums*, forms of *Pelargonium peltatum*, have increased in popularity during recent years, owing mainly to the introduction of some fine double varieties. Generally double *Geraniums*, especially among the *Zonale* type, are not considered as handsome as the single varieties, but they are more serviceable for cutting. The double Ivy-leaved varieties rival in beauty the double *Zonals*. The stems are longer, the flowers larger, more double and more delicately colored, mostly in rose and scarlet shades, and the individual flowers on some recent importations measure fully one inch across. Owing to their prostrate habit, Ivy-leaved varieties are well adapted for hanging baskets, and several of these formed an interesting feature of the display above alluded to. But after the brightness of the Zonal display had departed, and the plants had been removed to undergo another summer's preparatory treatment these Ivy-leaved varieties bloomed on in good condition for nearly the whole summer.

Wellesley, Mass.

T. D. Hatfield.

Cypripedium insigne.—This popular Lady's-slipper is one of the best Orchids of the present season. Very floriferous, it is seen in a great number of varieties of a more or less bright yellow color, with the dorsal sepal marked with brighter or fainter black or maroon spots, and more or less white on the upper half. The foliage is always bright green and quite attractive. This species is the parent of innumerable hybrids and varieties which all bear a resemblance to the type. Some are rare and costly, but, perhaps, of no higher ornamental value than the species itself, which is now as cheap as a good *Begonia* or *Cyclamen*. This Orchid can be grown by anybody in a warm apartment or greenhouse. It thrives well in a mixture of peat and sphagnum-moss in well-drained pots. Occasional watering with liquid-manure is very beneficial. Light sprayings of the foliage in summer and a pure and warm atmosphere are essential to success. In December or January the flowers expand and keep in perfect condition for months.

Newark, N. J.

N. J. R.

Jatropha hastata.—This is a curious and interesting stove plant. The stem is somewhat pear-shaped, being much more swollen toward the base than the top, and it seldom branches. The leaves are few in number, usually not more than four or five, and arranged alternately round the upper end of the stem; they are hastate, as the specific name implies, and lobed with from three to five lobes. The leaf-stalks are about five inches long, and the blade is rather larger than the palm of the hand. The plant is deciduous and generally loses its leaves in December. On the stem between the leaf-stalks are what appear to be undeveloped leaves, not unlike small forked spines, which become hard with age; these and the upper

portion of the stem are covered with a sticky substance, apparently to prevent insects or ants from climbing up the flower-stalks (which rise immediately from the summit of the stem) and stealing the nectar secreted in the flowers. The flower-stalks appear early in the year and are about five inches in length; the inflorescence is corymbose. The flowers are monoëcious, the pistillate flowers being borne in the axils of the forked inflorescence. The flowers are all borne on short pedicels of a bright coral color, and these are not only more beautiful than the flowers themselves, but they persist long after the flowers have fallen away. As the plant rarely branches, and the flowers are monoëcious, it is somewhat difficult to propagate. Last February I used a camel's-hair brush to bring about artificial fertilization, and I succeeded in getting a pod of seed, which is just ripening. *Jatropha hastata* is a native of Cuba and belongs to the *Euphorbiaceæ*. It delights in a warm temperature and a soil composed of half loam and half good fibrous peat, with a little silver sand added, in well-drained pots. During the growing season plenty of moisture is needed, but when the leaves begin to mature, water should gradually be withheld and the plant allowed a season of rest.

Correspondence.

Propagating Hickories.

To the Editor of GARDEN AND FOREST:

Sir,—How shall I go to work to propagate in quantity different varieties of the Hickory—for example, some which bear remarkably large and thin-shelled nuts? I have been told that it is next to impossible to graft them.

Morristown, N. J.

S. A.

[We have referred this inquiry to Mr. Jackson Dawson, who says that although he has never tried to graft a Hickory out-of-doors, and it is true that these trees are somewhat difficult subjects, nevertheless he does not hesitate to say that with proper stock and precaution they can be as readily propagated under glass as most of the so-called difficult plants. He has experimented with most of the species, and has succeeded with all he has tried. This success with several species and varieties of Hickory has been gained without any special preparation of the stock, and, in fact, most of the time he has gone to the woods and dug up the stock after he had received the scions. Of course, this made the work still more uncertain, and yet in the worst cases he has saved twenty-five or thirty per cent. of the grafts.

"My method," writes Mr. Dawson, "has been to side-graft, using a scion with part of the second year's wood attached, binding it firmly and covering it with damp sphagnum until the union has been made. The best time I have found for the operation under glass has been during February, and the plants have been kept under glass until midsummer and wintered the first year in a cold frame. In all genera I find certain species which may be called free stocks—that is, stocks which take grafts more readily than others. Thus, nearly all the Oaks will graft readily on *Quercus Robur*; the Birches will graft more easily on *Betula alba* than on others; so of the Hickories, observation has led me to believe that the best stock is the Bitter Nut, *Hicoria minima*. This species grows almost twice as rapidly as the common Shag-bark Hickory, and while young the cambium is quite soft. I should advise any one who wishes to propagate Hickories on a large scale to grow stock of this species in boxes not more than four inches deep. In this way all the roots can be saved and there will be no extreme tap-root, and when shaken out of the boxes the plants are easily established in pots and ready for grafting. If taken up in the ordinary way from the woods it requires almost two years to get them well-rooted, and often the stocks die for want of roots after the graft has really taken. If grown in rich soil the stocks will be large enough to use in one or two years. I should then pot them early in the fall, keeping them from heavy frosts and bringing them into the house about the first of January, and as soon as they begin to make roots I should side-graft them close to the collar and plunge them in sphagnum moss, leaving the top bud of the graft out to the air. The graft ought to be well united about the last of March, when the

plants should be taken from the sphagnum and set in the body of the house to finish their growth. After carrying them over the next winter in a cold pit they could be planted out the following spring and the second year they could be set where they are to remain, unless they are transplanted every second year."—Ed.]

Growing Lettuce under Glass.

To the Editor of GARDEN AND FOREST :

Sir,—The conditions under which Lettuce has been forced this winter have differed materially from those of the past two seasons, and a succession of almost sunless days, with damp and warm weather, has made it difficult to grow Lettuce heavy enough to count much when it comes to be weighed up for market. Prices have been the same as in recent years. We have been obliged to keep part of the steam lines on the houses and the ventilators raised partially to prevent rotting off, and even with this treatment the bottom leaves decay as soon as the plants get large enough to touch each other, and when ready for cutting the plants do not weigh more than half as much as they should.

We are using both subirrigation and surface watering in growing Lettuce, and while there is some difference in favor of subirrigation, it is not enough to pay for the extra cost of constructing the beds. We have one house, twenty-two by seventy feet, with solid benches, and two and a half inch tile laid eight inches apart crosswise of the benches, and soil about eight inches deep. The tile gives good drainage and ventilation through the bed, but the watering is all done from above. Last year in this house we grew two crops of Lettuce and one crop of Cucumbers, which sold for exactly \$400.

Adjoining this house we have another, twenty-two by seventy feet, with solid benches and cemented bottoms. The tile in this house runs lengthwise, and is connected with open troughs at the ends and centre. The soil is about the same depth as in the first house. The beds are watered by subirrigation through the tiles, the water being turned into the troughs at the two ends and centre of the house. We find this method convenient, and in dark cloudy weather it is more effective than surface watering, because the ground can be kept moist without wetting the leaves. But, as already stated, it will not pay for the extra labor and cost of constructing the benches unless there is a more marked difference than has shown thus far.

Lettuce is selling now at fourteen cents a pound in the Cleveland market. It takes two weeks longer to grow the plants to marketable size than it did last year, and then they do not weigh nearly as much. If we sell half as many dollars' worth out of our houses this winter as we did last we shall think we have done fairly well.

Lakewood, O.

F. E. Carr.

Cypripediums at Langwater Gardens.

To the Editor of GARDEN AND FOREST :

Sir,—The collection of Cypripediums in the greenhouses belonging to Mrs. F. L. Ames, of North Easton, Massachusetts, is one of the largest in the United States. Among Orchids, Cypripediums have a beauty all their own; some others are more brilliantly tinted, but are only attractive when in bloom, and even then the stems of some of them, as of many Cattleyas, are awkward, to say the least. The beautifully mottled foliage of the Cypripediums vies in attractiveness with the curiously shaped and oddly marked flowers.

This collection is rich with many hybrid forms which have been raised here. Cypripedium Jack Ames is a cross between *C. Lawrenceanum* and *C. ciliolare*. The plant is much larger than either of its parents. The foliage is particularly large and handsomely shaded in light and dark green. The prominent violet markings on the dorsal sepal are characteristic of the seed parent. The warted, or black hairy spotted, petals are characteristic of both, although in the number and distribution of the spots it more closely resembles *C. ciliolare*. The gem of all is the primrose-yellow *C. insigne* Sanderæ. Among several so-called yellow varieties this is the only one worthy the name. If there is anything to mar its beauty it is the merest trace of brown on the lower part of the dorsal sepal and a scarcely distinguishable margin of white on the upper edge. The hybrid Juno (*C. Faireanum* × *callosum*) resembles in many respects *C. callosum*. The curiously twisted petals characteristic of *C. Faireanum* are very prominent. *C. Winnianum* (*C. Druryi* × *villosum*) is a handsome kind with a dark brown line along the centre of the dorsal sepal and a wide

margin of white. Orion (*C. concolor* × *insigne*), as might be expected, is a pretty hybrid with pale yellow flowers spotted with brown. Minnie Ames, a handsome dwarf hybrid between *C. concolor* and *C. niveum*, is white, suffused with purplish pink dots. In *Electro* the large dorsal sepal is nearly white. The petals are recurving, violet-spotted, on a green ground. *Aphrodite* is between *C. niveum* and *C. Lawrenceanum*. It is distinguished by a white groundwork on the dorsal sepal, with violet lines running through and violet spotting on the other parts of the flower.

Cypripedium Niobe (*C. Faireanum* × *Spicerianum*) has the good qualities of both parents. Its foliage is beautiful, and it has the graceful recurving petals of *C. Faireanum*. *C. Sallieri aureum* (*C. Villosum* × *insigne*) was known as the yellow Cypripedium until the appearance of *C. Sanderæ*. It is a distinct and beautiful hybrid. It loses none of its beauty by comparison with *C. Sanderæ*, and would never be discarded on account of it. *C. Sallieri aureum* is rather orange-green than yellow, with a few dark spots on the dorsal sepal, and is white on the upper part. The rare *C. Chamberlainianum* is among the most beautiful and attractive of Orchids. It alone is worth going a long way to see. The type is unique. The foliage is very broad, flat and attractively variegated. The large sepal is green, with a lighter-colored margin and dark lines. The petals are long and twisted, screw-like, and deeply colored with a violet and brown metallic-like lustre. The edges of the petals are hairy. The pouch is violet, dotted with purple, with a band of orange about the mouth. The staminate node is very large and bronzy green. *C. (Selenipedium) Schroderæ* is the finest of its type. The whole of the flower is bright reddish pink, prettily spotted with lighter shading on the infolding lobes of the orifice of the pouch. *C. Germinyanum* (*C. villosum* × *hirsutissimum*) is a beautiful flowered hybrid with the purplish pink petals characteristic of *C. hirsutissimum*, the dorsal sepal bronzy green, with lighter shadings. *C. Leeannum giganteum* is the best of all the varieties of this type. The dorsal sepal is very large, and, with the exception of a line along the centre, it is white. The petals are orange-green, with lines and markings of reddish bronze. T. D. Hayward is a cross between *C. Druryi* and *C. superbians*. The groundwork of the large sepal is white, with bright violet lines running through it, and a heavier medium line. The pouch is silvery pink, and the petals pink, with a deeper line along the centre. In *C. Measuresianum* the petals and pouch are both reddish bronze. The dorsal sepal is green, with deeper lines and margined with white. *Creon* is another beautiful hybrid. The large sepal is almost wholly purple, there being merely a narrow margin of white. *C. (Selenipedium) Brysa* (*reticulatum* × *sedeni*, var. *candidulum*) is still among the best hybrids of the New World type. The whole of the flower is white, tinted with rose. The infolding lobes of the pouch are spotted. *C. Phæderæ* (*Lindleyanum* × *sedeni*, var. *candidulum*), another of this type, is deeper in tone than *Brysa*. It has the vigor of *C. Lindleyanum*, and is also a very free bloomer. Like all the *Selenipedium* type, it is seldom out of flower, and there have been as many as seven flowers open at one time on one flower-stem.

Meetings of Societies.

The Western New York Horticultural Society.—IV.

CRIMSON CLOVER IN HORTICULTURE.

Mr. George T. Powell read a paper on this subject in which he said that this crop was attracting attention, largely because it is an annual and grows at a season when the land is otherwise unoccupied. The frequent failure of Red Clover is a discouraging feature of our agriculture. Crimson Clover germinates quickly and develops rapidly. On Mr. Powell's farm leaves had been seen forty-eight hours after the seed was sown. In Delaware and New Jersey hundreds of acres are sowed with the seed after other crops have been harvested, and in one field from which fifteen tons of tomatoes had been gathered seed was sown in September, and in January plants were dug with the roots three feet long. With Mr. Powell a block of Pear-trees where this Clover had been sown gave a much better crop than an adjoining block where there had been none. Sweet Potatoes, followed by a crop of Crimson Clover, and when planted in the same place next year, showed an increase of yield, owing, it is thought, to the plant-food gathered by this plant. As a special protection for an orchard against drought, Rye four feet high was chained and plowed under, and Crimson Clover sown on the field in July made a great growth. It is a good winter covering and mulch; it

brings valuable fertilizers to the surface as well as collects nitrogen; it checks the late growth of trees so that they will ripen their wood, and in all these ways it is a useful crop for orchards. A growth of Crimson Clover six inches high will add nitrogen to the soil which would cost \$16.00 in money. A growth thirteen inches high will add \$25.00 worth of the same plant-food to an acre. Where this Clover fails the cause is usually poor seed.

IRRIGATION IN FRUIT CULTURE.

Although the artificial application of water has been practiced for some time in our western states, it has not been considered heretofore essential to fruit culture in the east. But Mr. Hale, in an interesting address, argued that an extra water-supply would be necessary in the horticulture of the future in the eastern states. The cultivation of fruits requires careful labor; much capital has been invested in plants and plantations, with facilities for handling, and the grower ought to go a step farther and insure his crop. Mr. Hale had lost half a crop by drought many times. A neighbor of his had invested \$800 in a ram and reservoir, seventy feet above his fruit garden, and had applied water at the rate of one inch a week for three weeks, and thereby increased his product in quantity 150 per cent., while it was of much better quality, so that while the abundant berries on the irrigated land brought eleven cents a basket, the smaller crop on the other land was bringing but nine cents. The increased value of his fruit on three acres paid in one year the cost of his plant. Another neighbor ran a stream through open ditches and doubled his product on an average of nine years, although there was only one severe drought during the time. Last year was a dry one in Connecticut, but on the first of August there came three inches of rain at the home farm, with not a drop at the other orchard. The result was that sixty per cent. of the fruit in the home orchard was classed as extra, while only twenty per cent. in the other orchard reached that grade. In the home orchard twenty-eight per cent. only was in the second-best grade, while forty per cent. was in the second grade in the dry orchard, the remainder in both being of two lower grades. This one shower made a gain in the home orchard of from \$1,200 to \$1,500. Mr. Hale has planned to irrigate his farm by putting in a six-inch pipe from a spring-fed reservoir on high ground and a four-inch pipe farther down. The farm is like most of those in the Connecticut valley, long and narrow, sloping back from the river, and the pipe has been laid along the contours of the highest ground, with a hydrant every two hundred feet. He has not devised completely a scheme for distributing the water, but he is sure this can easily be done, and he thinks there is not one farm in ten where water cannot be secured for irrigation at an expense which would be met by the increased product. A man near Pittsfield, Massachusetts, buys water from the city at ten cents a thousand gallons, and has put in a pipe to distribute it. He has no doubt that it will pay a good dividend on grass crops, and much more on fruit. It is just possible that the fruit may be of lower quality, but that is by no means certain, but certainly it would be larger, more beautiful and more salable. Windmills are too uncertain, because when water is wanted it is wanted badly. Steam power is used on some farms near Boston, and Mr. Hale believes that if eastern men who have put their money in western irrigation plants had invested it at home it would have yielded a rich return.

NEW STRAWBERRY CULTURE.

Mr. L. J. Farmer explained the great change in the methods of growing Strawberries during the last ten years. In fertilizers we are now using large quantities of potash and phosphoric acid and less nitrogen. In transportation we use light cheap crates as gift packages. In the actual cultivation we have made less progress, and there is still too much hand labor. The old way was to set the plants early and cultivate all the season. The new way is to take up the plants at the usual time, trench them in and then transplant to the field about the first of June. The trench is made deep by the plow and the plants are set against the landside, twenty-four to the foot, and left until set out. The rest of the soil is worked deep until planting-time, so that the white grubs are turned up for the birds and the weeds are killed. The plants are sprayed the first season, as can easily be done in this close row, and should be done every week. If planted in ground that has not been affected by old beds they will need no further treatment. He wets the plants before moving them; takes abundant earth with the roots, and they keep right on growing. In transplanting it is not necessary to pinch off the leaves, as the plants are like potted plants, only better. In the field the rows are five feet apart and the plants a foot apart in the row. If confined to one berry, he would plant the Parker Earle.

NUT CULTURE.

There is much encouragement to plant our native nuts and some of the foreign ones. As a rule, our indigenous trees are good bearers, and, in Mr. Van Deman's opinion, they produce nuts of better quality than foreign ones. The Chestnut is receiving the most attention now, and there are a few well-marked native varieties of value. Although they are smaller than the European varieties, they are of better quality and very productive. The best are Delaney, Excelsior, Griffin, Hathaway, Morrell and Otto. Rocky hillsides and other places unsuitable for tillage can be used with profit for nut-trees, and they can be set about buildings and in pastures. The European varieties seem more profitable. It seems to be a rule that the more pubescence the nut has the better its quality. European varieties are more fuzzy than the Japanese, and less so than the American sorts. The most prominent of these are the Paragon, Numbo, Ridgely and Hannum. Japanese Chestnut-trees have a more dwarf habit, and the nut has a bitter skin. They graft quite readily on American seedlings, and the best varieties introduced are Alpha, Early Reliance, Grand and Superb. Among the Hickories the best nut-tree is the Pecan, a native of our southern states, and the Shell-bark Hickory, common throughout the north-eastern states. A firm in Pennsylvania ships more than twenty tons of hickory nuts every year. The nuts should be planted in rough places four feet apart each way and thinned as they grow. Seedlings are variable, and so they must be grafted. The principal varieties are Hale's, a large thin-shelled sort, Leaming, Curtis, Elliott and Mulford. Among the Walnuts, our native Butternuts may, perhaps, be improved, but the so-called English Walnut is the best of the family, although it is difficult to grow as far north as New York. There is no doubt that nut-trees are hard to graft and to bud. Evaporation should be prevented until the sap begins to flow. When the sap starts the grafts should be put in underground. The scions should be cut so as to have the pith all on one side, or, if necessary to graft above the ground, they should be covered well to prevent all evaporation possible.

Lessons in Elementary Botany for Secondary Schools.
By Thomas H. MacBride, State University of Iowa. Boston: Allyn & Bacon.

With so many excellent elementary text-books on the science of botany, any newcomer is apt to find a crowded field. But the new year has brought a new botany, which is in a measure a new departure. The plant-lover who has learned his plants in the woods, who has been impressed with the wonderful order and beauty of the trees as they spread their naked branches against a wintry sky, and watched the swelling of the Cottonwood-buds in early spring, seen the Box-Elder twig take on an added color as the warm days approach, and admired the orderly arrangement of the scales in the bursting Lilac-buds, has often wondered that no book-maker has adapted a botany to what he sees about him. The boys and girls begin their study of botany usually just after the Christmas holidays, when all the land is bare, while the text-books have usually begun with the germinating seed, or the tiny seedling. Professor MacBride has been impressed with this incongruity and has endeavored to prepare a book adapted to the season when botanical study usually begins. In doing so he wisely places in the hands of pupils twigs of the trees and shrubs growing all about them—and with which many of them never become acquainted. The author has an important secondary object in view, for in his preface he says: "We have before us the spectacle of a great nation absolutely ignorant of the principles of forestry. If the schools can so shape botanical instruction as to make it practical in the direction of a better appreciation of the value of a tree, they may in so doing advance, not the cause of science only, but of humanity." This sentiment will find emphatic approval in the heart of every tree-lover, and it is a pleasure to add that Professor MacBride's book goes far to fill the purpose noted.

It is a modern book and demands a modern teacher. The days when a student could "pass" in botany without ever having handled a plant, gaining his limited knowledge from the text-book, are over. The book under consid-

eration has little of the didactic in its method. The pupil is forced to study the plant, and the book is merely incidental—a part of the apparatus he uses in reaching his determinations. With the whole realm of outdoor nature as a laboratory, twigs, buds, seeds, seedlings, leaves, buds again, flowers and fruit are inspected in turn, and with the passing season the pupil knows something of his plants and has thought little of his book. This is the true method, and a welcome addition to efficient helps in teaching.

Notes.

In regard to the statement that the Idaho Pear is hardy where other varieties fail, Dr. T. H. Hoskins writes that he does not find it sufficiently hardy for north-western Vermont, or, at least, not more hardy than *Flemish Beauty* or *Ondaga*. The trees will live until they begin to bear, but producing fruit and resisting cold winters together prove too severe a strain upon them. The only Pears which have succeeded in northern Vermont are the Russian varieties, which are entirely at home and yield abundant fruit.

A correspondent of *The Independent* writes that the original Apple-tree from which the variety known as Grimes' Golden Pippin has been distributed, is still standing two miles from Wellsburg, West Virginia, at the head of a deep ravine. The tree is about a hundred years old, and Mr. Thomas Grimes, who originally brought the fruit to notice, has but recently died. The tree is untrimmed, neglected and shows many signs of age and decay, and there is nothing about it to indicate that it is the parent of trees scattered all over the world, for even in Australia Grimes' Golden is a famous apple.

A spar of Douglas spruce, which has been one of the conspicuous landmarks at Kew, where it has been used for thirty-five years as a flagstaff, has become decayed at the base, so that it was necessary a short time ago to cut off several feet of it. A new piece has been spliced on and strengthened by iron bands, and the staff is once more erected. The spar was presented to the Royal Gardens in 1861 by Edward Stamp, Esq., and was cut in the woods of British Columbia. Its total height is 159 feet, of which twelve feet are sunk in a brick pit. The age of the tree was about 250 years and its total height about 180 feet.

Mr. J. Hale says that a Peach-tree three or four years old should not be allowed to bear more than 250 peaches, one four or five years old not more than 300, and a full-grown tree not more than 500. This means that the peaches should be at least six inches apart. Five hundred peaches make six to eight baskets of fancy fruit. Three thousand peaches to a tree would sell for less money and ruin the tree. Mr. Hale puts step-ladders under the trees and begins to thin when the peaches are about three-quarters of an inch in diameter, and every fruit that is diseased or stung by the *curculio* is carried away to be burned. The rest of the thinnings are thrown on the ground and left there.

Oranges are in plentiful supply from the Pacific coast and the Mediterranean, and continue to sell at low figures, although there has been an advance of fifty cents a box during the past fortnight. While Florida oranges are extremely scarce and consequently high-priced, \$1.00 apiece, as stated by us last week, is evidently an error, that being the rate for a dozen. Grape-fruit, the high price of which we noted last week, has since then continued to advance, and the limited importations, now at the close of the season, are commanding extraordinary sums. A few days since two barrels of small-sized grape-fruit realized the extraordinary price of \$20.00 each in this city, and seven barrels were sold in Philadelphia for \$22.00 each.

The floral decorations at Delmonico's on Monday evening for the last of the Patriarchs' halls of this winter, while the most elaborate of the season, were characterized by marked simplicity. In the ball-room the rich cream-colored walls, delicately touched with gold, served as an admirable background. Graceful festoons of wild smilax, from Alabama, depended from the cornice. The unconventional treatment of the large mirrors which comprise the sides of the room was in striking contrast with the profusion of Orchids used in previous years. A hidden trellis of wire half-covering the upper part of each mirror in irregular outline was gracefully covered with the smilax and roses, the effect being that of a wild Rose-bush clambering at will. An effort had been made to use *Bougainvillea glabra* for color instead of Bridesmaid and Madam Cusin roses,

but persistent search in New York, Philadelphia and Boston secured only enough for one mirror. La Reine tulips, in heavy garlands, afforded the color-relief between the windows, and the chandeliers and music-balcony were gracefully ornamented with roses and asparagus. This color-effect was continued in the corridor, where the walls were heavily banked with pink azaleas, luxuriant plants of *Kentia Belmoreana*, their immense drooping leaves contrasting with bushy plants of no less graceful *Arecas*, and with young trees of native New Jersey Red Cedar. Well-grown plants of *Nephrolepis davillioides* ferns massed with tulips and other pink flowers formed banks for the mirrors in this sheltered promenade.

A bulletin has just been issued by the Division of Botany of the United States Department of Agriculture on Legislation Against Weeds. Laws against noxious weeds are already on the statute books of twenty-five states, and as these are all quoted a comparison between them is interesting. In most of them the common names alone of the weeds to be suppressed are used, and, therefore, in some cases it is doubtful what species is meant. Again, the laws of Wisconsin and Minnesota proscribe species which do not grow in those states, and by a misuse of technical names Wheat and Oats are proscribed in a late Minnesota law. In the Iowa law against Thistles the common name of the Canada Thistle is followed by the botanical name of another plant, and since the law is evidently meant to apply to one species it may be doubtful which of the two is meant. A table of all the proscribed weeds in the different states is given, and Mr. Lyster H. Dewey, who has prepared the bulletin, observes that although the Canada Thistle is proscribed in almost all the states, it is not as generally troublesome as this would indicate. In two of the states Sweet Clover is proscribed, a plant which is rarely harmful as a weed, and in certain places it has been found valuable as a renovator of the soil and as a forage-plant. In the southern states, where the Nut Sedge, the Giant Ragweed and the Wild Onion are most serious pests, there are no laws whatever against weeds, while Arizona is the only state of the Rocky Mountain region and in the Great Basin which has passed such a law, although this region is inhabited by many native weeds which are particularly aggressive, and many introduced weeds thrive with great vigor in irrigated fields. The most interesting part of the bulletin is the chapter on the essential provisions of a general state weed law, which we commend to the legislatures of the various states, most of which are now in session.

On the 5th of February, Mr. Frank H. Nutter read a paper at Taylor's Falls, Minnesota, in which, after discussing in a general way public parks and reservations, with their history and treatment, he gave a preliminary report on the proposed interstate park at the Dalles of the St. Croix, where something like four hundred acres of land, partly in Minnesota and partly in Wisconsin, have been acquired as a public reservation. The Falls proper are not high, but the Dalles, with their lofty and precipitous rocks on either side, stained with brilliant colors from oxides of copper, or painted with Lichens and Moss, make a most interesting passage of natural scenery. Mr. Nutter says it would be difficult to find a more attractive combination than the cheerful sparkle of the upper rapids with its tributary brooks, the gloomy grandeur of the Dalles themselves, the quiet beauty of the lake, the sunny intervals dotted with park-like shade-trees, the lofty hills on the Wisconsin side and the gorges across the river, the picturesque cliffs, the plateau on the western bluffs, with its stretch of virgin forest and a westward prospect over rolling farm-lands. Mr. Nutter has made a hasty survey of the place, and, therefore, does not propose anything like a complete plan, but he feels it necessary to state that any comprehensive improvement on this reservation should be based upon a design prepared after a thorough study of the subject as a whole and in detail, so that whatever is done should be done with an eye to what the park shall be as a unit when it is completed. It is a pity that an elementary statement like this needs to be made to an intelligent American audience, but we very much fear that the people of the east, as well as those of the west, will need to be reminded of such truths over and over again before landscape-gardening assumes its true rank among the arts of design. Of course, Mr. Nutter is right when he says that the future possibilities of such a park, if it is enlarged according to his suggestion, should not be developed by the addition of exotic shrubs and the obtrusion of much artificial adornment, but rather by fostering, protecting and emphasizing its natural features, for a true artist in landscape is the one who strives primarily to develop the poetic charm of the place and preserve its spirit in the line of the sentiment which it naturally inspires.

The Mountains of California.

THE two great mountain ranges of California, united at the north by a transverse and broken mass of high ridges, but otherwise distinct—the Coast Range rising to elevations of from 2,000 to 8,000 feet and composed of innumerable spurs and rolling hills, enclosing many long valleys opening to the sea, and the Sierras separating the great central valley of California from the deserts which extend from its eastern base to the Rocky Mountains—are the predominant features of the state. The Sierras have a total length of five hundred miles, with a width of some seventy or eighty miles, and several of the highest peaks ascend to over 14,000 feet above the sea-level, Mount Whitney, its culminating point, being the highest mountain in the United States, with the exception of some of the Alaska giants. One of the most beautiful of mountain ranges, it possesses extraordinary interest in the history which is printed on its ice-swept pages, and in the forests of conifers which now clothe its slopes; and in the fascinating book whose title appears at the head of this article Mr. John Muir tells this history and describes the forests, their trees, and several of the animals which live among them, speaking out of a full knowledge and with the feeling and affection of a devoted lover of nature. No one has had such opportunities for studying the Sierras, or knows them so well; and no one, it may be said, has done so much to preserve their beauty by securing the establishment of the Sierra Forest Reservations. Summer after summer, with a blanket twisted over his shoulders and a bag of dried bread crumbs and a pouch of tea at his belt, without a gun or any companion but his own thoughts, he has tramped over the whole range, tracing the lines of extinct glaciers and exploring the highest peaks and the most remote and inaccessible gorges; only descending to replenish his scanty stock of food and passing long winters in a hut in the Yosemite Valley in order to become familiar with his beloved mountains and trees in winter as well as in summer. Interesting as is the story which he tells of the gradual modeling of the Sierras into their present form by the action of ice exerted through countless centuries, it is of the Sierra forest and the Sierra trees, of which Mr. Muir has succeeded in drawing pictures of life-like accuracy and

remarkable beauty, that we must speak to-day. A paragraph like the following, describing the forests of the central Sierras, which seem to live in the picturesque language of which Mr. Muir is master, is a good example of his method:

Here, too, in the middle region of deepest cañons are the grandest forest-trees, the Sequoia, king of conifers, the noble Sugar and Yellow Pines, Douglas Spruce, Libocedrus, and the Silver Firs, each a giant of its kind, assembled together in one and the same forest, surpassing all other coniferous forests in the world, both in the number of its species and in the size and beauty of its trees. The winds flow in melody through their colossal spires, and they are vocal everywhere with the songs of birds and running water. Miles of fragrant Ceanothus and Manzanita bushes bloom beneath them, and Lily gardens and meadows, and damp, ferny glens in endless variety of fragrance and color, compelling the admiration of every observer. Sweeping on over ridge and valley, these noble trees extend a continuous belt from end to end of the range, only slightly interrupted by sheer-walled cañons at intervals of about fifteen or twenty miles. Here the great burly brown bears delight to roam, harmonizing with the brown boles of the trees beneath which they feed. Deer, also, dwell here and find food and shelter in the Ceanothus tangles, with a multitude of smaller people. Above this region of giants the trees grow smaller until the utmost limit of the timber line is reached, on the stormy mountain-slopes at a height of from 10,000 to 12,000 feet above the sea, where the Dwarf Pine is so lowly and hard beset by storms and heavy snow, it is pressed into flat tangles, over the tops of which we may easily walk. Below the main forest-belt the trees likewise diminish in size, frost and burning drought repressing and blasting alike.

In the chapter devoted to the forest all the principal Sierra trees are described, not in the dry and often obscure language of the botanist, but in the words of a literary artist who has studied them in all their varied aspects; and of all the descriptions of trees which we have read these are the only ones which enable the untraveled reader to form, without the aid of a photograph, a really correct and accurate idea of the appearance of the tree in question. Take, as example, Mr. Muir's description of the Juniper of the high Sierras (*Juniper occidentalis*):

The Juniper is preëminently a rock-tree, occupying the baldest domes and pavements, where there is scarcely a handful of soil, at a height of from 7,000 to 9,500 feet. In such situations the trunk is frequently over eight feet in diameter, and not much more in height. The top is almost always dead in old trees, and great stubborn limbs push out horizontally that are mostly broken and bare at the ends, but densely covered and embedded here and there with mossy mounds of gray foliage. Some are mere weathered stumps, as broad as long, decorated with a few leafy sprays, reminding one of the crumbling towers of some ancient castle scantily draped with ivy.

Here, in a few words, is a description which presents the living tree to our eyes as clearly as if it was standing before us as we read, and it is this clearness and simplicity in description which seems to us to be the great charm and merit of the book.

Of especial interest are Mr. Muir's studies upon the history, distribution and age of the Sequoia gigantea, one of the most interesting as it is the largest of American trees. The Sequoia grows in a widely interrupted belt from the middle fork of the American River to the head of Deer Creek, a distance of about 250 miles, the elevation of the belt above the sea varying from 5,000 to 8,000 feet. At the north the Sequoia occurs only in small isolated groups, which are sometimes from forty to sixty miles apart, but south of King's River it is not restricted in groves, but extends across the broad basins of the Kaweah and Tule rivers in noble forests for a distance of nearly seventy miles. South of the cañon of the south fork of King's River there is a forest of Sequoias about six miles long and two miles wide. This is the most northern assemblage of this tree that can be called a forest, the very finest being found, however, on the north fork of Tule River. It has long been known that in the northern groves there are comparatively few young trees or saplings, and this fact led to the belief, before the discovery of the southern forests, that the Sequoia was gradually dying out. But in

the southern forests Mr. Muir finds "that for every old storm-stricken giant there are many in all the glory of prime vigor, and for each of these a crowd of eager, hopeful, young trees and saplings growing heartily on moraines, rocky ledges, along watercourses and in the moist alluvium of meadows, seemingly in hot pursuit of eternal life."

The largest Sequoia Mr. Muir has measured is in the King's River forest, and is thirty-five feet eight inches in diameter inside the bark four feet from the ground. Such a tree he believes to be more than five thousand years old. His observations upon the age of the Big Trees are interesting and important. The stump of a tree in the Calaveras grove, when examined many years ago by Professor Asa Gray, showed about 1,300 layers of annual growth, and led him to believe that the reputed age of these trees had been greatly exaggerated. A tree cut in the King's River forest, however, of about the same size as the Calaveras tree, and not very old-looking, Muir found to be 2,200 years of age, while the King's River giant displayed over 4,000 rings in an incomplete section which he was able to examine. "No other tree in the world," he says, "so far as I know, has looked down on so many centuries as this Sequoia or opens such impressive and suggestive views into history." It has generally been believed, too, by naturalists that the Sequoia was once far more widely distributed over the Sierras than it is at present. Mr. Muir, however, has reached the conclusion that it has never been at any time since the glacial period more abundant than it is now, his careful examination failing to reveal a single trace of its previous existence beyond its present bounds. Sequoias, apparently, do not die a natural death, and, barring accidents, appear to be immortal, living on indefinitely unless destroyed by man or fire, smashed by lightning or thrown down by storms or by the sliding down of the ground on which they stand. When one of the Big Trees falls, the trunk, which is practically indestructible by the action of the weather, may remain on the ground for centuries, and when it is finally destroyed by repeated burnings, a great trench, caused by the weight of the falling tree, permanently marks the place where it has laid. Such trenches exist in all the Sequoia groves and forests, but beyond their limits Mr. Muir has searched for them in vain—conclusive evidence, it would seem, that the Sequoia belt has not undergone any great diminution since the close of the glacial epoch.

The Sequoia was probably one of the first trees that obtained a foothold on the Sierras after the ice-sheet began to break up into individual glaciers, and its distribution in isolated groves and forests may be accounted for, as Mr. Muir suggests, by the fact that when it first appeared on the exposed ridges the intervening space was occupied by glaciers. The Sequoia belt, therefore, attained its greatest development at the place where, owing to topographical peculiarities, the ground had been most perfectly protected from the main ice rivers that pour down from the summits long after the smaller local glaciers had melted. Contrary to the now generally accepted theory that the Sequoia which existed in the Arctic Circle during the tertiary epoch reached California from the north, Mr. Muir believes "that as the Sequoia forests present a more and more ancient aspect as they extend southward, the species was distributed from the south, while the Sugar Pine, its great rival in the northern groves, seems to have come around the head of the Sacramento Valley and down the Sierra from the north.

We wish space would permit us to speak of the chapter devoted to the Douglas squirrel, the great Sierra forester, as Mr. Muir calls him, the devourer and incidentally the disseminator of coniferous seeds, and of the other animals and birds whose habits he describes with such delightful freshness; but for these we must refer our readers to the book itself. During the last fifty years a number of books in which nature and natural objects have been discussed in what may, perhaps, be called the poetical method, have appeared. None of them, however, in our judgment, com-

pare with Mr. Muir's production in truthfulness of observation and beauty of expression, and The Century Company has done a useful thing in collecting in a volume these essays on the Mountains of California, which first appeared in slightly different form in the pages of *The Century Magazine*.

The Strawberry in New England.

IT is well known that this fruit has been cultivated for centuries in the Old World, but some misconception seems to exist in regard to the date of the cultivation of the Strawberry in New England, as well as to its abundance in early times. In the last report of the Connecticut State Board of Agriculture, page 66, a member stated that he could not find that the Strawberry was cultivated here in gardens previous to 1824. Dr. Timothy Dwight, in his delightful volumes of *Travels in New England*, published in 1821, though written earlier than 1817, gives a list of five different varieties of Strawberries, four of which he had under cultivation in his garden. He mentions the following varieties: The Red Meadow, White Meadow, Field, Hudson and Hautboy. Dr. Dwight says: "The Meadow Strawberry of this country is the best fruit of the kind which I have seen. It is rather larger than the Chili Sweet, and more prolific. It also improves greatly by culture. I have seen several which were four and a half inches in circumference, many which were four, and bushels which were between three and four." And he further states: "I have cultivated the Wild Meadow Strawberry more than twenty years, and during that time it has increased to twice its original size."

In regard to the Field Strawberry, he says that it "is sweeter, ten days earlier, but much smaller, than the Meadow Strawberry, and has not increased in size by a cultivation of eight years in my garden. The plants become immediately much larger, but the fruit has not been changed at all." He also mentions the Hautboy and Hudson varieties as having been in cultivation for many years in his garden. The former variety is a well-known European form; the latter is a form I am not familiar with, although I suspect it to be an old cultivated variety common in these days. These statements of Dr. Dwight, who died in 1817, show that the Strawberry was in cultivation in New England before the beginning of this century.

He, moreover, states that the Hautboy Strawberry, *Fragaria elatior*, has been found growing spontaneously in two distinct and remote localities in Connecticut. This statement, if true, would undoubtedly indicate that they were introduced through the agency of birds.

The White Meadow Strawberry which he calls attention to is a mere sport or variety of the ordinary Red Strawberry. It is also mentioned by Dr. Dewey in his *Plants of Massachusetts*, 1890, page 59, as occurring plentifully in the Berkshire Hills.

In regard to the abundance of the Strawberry in early times there appears to be some misconception also. Every one is aware that there are few places in Massachusetts where it would be possible now for one to gather more than a few pints of strawberries in a whole day. In early times, however, when there was more virgin soil than there is to-day in New England the wild Strawberry was very abundant, and frequently grew to a much larger size than at present; and even within the recollection of men now living this fruit was by no means rare in this state, neither is it in Nova Scotia and New Brunswick to-day. William Wood, an early visitor and accurate observer, states in his *New England Prospect*, published in 1635, that "there is likewise growing all manner of Hearbes for meate and medicin, and that not onely in planted Gardens, but in the woods, without either the art or helpe of man. . . . There is likewise Strawberies in abundance, verie large ones, some being two inches about. One may gather halfe a bushell in a forenoone." And in 1643 Roger Williams wrote: "This berry (Strawberry) is the wonder of all the fruits growing naturally in those parts; it is of itself excellent, so that one of the cheiftest doctors of England was wont to say that God could have made, but never did, a better berry. . . . In some parts, where the natives have planted, I have many times seen as many as would fill a good ship within a few miles' compasse. The Indians bruise them in a mottar and mixe them with meale and make Strawberry bread." Strawberry bread appears to have been in common use among the Indians, as we find it mentioned by other writers, notably Gorkin, who was a co-worker with Rev. John Eliot among the Nipmucks and other Massachusetts tribes. These statements, with many others which could be cited, show conclusively that the wild Strawberry was once very abundant here in New

England, and undoubtedly the principal reason for the decline of this wild fruit is the exhaustive conditions of our soil. In early times the clearing of an old wood gave rise to abundance of these berries, and they were noted as being abundant in our meadows. The Strawberry, however, is not the only natural crop that has changed. Many of our meadows, which now produce a crop of grass hardly worth cutting, once supported a luxuriant growth of the Fowl Meadow Grass, "thick and long, as high as a man's middle, some as high as the shoulders, so that a good mower might cut three load a day." To-day, however, hardly less should be expected, since for generations crops have been removed from the soil without the return of any plant-food, whereas in olden time, before the advent of the white man, everything was allowed to decay where it fell, which meant a considerable yearly increase of organic matter to the soil.

Foreign Correspondence.

Orchids at Kew.

A HAND-LIST of Orchids cultivated in the Royal Gardens, Kew, has just been issued and may be obtained from the Curator, price sixpence. This is the fourth of the series of catalogues of the Kew collections of living plants printed within the last two years, the other three being part I. of the hardy trees and shrubs, Ferns and Fern allies, and hardy herbaceous and alpine plants. The intention of the Director is to catalogue the whole of the collections of living plants at Kew, the total number of species being estimated roughly at twenty thousand. A list of the conifers is already in the printer's hands, and this will be followed by the second part of the hardy trees and shrubs.

These lists are of horticultural value because, while they comprise a large number of species of more or less interest to botanists, they also include practically all the plants cultivated in gardens for ornamental or economic purposes. No pains have been spared to make the nomenclature accurate and in accordance with the views of recognized authorities. Many garden names are reduced as synonyms or errors, but through lack of sufficient material or information some which are provisional have been retained. The author of the name, habitat of the plant and, where possible, a reference to a published figure are given with each species. The value of these lists must be evident to any practical horticulturist who has to deal with large collections and to whom the almost hopeless confusion of names by dealers and others must have often presented difficulty. By dealing thus thoroughly and comprehensively with the whole of cultivated plants, Kew has rendered great service to horticulture, whose followers, it is to be hoped, will adopt the names preferred by the Kew authorities and thus bring about uniformity where, till now, there have been confusion and doubt.

The Orchid list enumerates 200 genera and 1,800 species (including about fifty garden hybrids) as being represented by living examples at Kew. The greater proportion of these are what are popularly known as botanical curiosities, which would not find favor with those who are interested in beautiful flowers, but which, nevertheless, are worth a place at Kew, where the main object is botanical, and to represent the order in as comprehensive a way as possible. As an example I may cite the genus *Pleurothallis*, of which there are forty species at Kew, but not more than half a dozen of them would be looked at a second time by the ordinary collector. The genus *Bulbophyllum* is represented by sixty-four species, *Cirrhopetalum* by thirty-one, *Angraecum* by thirty-nine, *Dendrobium* by one hundred and forty, *Masdevallia* by eighty, *Oncidium* by one hundred and eight species, and so on.

This collection has been slowly built up in various ways, partly by purchase or exchange, partly through the kindness and interest of travelers and residents in countries where Orchids abound, and by the generosity of some of the collectors and cultivators of Orchids in this country. Many of the plants are small, perhaps obtained from a scrap taken from a specimen sent to the herbarium for

identification, all such that come into the Kew net being good fish.

The introduction to the hand-list contains some interesting information about the Kew collection in particular, as well as about Orchids in general. The accommodation for Orchids at Kew is not first-rate, only two houses to which the public are admitted being available for their display, and these are so ill-adapted for the cultivation of Orchids that they are practically only show-houses in which the plants are placed when in flower. The bulk of the collection is grown in some half-a-dozen small houses to which the public cannot conveniently be admitted. It would, however, be possible to provide houses which would be suitable for the culture of Orchids, and to which the public might have free access.

Orchids have been continuously cultivated at Kew from their earliest introduction into this country. The varied fortunes which have attended the collection practically reflect the history of the progress which has been made in the art of growing Orchids under artificial conditions.

The first exotic Orchid which was introduced into English gardens was *Bletia verecunda*, which was obtained from Providence Island, Bahamas, by Peter Collinson, in 1731, and flowered in the following year in the garden of Mr. Wager. About the year 1778 *Phajus grandifolius* was imported from China by Dr. Fothergill, and a full-sized colored figure of it is given in the first edition of the *Hortus Kewensis* under the name of *Limodorum Tankervilleæ*. A peculiar interest attaches to this plant because it was in it and at Kew that in 1802 Francis Bauer, who was "resident draughtsman for fifty years to the Royal Botanic Garden," discovered and figured the "nucleus of the case," an all-important body, the first description of which was published by Robert Brown in 1833.

In the first edition of Aiton's *Hortus Kewensis* fifteen non-British species are enumerated as cultivated at Kew. Sir J. E. Smith wrote: "We have scarcely seen any one species of this genus (*Epidendrum*), except in a dry state, before the year 1787, when *E. cochleatum* flowered at Kew, nor was it till October, 1782, that *E. fragrans*, of Swartz, exhibited its rich and elegant bloom in the same rich collection. At present several species are to be seen flowering in the spring and autumn."

In the second edition of the *Hortus Kewensis* (1813) 115 species are enumerated, of which eighty-four are exotics belonging to thirty-nine genera. In 1848 the number of species cultivated at Kew had increased to 755, and in 1872 the number of species and varieties was 851, belonging to 138 genera. Since then the collection has grown steadily. The collection of Orchids in the botanic gardens at Glasnevin, Dublin, is almost, if not quite, as rich in species as that at Kew.

The essential cultural requirements of Orchids were not known till long after they had attracted the attention of horticulturists. It is interesting to note the struggles of our great-grandfathers to discover the conditions most suitable for them. We who know all about it are surprised that any intelligent cultivator should have tried to grow epiphytic plants "in common soil in pots plunged to the rim in a tan bed." Teak baskets, sphagnum moss, peat fibre and charcoal appear to us to be exactly what any intelligent schoolboy would have recommended as supplying the right material for an epiphyte. But, like all useful discoveries and inventions, simple as they appear to us, they were not worked out without much thought, experiment and the sacrifice of many plants. One of the shrewdest of botanists working in the van of the horticultural art of his time, Dr. Lindley, stated in a paper read to the Royal Horticultural Society in 1830 that "high temperature, deep shade and excessive humidity are the conditions essential to the well-being of Orchids." Thirteen years later another Orchid authority, Mr. Bateman, recommended the same treatment, adding that a resting season was necessary. This treatment became the only orthodox one, and was persisted in for upward of thirty years.

Two men, however, broke away from the current tradition, and with conspicuous success. One of the first of these was Joseph Cooper, gardener to Earl Fitzwilliam, at Wentworth (1835). A still bolder innovation was adopted shortly afterward by Paxton, at Chatsworth. In both cases the essential innovations were lower temperature and increased ventilation. The old tradition still, however, held its ground; plants perished under the barbarous treatment they received in the hot-houses of this country almost as fast as they were imported. To such an extent were the losses felt that Lindley, in a remarkable article published in *The Gardeners' Chronicle* toward the end of 1859, pronounced their treatment "a deplorable failure," and which Mr. Bateman also some years later characterized as "incredible folly."

Even within the last twenty years considerable advance has been made in the art of Orchid culture. We now recognize that fresh air at all times is essential, that many Orchids enjoy bright sunshine, that while some require plenty of moisture all the year round, others require it only for a portion of the year, and that some even thrive only when treated as if they were Cacti. The temperature for exotic Orchids varies from a purely tropical to that of a few degrees above freezing point, and while some species during growth are kept in a hot steamy atmosphere, and after growth is completed are removed to comparatively cool and dry conditions to afford them a rest, others suffer if the conditions are not fairly uniform all the year round.

London.

New or Little-known Plants.

Viburnum erosum.

THIS is one of a small group of North American and Asiatic *Viburnums* whose leaves are furnished with small linear stipules. It is a stout shrub five or six feet in height, with slender much-forked branches covered with orange or reddish brown bark. The leaves are oblong-ovate or oblong-obovate, acuminate, gradually narrowed, wedge-shaped and often unequal at the base, erose-serrate, with slender spreading rigid teeth, stellate-pubescent, membranaceous, dark yellow-green on the upper surface and pale and rather lustrous on the lower, and rusty-pubescent on the under side of the thin midribs and in the axils of the remote primary veins; they are from two to three inches in length and from an inch to an inch and a half wide, with stout pubescent petioles about a quarter of an inch in length. The flowers appear in May in lax pubescent long-stalked corymbs about three inches across, with linear-lanceolate scarious reddish bracts and bractlets. The corolla is rotate and greenish white, with rounded lobes about half as long as the stamens. The fruit is red, with a flat stone, slightly thickened and obscurely two-ridged on the back, and furnished with a short mucro at the apex.

In Japan *Viburnum erosum* inhabits the southern island of Kiushiu and southern and central Hondo, where it is not rare at elevations of three or four thousand feet above the sea in the mountain districts crossed by the Nakasendō; it also inhabits Formosa, southern and central China and Corea.

*Viburnum erosum** has been cultivated in the Arnold Arboretum since 1880, having been received in that year from the Parsons' Nursery in Flushing, Long Island; and the flowering branch in the illustration on page 85 of this issue is from a specimen grown in the Arboretum; the fruit represented on the plate is from a wild Japanese specimen. Of considerable interest botanically, *Viburnum erosum* is less desirable as an ornamental plant than several of the North American and Japanese species now to be found in gardens.

Vegetable Notes.

ALTHOUGH the cultivation of Cucumbers during the winter months is somewhat troublesome, they are comparatively easy of management during the longer and brighter spring days. Plants from seeds sown at the end of February will give a supply of fruit from about the middle of April until plants outside begin to bear. The starting of seeds is sometimes troublesome on account of damping off just after germination has begun; this can be prevented by careful planting. A little study of the habit of the seed will show that the embryo breaks through the shell at the point or thin end, the root being first produced. The seeds should be set so that the root can go directly down into the soil and the top shoot upward. If the seeds are sown at random the little plant, after germination, is sometimes in a position from which it cannot extricate itself. They should be sown in small pots in a light sandy soil and placed in a good bottom-heat; as soon as the plants are up they should be removed to a light situation near the glass, but shaded from strong sunlight. They must be shifted into larger pots as soon as they are strong enough, using a heavier soil than before, and which the roots will now be able to take hold of. When planted into their permanent quarters a few tobacco-stems spread about will help to keep off the black fly, which is always a ready enemy. It is necessary to keep the atmosphere moist and to syringe twice daily on bright days, but the syringing must be done lightly, as the leaves are tender and easily damaged. On this account smoking should never be resorted to as a means of destroying the fly, but if this pest becomes troublesome fresh tobacco should be spread over the pipes and sprinkled with water. This should be done when the pipes are warm and the house is closed. A night temperature of sixty degrees is sufficiently high, with a rise of fifteen degrees through the day. The plants may be slightly shaded to advantage when the sun is bright. We have tried several varieties, but find none equal to Telegraph for quality, productiveness and free growth.

A sowing of Cauliflower seed for frame work should be made toward the end of February, and the last batch should be planted indoors. It is not advisable to plant indoors any later, as the bright sunlight proves too much for them after the beginning of April. No matter how carefully they are watered and aired after that date the plants will flag on bright days. This flagging has the effect of injuring the quality and reducing the size of the head, and also induces a number of heads to come hard and open and unfit for table use. While in frames the plants are not subjected to the same drying influences and can have more air by removing the sashes during favorable weather. If the soil in the frames has already been used for a similar purpose, about a foot of it should be removed and replaced with well-enriched fresh soil. For this, as for greenhouse work, the dwarf varieties, such as Snowball and Dwarf Erfurt, should be chosen, since they give the best returns in the least space.

Sowings of Boston Market and Tennis Ball Lettuce should be made in flats for planting in frames later on, and of Golden Queen for indoor work. We find this latter variety resists heat better than any we have yet tried and can, therefore, recommend it to keep up the supply. During the winter months it can be grown at a night temperature of fifty degrees, while such varieties as Rawson's Hot-house and Boston Market do better ten degrees lower. The latter varieties would probably take from ten to twelve weeks to mature, while Golden Queen, at a night temperature of fifty degrees, can be had fit for use in eight weeks from the time of sowing. It also does well at a lower temperature, though the growth is correspondingly slower, and it is questionable if it pays to maintain a high temperature for Lettuce during winter, except in cases of emergency.

Early Warwick and Red Valentine Bush Beans still prove the most suitable varieties. Successive sowings may be made in benches or in pots. They are convenient in pots during the spring months, as they can be shifted about to economize space in the benches. The Beans are sometimes hard to start for lack of bottom-heat, but the pots can be set directly over the pipes, and if kept well supplied with water the seed comes up quickly. Ten-inch pots are a convenient size. They should be only two-thirds filled with soil when the seed is sown, the other third being added after the plants are large enough to permit of it. Five or six plants are enough to a pot of this size, but it is better to sow plenty of seed and thin out after the strongest plants can be selected. If subjected to a dry atmosphere red spider is apt to be troublesome, but syringing may be freely practiced, and this will help to keep the plants clean. A light situation and full exposure to sunlight suits them best.

Seasonable Notes on Chrysanthemums.

WITH the distribution of new Chrysanthemums we may say the season of these flowers for 1896 has commenced. With the watchful cultivator it has never ended. When the last flowers are cut we gather our stock for the coming season, study notes, and secure what we can of the new varieties which have impressed us favorably when visiting our neighbors and at the exhibitions. As often happens, the stock of some varieties, much sought after, is limited, and so we are propagating and growing all winter long. The bulk of our stock plants are yet in cold frames. They have not been frozen during this uncommonly mild winter, so that cuttings have been taken as needed. It is only during recent years that we have come to pay due attention to our stock during what

the season before for specimen blooms. I have tried this plan, but with indifferent success. Young plants taken as cuttings, when old plants were started, outgrew them in four months, which is only about half a season's growth. I am told that one gardener, following the English practice, grew some plants all last season for the sole purpose of making specimens of them this. It is to be hoped that these plants will be exhibited, so that we can have an opportunity of judging between the English and American methods.

Experience shows that cuttings root better during the month of March than at any other time. Later, as the sun gains power, the air grows drier and closer attention must be given to the work of propagation. Indeed, I am acquainted with good gardeners who have been unable to understand why they lost a large percentage of cuttings during the late spring

Fig. 9.—Viburnum erosum.—See page 84.

may be termed the resting season. It has been too much the custom to shove the plants under benches and pay little or no attention to them until they were needed. We were certain in this way of some sort of cuttings, but experience has proved that it is advantageous to have our stock hardy, healthy and exposed to air and sunshine on every available opportunity. Some growers now even take the trouble to grow plants in the open garden exclusively for stock.

As stated in previous notes, our plants intended for specimens were started a month earlier than usual, and we have lately moved them into six-inch pots. Ordinarily we should now have them in four-inch pots. In this stage they would be early enough for all practical purposes and would make quite large specimens. Some English growers start plants in December and grow on old plants which have been cultivated

months. During the months of May and June a close, well-shaded propagating frame is essential, and complete saturation for the first four or five days. It is hard to remedy the results of exposure even for a few hours, except in moist weather, or evening and early morning. The value of new varieties has almost invariably been estimated with a view to specimen blooms, and judges have never required that exhibitors of such varieties should show growing plants. It has, therefore, been with difficulty that those interested in specimen plants have been able to select such as are useful for their purpose among novelties. But, so strong is the desire to be abreast of the times, that in nine out of ten places one visits he will find growers relying on untested novelties and discarding many available varieties which have been tried and found suitable. I have done this myself. Due credit, however, is always given

to novelties shown in first-class condition, so that, while not relying upon them, we always grow to the best advantage such as are most promising. Our list of varieties suitable for specimen plants has been made with care, and, although extending over a number of years, is by no means large. Practical experience must alone guide, and when looking over the lists I often see kinds noted as suitable for specimen plants which have not proved so with me. To give an idea how few plants are really suitable for this purpose I will say that *Crystalina*, a dwarf early white, and *Mrs. S. T. Murdock*, pink, were the only real good ones found among all the introductions of 1895. The most promising varieties for 1896, so far as I have seen, are *Mrs. Perrin*, pink; *Gretchen Buettner*, white; *Violescent*, bluish, and *Columbine*, bright bronze, the latter being especially recommended.

It has been said that the popularity of the *Chrysanthemum* is on the wane. No doubt, the Japanese varieties have been overdone, but that the *Chrysanthemum* will ever become unpopular I do not believe. There will rather be a return to a larger variety of types, and many of the old kinds will come into favor. Already we see this. We shall see more pompon-flowered varieties grown as pot-plants. They are handsome in all sizes and shapes, and, being naturally bushy in habit, are less formal than trained specimens; they are nice, too, for cutting in sprays. Anemone-flowered varieties have a beauty all their own. They do not mix well with the large Japanese or formal Chinese sorts, but they supplement them, and small plants are very effective in grouping, far more so than the large-flowered varieties.

Varieties fresh from the introducers usually come with the balls of earth pressed closely about the plants. I find it a good plan to carefully loosen the soil by gentle pressure before placing them in new soil. Of late years, mainly for want of space, I have put mine in flats, with plenty of room for branching, placing them on shelves near the glass. Here they make good stocky plants. I take the tips off as soon as the plants become hardened, and root them. These often make better plants than the original stock. Such varieties as I wish to grow solely for specimen blooms I cut in hard. This encourages shoots of the sucker type, and these make the very best cuttings. Leaf-eyes of any exceptionally rare variety, such as *Philadelphia* was last season, or *Mrs. Perrin* will be this, may be rooted quite as easily, and some of the finest blooms have been raised in this way.

Pentstemons.

THE old-fashioned border flowers are no longer so carefully tended as they once were by the specialists, and it is a rare thing now to find a good collection of Tulips, Auriculas, Carnations or Picotees. In the old days the number of plants in cultivation was small in comparison to what it is to-day; the limits of horticulture were circumscribed for those of moderate means, and the result was that these classes of plants were taken in hand by enthusiasts who became identified with one or more of each and made a close study of them, with the result that they were improved to the utmost limit, and there are no better kinds to-day than there were a generation ago. The old-time exhibitions have largely died out, too; many, if not most, of the plants formerly displayed it would be impossible to obtain now. This must not be considered a retrogression altogether, but rather an indication that gardening is too broad a subject to be restricted to exhibition limits, and border Carnations, Tulips, Auriculas and Pentstemons are grown now to be enjoyed in the garden instead of on the show board with the regulation frilled white paper collars round each bloom.

It is more especially of the *Pentstemon* that I wish to speak as I saw it at its best in English gardens last August. At Kew especially, in the public parks and everywhere in home gardens, large beds were devoted to them, and the colors were as brilliant as those of *Gladioli*, and with about the same range of colors, too, but with more elegantly shaped flowers. The flowers were as large and the spikes as tall as well-grown Foxgloves, and admirably adapted for house decoration when cut. The season of bloom, too, lasted for two months I was told, and it seemed there were few plants that could give such returns for so little trouble. When asking about the sorts I was told that they were in all cases seedlings raised from a sowing made early in the year and set out in summer, the plants being treated as annuals instead of perennials; in this way winter storing was dispensed with. Seed was saved from the best flowers each year for the display to follow. Now, it at once occurred to me that the progenitors of this race of garden *Pentstemons* are all north-western American plants, the domi-

nating blood being that of *Pentstemon Hartwegii*, its brilliant scarlet being very evident, while the more sombre purples and blues were derived from *P. Coboca* and others. As now grown, however, they are distinct enough in themselves to lose any identity with any particular species.

There seems to be no reason why we cannot have beds of these fine border flowers as easily as they are obtained in Europe. There may be cultivators of *Pentstemons* here, but I have not seen them. Here we have made a start in the right direction by securing seeds from several sources and the plants are well up now; the results will be noted later in the summer, but there seems to be no reason to doubt that the experiment will be a success.

Warming Tanks for the *Victoria regia*.

DURING the past season the *Victoria regia* was grown most successfully in some of our public parks and gardens for the first time, and excited much interest in aquatic gardening. Where the *Victoria* can be grown well it is always a surprise to those who are not familiar with it, and every one is impressed with its queenly rank among Water-lilies. To secure a perfect specimen it is necessary to have an artificially heated tank, for our season is otherwise far too short. The plant cannot be safely set out until settled warm weather, or about the end of June or beginning of July. With continuous summer weather the plant attains only fair proportions when cool nights and shortening days are upon us, but with artificial heat a tropical temperature can be maintained for six or eight weeks before warm weather sets in, and the plants will have reached good proportions and be a source of enjoyment throughout the summer months. Few plants are grown entirely under glass during the whole season, although there are advantages in such treatment. It is much more enjoyable, however, to inspect these marvels of the tropics in the open air rather than under a glass roof in summer's heat.

Plants for the open-air pond or tank should have attention now. The seeds may be sown any time before the second week of March in water kept at a temperature of eighty-five to ninety degrees, Fahrenheit. They will germinate in about twenty days. The plants make rapid growth and will require repotting at intervals before becoming pot-bound or exhausted in small pots. If this detail is attended to the plants will make satisfactory growth and be of the first size for planting out when the season arrives. The plants should be kept steadily growing from the seed-leaf to the mature plant. The matter of heating tanks for *Victoria regia* and for other tropical aquatics has received attention from many cultivators since the *Victoria* was first introduced. Several systems, more or less satisfactory, have been adopted, but I feel sure that the best and most satisfactory has yet to be adopted. If a system of hot-water heating is already in use in the establishment, it is advantageous and economical to adopt this for heating the tank. But a long stretch of piping in one tank is not practicable, as the heat is soon given off and a great portion of it is therefore useless. I have used hot water under pressure for heating tanks in connection with the greenhouse plant, and found in shallow tanks, eight inches deep, that one one-inch pipe through the centre of the tank is as effective as a one-inch flow and return pipe through the same. The return pipe is cold almost always, except during hard firing in severe weather in winter. Steam-heating in the ordinary way is to be condemned. It is unreliable, unsteady and dangerous, and needs constant and careful watching. At the point of contact, where the steam-pipe enters the tank, the water will be very hot, the steam condensing as soon as it enters the submerged pipe, and little heat is conveyed a few feet farther along. Consequently a tank twenty feet long would be very hot at one end and many degrees colder at the other. Having recently had a house one hundred feet long fitted up for aquatics and heated by steam, I endeavored to have a large tank heated by the same system, and to overcome the difficulties mentioned I selected a two-inch pipe to run through the centre of the tank on the floor. Through this pipe the steam-pipe (one inch) was conveyed, making the ends of ingress and egress perfectly water-tight, and thus forming an air space between the steam-pipe and the radiating surface of the two-inch pipe. By such an arrangement the steam-pipe at no time comes in direct contact with the water, and the air space is uniformly heated through the entire length. The water in the tank is also uniformly heated and an even temperature is maintained. This plan obviates the objections to the ordinary steam-pipe submerged, and it is the best method I have found for warming the water in Lily-tanks by steam-heat.

Correspondence.

Daffodils in California.

To the Editor of GARDEN AND FOREST :

Sir,—It is probable that more Daffodils are in bloom now (February 1st) on the farm of James Shinn, near Niles, Alameda County, than can be found in all the rest of the state put together. The original stock was imported about thirty years ago by the late E. P. Sanford, of Oakland, a prominent druggist, whose garden was for many years one of the notable features of that town. When the growth of Oakland made the sacrifice of the garden necessary, part of the stock of Daffodils, then greatly increased, was taken to Niles, and received a judicious amount of neglect for many years.

At the present time the Daffodils have taken possession of a large part of the available garden area. They are allowed to grow in clumps for five or six years without separation, and then it becomes necessary to extend the plantation further and further into the surrounding orchard. The surplus flowers are sent to San Francisco for sale, and the following items from the beginning of the present season will serve to show how well suited the climate is for this flower :

Three dozen flowers were shipped as early as January 17th ; by the 24th the daily cutting was thirty-five dozen, and by the 31st it had reached 300 dozen, with the supply still increasing and destined to continue for several weeks.

We have been trying to identify the leading variety represented here. Ninety-nine out of a hundred flowers are a large, firm, rich-colored, single Trumpet Daffodil, much resembling the Ard Righ, though earlier ; at least, earlier than imported Ard Righ bulbs when planted alongside of them. We have planted a good many named varieties which may develop better qualities in course of time, under the favoring conditions, but at present nothing among the yellow Trumpet varieties is equal to our own stock in earliness or excels it in general effectiveness.

As a rule, Trumpet Daffodils bloom here under open-air culture by the middle of January. The Paper-white Narcissi are in bloom by December 1st, and often a fortnight earlier. They are still blooming (February 1st), while the Trumpets are approaching their prime. A few double Trumpets are now in bloom, but the majority will not appear for a fortnight or more, and, in fact, the double forms of the *Medii-coronatae* group are not at all prominent until the single Trumpets have gone. Various types of the *Polyanthus Narcissus* are naturalized in large clumps in the shrubbery, as are many others of the true Daffodil sections, but none of the clustered Narcissi seem quite as much at home as do the single Trumpet Daffodils.

Niles, Calif.

Charles H. Shinn.

Bulb-farming for the South-west.

To the Editor of GARDEN AND FOREST :

Sir,—Recent experiments indicate that certain favored sections of this country are as well adapted as Holland to the production of an extra quality of bulbs, and this is a matter worth investigating since America imports these bulbs by the million every year. Here and there through the south favorable reports have been made. In particular, Professor Massey, through the columns of GARDEN AND FOREST, has called attention time and again to the possibilities of North Carolina in this direction. The South Ozark region, in my opinion, is another promising field for bulb-growing on a large scale. This region, according to a recent isothermal map, consists of about three tiers of counties, five or six of which are in south-western Missouri, and ten or twelve in north-western Arkansas, together with a strip of Indian Territory adjoining them. From the greater height of the mountains and the different slope of the ranges this belt of land has a warmer climate than the country to the north, south and west of it, and the conditions of local rainfall are much modified also. The distinctions of soil are even more marked. Although rough and broken, it has a peculiar quality that produces remarkably fine fruit. This is the country which sent out the big red apples to win the world's prize and make Arkansas famous at the Columbian Exposition.

This same quality of soil produces as noticeable a development of bulbous plants. Except Hyacinths and Crocuses, which, while they do not really run out, do only fairly well, other spring bulbs multiply so rapidly and grow so large as to suggest competition with Holland. Tulips, particularly the later sorts, increase wonderfully, and the bulbs are large and plump. But, above all, this is a paradise for *Narcissus*. Six undersized bulbs of one of the varieties of the *Incomparabilis*

section were planted nine years ago, and lifted last fall, when their increase nearly filled a half-bushel. More than that, many of the bulbs were larger and heavier than any imported ones I ever saw. Impressed by the fine appearance of Ozark-grown bulbs, I have for several years tried various members of the *Narcissus* family for forcing, and can say positively that they are all excellent for this purpose. I have tried the *Polyanthus* varieties only slightly, but they promise well also, and seem to show no sign of tenderness.

Summer bulbs also do exceedingly well in this same region. *Gladioli* and *Tigridias* produce bulbs, or corms, of prodigious size, and whereas eastern growers complain that their largest bulbs of *Gladiolus* do not give as fine flowers as those of smaller size, the larger our bulbs grow the longer are the flower-spikes and the larger the individual flowers. It would seem that a *Gladiolus* or *Narcissus* farm might prove a paying venture here.

Lora S. La Mance.

The Forest.

Forest Protection.—I.

The fourth volume of Dr. Schlich's *Manual of Forestry* deals with the very wide subject of Forest Protection. It is a translation and an adaptation of *Der Forstschutz*, by Dr. Richard Hess, Professor of Forestry in the University of Giessen, by Mr. W. R. Fisher, of the English Forest School at Cooper's Hill. Mr. Fisher has improved upon Dr. Hess, not only by a very important addition from his Indian knowledge of forest subjects, notably with respect to forest fires, but also by drawing from the resources of French literature on the subjects of torrents and dunes, and by adding the results of the more modern research on the constitution of woody plants from the works of Robert Hartig. The result is a thoroughly practical book, peculiarly distinguished by the range of experience made tributary to its pages. It has the further conspicuous merit that the translation does not continually suggest the German phrase behind it, but, on the contrary, is uniformly simple and direct. This use of English construction is especially gratifying because of the striking contrast it offers with other recent translations from German works, in some of which the English is so involved and distorted by the retention of the German structure of the original as to be almost unreadable.

"Forest Protection," so runs the definition, "has for its object the security of forests against unfavorable external influences, as far as lies within the power of their owners," consequently the whole subject of forest law is outside the range of the present treatise. Within the boundary thus defined the attempt is made to lay the foundations of successful forest protection through a knowledge of the phenomena and causes of all possible damage, of all preventive and remedial measures, and of how to apply them. More than in any other similar book with which I am acquainted, the attempt has been made to facilitate original and independent study and decision by furnishing a sufficiently wide basis of acquaintance with the causes of injury.

Following upon the definition of Forest Protection and the description of its position in forestry there is a very brief and interesting notice on the historical development of Forest Protection, which traces it back to the religious care of sacred trees in groves. Later on forests were protected chiefly as the resting-place for wild game. A curious illustration of this point of view is contained in John Manwood's black-letter *Treatise and Discourse of the Lawes of the Forrest*, published in London in 1798, which is, I believe, the earliest English book on the subject. On page 15, which lies before me, he says :

And hereupon the Latinests haue framed this latin word, Foresta, for a Forrest, being compounded of those two words, fera, and Statio, so that Foresta est ferarum Statio, which is, that a Forrest is a safe abyding place for wild beasts. And euen according to the same manner, imitating the Latinests, we haue framed this English word, a Forrest, being compounded of these two words, For, and Rest: And because a Forrest is a safe abyding and priuiledged place for

the king's wild beasts for rest, which two words (For and Rest) being put together and made one word, is Forrest, or a Forrest, taking his name of the nature of the place, which is privileged by the king for his wild beasts, to have their safe abiding in for rest.

It should be added that a more recent philology derives the word "forest" from the Latin "fores," meaning "out-of-doors." But, although we have discarded Manwood's definition, both of the word and the thing it denotes, the traces of the view he represents still remain in the Scotch "deer forests," which often do not contain a single tree. Nor will it be apt to disappear even in this country while great game preserves, such as the Yellowstone National Park, continue to be of like conspicuous public service.

The question of boundaries, with which the book proceeds, is of comparatively little interest to us, because forest boundaries, such as are here in question, do not exist in the United States; but the second chapter, which deals with protection against avoidable damage in the use of the forest, is of direct value. The sections on bad felling and careless conversion are full of excellent practical advice, and, with a few additions and subtractions, would be models for use in this country. Among others less applicable the author recommends the following precautions, which are not only germane, but are deserving of widespread use in this country:

Measures for the prevention of mischief are: (1) Employment of competent and trustworthy woodcutters, and careful supervision of their work. It is generally advisable to employ the same men year after year, and to withdraw from the gang all those who fell badly, and encourage the best men by instruction and higher wages. (2) Throwing trees on to bare spots and not among young growth. (3) Careful felling of coppice with sharp instruments and with a clean and sloping cut. (4) Avoidance of throwing felled trees on to rocks, stones or other stems; felling uphill or sidewise, so that there may be a minimum of breakage.

Forest pasture is another practical matter intimately connected with the needs of forestry in the United States. Speaking of the damage done by goats the author says:

To take some out of the many instances of the destruction of forests by goats: In the Tyrol and southern Switzerland, and in the Himalayas, fine forests have been completely destroyed by them, and in Ajmere and Merwara, whose hillsides, where vegetation once flourished, have been laid almost bare, with nothing left but deformed, thornshrubs. In France, since 1665, goats have been excluded from all forests managed by the State Forest Department, and no legal right can be enforced to graze goats in private forests, as the grazing of these animals is considered incompatible with the maintenance of the underwood.

It is true that conspicuous damage on a large scale has, so far, been done in the United States only by sheep, and that notably on the Pacific slope. Similar damage, longer continued, and, therefore, with far worse consequences, has taken place in the Alps of southern France. To this the writer does not refer, but the extent to which the summer pasturage of sheep was carried there may be gauged by the fact that flocks of fifteen to twenty thousand head were frequently driven into the mountains from the lowlands. Monsieur Boppe, the present Director of the French Forest School, mentioned in a lecture which I had the pleasure of hearing that one flock, which he had himself seen, occupied seventeen hours in passing over a bridge thirteen feet wide.

The third chapter, on Forest Offences, has only a potential interest here, and the same is true of the chapter on Forest Servitudes. It will be an enormous advantage when Government forest management comes to be introduced, that rights of user cannot accrue on the public lands of the United States. In India, on the contrary, nearly all of the Government forests were at one time burdened with these rights. At present they have been settled (which does not at all mean extinguished, but only limited and defined) on about 80,000 square miles of Government forest-land, while 50,000 more are still under settlement. With an annual budget of about eighteen million rupees, Mr. Ribbentrop,

the present Director General of Forests to the Government of India, estimates that the cost of prescriptive rights to the Forest Department is at least equal to that of its whole establishment. Yet, in spite of this fact, the forests yield an increasing net annual revenue, which now amounts to nearly three million dollars.

New York.

Gifford Pinchot.

Exhibitions.

Eleventh Annual Exhibition of the Architectural League of New York.—I.

POSTERS and book-covers, jugs, curtain-poles, hat-racks and burnt wood table-tops are not things of the highest intrinsic importance, and they have but the slightest connection with architectural art; yet, in this architectural exhibition, scores of things of these and similar kinds, and of designs for such things, have good places on the well-lighted walls of the galleries, while a series of very interesting park and garden designs, including some of the most important of Mr. Olmsted's recent works, are consigned to the walls of the entrance corridor, where they cannot be seen at all until the approach of evening commands artificial illumination. Moreover, while all the hat-racks and the poker-work and the American designs for Chinese rugs are carefully paraded in the catalogue, it makes no mention whatever of these valuable designs in the corridor. The Architectural League's Hanging Committee and Catalogue Committee seem to have united to declare what has often been said by outsiders—that almost every one in America knows the value of landscape and garden art better than the architects, who ought to be the foremost celebrators of its importance. Certainly the League cannot complain if the practitioners of this art refuse to contribute again to its exhibitions.

The most interesting thing in the whole exhibition, to the general public, and the most instructive, were it properly displayed, would be Mr. Olmsted's scheme for the permanent disposition of the quondam Fair Grounds at Jackson Park, in Chicago. It is a masterly piece of work in conception and in execution. The good sense, the imaginative force and the artistic skill shown in remodeling the features of land and water and the architectural elements bequeathed by the Fair, and forming them into a coherent, varied and beautiful lake-side pleasure-ground, are as great as those that were shown by the original transformation of a desert swamp into a sumptuous place of palaces. This design will soon be reproduced in the pages of GARDEN AND FOREST.

Among the other designs by Mr. Olmsted and his associates which have been relegated to the corridor's outer darkness are those for the grounds of Biltmore, Mr. Vanderbilt's place in North Carolina; for Auldwood, Mr. Hoagland's place at Seabright, on the sandy New Jersey coast; for Bleak House, Mr. Winans' place on the rocky shores of Newport; for Mr. D. Willis James' inland place in New Jersey; for the grounds surrounding the mansion which Mr. Hunt built for Mr. Ogden Goellet in the heart of Newport; for the grounds of Washington University, at St. Louis; for Seneca Park, in Rochester, and for South Park, in Buffalo. These form a remarkable series of varied works, showing many types of garden and park design from the almost strictly formal treatment appropriate on a small Newport place, where the house is an adaptation of a stately French château, to the markedly naturalistic treatment befitting a site like that of the Rochester Park, where water plays almost as prominent a part as land in the general effect. Had they been displayed as they should have been, conspicuously, in some position of especial honor, the League would have shown that it understood the meaning of art in the noble sense of the word, and realized the intimate relationship between gardening art and architectural art, and the public would have been interested and instructed as we cannot hope will now prove to be the case.

When the architectural designs in the galleries are studied the action of the two committees seems all the more inexplicable; for they reveal among our architects a growing sense of the need for gardening art in connection with all buildings which do not stand upon crowded city streets. Chief in importance, perhaps, is the elaborate design of Messrs. Carrère and Hastings for a large country house set at the end of a long narrow, rocky point projecting into Long Island Sound, and approached through a natural forest with which it has been united by formal gardening arrangements, conceived on a larger scale than has often been seen in this western world. This scheme, I hope, may soon be reproduced in these

pages; and likewise an interesting suggestion of Messrs. Bell & Langton's for the rearrangement of Madison Square in this city.

Many pictures of country houses, whether good or bad in themselves, gain interest by the incorporation of their environment in the architect's design. I do not mean that this environment is always better imagined than the house itself, or even as well imagined; merely that any proof that our architects are coming to realize the interdependence of the two arts is very welcome. One common fault is still the undue prominence of stretches of gravel in the vicinity of the main front of a house. Of course, it is often involved in the mistake of incorporating the carriage-entrance with this front. But there are instances where the carriage-drive runs to an entrance in another side of the house, yet, nevertheless, a gravel path cuts off the main façade from the lawn, not only offending the eye by its own barren line, but preventing any proper system of planting about the house to connect it integrally with the soil and give it an air of harmony, unity and repose. Summer days are few in our climate when a lawn is unfit to tread upon; and, to preserve its beauty and that of the house itself, other entrances than the one which should lead immediately to the grass might well be used upon these days. Messrs. Rossiter & Wright have grasped this idea in several excellent designs. A striking instance of too much gravel, necessitated in part by a faulty placing of entrances, is Messrs. Parfitt Brothers' "Three Houses at Hill Crest," No. 112. In their "House at Cedarhurst," No. 127, Messrs. Romeyn & Storer have drawn no gravel line between the main front and its lawn; but they have based the semicircular porch upon a wide rectangular stretch of flagstones, not even raised to form a terrace, which makes an ugly blot upon the lawn, and has not as much excuse in the way of possible convenience as a path.

No carriage drive reaches the door in the long façade of Messrs. Renwick, Aspinwall & Owen's "House at Baltimore," No. 148; but the straight path which approaches it, between two stretches of grass surrounded by low hedges, is absurdly broad—almost one-third the width of the façade. Apparently to relieve the barren effect thus produced, the centre of this path has been filled with a group of flower-beds, which, of course, as they are evidently out of place, merely add to its ugliness, and also interfere with the convenience of pedestrians. Equally bad, in another way, is Mr. A. P. Valentine, Jr.'s, "Plan of a House and Home Grounds," No. 179, where there is no grass at all, but a meaningless arrangement of multiplied straight-lined paths intersecting monotonous shrubberies; and still worse is Messrs. Jardine, Kent & Jardine's "First Study for a Country House near New York," No. 226. Here the large house stands upon a high terrace, and below this the foreground is filled with wide, contorted paths and large flower-beds of graceless and inharmonious shapes, encircling an oval basin of water which is not brought into any relation with the architectural lines beyond it. More ambitious and more interesting is Messrs. Snelling & Potter's "Sketch for a House at Tuxedo," where the disposition of the paths and drives is both sensible and pleasingly symmetrical.

In pleasing contrast with garden arrangements appropriate to our climate is the entrance path to a cottage at Burlingame, California, shown in a water-color drawing by Mr. A. Page Brown, No. 330. Among the distinctively rural structures which seem particularly good I may note Messrs. Wainright & Munoz's "Golf Club House at Seabright," No. 76, and Mr. Atterbury's "Model for a House on an Adirondack Lake," No. 373. This is an interesting example of a large house kept low, as is appropriate in the indicated situation, and built of stone and unhewn logs. It may be thought, however, that in the Adirondack woods a shingled roof would have more of the virtue of fitness than the tiled roof which the house now bears.

Several well-designed tombstones of a simple kind prove that we are gradually learning that it is not only large and costly memorials to our dead which demand an artist's care. Among them are Mr. Robert Brown's "Memorial Cross," No. 175, and the "John Hancock Memorial," No. 167, by Mr. Schweinfurth, the designer of the excellent simple tombstones, a series of which were published in GARDEN AND FOREST, vol. ii., p. 198. Very beautiful in a more elaborate way is the late Mr. Hunt's design for the Belmont tomb at Newport.

A dignified and wholly appropriate design is Messrs. Cady, Berg & See's "Memorial Gateway for Yale University," No. 339, with simple brick piers and delicate elaborate wrought-iron work. In a series of beautifully executed water-color drawings, Messrs. Howard & Cauldwell suggest a number of gateways for the new parks in the northern part of New York city. Their conceptions are excellent, in so far as the modest size and open, unobstructive air which should characterize the entrances to naturalistic parks are concerned. But the partic-

ular architectural style chosen for their piers and pillars seems less well imagined. Something more simply classical would be more pleasing to a cultivated taste and more in keeping with the general character which American architecture bids fair to develop, than these rather heavy, baroque, seventeenth-century motives. And a singular carelessness of the requirements of scale is seen in the same artists' "Birds'-eye Perspective of Proposed Park and Approach to Grant's Tomb," No. 181. It is a good idea that Morningside Park and the Riverside Drive should be connected at this point, and that in this way a dignified vista should lead the eye toward the tomb when approached from the east. The idea is well carried out by making a wide, straight avenue form each end of the approach, while halfway between the two parks it broadens out into an open space covering the area of four city blocks. But this area is designed by Messrs. Howard & Cauldwell in a way that would be appropriate to a small courtyard. The features they have selected are so few and of such a character that only after long study does the observer realize how wide the included area really is. Quite a different scheme, and one of many more parts, would be needed to give the space of four city blocks a suitable effect. And, by the way, our general ignorance in regard even to the nomenclature of gardening art is shown by the fact that this bald and strictly formal arrangement is called a "park."

In conclusion, it may be said that, while the drawings in this exhibition show a commendable growth in the desire to utilize the resources of gardening art, they prove that our architects have still a great deal to learn, not merely with respect to its right management, but also with respect to its ideals and the difference between its various branches. They prove how very wise it was, even in such a case as that of the Golet place at Newport, where only strictly formal gardening elements were desirable, to combine the work of a landscape-architect like Mr. Olmsted with that of an architect like Mr. Hunt.

New York City.

M. G. Van Rensselaer.

American Carnation Society.

THE fifth annual convention of this progressive society brought together from various states the largest and most enthusiastic gathering of specialists in Carnation-culture which has ever met in this city. The Carnation has reached a leading place among commercial flowers, and there are, of course, novelties enough every season to tempt the most conservative grower who expects to keep his hold on the best market. Every year he sees fine profits made by some enterprising growers of kinds which take the popular fancy while the old kinds are scarcely paying the coal bills. Little wonder, then, if the Carnation exhibition which was held at the Grand Central Palace, in connection with the annual meeting, had very much the air of a speculative exchange, only the beautiful flowers softened what otherwise would have been its hard business aspect. There were many thousand flowers on the tables, but, as is usual in trade exhibitions, in not a great number of varieties. All the favorite varieties were shown in great profusion, and generally in the finest possible condition, except, possibly, the favorite Daybreak, which, curiously enough, while most plentiful, was in no single instance up to its best condition. Of previous introductions Bridesmaid took the honors for best pink; Storm King was the best white shown, and Meteor, Helen Keller and Bouton d'Or were the best of their respective colors, and all well shown. The most striking novelty for 1896 was Della Fox, a seedling from Myers & Santman, Chestnut Hill, Pennsylvania. This is said to be a cross between Grace Wilder and Daybreak, and is a most captivating shade of pink of the Daybreak quality, but much darker than that popular kind. In size, form, habit, etc., Della Fox apparently left nothing to be desired.

The exhibit of Mr. Hill, of Richmond, Indiana, was the centre of interest, as it comprised mostly novelties finely grown and most beautifully shown in masses tastefully set up in large vases. Mr. Hill's Jubilee has been seen here before, and it is likely to take the lead among the dark scarlet flowers. Abundance (1896) is a deep pink with rather short stems, and likely to be valuable for its freedom, especially when grown outside. Triumph, which is a purer pink, is thought to be very promising and of a high class. Armazindy is a scarlet flake of the largest size, hardly as refined as Helen Keller. Mr. Hill received a certificate for Flora Hill, a grand white, which has been grown three years, but is not ready for the market. The judges also gave a certificate and ninety-two points for Mrs. McBirney, a fine flower of the Daybreak order. Mr. J. N. May, being a judge, had nothing in competition, but made a most tasteful and attractive display of Mrs. Pierpont Morgan Roses, flanked by handsome Carnations, of which Maud Dean, when

offered, is sure to meet with favor as a fancy distinct variety of the first class, it being a dainty pink with depth of darker color at base of the petals. For a darker pink none seems to us more pleasing than Mr. May's Lena Saling, inclining, as it does, to the salmon. It is of great diameter, but not very deep. Peter Fisher, of Ellis, Massachusetts, exhibited the greatest variety of seedlings, and received honorable mention for Edith Foster, a promising white.

In spite of the numerous varieties of the Carnation, many of which to the layman seem much alike, there is room for others, for, after all, there are very few which, like William Scott and Daybreak, will grow in every soil and for every one.

Notes.

Strawberries, from Florida, are selling at the reasonable rate of fifty cents for a quart of well-grown fruit, and more delicate strawberries from near Charleston, protected under glass without any artificial heat, sold on Monday for \$1.00 a box at wholesale. No better oranges are ever offered here than some of the last Jamaicas, now being sold at fifty to seventy-five cents a dozen. The last of the Jamaica grape-fruits will soon be followed by the earliest of this fruit from California.

The Smooth Brome Grass, *Bromus inermis*, of south-eastern Europe, is commended in a recent bulletin of the South Dakota Experiment Station as a valuable grass in that state, both for permanent pastures and for meadows. Other grasses at their best may give a better quality of hay, but none has been tried there which yields as good a return one year with another. All kinds of stock eat this Brome Grass readily, and an aftermath springs up immediately after it is cut, so that it makes good grazing for fall and early winter. It is hardy against cold and has great drought-resisting powers and is one of the very earliest grasses to start in the spring.

Four species of Eucalyptus in New South Wales are called Ironbark, the best of which is the so-called White or Gray Ironbark, *E. paniculata*. This wood is very heavy and hard; its most characteristic property, however, is a certain gumminess; when planed it shows more or less parallel lines of close fibre which resemble horn, and between these in the parts where the grain is more open are shallow pits filled with a resinous substance. The best Gray Ironbark is very pale, and can hardly be excelled by any wood for its combined strength and durability. Railway ties made of this wood, which have borne the heaviest traffic of the main line near Sydney for twenty-five years, are said to be as sound as they were when they were laid.

No insects are more dreaded by the general farmer than wire-worms, and we are glad that Mr. M. V. Slingerland has republished the essential parts of a bulletin, now out of print, which gave a detailed account of three years of experiments with these pests. A few recent observations are embodied in this new bulletin, so that the information is brought up to date. The practical summary of the whole is that there is no reliable way of protecting seed by poison or of destroying immature wire-worms in the soil. But the life-history of these worms shows that they live for three years at least in the larval state, and when fully grown they change to soft white pupæ in July, and the insect assumes its adult form in August. Singularly enough, the insect remains in the cell until the following April or May—that is, nearly an entire year—and they perish whenever the soil is disturbed so as to break these earthen cells. Of course, this indicates that if infested fields are plowed after the 20th of July, thoroughly pulverized and kept stirred up, many of these cells will be broken and the tender beetles destroyed. Wheat or rye may be sown after this cultivation. Farmers who practice a short rotation of crops and fall plowing will not be troubled seriously with wire-worms.

The windows of the flower shops have a suggestion of the Lenten season in their less rich and profuse dressing with simple blossoms for home use, instead of the more brilliant and gay flowers used for public social functions. The one striking decoration in the up-town Broadway establishments early this week was the large section of a tree, bare and wintry-looking, draped with Florida moss, the rich chrome and greenish gray of bark and moss, enlivened by luxuriant long sprays of *Bougainvillea*, all illuminated by tiny electric lights. This particular window held, with other flowers, a varied collection of choice Orchids, but, as a rule, the kinds of flowers which appeared most abundantly suggested the garden and meadow and woodland rather than the greenhouse and conservatory. Tulips of various colors and narcissus of many forms were

most plentiful and sold for \$1.00 a dozen. Roman hyacinths were among the most popular flowers. Dutch hyacinths showed the effect of the season in the unprofitable price of fifty cents a dozen, and freesias were plentiful at thirty-five cents a dozen. Four or five branches of lilacs, each carrying two panicles, cost \$1.50, and a tight little nosegay of large single California violets the same price. A bunch of forget-me-nots, the winning little flowers peeping from luxuriant stems and foliage, could be had for fifty to seventy-five cents, and a dozen stalks of lily-of-the-valley brought but seventy-five cents.

Mr. B. E. Fernow, in an article in *The Independent*, to show that permanently good roads are an important element in any rational system of forestry, cites the example of the little city of Goslar, in the Harz Mountains, of Germany. This old town owns a forest of 7,500 acres, which the citizens treasure as one of their best investments, because it not only furnishes them outing grounds and good sport in the way of hunting, but with a sure and continuously increasing revenue. Under conservative management the annual cut is 350,000 cubic feet of wood, and the net income from the sale is, in round numbers, \$25,000 a year, or \$3.50 an acre a year, which is a good return from soil unfit for agriculture. Formerly the district was without good roads, but in 1875 the forest manager persuaded the city fathers to appropriate enough money to construct a first-class road system, which was gradually completed. In 1891, \$25,000 had been spent on roads, and 141 miles of these roads were in good order. The manager kept an account of the influence of this improvement on the profits and cost of his forestry operations, and he was able to show that the annual cost of logging had been reduced by \$2,450, the cost of hauling by \$2,520, and the result of the sales due to the fact that much formerly unsalable material could now be disposed of and all could be transported more conveniently was increased by \$3,255, being a net increase of \$8,255, or nearly thirty-three per cent. of the amount invested in road improvements. On one road which was macadamized and maintained for a year at a cost of \$7,440 an instructive comparison was made between the cost of hauling 470,000 cubic feet of wood over the old and over the new roads. On the old road 4,273 loads were required of 110 cubic feet each, and costing \$3.60, or amounting in total to \$15,282.80. On the new road the same quantity was moved in 2,652 loads of 177 cubic feet each, and the cost, at the same price a load, was \$9,547.20, which means that the saving in haulage alone was \$5,735, or seventy-five per cent. of the cost of the road in one year.

Among many sorts of fresh vegetables now in the regular stock of first-class dealers is asparagus from Missouri, which costs forty cents for six long white shoots, while the best from South Carolina costs \$2.75 for a generous-sized bunch, and a dozen long green stalks from hot-houses in Illinois bring \$1.10. Cauliflower is coming from near-by hot-houses, Florida and France, and costs fifteen to fifty cents a head. New peas, from Florida, the pods small, but well filled, cost ninety cents a half-peck, and well-grown string-beans from the south command thirty cents a quart. Okra, from Cuba, costs ten cents a dozen, and egg-plants, from Florida, bring twenty-five to thirty-five cents each. New beets come from Florida and Bermuda, a half-dozen bunched with the tops costing ten cents, and loose ones fifteen cents a quart. Kohl-rabi comes from the same localities, and cost fifteen cents for three. Tomatoes, from Florida, firm and well ripened, bring twenty-five cents a pound, the hot-house product from Pennsylvania costing forty cents. Tender radishes from near-by hot-houses may be had for seven cents a bunch, and rhubarb, grown under glass on Long Island, for ten cents. The supply of celery is partly drawn from Florida. Rochester furnishes some which is better blanched than that from the south and of sweeter flavor, while that from California is entirely white and brings seventy-five cents to \$1.50 for a dozen stalks. New cabbage, from Florida, is not yet plentiful and costs twenty cents a head, that from Germany bringing half this price. Parsley comes mainly from Bermuda at this season. Dandelion, from Boston and near-by hot-houses, costs twenty-five cents a quart; Romaine lettuce, from Bermuda, fifteen cents a head; hot-house lettuce, from Boston, ten to fifteen cents, and larger heads, from Florida, ten to twenty cents each. Heads of chicory, with blanched centres, and the broader-leaved Escarolle cost fifteen cents each, while importations from France, the large heads fresh as though just gathered, command twenty-five cents. Mushrooms bring ninety cents a pound. Hot-house carrots cost five cents a bunch, and those from Bermuda seven to ten cents, and hot-house cucumbers from Boston are a luxury at thirty to thirty-five cents apiece.

Farming on Vacant City Lots.

DURING these times of agricultural depression the profits realized by farmers, even under the best conditions, are meagre enough, and, therefore, when Mayor Pingree, of Detroit, first conceived the idea of utilizing vacant city lots for the growing of potatoes by the unemployed of that city—that is, by men who were generally quite ignorant of the theory and practice of cultivating the soil—the experiment was looked upon as visionary, if not ridiculous. The result of the first year's cultivation, however, which enabled nearly one thousand families to support themselves through the winter by their crops alone, stimulated certain public-spirited citizens of New York to make a similar effort here, and the result is published in No. 1 of the periodical *Notes*, published by the New York Association for Improving the Condition of the Poor. Of course, the philanthropic aspect of this experiment is the one of prime importance. The result proves that many persons who own vacant land would prefer to have it cultivated instead of lying idle and unproductive, and that a very limited area will suffice to raise enough vegetables to contribute largely to the support of a family through the winter. It proves, too, that very many of the destitute people in tenement-houses are willing to work and can be made to support themselves with a very little help advanced as a loan. Besides this, the project offers a natural plan for giving to the people who dwell in stifling tenement-houses opportunity to work for themselves in the open air and under healthful conditions. It gives mothers the advantage of taking their children out of the heated houses and giving them a taste of rural life. It enables the superannuated and partially crippled to support themselves. In addition to these advantages, the entire scheme has a substantial business basis, with none of the odious and depressing suggestions of a charity.

Naturally, however, the educational side of this vacant-lot farming will have a special interest to readers of a journal devoted to the art of cultivating the soil. Whatever is the fundamental reason for the widespread discontent with rural life now prevalent, for the general exodus from the country to the town, for deserted farms and the depre-

ciation in the value of land, every one admits that the one thing needed to insure a living profit from the cultivation of the soil is greater skill and higher intelligence applied to agricultural practice. A very striking proof of this is given in another leaflet published by this same association, and entitled *An Inquiry into the Causes of Agricultural Depression in New York State*. An observing agent—a Pennsylvania farmer named J. W. Kjelgaard—was employed to travel through the agricultural districts of New York for the purpose of making inquiries and reporting on the various phases of this problem, and he observed a singular air of prosperity in the farms about Ithaca which he had not met with elsewhere. The reason for this was discovered to be that an agricultural experiment station was in the centre of this fortunate area. This is a significant fact, and Mr. Kjelgaard reported that all farmers agreed that the station was an obvious help to them. He found, too, that a hundred miles from Ithaca one man who had taken a course of agricultural training at Cornell University was carrying the benefit of his knowledge to his neighbors, so that they were plainly profiting by it. Correspondence with the other stations brought out the fact that the stations were all bearing excellent fruit in this direction. Farmers in distant parts of the state not only write to inquire as to the best methods of cultivation of particular crops, and how to ward off the ravages of disease and insects, but they actually come to the station in considerable numbers to see and to learn.

In every city where this vacant-lot farming has been successful the soil has been cultivated in accordance with the teachings of science. The original ignorance on the part of some of these tenement-house farmers as to the simplest principles of plant structure and plant growth was almost pathetic, but pains were taken to show them how land should be broken up, how the fertilizer should be used, how the seed should be sown, and how the plants should be set, with the reasons for these operations. Every process from the very beginning to the end was carefully supervised, so that this vacant-lot farming, apart from its direct pecuniary profit, had a much more important function as a school of agriculture. It not only furnished healthful and profitable work for a great many people, but it gave these same unskilled people an opportunity to use their minds; it encouraged thought and aroused sluggish intellectual processes. These people are actually learning a trade, an honorable and profitable trade, and learning it in the best way possible. A man who raises half an acre of potatoes and early vegetables under wise direction need no longer call himself unskilled, and it is his own fault if he is shiftless. It may be added that these tenement-house farmers learn a great many things besides the mere cultivation of land. They learn, for example, how to sell—that is, how to transact business in the most effective way. Of course, potatoes and vegetables sold from a miniature farm at wholesale prices would not pay ordinary wages. But the potatoes, instead of being sold by the barrel, are, in many instances, handed out by the quart and half-peck at the best retail prices. In this way these small farmers learn the value of quality in their products. They find that they can take a bunch of choice radishes, freshly picked from the ground and carefully put up, and sell it for five or six cents when the market rate is only two or three cents. The quality of some of the products of this experiment may be estimated by the fact that the second prize at the late Live Stock Show in this city was awarded to the potato exhibit from these vacant-lot farms.

We cannot but assume that many of these tenement-house farmers who have had the advantage of this year of schooling will discover that there is a happier and wholesomely life for them outside of the congested districts of great cities. It would not be surprising if some of the graduates of these schools, who have learned to make a livelihood by truck-farming, should go into the rural districts and instruct farmers in their own calling. Now, it is the ambition of the country boy to get to the city, while the

inhabitants of even the most crowded city districts have an absolute antipathy for the country. If this system can be made to work in one or two cities, why should it not be made to work in all, and why may we not hope that if this practice is adopted generally and intelligently in different cities that this will prove the beginning in a small way of the return from the city to the country? And if, under capable instruction, agriculture can be made profitable in city lots, and if the good example of experiment stations is visible in better farming all about them, why should not actual instruction in agriculture be made a part of the curriculum of rural common schools? It certainly is not too much to hope that we can have advanced dairy schools in the grazing districts and experimental instruction in fruit culture, or in truck-farming, or in any other branches of agriculture in the locations best adapted to each.

We have only touched upon a few of the points which are suggested by this instructive pamphlet, which is published in this city at 105 East Twenty-second Street, and can be bought for ten cents. No public-spirited man or woman can read it without feeling that a new and promising outlet for philanthropic activity is here presented, while any one interested in the cultivation of the soil will find here subject-matter for reflection and a new and striking proof of the value of intensive farming. The illustrations, from photographs of natural scenes, are a most helpful addition to the text, which, it may be added, is a clear, straightforward and forcible piece of work from a literary point of view.

Rate of Growth of Loblolly Pine.

THE rate of growth of Loblolly Pine, *Pinus Taeda*, may be fairly indicated by the analysis of 47 individual trees, which were selected for the study in the Division of Forestry on various sites within the geographical range of the species. The comparison of the growth of Loblolly Pine on sites of different descriptions also throws some light upon the silvicultural requirements of this species, and suggests forest conditions favorable or unfavorable to its development.

HEIGHT GROWTH.—The height growth of Loblolly Pine is very vigorous. For the first 10 years it reaches a height from 18 to 20 feet, thus producing from 22 to 23 inches annually. The second decade seems to be the period of most rapid height growth, during which period the annual accretion gradually increases and reaches the maximum between the 15th and 20th year, that maximum being somewhat more than 24 inches. With the third decade the annual accretion begins to lessen, though the height growth is still vigorous, and gives an annual increase from 15 to 16 inches. A tree 30 years old is 50 feet high. From the 30th year the decrease in the height accretion becomes more noticeable; for the next 20 years the stem lengthens only by 20 feet, or by an annual increase of only 12 inches. A tree 50 years old will be 70 feet high. From this age the annual height growth decreases considerably, being nine inches for the sixth and seventh decades, and six inches for eighth and ninth decades. Thus a tree at the 90th year of its age reaches a height of 95 feet. At this age the Loblolly Pine actually reaches its full height growth, for the height accretion after 90 years becomes in most situations insignificant, and does not exceed more than from three or four inches annually.

Though such a rate of growth in height may be looked upon as a rapid one, still we learn from the analysis of the individuals taken from sites of better descriptions that the capacity of this species is considerably greater than that shown by the average of all the trees analyzed; for which the forest conditions, to be sure, were far from being favorable ones in all cases. We find among the trees measured one 36 years old with a height of 77 instead of the 56 feet average. The excess of 21 feet is due to the more favorable conditions under which it grew. The tree was taken from a grove of the same age and size, and dense enough

to keep the individuals constantly in a struggle for light, forcing them to lengthen their boles and to lift their crowns above the others. Another tree taken from young growth of Long-leaf Pine mixed with Loblolly Pine reached in 44 years a height of 76 instead of 65 feet. We find also in the tree records two individuals 100 years old, with a total height of 118 instead of the average 98 feet. These instances show that the height growth of Loblolly Pine could be considerably increased by proper care.

DIAMETER GROWTH.—The stage of most rapid diameter growth of Loblolly Pine occurs in the first 10 years, during which it forms a stem of two and a half inches at breast height (bark excluded). The second decade shows a decrease to 2.3 inches, the third to 2.2 inches, the fourth to two inches; a tree 40 years old would, therefore, be about 10 inches in diameter at breast height, including the bark. The diameter accretion continues to decrease with age, being 1.8 inches for the fifth, 1.6 inches for the sixth and 1.5 inches for seventh decade. A tree 80 years old at breast height is 17 inches in diameter, including bark. From the 80th to 100th year the diameter increases with two inches, and the average accretion for the 10th decade becomes less than one inch. The diameter growth of Loblolly Pine, then, follows the same law which was observed for Long-leaf Pine—that is, the diameter accretion invariably decreases with age, while the area accretion remains almost the same. From the table of growth given below it is seen that, with the exception of the first three decades, the areas formed on the cross-sections for each of all the successive decades are almost equal, while the width of the rings changes gradually from two and a half millimeters, which is the width of a ring for the fourth decade, to 1.2 millimeters, which is the width of a ring of the 10th decade. This law has a biological significance. It shows that the mass increment, allotted to each of the stages of growth into which the tree development may be divided, is equally distributed over the years constituting the period. The successive layers being spread over a larger surface area are, therefore, successively thinner. The value of this law will be more appreciated if looked at from a practical forestry point of view. It establishes a definite relation between the area accretion and the number of years required for its formation; it says that the ratio between them is a constant one. This constant factor may be obtained from the analysis of a large number of trees, and once determined, it may be applied in anticipating the average diameter dimensions of a tree at any given age, for then a simple multiplication of the factor and age is required to establish the area, and hence the diameter for that age. The knowledge of the dimensions of a tree at any given age, and hence the knowledge of the future yield and increment of the forest at any given period of its life, is the corner-stone on which forestry economy bases its financial calculations.

MASS ACCRETION.—The rate of volume growth of Loblolly Pine is subjected to the law observed to be true with regard to all other species. It begins comparatively slow, increases gradually with age until it reaches its maximum point, remaining at that point for a few years, then enters into a stage of growth where the volume accretion becomes smaller again. From the table given below it is seen that Loblolly Pine produces for the first 50 years 25 cubic feet and grows with an average annual accretion of half a cubic foot. For the next 25 years it produces as much as for the first 50 years. A tree 70 years old has a volume of 49 cubic feet. From the 70th to the 100th year the volume accretion equals 40 cubic feet, and the total volume of a Loblolly at 100 years is 89 cubic feet. In the table is shown the increase of volume for every 10 years. Examining the last two columns of the table it will be seen that while the current accretion, passing its maximum point in the ninth decade, begins to lessen, the average annual accretion still increases, approaching its maximum between 100 and 110 years. By that time the average annual accretion will become equal to the current accretion; that signifies, as we already know, that here Loblolly Pine reaches

the stage of its maximum growth, and the rotation for maximum production would lie between 100 and 110 years. It may be said, unhesitatingly, that Loblolly Pine is a rapid-growing species. It produces in 100 years wood almost double the amount of that of Long-leaf Pine; it grows well under the conditions in which we find it now; it grows better on sites of better descriptions; it requires a good deal of moisture; it needs plenty of light and is sensitive to light conditions, especially when it is approaching the state of maturity; it does better when mixed with other species than when left to itself.

the limbs of the taller trees, whose perfectly free crowns received all the light necessary to make them thrifty. The dense position of the many trunks of all species constituting the forest checked the winds, preventing the litter, the manure of the forest, from being blown away and the moisture from being rapidly evaporated. The rate of growth of the favorites is remarkable in consequence. Tree No. 216, 101 years old, formed 167 cubic feet in a trunk 111 feet high and 26 inches in diameter at breast height. The second table gives the progressive development of the diameter, height and volume growth of trees No. 26 and No. 297.

Comparing these figures with those given in the table of average rate of growth, it will be seen that Loblolly Pine for the first 50 years, if properly managed, would produce double the amount of wood which it produces under the usual natural conditions. It will be seen that for 65 to 70 years Loblolly Pine could form a trunk of the same dimensions, with the same amount of merchantable timber, as that which it forms now in 100 years. The rotation consequently could be brought down to the 70th year. In other words, by the employment of knowledge and skill, each dollar could have been realized 30 years earlier and could have earned in the 30 years, at three per cent. compound interest, \$1.42, which is lost by the absence of forest management.

Washington, D. C.

A. K. Mlodziansky.

Among the trees analyzed we note a few which found all the requirements of this species necessary for rapid development. Tree No. 216, 101 years old, was taken from a young growth of Long-leaf Pine, with the scattering mature Loblolly Pine. Tree No. 297, 100 years old, was taken from a moderately dense forest of Pinus Tæda, mixed with Cuban Pine, Liriodendron, Magnolia, Laurel Oak, with an undergrowth varying in density, of Red Bay and Andromeda.

Tree No. 26, 92 years old, was taken from an open forest of Loblolly Pines, intermixed with various Oaks and Gums, with a dense undergrowth of the deciduous species named. In all cases there was a sufficient supply of moisture; in all cases the forest was a mixed one, and the different species, due to difference in age and habits, formed a canopy of varying height, a roof of two, three or four stories. Each story had its favorable influence: the first, formed by the undergrowth, protected the ground from the burning sun; the second and the third shaded the trunks and cleared off

Foreign Correspondence.

London Letter.

ADONIS AMURENSIS.—This interesting plant was described and figured in Regel and Herder's *Plantæ Raddeanæ*, and in a Japanese work, entitled *Fuko Juso Shin Dsu*, there is a series of no less than twenty-one colored figures representing distinct varieties and showing that this species must have long held a prominent place among garden-plants in the far east. There are double and single flowered varieties, others yellow or greenish yellow, or orange or bright red. Plants of a yellow-flowered variety are now flowering in the rock-garden at Kew, probably for the first time in Europe. In habit this species resembles Adonis Pyrenaica, but it differs from that species in not having hooked achenes. The flowers on the Kew plant are yellow, over an inch across and not unlike those of the common *A. vernalis*. The leaves are comparatively long-stalked, loose and finely cut, suggesting the leaves of a Carrot. It is possible that some of the bright-colored varieties of *A. Amurensis* have been introduced from Japan into American gardens, but, so far as can be ascertained, they have never been grown in England, and, judging them by the pictures in the Japanese work above named, they are well worth a place in the garden to flower in early spring.

LEUCOJUM CARPATHICUM.—This name was given by Herbert to an exceptionally large-flowered variety of *Leucojum vernum*, the Snowflake which grows wild in the south of England, and is one of the most charming of the early harbingers of spring in the garden. Plants of the former were exhibited this week by Mr. Ware, the Tottenham nurseryman, and were awarded a first-class certificate by the Royal Horticultural Society. The leaves are broader, the scapes taller and the flowers about twice as large as in the type, and as each scape bore two flowers the effect of a tuft of plants in bloom was exceptionally pleasing. The nodding bell-shaped flowers were over an inch in diameter and white, with a conspicuous spot of bright green near the tip of each segment.

GALANTHUS ELWESI, var. F. FELL.—This is an unusually large-flowered variety of the king of Snowdrops, but I have seen plenty quite as large among the millions of this plant that stud the lawns, borders and wild gardens at Kew. It is impossible to speak too highly of a plant which is almost dirt cheap if procured from big dealers, and which can be dibbled into lawns and borders by boys to produce a dis-

play of flowers for a month or more in the dawn of the year.

IRIS STYLOSA.—This beautiful and deliciously fragrant Iris has been flowering freely in the open air at Kew since the middle of December, and is likely to keep on till well into the spring. Planted against the south wall of a greenhouse, with its roots pressing against the bricks, it has formed dense tufts of elegant linear leaves a foot or so high, and rising among or above these are numerous flowers of a lavender-blue, blue-purple or white color, and varying in size from four inches to two inches in diameter. There are some half a dozen named varieties, all beautiful, all very fragrant, and a bunch of them in a vase in a room in mid-winter is in every sense a delight. They last three or four days if cut just as they are unfolding, and they are produced in such abundance that half a dozen plants will keep up a constant supply of cut flowers if the weather be not too severe. Although an old species, this Iris is comparatively little known, probably because it will not thrive away from a south wall. The Kew plants were placed in their present position as an experiment, and it has proved a perfect success. The species is wild in Algeria, and I believe it is grown by the Scilly nurserymen. I see it is called *I. unguicularis* by Mr. Baker.

BLUE PRIMROSES.—A purple-blue-flowered sport from the common Primrose, *Primula vulgaris*, has for several years past been in the possession of Mr. G. F. Wilson, of Weybridge, but it has lately passed into the hands of Messrs. J. Veitch & Sons, who now hold a fine stock of it, and by whom a large batch of it was shown at the Royal Horticultural Society's meeting this week. In foliage, vigor and floriferousness the blue-flowered variety does not differ from the type, and it grows freely out-of-doors wherever the common Primrose thrives. The plants shown had been lifted from the open ground and planted in five inch pots, each with a tuft of rich green leaves and from twenty to thirty open flowers. The color varied from a rich purple-blue, nearly true blue, in fact, to deep purple and lavender, a ring of yellow or red occurring at the mouth of the tube in some of the varieties. I learn from Messrs. Veitch that about twenty per cent. come blue from seed. A sentimental objection was raised to a blue Primrose because it was said a Primrose should be yellow, but I am of opinion that these blue Primroses will become popular for the garden in spring.

CYRTANTHUS PARVIFLORUS.—This species was described by Mr. Baker in 1891 from specimens flowered in England and others collected in the Transvaal. A beautiful example of it was shown at the Drill Hall this week by Mr. Woodall, of Scarborough, who grows it in a cool greenhouse, where it is as floriferous and free as *Cyrtanthus Mackenii*. The genus may be divided for horticultural purposes into two groups, namely, one represented by *C. Mackenii*, *C. lutescens* and *C. parviflorus*, which are as easily managed as *Lachenalias*; the other, represented by *C. rectiflorus* and *C. Macowani*, which are beautiful in flower, but difficult to cultivate. The addition of *C. parviflorus* to the easily managed lot is a decided gain. It produces leaves and flowers together, the former being bright green, linear and a foot long, the latter in elegant umbels of about a dozen borne on scapes eighteen inches long; each flower is tubular, an inch and a half long and colored bright scarlet. The plant was well worthy of a first-class certificate. I can recommend this for its red flowers, *C. Mackenii* for its white and *C. lutescens* for its yellow flowers, as good useful greenhouse plants.

LACHENALIA NELSONI.—When well grown this is one of the most useful of all spring-flowering bulbous plants for the greenhouse. It was raised by the gentleman after whom it is named about twelve years ago from *Lachenalia aurea* crossed with *L. tricolor*, and it combines the best qualities of both. In the garden of Lord Suffield, Gunton Park, Norwich, it is grown better than usual, a group of plants sent by him to the Drill Hall this week exhibiting excellent cultivation. They were in six-inch pots, which were almost hidden by

the drooping foliage, and each pot contained from twenty to thirty scapes a foot high, and each bearing about twenty expanded flowers of a deep glistening yellow color, the few globose buds at the apex of each scape being colored bright red. I told the story of *Lachenalias* and their cultivation in *GARDEN AND FOREST* about a year ago. They are of that class of plants which are apt to be overlooked by cultivators or discarded as weedy and unsatisfactory through initial failure with them. When once understood, however, they are very easily managed and they are worth growing for the supply of cut flowers in early spring.

THE GARDEN CINERARIA.—A few months ago a spirited discussion was carried on in several scientific journals with reference to the origin of the popular greenhouse *Cinerarias*, some authorities holding that they are the product of several species crossed in the early part of the present century, while others held that, although there was no evidence of a hybrid origin in the plants themselves, there was plenty to show their close relationship with the annual *C. cruenta* of the Canaries. To test the two theories, *C. cruenta* was crossed at Kew with the garden *Cinerarias*, a similar cross being made by Messrs. Veitch. The plants obtained are now in flower at Kew and in the Chelsea nursery, and some of the latter were exhibited this week under the name of *C. Langleyensis*. There is no essential difference between these and the common garden kinds; indeed, beyond being a few inches taller and having flowers a trifle smaller and looser, they do not differ at all. On the other hand, a cross between the garden *Cineraria* and *C. L'Heritierii*, the other hypothetical parent of the garden race, is now in flower at Kew, and this is widely different in habit and flowers. Here we have strong evidence of a negative character in support of the view that *C. cruenta* is the sole parent of the garden *Cineraria*.

New or Little-known Plants.

Nolina recurvata.

A SPECIMEN of this south Mexican Liliaceous plant in Professor Sargent's garden, in Brookline, near Boston, has flowered this winter, this being the first time that this species has flowered in the United States, so far as we have been able to learn. In September, 1861, a plant in the garden of Monsieur Beaucarne, at Eename, in Belgium, produced a panicle of staminate flowers. This is the only other case we find recorded of this species flowering in cultivation, although, as it was introduced into Europe in 1845 by Van der Maelen, of Brussels, and widely disseminated in gardens many years ago, its flowering in those of southern France or Italy may not be an uncommon occurrence, especially as an allied species, *Nolina longifolia*, frequently blooms on the Riviera.

Nolina is a genus of about a dozen species distributed from the south Atlantic states and Texas to southern Mexico and Lower California, distinguished by its arborescent or abbreviated caudex, elongated unarmed leaves, and polygamo-dioecious flowers produced in loosely racemose or compound panicles with lanceolate bracts and bractlets. The flowers are small, greenish white and articulated on slender pedicels in one to four flowered clusters; the perigone is campanulate and composed of six nearly equal spreading oblong-ovate segments; the stamens, which are usually described as shorter than the segments of the perigone, are in *Nolina recurvata* nearly twice as long; they are inserted on the base of the segments, and composed of tapering filaments and ovate or oblong versatile anthers attached on the back, and in the pistillate flower reduced to anatherous staminodia; the ovary, which in the staminate flower is abortive or wanting, is sessile, three-celled, with three nearly sessile or short-stalked stigmas and two ovules ascending from the bottom of each cell. The fruit is thin and dry, usually three-winged, indehiscent, although

sometimes bursting irregularly at maturity, one to two celled, with an obovoid or globose seed in each cell.

Of the dozen species of *Nolina* which have been described by botanists at least nine inhabit the territory of the United States, including the type of the genus, *Nolina Georgiana*. Of the United States species nearly all are stemless or form short thick stems rarely more than three or four feet high, but *Nolina Bigelovii*, of the mountains of

the life histories, specific characters and distribution of *Nolinas* remarkably little is yet known, considering the length of time some of the species have been cultivated and their value as decorative plants.

The flowering plant of *Nolina recurvata*, whose portrait appears on this page, is one of a pair imported from Belgium nearly twenty years ago. It is four feet ten inches in height from the surface of the soil to the base of the crown of leaves. The stem is two inches in diameter at the apex and twenty inches across the bottom of the bulb-like base, and is covered with pale rugose bark. The leaves are lanceolate, gradually narrowed from the broad clasping base, thin but very tough, nearly three feet long, three-quarters of an inch wide near the middle, where they are broadest, dark green and lustrous except at the apex, which is brown and scarious, conspicuously veined, and roughened on the pale margins with minute serratures, closely imbricated, and pendulous. Early in December the pale yellow glabrous panicle appeared, and was fully grown at the end of six weeks, when it was four feet high, with a stout peduncle furnished with leaf-like bracts nearly two feet long, and slender branches slightly angled above, flattened below, twelve or fourteen inches long, and produced from the axils of leaf-like bracts, clasping, white, and more or less tinged with pink at the base, and six or seven inches long; the secondary branches, which are inserted at acute angles, are slender, six inches long at the base of the branch, and not more than two inches in length at the apex; on these the flowers, which are all staminate and fall a day after they open, are remotely scattered, usually in one, or, occasionally, in two or three flowered clusters, and are borne on slender pedicels about an eighth of an inch long from the axils of scarious white bractlets from an eighth to a quarter of an inch in length. The flower when fully expanded is a quarter of an inch across, and slightly and pleasantly fragrant, with white boat-shaped, nearly equal, segments, which are rounded at the apex and not more than half as long as the stamens; these spread outward and are composed of flat white filaments, narrowed upward from a broad base and crowned with oblong, cordate, slightly emarginate, light yellow anthers. The ovary is reduced to a cushion-like three-lobed body covered with nectar.

*Nolina recurvata** requires the same treatment as the Agaves, and can be wintered in a dry house in which the temperature is not allowed to fall much below forty degrees, Fahrenheit. It is an excellent plant for the summer decoration of terraces and other exposed situations, as its tough leaves are not torn by wind or burnt by the sun. Like the Yuccas, Agaves and other so-called succulent plants, it will, of course, flourish in southern California in the open ground.

Plant Notes.

BOWIEA VOLUBILIS.—This interesting plant, discovered in 1866 in south Africa by J. Bowie, a botanical collector for the Royal Gardens, Kew, London, and named in his honor, belongs to the Lily family. As its specific name indicates, it is a twining plant and admirably adapted for the pillars or supports of a greenhouse, and it has a bulb not unlike a

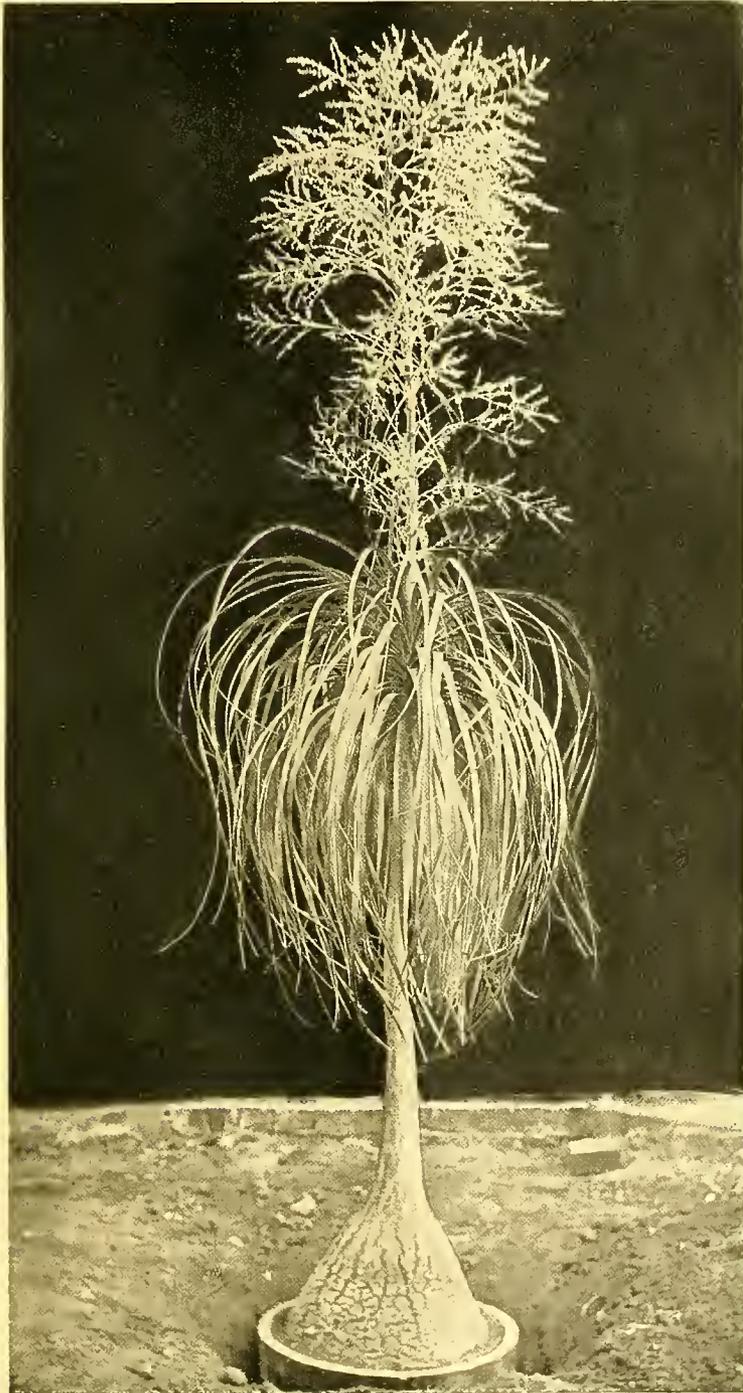

Fig. 10.—*Nolina recurvata*.—See page 94.

San Diego County, California, often produces a taller trunk, and may, perhaps, properly be considered a tree; and in Lower California *Nolinas* grow to a still larger size with stout trunks and broad heads of foliage. All the *Nolinas*, with, perhaps, the exception of *Nolina Georgiana*, are desirable ornamental plants, especially for dry warm regions, although many of the species flourish when cultivated in pots and protected from cold in glass houses. Pincinetia tuberculata, *Hort.*

large Globe onion. It apparently does not produce leaves, but, instead, green, abortive-panicled inflorescences. The way these abortive panicles branch from the main stem is remarkable, the axils being below the branches instead of above, which gives the plant the appearance of growing upside down. The branching also is very irregular. A few inconspicuous flowers are produced at the extreme upper end of the stem; these are small, green, with white stamens; they produce seed, however, by which the plant is propagated. A specimen is now flowering in the Botanic Gardens of Smith College, and Mr. Canning writes that it does best in a light rich soil, like all bulbous plants requiring a season of absolute rest. At the first signs of growth the bulb is turned out of the pot, all the old soil shaken off. After being repotted it makes all its growth in about three weeks. It then commences to flower and lasts in flower about three months. As soon as the flowering period is over the plant begins to show signs of maturity, when water should gradually be withheld. A temperature of fifty-five suits it well.

MAGNOLIA KOBUS.—Of the Japanese Magnolias which become large trees, perhaps the best for cultivation in our north-eastern states is *M. hypoleuca*, which is still a rare tree, although it was introduced into this country more than thirty years ago by Mr. Thomas Hogg. This is one of the species whose flowers appear after the leaves are spread, and in form and habit it is somewhat akin to our native *M. tripetala*. There is no doubt, however, that *M. Kobus*, which also grows to a height of eighty feet in Japan, will in time become one of the most striking ornaments of our parks and pleasure-grounds. We have just been observing a specimen some twelve years old, and after the severe weather the smooth reddish bark of the branchlets looks fresh and healthy and every bud is plump. There is no doubt of the hardiness of the tree even in New England, and it grows with as much rapidity and vigor as any other species. It belongs to the section in which the flowers appear before the leaves, being classed in this respect with the well-known Chinese Yulan Magnolia and its various hybrids and varieties. Its blossoms are pure white and fragrant, and when fully expanded as much as five inches across. Although this species was also among Mr. Hogg's introduction, the tree is comparatively rare in American gardens, and as it does not seem to flower freely when young few persons have ever seen it in bloom. If, however, it flowers as abundantly here as it does at home when it arrives at full age it will present a magnificent spectacle in early spring. The Magnolias, both native and Asiatic, are celebrated, as a class, for their handsome flowers and large, beautiful leaves, and our climate is especially suited for their cultivation. *M. Kobus*, so far, seems as thrifty here as in its native forests. It has been developed, however, in a climate where moisture never fails, and long experience alone can prove whether its constitution can endure the strain of a series of summer droughts such as sometimes occurs in this country.

Cultural Department.

Indoor Ferneries.

WARDIAN cases may afford ideal facilities for indoor Fern-culture, nevertheless their size and expense are formidable drawbacks to many devotees of the Ferns. One authority claims to have an improvement on Mr. Ward's invention which secures better ventilation by sliding panels, but the principles are much the same in all cases—namely, an atmosphere free from soot, too much light, heat, moisture and change. Another essential is good drainage; much pleasure and profit, however, may be developed with a bell-glass and soup-plate.

Three such glasses stand in a north window of my house; a ten-inch chestnut shelf, partially supported by light iron brackets, having been inserted in place of the regular sill for this purpose. The largest shade, a ten-inch glass, rests upon the rim of a plate well on in its second century, which, apart from its æsthetic value, has the intrinsic merit of possessing a

broader rim than modern ware, thus affording desirable space between the glass and the plants within. Broken crocks and porous matter from coal-sittings fill the bowl of the plate and make excellent drainage; leaf-mold or soil taken from the native haunts of the Ferns is placed over this in the shape of a mound. I am often asked how I keep the Ferns and Mosses in place, and my reply is that hairpins are useful for many purposes, and when the house supply of these falls short deftly concealed toothpicks are passable makeshifts.

Overcrowding is to be avoided; only three varieties are growing under the glass referred to. Of these *Asplenium ebeneum* is most conspicuous because of the sentinel-like precision of its narrow fertile fronds. It is a Fern of good substance, rich color and gloss; the barren fronds are properly subordinate, spreading themselves in loose rosettes after the manner of its more dainty relative, *A. Trichomanes*. A specimen or two of the Walking-leaf, *Camposorus rhizophyllus*, add variety in shape of frond and shade of color, relieved by gray lichens and red berries of the Wintergreen.

From a branch of a rustic twig firmly inserted in the midst of the pile there hangs a tiny basket, from which emanates a graceful plant, spreading and filling the upper part of the glass and showering pink petals on the mossy carpet below; this plant is none other than the common herb Robert, *Geranium Robertianum*.

The second glass is devoted chiefly to fine specimens of *Camposorus rhizophyllus*, *Polypodium vulgare* and *Asplenium Trichomanes*; unsuspected prothalliums have added an *Aspidium* or two, which, with various mosses and stray wildlings, are all confined by an eight-inch glass. Here the Walking-leaf grows with the wildest luxuriance, nearly every frond rooting at its apex, but, lacking proper environment, the rootlets are held forlornly in the air, or else, as in a case recently observed, they lodge themselves in a cluster of Wintergreen leaves and skeletonize them in a short time, a parasitic performance which I have never seen recorded of any Fern.

A groove inside the scalloped edge of a glass dish just fits a six-inch bell-glass, and is the prettiest receptacle of the three. Saving a frieze of moss and a few berries, *Asplenium Trichomanes*, the English Maidenhair, has entire sway; a dainty and bewitching little plant and historically interesting, as the vaunted hair-restorer of earlier times, Parkinson, the celebrated apothecary of 1640, tells us that "it both stayeth the shedding of the hair and causeth it to grow thicke." Gerard is even more explicit: "The lye wherein it hath been sodden or laid to infuse is good to wash the heads, causing the scurffe to fall off and hair to grow in places that are peld and bare."

Change of air is as necessary to plant-life as to animal-life. The shades should be removed for a few minutes every day, and to insure a constant supply of air and prevent damping off a match or two can be sometimes inserted under the glasses. A gentle shower-bath of tepid water should be given once in ten days, after which the plate may be tipped to allow surplus water to drain off; this is essential, for a water-logged condition is disastrous. In spite of extreme vigilance, with every supply of fresh moss comes an invoice of pests. Worms and snails breed with such rapidity to prey upon tender fronds and the pulp of berries that constant watchfulness must be exercised against these marauders.

The growth and longevity of Wintergreen berries under glass is remarkable. Rooted and fruited specimens, put in late in the fall, not only send up young shoots in March, but hold their fruit in good condition for months. A cluster of nine large berries which had been fourteen months under glass was destroyed by tiny mollusks—dwellers in pointed shells about a quarter of an inch long. After this I observed that a fluted specimen of brown Thallophte was an excellent trap—possibly a breeding-ground—for the glistening shells were easily seen and destroyed on it. The addition of a tuft of exquisite moss brought disaster to a cluster of three perfect berries and broke their record of seventeen months. A novel spectacle was then before my eyes: the gable-end of the residence of a full-grown mollusk was protruding from the biggest berry of all, while at the foot of the plant were two more of its kind. Truly, life under glass furnishes ample food for thoughts not strictly horticultural.

Vermonth.

G. A. Woolson.

Cephalotus follicularis.

WHERE a collection of cool greenhouse insectivorous plants are grown this little species can be successfully cultivated without much extra care. In European collections it is usually seen growing under bell-glasses in the full sun. Conditions such as these do not suit its requirements here when the sun gets powerful, unless continual attention be

given to airing and shading, and even then the atmosphere is apt to become too dry. The *Cephalotus* does not need a high temperature; it ought to be kept in the coolest part of the house, but it certainly delights in an atmosphere heavily laden with moisture. I prefer to grow it, especially in summer, in a roomy glass case, shaded on the sunny side with a piece of light cloth, which in dull weather can be removed altogether. In the case I put about six inches of sphagnum moss and plunge the pots in it; such plants as *Dionæa* and the *Droseras* do splendidly under similar conditions; in fact, it is about the only way in which they can be grown to perfection, so that the glass structure can be made to contain quite an interesting collection.

The *Cephalotus* must have material to grow in which is free from any decomposed matter. A good mixture consists of equal parts of fibrous Orchid peat, pulled apart into quite small pieces; live Sphagnum moss, chopped fine; coarse-grained sand and broken charcoal. Too much care cannot be used when renewing the material about the roots. The best time to perform the operation is about the end of March before the plants start into growth. It is seldom we see a plant too large for a four-inch pot. Drain the pots well, putting a large piece of broken pot over the hole and some smaller pieces over that again; pot as firmly as possible without injuring the roots, keeping the plants well above the rims of the pots; finish off with the growing points of Sphagnum, and water thoroughly. When the plants are put in smaller-sized pots than fours it is a good plan to plunge them in larger ones, using small gravel to fill the space between the pots; this not only helps to keep the roots cool in summer, but is an important aid to the drainage.

The *Cephalotus* belongs to the Saxifrage family, and is not related to any of the other well-known insectivorous plants; most of its leaves are in the form of pitchers, a trifle resembling those of the *Nepenthes*; although small, they are as handsome in appearance as any of the *Nepenthes*. The plant is a native of west Australia.

Botanic Garden, Washington, D. C.

G. W. Oliver.

Fuchsias and Gloxinias.

OLD Fuchsia bushes which have been resting in cool quarters may now be brought into genial warmth and pruned of all dead and surplus growth. As a rule, these plants make the most effective specimens when trained as pyramids. It often happens, however, that varieties of a naturally weeping habit have so crowded the lower branches during the previous season's growth that these are much weakened and do not trim out well into shape. Such plants may be formed into standards by cutting out all the lower branches. They are equally effective in grouping. Repotting should be deferred until there are signs of root-activity and some budded growth is made. Fuchsias are gross feeders, and an abundance of well-decayed manure should be mixed with the soil used for them. The drainage must be free and water be given sparingly until the plants are in active growth. From this time onward their culture is simple. All that is required is to keep the plants in shape by taking out the tips of the strongest shoots and all flower-buds until within a week or two of the time they are required to bloom. Such plants as are not wanted for growing on will come in useful for odd corners, or for use in mixed subtropical beds. Not the least attractive feature in an amateur's garden last summer was a bed wholly composed of Fuchsias, arranged with excellent taste and trimmed with care, until it became a perfect mound of bloom. Some plants of the yellow-leaved variety, *Wave of Life*, were used as an edging.

During the early spring months cuttings of such varieties may be rooted as it is wished to retain, for old plants are not to be relied upon to winter over. These cuttings often make attractive plants during the season, shifted on into six or seven inch pots, and they are a most convenient size for hall, piazza, or table decoration. It is hardly necessary to draw attention to the many beautiful florists' varieties which are mainly hybrids between *Fuchsia triphylla*, *F. fulgens*, *F. corymbiflora*, *F. serratifolia*, *F. macrostema* and others, for, whether species or hybrids, they are all beautiful. Particular attention should be drawn, however, to some of the winter-flowering kinds, natives mostly of South America. *F. corymbiflora* is one of the most beautiful of these. It is a rambling plant when grown naturally, and best suited for a pillar, rafter, or a wall where it can get plenty of sunshine. I do not know of any American gardens where it is grown, but presume it is plentiful enough in European gardens, and could easily be obtained. One sort I know as *F. speciosa* and another as

Lord Beaconsfield, of similar character, are both good winter bloomers, with extremely long, showy red flowers. Then there are some dwarf, small-flowered kinds, almost hardy everywhere in England. It is seldom they are killed outright, however much they are cut above ground. I remember *F. Riccatorie* and *F. gracilis* among these, and believe they are varieties of *F. macrostema*, a native of Chili. *F. gracilis* makes a handsome basket plant.

Tubers of *Gloxinias* are disposed to start with little or no root moisture. Of late years we have rested ours in the pots they bloomed in, and although kept in the coolest quarters we can give them consistent with safety they have made considerable leaf-growth. It seems natural that they should start during the month of February. Enforced rest, such as is given when the tubers are taken out of the pots and stored in sand, has always appeared to me unnatural; even if all the plants live over, which is doubtful, their vitality will be lessened. Since I have kept my plants in pots I have found live roots at all times, even though there was no sign of life above ground, and active roots quickly form with the merest trace of moisture as soon as the sun gains power. Last season I grew along a batch of old tubers without repotting, and with the aid of weak liquid manure, given when the plants were in good growing condition, they increased in size and flowered better than they did the year before. It does not seem to me that success depends as much on the nature of the soil as upon location and careful watering until root-action is well established. Situation is more important than it would appear to be, as all growers of experience will agree. Good light, but not direct sunshine, after March begins, and plenty of fresh air are essential.

Small bulbs from seeds sown last July are beginning to start, and these will grow into good specimens, coming in as a second batch. Seeds sown now will give a good percentage of seedlings for bloom during the autumn months. Seeds should be sown on pans of fine soil previously moistened, and later, as moisture is needed for germination, it should be given on the subirrigation plan—that is, from below.

Wellesley, Mass.

T. D. Hatfield.

Native Cypripediums.—Last November we secured several clumps of *Cypripedium spectabile* and *C. parviflora*. These were potted in a mixture of peat and loam and placed on a temporary shelf under one of the stages in the cool temperate house. About the middle of January they began to show signs of growth. They were then placed in a light position in the same house, where they could also get abundance of air, and kept well supplied with water. They made strong growth, and have now perfected their flowers, which are truly beautiful and greatly admired by the many visitors to these greenhouses. It is the opinion of many that the exotic species of *Cypripedium* cannot compare with these native ones for brilliancy of color and grace of form. Like many other plants, they come to far greater perfection when grown under the protection of a greenhouse than when growing in their native wilds and buffeted by wind and storm. They also last in flower considerably longer. *C. parviflorum* has also a delicate perfume. We hope to try several other native Orchids in the greenhouses another year besides *Cypripediums*, and suggest that the experiment is worth trying elsewhere.

Northampton, Mass.

Edward J. Canning.

Begonia Socotrana.—This plant, which was recently recommended in GARDEN AND FOREST for its ease of multiplication and abundant flowering from October to December, has a greater significance for the plant breeder. It is highly probable that the gulf separating the shrubby and tuberous sections of *Begonias* is to be crossed by this single drawbridge. The shrubby plants have the best leaves and the poorest flowers, while the tuberous *Begonias* have less showy leaves and flowers with great possibilities of development. We ought to have the best flowers with the best foliage and habit. The tuberous *Begonias* flower in the summer and die down yearly, while most of the shrubby forms are perennials, blossoming in the winter, when color is scarce. In *B. Socotrana* the two sections seem to meet on common ground. The bulbs produced above ground unite the plant with the tuberous section. It is a waste of time to try to cross the two sections directly; the shrubby plant should be crossed with *B. Socotrana* and *B. Socotrana* with the tuberous *Begonias*, and these two primary hybrids with each other. The intermediate character of this *Begonia*, developed on an isolated island two hundred miles from Africa, has been insisted upon by Nicholson, in his *Gardeners' Directory*, as the clue for plant breeders to work with.

Bedding Plants at the Botanical Garden, St. Louis, Missouri.

To the Editor of GARDEN AND FOREST :

Sir,—Among the bedding plants used at the St. Louis Botanic Garden last year nothing was prettier than *Lantana Californica*; its dwarf growth, spreading habit and abundant production of soft yellow flowers in corymbs all being desirable characteristics, and as seen here it is always in bloom. To do their best the plants must be two years old. Younger ones will not flower satisfactorily.

Nothing in the garden was more charming than beds of *Plumbago Capensis*. Its lovely shade of blue is unusual in bedding plants at any season, but in late autumn, when the *Plumbago* seems to be in perfection, blues of any shade are extremely rare, and this especial shade combines most happily with the yellow of the *Lantana* mentioned, and the two can be associated in one bed advantageously by using the informal *Plumbago* in the middle, surrounded by the dwarfier and more regularly shaped *Lantana*.

A unique effect was produced by a closely filled bed of *Russelia Juncea*. Its rush-like foliage and bright scarlet Penstemon-like flowers are both pleasing and unusual. As grown out-of-doors here *Clerodendron Balfourii* was a revelation. The plants were crowded with thick masses of peculiarly attractive blossoms. In the St. Louis climate, when cut back hard, it makes a desirable bedder. The pretty, but unassuming, *Thunbergia elata* made a pleasing bed where allowed to creep over the ground and form a close mat. It is always in bloom. *Sedum carneum* was used to replace early-flowering plants, such as Pansies, which can never be depended on to flower through the season in this warm dry atmosphere as late-sown ones are expected to do in Chicago.

A large mass of single scarlet Chinese *Hibiscus* made a fine effect as seen against dark green trees and surrounded by a grass plot of at least four times its own area. Plants about five feet high were used in the middle, and each circle was set with plants of lower growth, the result being a mound of rich, glowing flowers set among their handsome, polished leaves. Tree-shaped plants of *Crape Myrtle* were surrounded by lower ones of *Phyllanthus roseus purpureus*, the foliage of the latter being in nice harmony with the flowers of the *Crape Myrtle*. Just inside the main entrance to the garden two beds of *Euphorbia splendens* flanked the way with good effect. Their gem-like blossoms and writhing, spiny stems seemed appropriately set against the gray limestone lodge at the gateway.

Among foliage plants two comparatively new ones, *Strobilanthes Dyerianus* and *Euphorbia atropurpurea*, were largely used. The first is especially commended by the authorities here for its power to endure strong sunshine without flinching or changing color, while the *Euphorbia* is liked in mixed groups. *Sanchezia nobilis* looked remarkably well, its green leaves, each about twelve inches in length and beautifully veined with deep cream color, being highly decorative. Its endurance of strong sunlight also makes it desirable in this hot, dry climate. The new *Abutilon Souvenir de Bonn*, possesses the same good qualities and retains its distinct variegation throughout the season. Two hardy foliage plants, *Artemisia stellarina* and *Salvia officinalis*, are found useful here, the latter especially holding its variegation perfectly in the hottest weather.

St. Louis, Mo.

Fanny Copley Seavey.

Lettuce under Glass.

To the Editor of GARDEN AND FOREST :

Sir,—We have recently had several days of clear, sunshiny weather, and the Lettuce crop has responded wonderfully to the change. Now that the plants have started into vigorous growth there is little trouble from rot, prices are better, and altogether the outlook is less gloomy.

One mistake every autumn heretofore has been our failure to get the soil composted early enough for the Lettuce crop. When the soil is first put into the houses it seems a little green, and the first and second crops never do as well as the third and fourth. To avoid this condition for next year we stacked our soil and manure early last fall and turned it once or twice before winter set in. It will be handled several times during next summer, and for use next fall we expect to have some soil that will be right for the first crop. Our soil is made of half well-rotted manure and half clay loam from the river bottom. We also use a little nitrate of soda as a top-dressing among the plants.

After the present crop of Lettuce comes off the houses will be planted to Cucumbers and Tomatoes. We find that cucumbers pay us far better than tomatoes, as the price of tomatoes here is not more than half that paid in other markets. At the prices paid to the State Experiment Station in Wooster, tomatoes are more profitable than cucumbers, while with us the past two years tomatoes have not paid more than one-fourth as much as cucumbers.

We plant our Cucumber seeds in pots or in sods, and when the plants are just beginning to fall over and to run they are placed in the benches about four feet apart each way. We are able to get a small crop of Lettuce from between the plants before the room is needed by the Cucumbers. As soon as they begin to blossom we have a hive of bees ready to place in each house, which saves us much time and labor in fertilizing the blossoms. The Cucumber crop from the greenhouses lasts about six weeks, and we continue cutting long after the crop comes in from the cold frames; in fact, as we do not try to grow a crop following the cucumbers we keep the houses very moist and as cool as possible, and have them bearing even up to the time cucumbers come in from the garden. The same method is practiced with Tomatoes, but the main crop is marketed during June. On account of the low prices in this market we shall only grow a few of them this year.

It is impossible to successfully grow both crops in the same house. Cucumbers need a high temperature, plenty of water and a humid atmosphere, while Tomatoes have to be watered sparingly and the air kept dry. We have learned to avoid the error of growing the two together by costly experience. We have tested the Telegraph Cucumber in a moderate way for two years and have so much confidence in it that we shall try to grow it for the midwinter market next season.

Lakewood, Ohio.

F. E. Carr.

The Mexican Plane Tree.

To the Editor of GARDEN AND FOREST :

Sir,—Referring to an article on Plane Trees in No. 415 of your journal, I beg to ask if *Platanus Mexicana* is decidedly preferable (and better in appearance) to *P. orientalis* as a street-tree; if it will grow in the United States, and where it can be obtained; also, if it has certain preferences as to soil or treatment, or peculiarities in the mode of growing?

New York.

B. H.

[*Platanus Mexicana* is more beautiful than *P. orientalis* in the silver-white coloring of the lower surface of the leaves. It is a smaller tree, however, and of less symmetrical habit. It may be expected to grow in the United States only in western Texas and southern California. So far as we know it is not cultivated except in Mexico, and probably seeds could be obtained only by employing some one to collect them from wild trees or from trees planted in such cities as Monterey or Salteo.—Ed.]

Recent Plant Portraits.

IN the February issue of *The Botanical Magazine* *Sternbergia macracantha*, which is described as the finest of all the *Sternbergias*, is figured. From the well-known *Sternbergia lutea* this plant differs in its larger flowers with long perianth tubes and in the fact that the leaves are produced in spring, and not with the flowers in autumn. The figure is from a plant which flowered last year in the Royal Gardens, to which it was sent by Mr. E. G. Whittall, of Smyrna, to whose zeal and activity the lovers of good bulbous plants are so much indebted.

In the same issue *Begonia umbraculifera* is first made known to science. It is the second of the genus in which hermaphrodite flowers have been noticed, and differs from all other *Begonias* in its peculiar habit with its simple, stout, erect stems, four feet in height, furnished with a few remote distichous, reniform, orbicular, peltate, fleshy leaves and bearing long-stalked supra-axillary flower-clusters, their stems concurrent at the base with the internodes above them. The flowers are white, rather small, chiefly male, and crowded into small corymbs with a few female and bisexual flowers.

The other plants figured in this issue of *The Botanical Magazine* are *Scutellaria Formosana*, an erect shrub with small blue flowers; *Hechtia argentea*, a representative of

a genus distinguished from the other genera of Bromeliaceæ by its small white subunisexual flowers, and represented by about ten species, inhabitants of Mexico and the southwestern United States, and *Bifrenaria tyrianthina*, a Brazilian Orchid with rather showy purple flowers.

The Forest.

Forest Protection.*—II.

PROTECTING the forest against game is a matter which may lay claim to our interest simply as a branch of its natural history. We have not yet reached that refinement of forest management which alone makes it important. Nevertheless, the capacity of our native game for destruction is worthy of remark. Of all the game animals of this country the beaver has the greatest power for injuring the forest in proportion to its size. The writer was fortunate enough to visit the small colony of beavers on Mr. Rutherford Stuyvesant's place in New Jersey, and was amazed at the number and size of the trees cut down in a year by a single family of beavers.

Within the deer tribe in America, so far as my information goes, the moose is by far the most destructive, as, indeed, might be inferred from its size and power. "From time to time," says a recent writer in *Forest and Stream*, "we came upon places where the young trees, Moosewood and Maple saplings, had been broken down, generally at a height of seven or eight feet above the ground, and where other trees of the same variety had been stripped of their bark. . . . This was accomplished, not, as writers used to assert, by riding the trees down between the forelegs, but by means of a twist of the powerful neck of the animal. A moose, like other deer, has no upper teeth, and the barking of the trees is accomplished by a long upward sweep of the jaw."

The food of the moose consists very largely of Maples, at least five species of which, of arborescent size, occur within its usual range. It feeds also on the White Birch, on several species of *Viburnum* and Willow and on other deciduous trees and shrubs, and occasionally strips the bark from the Balsam Fir. The enormous strength of the great deer is strikingly illustrated in the following extract from a recent issue of *Shooting and Fishing*: "Turning his head, he (the moose) caught a White Birch as large as my arm between his antlers, and with as much apparent ease as you would bend a willow twig between two fingers, twisted his neck and broke it squarely over. The tree was certainly three inches through."

Among birds, grouse devour buds in great numbers, and blue jays are very destructive to seed. The wild turkey also consumes large quantities of certain seeds, often pulling up young Chestnut seedlings in their first spring to devour the nut out of which they grow. Woodpeckers, on the other hand, are said to deserve protection.

The general breadth of view already referred to as characterizing this work is pleasantly shown in the introduction to the discussion of injurious insects. The statement preliminary to the description of individual harmful species indicates the position of the insects in the animal kingdom, and gives the divisions of the class itself, with their characteristics. A section is devoted to the distribution of insects, and others to their life-history, their numbers and to the useful kinds of forest insects. The latter is especially valuable, from one point of view, since the idea so generally prevails that insects of every sort are to be classed together as injurious.

The following sentences, coupled with the general statement that conifers are far more susceptible to attack than broad-leaved trees, may serve to give a succinct view of the relation of insects and the forest.

The greatest number and the most harmful species of injurious forest insects belong to the orders Coleoptera (beetles)

and Lepidoptera (butterflies and moths). Next in importance to these come the members of the orders Hymenoptera (bees and ants) and Orthoptera (locusts and termites). The orders Diptera (flies) and Hemiptera (bugs) only include species which are moderately or slightly injurious, and the Neuroptera (lace-winged flies, etc.) include no injurious species. . . . In India and other hot countries, the family of termites, or white ants, . . . is probably more destructive to vegetable substance, though chiefly when no longer living, than any other insect family.

Among the Coleoptera, those which are of greatest interest to us are the bark beetles of the genus *Tomicus*, which are extraordinarily destructive to Spruce forests. The singular dying out of the Adirondack Spruce over large areas at the same moment, which was for a long time unexplained, has been found to be due to a bark beetle closely related to the European species here described. That we are not alone in suffering from them appears from the following extract: "Some details may be given of the latest plagues of bark beetles in the Bavarian and Bohemian forests. In the former about 24,700,000 cubic feet of wood was killed in six forest ranges. The beetles were occasionally so numerous as to obscure the sun. Accompanying *Tomicus* typographus were *T. chalcographus*, *Hylastes palliatus*, etc. In the Finisterau range 1,000 woodmen were engaged to fell and bark the trees, and, as local labor was insufficient, Bohemians and Italians were recruited for the work. In the Bohemian forest the damage done was even on a larger scale: between 1872 and 1874, on 9,012 hectares (22,530 acres), 3,632,050 cm. (127,964,000 cubic feet) of wood, or about 450 cubic feet per acre, were felled. Thus, altogether, in Bohemia and Bavaria, 152,600,000 cubic feet of wood was killed by these insects."

Another species, *Hylurgus piniperda*, while it is responsible for far less damage than the species of *Tomicus*, has interest in that it attacks Pines instead of Spruce, and among them our own *Pinus Strobus*, where it has been planted in Europe. Nothing is said of the Elm beetle, which has been proving so extremely destructive to both native and European species of Elms in the northeastern United States. This species is not a native. Among the Lepidoptera, all species destructive on a large scale are moths. One of the most dangerous is the Pine moth, *Gastropacha Pini*, the caterpillar of which feeds upon the needles, and of whose depredations Mr. Fisher says: "In 1878, in Plietnitz, in West Prussia, forty-five millions of caterpillars were destroyed by means of tar rings, at a cost of 7s. per ten thousand caterpillars. In woods under sixty years old the hibernating caterpillars were collected at a cost of 20s. per ten thousand. The value of the annual increment of wood saved was 8s. per acre, as against 7s., the cost of the tar rings."

Another moth whose depredations are yet more dangerous is the Black Arche or Nun moth, whose attacks are chiefly confined to the Spruce. Some idea of the severity of this pest may be gathered from the fact that in East Prussia, between 1853 and 1863, trees containing 467 million cubic feet of wood were killed by the Nun moth. The damage done in the neighboring Russian province was still more serious, so that in Russia and Prussia together about six and one-half billion cubic feet of timber was killed. It is but just to add that a part of this damage was to be attributed to bark beetles, but it is probably true that they would have done little harm except for the weakened condition which followed the attack of the Nun.

The account of dangerous insects concludes with an interesting list, which names, under the head of the kind of tree attacked, the insect enemies of every part of it.

New York.

Gifford Pinchot.

Notes.

A correspondent of *The Rural New Yorker* writes that for giving young trees a strong, healthy growth in the nursery he has found no fertilizer as good as the combination of six hundred pounds of pure steamed bone and a hundred pounds of nitrate of soda applied in the spring, while later in the season

* *A Manual of Forestry*, by Dr. W. Schlich, C.I.E. Vol. iv., Forest Protection, by W. R. Fisher, B.A. London: Bradbury, Agnew & Co.

two hundred pounds of muriate of potash can be added to the acre. For the supply of phosphoric acid ground bone in some form is unexcelled.

Do not be in a hurry when the first warm days come, in March and April, to take the litter from the Strawberry beds. This blanket should not be entirely removed until the growth of the plants actually begins, although it is well to lift it up and loosen it with a fork after the snow has gone, so as to allow the ground to dry out sooner and to give the plants light and air.

At the late meeting of the American Carnation Society in this city, Mr. E. G. Hill declared that he felt assured, from experiments with different varieties, that arsenic will check the dreaded rust on Carnation plants, and in some cases eradicate it. He began by using arsenic at the rate of one pound to forty gallons of water, but, of course, since the arsenic would not dissolve this is not a satisfactory way to apply it. He finally used Fowler's Solution, at the rate of one ounce to eight gallons of water, spraying the plants with it in the usual way.

An inventor in California has perfected a machine for making fruit-cans which can be operated by a child, and which, according to the accounts, is very effective. Sheets of tin are fed into the machine at one side and sixty-four cans of any given size are turned out every minute at the other. All the joining of the seams and soldering are done by the machine, and a California dispatch says that a few of them in one factory would be able to supply all the cans used on the Pacific coast for fruit, vegetables and fish at one-tenth of the present cost.

Professor Troup, of the Indiana Experiment Station, writes in *The North American Horticulturist* that sixty-seven trees of Missouri Mammoth Quinces near Indianapolis, and ten years old from the graft, yielded last year 140 bushels of the finest selected fruit. Quinces of this variety are said to ripen ten days earlier than Orange quinces; they are much larger, of firmer texture and quite as highly flavored. Professor Troup adds that the failure of a Quince-tree to produce a good yield is more often due to neglect than to any deficiency of soil or severity of climate.

The sixtieth year of the existence of the Hamburg Gartenbau-Verein is to be celebrated in 1897 by an international exposition devoted to gardening in all its branches, and lasting from the end of April until September. There will be a spring exhibition of about five days' duration early in May, a summer exhibition lasting a week in June, and an autumn exhibition extending over ten days in September, with several exhibitions arranged for intervening periods in addition to such features as can be maintained continually throughout the season. It is to be hoped that American growers and dealers will be represented at this exposition, not only by displays of decorative plants, but by those of commercial value and interest. Roomy conservatories are promised, and an adequate list of premiums and medals will be issued. All persons interested in this project are invited to communicate with Professor Dr. E. Zacharias, Hamburg, Germany.

Since the 20th of January the weather in California has been extremely warm, and practically no rain has fallen. The rains in December were unusually heavy, but their effects have all disappeared since then in the heat and drought that has followed, so that not only the Wheat growers of the San Joaquin valley and the southern counties are threatened with serious loss, but the orchards are already suffering from lack of moisture. For twenty years past there has been no February when the temperature ranged so high and the rainfall so low. Almonds were in bloom a week ago and Apricots are in full flower, the orchards being as far advanced as they usually are in the latter part of March. If frost should come, as it sometimes does at this season, the crop of peaches and other fruits would suffer seriously, and preparations are being made on a large scale for protecting vineyards and orchards against sudden falls of temperature to the freezing point. The plan most generally recommended is to kindle slow fires and then use water in a very fine spray.

In speaking of the city-lot farms which have been made the subject of an editorial article in our present issue, Mr. Kjellaard, the superintendent, recently stated as an interesting feature of the work last year that the most successful farmers were women. This year lots will be furnished to any woman who deserves them, so that if her husband is earning small wages she can help to support the family. One woman who was especially successful last year, when applying for a lot for next season, reported that she had still some potatoes left which she hoped to sell, and vegetables enough to carry her

through the winter. Last year when she applied for work her husband was employed on a small salary and they were very poor; now she has \$200 in the bank. It may be added that there have been many applications from the country, not only from New York, but Massachusetts and Connecticut, by landowners who want the services of these city farmers, and some of them are now arranging to accept these offers and take up farming as their occupation.

Five-pound baskets of Catawba grapes, from western New York, are still seen in the fruit-stores in fresh condition, and sell for thirty cents. There have been no hot-house grapes in the city for a week or longer, and the last importation from England commanded the extreme price of \$4.00 a pound at retail. Besides a small shipment expected during this week, the dependence for choice grapes will be mainly upon Almerias until April, when the graperies of Rhode Island will supply this luxury. The favor in which grape-fruit is held is shown by the keen competition for the limited quantities now arriving from Jamaica. On Monday of this week \$30.00 a barrel was the average price realized at a wholesale auction sale in this city. Large shaddocks sell at retail for fifty cents each, the same price asked for smaller grape-fruits, and the invoice of a Kingston steamer which landed here a few days ago included one hundred and twenty-six barrels of Forbidden Fruit. Any form of citrus fruit which can possibly be marketed as grape-fruit is being collected and shipped in this time of scarcity. The market is now clear of California oranges which were injured by frost in the last days of December, and California Navel oranges of really excellent quality are now offered at sixty cents a dozen. A good grade of Jamaica oranges, re-packed, sells for \$8.00 a barrel in wholesale lots, and the less desirable Cuban fruit, from groves neglected until the failure of the Florida supply, brings \$7.00 a barrel for selected oranges. The recent cold weather has prevented shipments of apples from the interior of the state, and less than 12,000 barrels reached this city during last week, besides about 2,000 barrels for export. The highest grade of Winesap apples, from Virginia, commands the readiest sale at high prices; these cost \$5.50 a barrel. York Imperials may be had for fifty cents less, Northern Spies, Ben Davis and Baldwins following in the scale of prices, with choice Greenings selling at \$4.00.

While most of the pineapples sold in the United States have, within recent years, come from Cuba, the cultivation of this fruit in Florida has rapidly increased, and last season 50,000 crates were shipped from sections in that state other than the Keys. The output from the central and northern part of the state this year is estimated at 35,000 crates, while, but for the damage to new plantations by freezing a year ago, a crop amounting to 250,000 crates was counted upon for the next few months. The Bahamas formerly furnished the main supply, which was carried in small sailing vessels taking four to five days to reach this port, while unfavorable winds made a voyage of twenty days not unusual. Most of the pineapples now coming from Nassau and other ports of this group are consigned to Baltimore, where they are canned. As many as 5,500,000 of these pineapples have reached that city within the past four years, and large quantities are canned on the islands. Nearly all the Cuban pineapples come to New York, 200,000 barrels and more constituting the imports for a year. These pineapples are all grown near Havana, and shipments continue throughout the entire year. The season begins, however, in the middle of March and continues at its height for four months, while the Bahama season is a month later in opening. Some of the choicest pineapples have in recent years come from the Indian River section of Florida, and exceptionally large and high-grade fruit comes from Porto Rico. The comparatively small supplies from Jamaica include some excellent varieties which are in special demand. The delay of a day in the transportation of this perishable fruit may mean a heavy loss, and twenty-four hours of warm, damp weather may injure a cargo to the extent of fifty per cent. of its original value. No vessels specially fitted for carrying pineapples are yet in service, and this tender fruit is closely packed in steamers carrying sugar and other heating articles. Quick transportation in steamers equipped with improved ventilation and the best storage facilities, as are already in regular use in the banana trade, would open up new possibilities for this department of the fruit trade. At this time when, besides the shortage caused by the loss in Florida, the trade in Cuba is affected by war, prices have been high. The grade known to wholesale merchants as Havana XX, thirty-five pineapples being required to fill a barrel, now commands \$9.00 a barrel, and this is also the importers' price to wholesale buyers for barrels holding forty-five and ninety of the fruits.

The Plunder of the Adirondack Reservation.

UNDER a resolution of the Assembly of this state, passed on the 3d of May, 1895, a committee of five was appointed to investigate certain alleged depredations on the Adirondack state timber lands. The committee, of which Mr. Howard Payson Wilds was Chairman, and Thomas H. Wagstaff, Secretary, have just made a unanimous report, based on some fifteen hundred type-written pages of testimony, from which it appears that a great portion of the timber owned by the state has been practically without any protection during five years past, and that any one who chose to do so could cut and sell it without molestation. The sixty-five witnesses examined at different points were lumbermen, contractors, jobbers, sawmill-owners, foresters, farmers and residents of the neighborhood of the state lands, and nearly all of them testified with reluctance. The facts obtained from them, after rigid examination, relate to 125 different lots owned by the state, and embracing altogether more than 35,000 acres of land. How much timber has been cut and sold from these lands can only be estimated roughly by the summary of the testimony given in this report, but a glance at the record showing that this lot "was nearly stripped of marketable timber"; that the next one was "well lumbered over"; that "500 acres were cleaned of everything marketable," and so on, suggests a very large sum total. The reason why it is difficult to obtain testimony was stated by one of the foresters: "They are all neighbors, and they all want to trespass some if they get a chance, and, as a rule, they won't squeal on each other. If a man does, and it is known, they turn him down pretty quick." The loss, then, of an enormous amount of timber, a local public opinion which justifies the pillage of the state lands, and the inadequacy of the machinery provided by the state for protecting its forests are the three facts which stand out prominently in this report.

It is difficult to say who is the leading criminal in the chain of agents, which extends from the chopper up to the mill-owner. The owners of sawmills and pulp-mills find

in the Adirondacks a source of cheap lumber, and so long as they want wood somebody will be ready to furnish the logs either from his own private lands or from the public lands adjoining them. The mill-owners buy the logs, after they are cut, of agents who sublet contracts to jobbers, and these to gangs of choppers, so that the contract passes through many hands before it comes to the man who actually does the work. In every case where timber was cut beyond the boundary of private property, and upon the state lands, each witness would transfer the responsibility to the next man in the line, and the final trespasser almost invariably declared that if the boundaries of the state land had been better defined he would never have crossed them. As a matter of fact, in most cases no monuments mark the boundary except an occasional tree blazed many years ago. On most of the land the blazed trees are down or destroyed along most of the lines. Many of the lumbered lots have been burned over and the old marks are all obliterated. The only accessible descriptive data as to the boundaries of the state lands are those which have been furnished in the lists published by the State Forest Commission, in the local assessment rolls and in the forest map published in 1893. It may be true, therefore, that there have been cases where trespass has been committed from inability to find the state line, but one searches the testimony in vain to find that any precautions to prevent the state lands from being cut over were taken by those who let the job. No surveys are made, no boundaries are pointed out, the men are left to cut where they will, and in case of trespass the responsibility is thrown upon the jobbers, who are men of little property and willing to take chances. These depredations of timber, then, may occasionally be committed by jobbers through ignorance, and more frequently through recklessness; but they are often committed intentionally and defiantly.

Now, it is not to be believed that the lumber contractors do not know or understand the general location of the state lands, for whenever they assert some pretended right or color of title to the timber on some of these lands they can find the lines readily enough, and they at once assume the ownership of it and cut and haul it away. As a rule, this cutting and hauling has been a matter of general knowledge, and yet no one has molested contractor or jobber, and having ventured once to cut timber without trouble or expense they do so again, knowing that the settlement will be easy even if they are detected in the trespass. In general the jobbers cut where the contractors and lumbermen employ them, and they cut without investigation or concern as to whether the land belongs to the state or not. The common workmen are still more indifferent as to the ownership of the land so long as they make a living from their work. All this is done so openly that concealment is impossible—indeed, it is never attempted—and yet it is a fact that seldom, if ever, have trespassers been caught in the act of cutting or hauling timber on state lands by the forester in the discharge of his duties. This officer rarely visits the state lands during the lumbering season, and he waits till the following spring to prosecute his investigations, such as they are. Rarely, indeed, has any careful search been made by a state official to ascertain the extent of trespass, or to identify the trespasser, or to trace the disposition of the timber. The most that has been done is to report the matter to the State Forest Commission with a recommendation as to what sum should be charged for the logs in case of settlement. No prosecution has been carried on in any case for trespass, the depredators being always dealt with as innocent trespassers. At least, it does not appear that a single prosecution for the statutory penalty has ever been made in any of the frequent cases of trespass shown in this investigation, although thousands of trees have been cut for which the penalty should have been enforced. Logs have sometimes been seized and sold for what was offered, or they have been left to lie where they were found, because no one in the neighborhood of the land or of the lumberman was willing to bid against the trespasser.

Occasionally the logs are traced, but the settlement for them is made in accordance with the recommendation of the forester on the stumpage value and for a quantity agreed upon, often without regard to the facts in the case, and seldom, if in any single instance, has the adjustment for timber cut on state lands been based on a value above the market rate for like timber standing. The trespasser, then, has one chance of profit by cutting his timber without any cost. If his trespass is reported he has another chance of profit from an understatement of the quantity of timber charged as taken, and he has still another chance by settling with the state at market rate, or lower still for stumpage.

It is very plain that unless some radical change is made in the law and in public sentiment or in both there will soon be no timber left on the state lands, at least on the small and isolated parcels of such lands. It is even contended by some that the forests are so vast, the number of persons united by an interest in the cutting of timber so great, and the state police force so small that it is impossible to prevent timber thieving. It is doubtless true, as is claimed by the Forest Commission, that the state lands in the main forest, scattered like the black squares over a checkerboard, and interspersed with private holdings, are hard to patrol with the small number of foresters at command, and it would be of great advantage to the state to buy up these scattered parcels within the reservation, to provide more protectors and place them where there is the greatest liability to depredation. Again, as this report insists, these foresters should be residents of the special locality assigned to their care, and they should devote their entire time to duties as forest guardians and travel over their district at least once a month. It should be their duty to follow up every clue and prosecute for recovery and punishment to the full penalty of the law, and they should be charged with the duty of enforcing all laws relating to the forest preserve. No one can doubt that these trespasses on state lands could then be materially lessened, if not altogether stopped. Property-owners and contractors would soon learn to know where their own boundaries were if they were sure of punishment when they transgressed them. That it is possible to protect the timber on state lands is evident from the fact that private owners are rarely troubled by timber thieves, because it is known that the full penalty of the law and the full value of the timber cut or taken will be exacted. A like enforcement of the rights of the state and of the penalty for every violation would operate in the same way to stop trespassers on state lands. There is a fine of \$25.00 for every tree unlawfully cut, but this extreme amount is never exacted, and this report rightly insists that, in addition to a money penalty, every one who cuts or aids in cutting or transporting state timber should be held guilty of a misdemeanor. The penal code provides for malicious injury and destruction of timber on state lands, and a person who willfully cuts down, destroys or injures any timber standing or lying on lands of the people of the state is punishable by imprisonment and fine, or both. But this does not reach depredations on timber within the forest reserve, nor does it prevent the violation of the constitutional prohibition for the sale and removal of timber on the reserve. It is, therefore, recommended that depredations on the forest reserve—that is, the felling and removal, or the causing to be felled or removed, of any timber on the state lands, or of receiving with knowledge timber taken from the state land without the authority of law—be made a misdemeanor in addition to the fine.

Beyond question, it should be made a criminal offense to steal timber from the state, but without a compelling public opinion behind it such an act would never be enforced. What is needed more than law is an aroused public conscience. A man is treated like a thief by his neighbors if he steals their timber, but so long as they consider him an innocent trespasser at the worst if he chances to be detected in appropriating the timber of the state, the public forests will be a public prey.

Notes of Mexican Travel.—XI.

CUERNAVACA.

MY eleventh Mexican journey was limited to the last three months of 1895. I found the rainy season drawing to a close when I reached my field at the end of September. Everywhere over south Mexico evidence of abundant rains was given by a better-developed vegetation than I had ever before seen. Not a few scarce plants which had hitherto eluded my endeavor to secure specimens in sufficient number for my large distribution, now easily yielded me ample material. In quest of these I tramped once more several familiar fields. I saw the delightful Jalisco region smiling with plenty, as always; its people happy and enterprising. Greatly increased traffic over the railroad attested their awakening activity—their really getting into line with the world's progress. A better illustration could scarcely be found of the civilizing and developing power of the railroad, and the Mexican Central, encouraged by such results, is advancing its line farther into this fertile state.

Again I visited for a few weeks the remote state of Oaxaca, traveling the dry and heated cañons of the lowland district of Cuicatlan as well as the elevated and heavily forested mountains to the north of its capital. My delightful occupation during the sunny days of the tropic autumn was the gathering of new or rare species located the previous year, as well as those which now surprised me by a seeming first appearance. Of nearly everything there was in this season a profusion. A chief object in climbing again the Sierra de San Felipe above the city of Oaxaca was to secure a full complement of specimens of *Pinus Teocote*, found there by Liebmann fifty years ago. The species occupies, almost to the exclusion of other trees, certain ridges on the flanks of the mountain at an elevation of about 9,000 feet over sea-level, the soil of which is a reddish clay—dry, hard and poor. In such conditions it is a slender tree of inferior, or, at best, but medium size, with hard and resinous wood of reddish color. *P. Montezumæ*, at the same elevation and below, mingles with the Oaks in more fertile and moister soil, while above, and especially on the summit ridges, it sometimes forms solid forests, the best-developed individuals of which (those standing in summit valleys) are three to four feet in diameter.

Several weeks of my brief season, while the course of vegetation was at its best, but swiftly passing, were devoted to work in a charming field which was to me a fresh one. Such was the country surrounding the city of Cuernavaca, which lies beyond the mountain-wall that forms the southern rim of the Valley of Mexico. Colonel Hanysson, who, with irresistible energy, is opening waterways and steelways over the Mexican Republic, had carried his Mexico, Cuernavaca & Pacific Railroad almost to Cuernavaca, some forty miles south from the metropolis, making the dreaded diligence ride over frightful lava-beds and over mountain heights a thing of the past. Finding now so easy of access a region whose praises had long been sung to me, the temptation to reconnoitre its vegetation, before traveling far away, was not to be resisted. The ride by train revealed magnificent scenery—the grandest seen in Mexico; and from my three days' trip I returned with so large a load of plants that I moved over to Cuernavaca and settled down to work there. Other regions might wait.

The Cuernavaca train, issuing northward from the Buena Vista Station, in Mexico City, first swings around to the west over salt meadows, then turns southward just back of the heights of Chapultepec, crowned with national buildings, to pass over Scott's battle-field of Molino del Rey, through Tacubaya and other suburban towns, most interesting with their magnificent villas, surrounded by parks and gardens, and over dry glades bristling with plantations of Maguey. About ten miles out the foot of the Sierra de Ajusco is reached. Here, after passing through a scattered forest of *Pinus leiophylla*, a symmetrical tree of medium size, with the slenderest leaves and densest among

Pines, we are confronted by lava-beds covering the mountain-side and spreading for miles over the valley at its foot, a wild waste, almost impassable even on foot, black, brown or red rock, but half-concealed by vegetation. Down the slope innumerable streams of molten lava once poured, crowding upon and overrunning each other, heaping up ridges and hillocks or plowing out channels, seething and swirling, and, as they cooled, cracking into chasms, or, by upheavals of crust, forming frequent little grottoes. Right over this pedregal, through devious loops and up toilsome grades, our train mounts to the summit of the Sierra. To scan the scenes through which we pass yields intense interest. This pedregal is seen to be a preserve of plants from far and near. For beauty, it is like a flower garden. From nooks and crannies of the rough rocks, or from open patches amid masses of lava, spring Dahlias and Begonias, Senecios and Stevias, Pentstemons and Salvias, flowering shrubs and flowering trees—blooms in every color to make the scene bright and pleasing. On driest crags stand great Cotyledons and Sedums, and in the partial shade of little grotts rugged walls are softened by delicate Ferns. Thus, on a gigantic scale, nature has here wrought at wild gardening with surpassing results. One catches glimpses of a thousand pieces of rock work which the gardener would covet and long to transport to his city parks. Higher up the scene changes for a brief space to one of extreme desolation, where fragments of lichenized rock strew the slope. Then, as we near the summit over such open slopes, our eyes turn to survey the Valley of Mexico, that wonderful valley, in the praise of whose beauty and grandeur the Spaniard exhausted the riches of his language. No better point of observation could be chosen. We are some 2,000 feet higher than the level of the valley, and are here sitting at our ease in a railway train. Nothing obstructs our view of the entire valley some fifty miles in breadth. We look down upon the great city in its midst, with its two hundred towers and domes; see the causeways, marked by bordering lines of Willows and Australian Gum-trees, which radiate from it across green meadows; count scores of villages nestling amid greenery and shade, and trace the shining lakes, white-rimmed by bare alkaline flats. We follow the complete circle of mountains which embrace this valley. Over against us in the south-east, and seemingly face to face with us at this height, dominating all the circle, stand the two great snowy mountains which are the crown of all the scene.

Crashing through rock-cuts on the verge of the summit we are swiftly borne into a thin forest of *Pinus Montezumæ*, with scattered lines of *Cupressus Benthami* along watercourses, then out over open grass lands, broken by fields of Wheat, Barley and Potatoes, and on among abrupt knobs of volcanic rock, with *Juniperus tetragona* finding congenial conditions in their scanty soil. A mile or two away on our right the bare peak of Ajusco rises some 3,000 feet above us; and nearer on our left are several prominent summits of rounded outline. Below us and near we mark a minor crater like those strewn eastward over the valley, a depressed cone of regular form and showing a sunken top. After a dozen miles of this mountain plateau, called the Serrano de Ajusco, we enter near its southern border a heavier forest of *Pinus Montezumæ*. This forest extends far down the southern slope of the mountain, but other species of trees gradually take the place of the Pine.

Cuernavaca is situated at the foot of the southern slope of Ajusco, where the cold storms which sweep the Gulf coast in winter can hardly gain access; hence it enjoys the perfection of a winter climate. Fields of tender vegetables, like tomatoes and squashes, planted in November for fruiting in winter, attest the absence of frost. Its summer climate is also agreeable, for its elevation of 5,000 feet above sea-level precludes oppressive heat. Moreover, the rain is said to fall here mostly by night. From this point one has a nearer view than from the City of Mexico of the

great snowy summits rising above forested slopes; and here the interest of the view is greatly enhanced by the striking contrast afforded by an intermediate range of bare red rock, disordered masses, serrated, castellated and pinnacled beyond description. Above and about the town the mountain side is furrowed by many ravines so deep as to receive the name of barrancas. Below the town these open out into a wide valley which is green throughout the year with plantations of cane. Streams of pure water course down through every street, and fountains are frequent. To this charming spot Cortez came to build his palace and enjoy the fruits of his conquest; to this quaint and quiet town, verdant and shady under bright, warm skies, was attracted the ill-fated Maximilian to make himself a secluded home, and hither he was wont to ride by night to hide from assassins in the thick wood of his high-walled garden.

The several barrancas of this neighborhood, with their brooks and waterfalls, their thickets of shrubs, their cliffs and bluffs, shaded or exposed, dry or wet, and the swampy meadows at their bottom offered me a field for botanizing which I have not seen excelled. The mountain woods more distant were hardly less inviting. The character of its plants indicates that this region belongs to the same floral zone as Oaxaca and Guadalajara, and I detected here twenty-five or more species which have been late discoveries in those fields. This fact may indicate that the botanists, Bourgeau and Bilimek, who followed Maximilian here, shared their master's fear, for these plants were growing within easy distance from the city; but, better than that, this district was still treasuring its own quota of undescribed plants to reward my eager search. The most conspicuous among the new plants found about Cuernavaca is *Lippia iodantha*, Rob. and Greenm. (see fig. on page 105), a shrub five to ten feet in height. Its small, yellow flowers are borne in purple bracted heads nearly an inch in diameter, and these profusely cover the branches of the plant, making it a lovely object through many weeks of the autumn.

Charlotte, Vt.

C. G. Pringle.

Notes on the Names of *Yuccas*.

FOR many years after their discovery by the botanists of the commission which established the boundary between the United States and Mexico, at the close of the Mexican war, misapprehension as to the specific rank and distribution of the baccate-fruited *Yuccas* of our southern territory existed, all the early collections being extremely meagre and unsatisfactory.

The first species of this group which was described is *Yucca baccata* (Torrey, *Bot. Mex. Bound. Surv.* [1859]). It is a plant with a short subterranean stem, or with a stem lying prostrate on the surface of the ground, glaucous concave leaves much roughened on the back, flowers often more than four inches in length—that is considerably longer than those of any other *Yucca* now known, and succulent black fruits furnished at the apex with short beaks. *Yucca baccata* inhabits arid plains and valleys in southern Colorado and Utah, and northern New Mexico and Arizona, and apparently never forms an upright stem or descends from the high Colorado plateau into the southern deserts. It was first collected by Dr. J. M. Bigelow in New Mexico, and the earliest mention of it is on page 147 of the fourth volume of the Pacific Railroad Reports. When Torrey described his *Yucca baccata* a few years later in the Mexican Boundary Report, he referred to it a *Yucca* which had been collected by Thurber, near Parras, in Cohahuila, and suggested the varietal name of *Macrocarpa* for a large arborescent *Yucca* which Dr. Bigelow had found on the plains of western Texas, alluding at the same time to a *Yucca* which Dr. Parry had gathered near Monterey, in California.

Dr. Engelmann, in his studies of *Yucca*, published in 1873 in the third volume of the *Transactions of the St. Louis Academy*, in which the characters of the genus and its natural sections are established, considered the Parras plant

of Thurber and the western Texas plant of Bigelow identical, and southern or arborescent forms of the stemless *Yucca baccata* (*Yucca baccata*, β *australis*) connected with that species by Parry's California plant.

In the spring of 1887 I was in Nuovo Leon and was able to establish the fact that the flower panicles of the large arborescent *Yucca* of that part of Mexico are pendulous (GARDEN AND FOREST, i., 78, fig. 13-14), a character peculiar, so far as is now known, to this tree; and that it had been described in 1873 from young plants in European gardens as *Yucca filifera*. It is this species, as shown by Thurber's specimen (No. 1857) in the herbarium of Columbia College, which appears in a picture on page 490 of the second volume of the Personal Narrative of the American Boundary Commission, where a wide-branched tree bears numerous erect panicles of flowers which display the zeal rather than the accuracy of the artist.

These erect panicles of the artist's imagination caused some confusion in Professor Trelease's paper on *Yucca* in the *Fourth Report of the Missouri Botanical Garden*, in which he recognizes the fact that the *Yucca* of the plains of western Texas is a distinct species for which he proposed the name of *Yucca australis*, joining with it, however, Thurber's Parras tree, which he recognized as distinct from *Yucca filifera*, the name proposed in an earlier paper for the Nuovo Leon, Parras and western Texas plants.

This arborescent *Yucca* of western Texas, which is the largest *Yucca* of the United States, is quite distinct from the stemless *Yucca baccata*, not only in habit and size, but in the color, shape and smoothness of the leaves and the character of their fibrous margins, the long pendulous branches of the panicles of flowers, which were well shown in the illustration in our last volume (p. 415); in the size and shape of the flowers and the size of the fruit. This plant having been first described as *Yucca baccata*, var. *macrocarpa*, should when raised to a species bear the name of *Yucca macrocarpa*, which I now propose for it.*

The confusion with the name *Yucca macrocarpa* is increased by the fact that in 1881 Engelmann gave it to an arborescent *Yucca* of the mountains of southern Arizona, which in 1873 he had described as *Yucca Schottii*, under the impression that the two plants were distinct, a view which the abundant material collected during the last few years shows to have been erroneous.

The synonymy of *Yuccas* has been further complicated by the use of the specific name, *macrocarpa*, for the *Yucca* found by Parry near Monterey, California, and always considered identical with Torrey's *Yucca baccata* until the naturalists of the United States Department of Agriculture connected with the Death Valley Expedition showed it to be distinct, and called it *Yucca macrocarpa* in the belief that it might be the same plant as Torrey's *Yucca baccata*, var. *macrocarpa*, of western Texas.

The habit of this southern California *Yucca*, the color, surface and margins of its leaves, and the size of its flowers abundantly distinguish it from the stemless *Yucca baccata* of Torrey and from *Yucca macrocarpa* of Texas. It is without a name, and I propose to call it *Yucca Mohavensis*,† as it is most abundant and grows to its largest size on the Mohave Desert, this, too, being the name which Dr. Coville, the botanist of the Death Valley Expedition, gave it in his manuscript notes of the expedition. C. S. S.

* The synonymy of this plant would be then:

Yucca macrocarpa.
Yucca baccata, var. *macrocarpa*, Torrey, *Bot. Mex. Bound. Surv.*, 222 (1858).
Yucca baccata, β *australis*, Engelmann, *Trans. St. Louis Acad.*, iii., 44 (in part) (1873).
Yucca baccata, Sargent, *Forest Trees North Am. 10th Census U. S.*, ix., 219 (in part) (1884).
Yucca filifera, Trelease, *Rep. Missouri Bot. Gard.*, iii., 162 (in part) (not Chabaud) (1892).
Yucca australis, Trelease, *L. c.*, iv., 190 (in part) (1893).

† *Yucca Mohavensis*.
Yucca filamentosa, ? Wood, *Proc. Phil. Acad.*, 1808, 167 (not Linnaeus).
Yucca baccata, Engelmann, *L. c.* (in part) (not Torrey) (1873). Trelease, *Rep. Missouri Bot. Gard.*, iv., 185.
Yucca macrocarpa, Merriam, *North American Fauna*, No. 7, 353, t. 14 (*Death Valley Exped.*, ii.) (not *Yucca baccata*, var. *macrocarpa*, Torrey, nor *Yucca macrocarpa*, Engelmann) (1893).

Foreign Correspondence.

London Letter.

DENDROBIUM SARMENTOSUM.—This is a new species allied to *Dendrobium barbatulum* and lately named by Mr. Rolfe from specimens now flowering at Kew and which were received from Burma. It forms an erect cluster of crowded proliferous, slender pseudo-bulbs, eighteen inches high, with deciduous leaves and axillary flowers, usually in pairs and developed freely by the last matured growth. The flowers are only about an inch across, white, with a yellow stain on the front of the labellum, and a few thin lines of red on the side lobes. A well-flowered specimen is attractive as a flowering plant, but its chief charm is in its powerful violet-like odor. Messrs. Low & Co., of Clapton, also lately imported this species from Burma, and they exhibited it in flower last week under the name of *D. fragrans*. This, *D. aureum*; *D. luteolum* and *D. Kingianum* are worth a place in every collection of tropical Orchids on account of the sweet perfume of their flowers. They all flower in winter, examples of them being in flower now at Kew.

DENDROBIUM CURTISII, a hybrid between *D. aureum* and *D. Cassiope*, raised by Messrs. F. Sander & Co., resembles *D. endocharis*, but promises to be stronger and more floriferous. Its pseudo-bulbs are from six to twelve inches long and bear numerous flowers two inches in diameter, white, with a dull crimson blotch on the base of the lip.

DENDROBIUM PALLENS, a new hybrid between *D. Findlay-anum* and *D. Ainsworthii*, raised in the garden of Sir Trevor Lawrence, is a beautiful addition to the numerous hybrid *Dendrobes* now in cultivation. Its flowers are large, white, faintly tinted with rose, the long cordate lip having a blotch of pale yellow in front. It is very free and appears to be a vigorous grower. A certificate was awarded to it.

DENDROBIUM BURFORDIENSE, a hybrid between *D. aureum* and *D. Linawianum*, raised in 1892 by Sir Trevor Lawrence, was exhibited splendidly in flower by him last week. It has flowers as large as a good variety of *D. nobile* and colored pale rosy mauve tinged with yellow, the odor being equal to that of *D. aureum*. This is another hybrid that deserves to rank with the best of garden Orchids.

ODONTOGLOSSUM RETUSUM.—One of the most interesting of the many rare Orchids shown at the meeting of the Royal Horticultural Society held last week was a plant of this *Odontoglossum* from the collection of Mr. Woodall, Scarborough, who has had the plant many years and finds it is happiest when grown quite cool. Sir Trevor Lawrence possesses a plant of it, and these two are the only examples known. It has the pseudo-bulbs and habit of a *Cochlidia*, to which it is evidently closely allied, but it differs from the several garden representatives of that genus in the stoutness, length, branching and number of flowers upon its scape. This in Mr. Woodall's plant was twisted several times around stakes, and it bore at least one hundred flowers as large as those of *Cochlidia Noëtzliana*, their color being rich orange shaded with crimson. *O. retusum* was described by Lindley from a specimen collected by Hartweg on the mountains of Saraguro, Peru.

HOULETTIA TIGRINA.—A plant in flower of this rare species was shown last week by the Hon. Walter Rothschild. It was first described about forty years ago by Lindley from specimens imported and flowered by Monsieur Linden, whose collector, Schlim, found it in Ocana, Colombia, at an elevation of 4,800 feet. I have never seen it in flower before. The plant shown had broad, plaited, erect leaves nearly two feet long and bore two short erect scapes, one with two, the other with four flowers, each of which was four inches in diameter, the sepals ovate, concave, straw-colored, with dull rose spots and reticulations, the petals smaller, acute, with a lobe on each side and colored like the sepals, and the singularly formed, fleshy two-horned lip white, spotted with crimson. Although not so attractive as *Houlletia Brocklehurstiana*, it is as good a garden Orchid as the other half-dozen species of *Houlletia* known,

but like their allies, the Stanhopes, they do not find general favor, notwithstanding the large size, rich colors and aromatic odor of the flowers of most of them.

LÆLIA EYERMANIANA.—An importation of this beautiful *Lælia* was sold recently by auction under the name of *L. Marriottiana*. It was first flowered by Messrs. Sander & Co. in 1888, when Reichenbach gave it the former name and suggested that it was a natural hybrid between *L.*

pale rose-purple, with tinges of a darker color on the segments, which are blunter than in typical *L. furfuracea*.

MASDEVALLIA SHUTTRYANA.—Sir Trevor Lawrence raised this hybrid in 1892 from *Masdevallia Shuttleworthii* and *M. Hareyana*. It has also been raised by Mr. Chamberlain, where it has lately flowered, and as the flowers of the latter plant are larger and of a brighter color the varietal name of *Chamberlainiana* was accepted for it by the Royal Horti-

Fig. 11.—*Lippia iodantha*, n. sp. Rob. & Greenm. ined.—See page 102.

majalis and *L. autumnalis*. Two years ago a number of plants of it were sold by auction for *L. majalis*. Some of these were obtained for Kew, where they flowered freely, as many as eight flowers being borne by some of the scapes. They have flowered again this year. There is not much to distinguish this from *L. furfuracea*, except its free habit and many-flowered scape. Mr. Rolfe thinks it is a natural hybrid between *L. majalis* and *L. albida*. The flowers are as large as those of *L. autumnalis* and colored

cultural Society. It is a remarkable hybrid, having short oblanceolate leaves, single-flowered scapes eight inches high and large flowers, somewhat like those of *M. Shuttleworthii* in shape, colored rich rosy mauve, tinged with red, the tails bright orange. Hybrids such as this are worthy additions to garden Orchids. The name is an attempt to hybridize the names of the parents.

MASDEVALLIA HENRIETTA, raised in the garden of Mr. F. L. Ames, Massachusetts, in 1893, from *M. Shuttleworthii* and

M. ignea, was exhibited in flower last week by Sir Trevor Lawrence, and was awarded a certificate. It bears some resemblance to the last-named hybrid, differing mainly in the color of the flowers, which are yellow, tinged with rose and red-brown.

PLEUROTHALLIS ROEZLII.—This, which is one of the most remarkable of the three or four hundred species of *Pleurothallis* known, is represented in the collection of Sir Trevor Lawrence by a very large healthy specimen which was exhibited last week bearing six flower-scapes springing from a cluster of healthy green leaves, the blades measuring a foot in length and the petioles six inches. Each scape was a foot long, nodding, and bore about a dozen partially opened, inflated, crinkled flowers nearly two inches long and an inch across and colored deep claret-purple, the color of *Veratrum nigrum*. English cultivators were first made acquainted with this plant in 1885, when it was shown in flower in London by Monsieur Godefroy-Lebeuf, of Paris. There is a plant of it in the Kew collection which was raised from a leaf of Monsieur Godefroy-Lebeuf's plant, *Pleurothallis* being readily multiplied in this way. According to Veitch, *P. Roezlii* was first described in 1862 under the name of *P. laurifolia*, a name which is descriptive of the sturdy healthy green leaves of the plant. It is a native of Colombia.

CYPRIPEDIUM NIGRITUM.—Collectors of *Cypripediums* may like to know that Messrs. Low & Co. have plants of this practically unknown species. It was first described in 1882 by Reichenbach from specimens supplied by Messrs. Wallace, of Colchester, who had imported it from Borneo. It has the leaves and habit of *C. virens* and the flowers of *C. barbatum*, but smaller, darker, with narrower, paler petals and smaller, more numerous marginal warts. The dorsal sepal is only an inch long. Reichenbach said it was near *C. barbatum*, but quite distinct. Plants of it have recently flowered in the Clapton nursery, and have been determined by Mr. Rolfe.

SELENIPEDIUM SARGENTIANUM has an exceptionally tall scape, a plant of it now in flower at Kew having a scape two and a half feet high. The flowers are developed singly on the upper portion, and they are about three inches across, yellowish green, with red margins to the segments. It is not likely to become a general favorite.

Cultural Department.

The Essentials of a Good Lawn.

THIS is the season when we are often asked how to establish a good lawn and insure its permanence. Downing names three essential requisites: (1) Deep soil; (2) proper kinds of grass, and (3) frequent mowing. For this climate I would add a fourth—that is, plenty of water. The air of an average American summer is not so well adapted to the production of a fine lawn as is the humid atmosphere of Great Britain. There, not so much attention need be given to the richness of the soil, as the moisture takes its place in a measure. But in this country the soil should be deep and rich, with a subsoil capable of retaining moisture, but not in excess. If the subsoil is hard and tenacious it should be well under-drained and trenched, or subsoiled to a depth of sixteen or eighteen inches, so as to create a reservoir for holding moisture which may be drawn upon by the plants as needed during dry times. This matter of subsoiling does not receive the attention it deserves in our climate. Many persons seem to think that if the surface soil is in good condition nothing further is needed. Such persons should bear in mind that it is a deep soil only which will furnish moisture for grass roots through continued drought, so that the lawn will remain green during the entire summer and autumn.

Again, too much attention cannot be given to the preparation of the soil before the seed is sown. It should be plowed and re-plowed, cultivated, harrowed and rolled until the whole is thoroughly pulverized and mixed to a depth of ten inches. This work should be done in the fall, and then the plot should be left to settle all winter before the seed is sown. The foundation will then be firm. This not only makes a compact bed which the tender grass roots need, but it will insure the lawn

against those little knolls and hollows which are so objectionable in appearance and do so much to obstruct the use of the mower.

Only two kinds of Grass are really worthy of consideration for this climate. These are Kentucky Blue Grass, *Poa pratensis*, and Red Top, *Agrostis vulgaris*. There are a few others, such as Rhode Island Bent Grass, a finer kind of *Agrostis*, which may be sown, but it is more expensive and little superior to a good strain of Red Top. A little Sweet Vernal Grass, or White Clover, may be added, but neither is essential. The coarser Grasses, such as Timothy, Orchard Grass or Meadow Fescul, should never be sown in a lawn. They are short-lived and too coarse and stiff to make a soft, velvety carpet. There are many lawn mixtures advertised and sold at high prices; some of them are good and will make excellent lawns; but, if analyzed, the best of them will be found to consist mainly of Blue Grass and Red Top, which may be bought in the market for from \$1.50 to \$2.50 a bushel.

To seed properly, from two to three bushels will be required to the acre, owing in some measure to the amount of chaff mixed with the seed. This should be sown as early in the spring as possible, so that the young plants may become well established before the hot dry weather of midsummer. The sowing of oats with the seed has been recommended as a protection to the young Grass-plants, but I have never yet found that a strong, gross-feeding plant like the Oat would furnish protection to a delicate, slow-growing one. On the contrary, the so-called protector will rob the weaker plant of its nourishment. Red Top germinates much more quickly than Blue Grass, and will furnish all the protection necessary, besides covering the surface with a green coat almost as quickly as Oats will. After the Blue Grass gets its roots well established in deep rich soil it will need no further protection, but will assume entire control in a very short time.

The third essential is early and frequent mowing. If the grass is allowed to get too large before being cut, the stubble will be too stiff, and we lose that soft velvety character which is only produced by frequent mowing. It is time to begin as soon as the grass is tall enough for the mower to catch it. A few annual weeds which may make their appearance during the summer will do no harm, as they will be kept down by the mower and not allowed to ripen their seeds; but such perennials as the Docks, Dandelion, Plantains and their kind should be dug up as soon as they can be seen, and water must be in constant supply to feed the grass, keep it green and growing. The deep-soil preparation will help to do this, but he is fortunate who can draw on some reservoir for occasional irrigation. Where water is always abundant less care need be given to fertilization, otherwise it will be well to top-dress the lawn early every spring with thirty or forty bushels of unleached ashes and three or four hundred pounds of bone-meal or superphosphate to the acre. This will keep the grass in thriving condition. Barn manure is too unsightly, and should not be used except in localities where snow covers the ground all winter, and then it should be raked off as early as possible in the spring. By following out the suggestions given here in providing the four essentials, we may have as fine lawns in this country as they do in England; lawns which will last a lifetime and be a continual source of pleasure to all who see them.

Orchid Notes.

DENDROBIUM THYRSIFLORUM is usually an easy plant to manage, and yet we often hear of its failure to bloom. While it is growing it should be helped as much as possible to make a strong, unchecked growth until December, when it should begin to rest. In January and February the plants should be dried until the pseudo-bulbs show signs of shrinking, and then water should be given. If this is kept up the bulbs ought to be one or two inches long by the middle of February. If dried too completely the buds blast, if kept too moist new growths are encouraged at the expense of flowers. *Dendrobium Hookerianum* and *D. Dalhousianum*, in order to be flowered successfully, need more severe drying. It treated as evergreens they flower sparingly. Indeed, I have known specimens of *D. Dalhousianum* to be five feet high that have not bloomed for years. With a good root-system and large, healthy pseudo-bulbs a little shriveling does not hurt them in the least.

Vandas which have flowered well have a tendency to give a second crop and should have the stems nipped out. Second flowering will debilitate the plants, and the lower leaves will be lost and those which remain will turn pale. *Vandas*, *Angræcums*, *Aërides* and *Phalænopses* should not be dried as

severely as *Dendrobiums*, *Lælias*, *Cattleyas* and the like, which have a reserve in their pseudo-bulbs to prevent any sudden dangers from a longer drought than is necessary.

Potting should now be attended to, and *Lælias*, in particular, need working over wherever the peat is sour or sodden. If the plant has settled too low or has overgrown its receptacle it should be repotted. Some will only need a little new fibre tucked under them here and there. *L. autumnalis* and its varieties which have shown a good start in the roots need immediate attention. After covering the bottom of a basket with potsherds a thick layer of peat fibre should be added with the fibrous material loosely shaken out. After trimming old shoots close up to the stem and cutting out any diseased or bruised pseudo-bulbs, basket them with more peat. If proper-sized pieces of fibre are used and skillfully worked in, little or no wire will be needed. When finished the plants should be entirely inside the margin of the basket and raised above the edge. A little live sphagnum can be used on the top layer when basketed. By all means have the plant firm, the stems not buried, and in a position that allows the developing break to push on unobstructed. When finished, hang up and do not water for three or four days, to avoid any danger of starting decay at the roots. In a week or two baskets may be top-dressed with live sphagnum and watering can be increased. An intermediate house suits these plants and they need abundant light and air, although, of course, they never should be subjected to a draft. If *Vanda Catharti* has made a good growth and appears healthy, but refuses to flower, bend the stem to an oblique position, and this will sometimes have the desired effect. A light form of *Cattleya Schröderæ*, with a beautifully marked and wide throat of orange, is now very handsome. The good forms of any recently imported plants can now be gone over and selected. Albinos usually have the outside of the base of the leaf of the same color as the remainder, while the usual forms are mottled with pink or red at the point of attachment. Albinos should be tried a second year before they can be considered lasting. They often assume a pinkish tinge after the first year.

Missouri Botanic Garden.

Emil Misch.

Begonia Socotrana.

IT is difficult to understand the force of Mr. Miller's remark on page 97 that the effort to cross *Begonia Socotrana* directly with the fibrous-rooted section would be a waste of time. In *B. Gloire de Sceaux* (*Socotrana* × *metallica*) we have had for a decade a very beautiful hybrid which is valued wherever it is known. *B. Bijou* (*Socotrana* × *insignis*) is also a distinct and pleasing hybrid, perhaps not so well known. Monsieur Lemoine's hybrids *Triomphe de Lemoine* and *Triomphe de Nancy*, crosses between *B. Socotrana* and perhaps *B. Roezlii*, are interesting plants with succulent stems and rather stiff habit, having very numerous persistent flowers. These plants offer much encouragement to hybridizers, and it is singular that they have not been followed by crosses with other herbaceous kinds which would be more likely to prove valuable than crosses between tuberous kinds to ordinary cultivators. *B. Socotrana* was quickly taken in hand after its first flowering in 1881, and though a number of hybrids have been offered by Veitch and Lemoine they do not seem to have become at all common in cultivation. Veitch's productions—*John Heal*, *Adonis* and *Winter Gem*—are not rapidly propagated, and I found *Adonis*, the one tried here, an obstinate plant. The Lemoine hybrid, *Gloire de Loraine* (*Socotrana* × *Dregii*), has wonderful racemes of flowers which persist for many weeks, but the plant is of a rather stubborn character, and it can scarcely be classed among varieties likely to become popular. In fact, it is not clear that tuberous hybrids are desirable unless they prove to be readily reproduced from seed. Tuberous *Begonias* are short-lived, and, with the exception of *B. Marliani*, they require frequent propagation from seed or cuttings. In view of such crosses as have been made it would appear that the infusion of the blood of *B. Socotrana* militates against the latter mode of propagation.

Begonia Socotrana is very interesting botanically and horticulturally. It is distinct, but scarcely as beautiful as many of its interesting relatives, for, among the numerous species and hybrids of *Begonias* are a great many which, if well grown, are most charming plants both in foliage and flower. They are easily cared for, but, as a rule, the plants have one serious fault. If one may use the expression, their articulations are very unstable, and a sudden falling of temperature, a little gas or carelessness in watering will cause them to shed their leaves and flowers with great promptness. The small-flowered kinds are as handsome as those with large flowers, and we do not need

any addition to the size, an illusion or delusion which too often misleads the hybridizer. But if we could have a few additions to the herbaceous kinds possessing some of the stability of *B. Socotrana*, with little or none of its resting or deciduous habit, they would be great gains and be appreciated by all lovers of greenhouse plants.

J. N. Gerard.

Seasonable Greenhouse Notes.

WITH lengthening days and increasing sunlight greater watchfulness in such matters as temperature, ventilation and watering is necessary. All possible potting should be completed before the spring rush commences, and nothing left undone which may as well be done now as later in the season when other work is pressing.

The propagation of bedding-plants will now require attention. *Coleus* quickly roots in a bottom-heat of seventy-five to eighty degrees. If a few old plants have been kept for stock and judiciously pinched in a moderately warm house plenty of cuttings may be procured. The tips taken from these young plants late in the season may be inserted. The old plants are liable to attacks of mealy-bug and should be consigned to the rubbish heap. *Alternanthera* delights in a warm moist atmosphere, and nothing equals a good hot-bed for these conditions. We cut our old plants well back, and these give a plentiful supply of cuttings in a week or two. If there is likely to be any shortage of *Zonale Pelargoniums*, cuttings inserted now will make good plants by bedding-out time. We find the middle of March early enough to start a lot of *Madame Salleria Geraniums*; this variety still remains unequalled for borders. *Fuchsias*, *Lantanas*, *Heliotropes*, *Stevias* and many other plants require propagating now, and the cutting-bench should be fully occupied. *Geraniums* which have been carried over winter in boxes of sand with only sufficient water to prevent shriveling have recently been placed in two-inch pots in a warm house. These are shifted about April 1st to four-inch pots in which they make neat little plants.

Cannas are among the most useful of summer bloomers; this is a good time to start the main supply. We cut the roots up, leaving an eye to each piece and pot in small pots, in light sandy loam. A temperature of not less than sixty degrees should be afforded them, and if bottom-heat can be used it is all the better. A shift into five-inch pots when the smaller pots are well-filled with roots will make good plants by the middle of May. Tuberous *Begonias* can now be started in boxes of light compost, and should be watered sparingly until well started. These we transfer to pots later on, and we find that tubers started later in the season and planted out from boxes do almost as well. Seedlings make excellent plants the first season. We sowed our seed early in February; when sufficiently large to handle these are pricked off into shallow boxes, and from these transferred to a gentle hot-bed where they are planted four inches apart each way, in light, rich compost. Strong plants are produced by the first of June.

Our earliest sowings of *Asters* and *Stocks* are now in rough leaf, ready to prick off. Of *Asters* we find *Queen of the Earlys* the best for an early crop, while *Boston Florists' Stock* comes in much ahead of any other sort we have tried. The latter makes a useful pot-plant, and we usually have some in flower for Easter by sowing in December. The main batch of *Asters*, *Stocks*, *Zinnias*, *Phlox Drummondii*, *Gaillardias*, etc., we sow about the middle of March. *Petunias*, *Lobelias*, *Verbenas* and a few other kinds are started a month earlier. *Salvia splendens* and its varieties, *Compacta* and *Le President*, are so easily raised from seed that it is not worth while keeping any plants for propagating purposes, and seed sown now will produce good-sized plants by the time they are required. As bench and shell room is now pretty fully occupied, boxes of newly sown seeds can be stood several deep after being watered. This prevents the surfaces from drying and germination is likely to be better better than when the boxes become more dry and require almost daily waterings. Sowings may be made now of *Aralias*, *Grevilleas*, *Solanums* and similar plants useful for winter decoration. Such seeds as *Cannas* and *Ipomœa noctiflora hybrida* germinate more quickly if soaked in warm water for twenty-four hours before sowing.

Every one having a glass house plans for an attractive show of flowers for Easter. *Easter Lilies* constitute the most important crop and the one most difficult to have exactly on time. We like to see the buds distinctly on *Lilium Harrisii*, *L. longiflorum* and *L. candidum* when Lent begins, and then, whatever vagaries of weather may follow, by forcing or retarding, the flowers may be had on time. A good deal of nice calculation is required to get all *Easter* flowers in at the right time. Green

aphis will injure Lilies if allowed to get a foothold, and they must be held in check either by dusting the tips with tobacco-dust, syringing with tobacco-extract dissolved in water, or by fumigation. Callas are useful for decorative purposes; we grow the large tubers of *C. Æthiopica* in ten and twelve inch pots, placing three and five to each pot. The variety Little Gem, while not of value as a winter bloomer, is now commencing to flower freely, and is useful to mix with other plants. Grown in eight-inch pots these will each have five to eight open flowers by Easter. Callas are gross feeders, and strong liquid food twice a week improves them. Spiræas are among the most useful plants for Easter. We prefer *S. grandiflorum* to the older *S. Japonica*. *S. astilboides* makes an elegant plant; it is taller in habit than the others, with handsomely cut and showy foliage and minutely branched panicles of white flowers; it requires two weeks longer forcing than the *Japonica* type to bring it into flower. Spiræas must have plenty of room to develop their foliage, stimulants and copious waterings. They are easily injured by tobacco-smoke, and it is well to remove them to another house while any fumigation is going on. I have seen many fine lots completely ruined by neglect of this simple precaution.

Easter comes a week earlier this year than last, and Hydrangeas will require considerable forcing to have them in good flower. The heads on our plants are now showing white, and will be well expanded by the required time. We have had to retard *Cytisus racemosus* and Indian Azaleas, but they are now being carried into heat. Bulbous plants, such as Hyacinths, Tulips and Narcissus, require some three weeks from the time they are housed until they are in flower. If the weather is very warm and sunny they may need holding back; if the reverse, some extra forcing may be necessary. Paris Daisies, especially the white variety, Grallert, are useful grown in six and eight inch pots. Plants of *Antirrhinum* in six-inch pots, carrying five or six spikes, are effective, and can readily be brought into bloom for Easter in an ordinary greenhouse temperature. We purpose trying the white *Swainsonia galegifolia* as a decorative plant this year for the first time. Its beautiful white sprays of flowers should make it extremely popular, and it is of easy culture. *Calceolarias* and *Pelargoniums* will both be somewhat late for Easter this year. Neither of these plants tolerate forcing, so it is useless to attempt to hurry them forward. Green aphis is very partial to both, and we pack plenty of tobacco-stems among our plants. A cool airy structure suits them, and they relish frequent syringings overhead until the flowers begin to expand. The flowering Begonias are among the most cheery objects in a greenhouse at this season, and florists are giving more attention to their cultivation. While they have comparatively little value as cut flowers for decorative purposes, as pot-plants they are unexcelled. A good batch of cuttings for next winter's crop should now be inserted. Later in the season the old plants grow finely if planted out in a partially shaded border. For midwinter blooming *Begonia incurvata* (called also *carminata*) deserves special commendation; we have just put in cuttings of this excellent variety. The old plants if cut back give abundant cuttings from the base, and these are preferable to those taken from flowering wood. The Cornell Experiment Station is trying to get together a complete collection of Begonias, and it is hoped all gardeners and florists will send to that institution varieties and species it may not have. A primary object in making the collection is to establish correct nomenclature of Begonias.

Taunton, Mass.

W. N. Craig.

Caryopteris mastacanthus.—This neat subshrubby member of the *Verbena* family is said to be hardy as far north as Boston. Thomas Meelan & Sons, of Germantown, state that they have thoroughly tested it for the last five years in their nurseries, and that it has been only slightly winter-killed. As the flowers are produced on the current year's growth this is no disadvantage, for, no doubt, like many other plants of this character, it will be benefited by being pruned annually. The plant branches freely from a woody base. The leaves are ovate and hoary, with adpressed, silky hairs in greater abundance on the lower surface. The flowers are lavender-blue, in dense axillary clusters, and are produced in great profusion during the months of September and October. It is one of the easiest of plants to manage, and in the greenhouse has been quite free from insect pests of all kinds. Our half-dozen plants were raised from cuttings taken from a plant purchased last spring. They made neat little bushes of ovate pyramidal form about two feet high. We grew three in six-inch pots, and they made the best of decorative plants. Those kept indoors ripened seed abundantly. The plant can be easily increased from cuttings as well, so that it will be plentiful.

Abutilon Souvenir de Bonn is the best *Abutilon* with parti-colored leaves that I have seen. The variegation is white and confined to a rather heavy banding on the margin of the deeply cut palmate leaves. It is a highly decorative plant, however used, and small specimens in pots are especially beautiful. For foliage contrasts in informal gardening it is most effective. The variegation does not seem to interfere with the vitality of the plants, and they are always healthy and vigorous. Unlike many *Abutilons*, it naturally forms a stocky bush of pyramidal form and never needs staking. The red-striped orange flowers contrast well with the foliage, as is not the case with the *Thompsoni* forms, which have yellow variegation.

Correspondence.

Decoration of School Grounds.

To the Editor of GARDEN AND FOREST:

Sir,—The subject of ornamenting our country roadsides with trees and shrubs has lately been treated interestingly in your columns, and I wish now to call attention to the tasteful planting of grounds about country schoolhouses. They stand at present, as a rule, as "ragged beggars sunning," without so much as a Sumach or Blackberry vine to adorn them. Not infrequently the playground is altogether omitted, and the children play in the road. Certainly the school-buildings in the country that are provided with pleasant grounds are exceptional, and although in a few instances sites have been chosen near native groves with pleasing results, planting is almost wholly neglected. This oversight where land is available and trees and shrubs can be procured at little or no cost, evidences lack of thoughtfulness on the part of the rural population rather than lack of taste. Children enjoy planting trees and seeds, but, as with other things, soon tire of the labor and care of cultivating unless stimulated by some unusual motive. The idea of ownership or proprietorship has been tried in many places with success, and children have been led to take pride in trees and shrubs placed under their care. As many children do not possess attractive homes the influence of a prettily decorated schoolhouse and grounds would add a much needed element in their education. The advantages to be derived by children from pleasant surroundings seem to have had little or no place in the arrangements for their earliest impressions at school in the country, where of all places the most natural beauty may be provided with the least exertion. Since childhood is the most impressive period of life it certainly is better to have schoolhouses and grounds comfortable and tasteful rather than inconvenient and unsightly. The remembrance of hours spent years ago in shady woods, among wild flowers and ferns, under orchard trees, or in old gardens, remains with us as we advance in life when later experiences are forgotten. Washington Irving wrote: "I thank God I was born on the banks of the Hudson! I think it an invaluable advantage to be born and brought up in the neighborhood of some great and noble object in Nature. I used to clothe it with moral attributes and almost to give it a soul." He traces to his companionship with it whatever is good or pleasant in his character.

Comparatively few are born with what are usually termed grand objects about them, but none in the country need be deprived of much that is refreshing and ennobling to the mind, provided the attention is early called to it.

White Pigeon, Mich.

Dorcas E. Collins.

John Brown's Grave.

To the Editor of GARDEN AND FOREST:

Sir,—The letter of Mrs. Van Rensselaer, in your issue of January 29th, in regard to the recent purchase by the state of New York of the John Brown tract, reminds me that it may be worth while to reproduce part of an article printed in *Kate Field's Washington*, under date of September 26th, 1894. This account was given to Miss Field by the Rev. H. C. Lyon, who lived in North Elba for several years and knew many of the Brown family personally.

"It is more than likely that of the tens of thousands who have visited the grave of old John Brown, at North Elba, in the Adirondacks, not fifty have ever heard the history of that inscription so deeply chiseled in the great granite boulder near the grave—'John Brown, 1859.' This boulder, with its clear-cut letters, will always be regarded as the real memorial. It is true that the thin stone slab which formerly marked the grave of Captain John Brown, the grandfather of John Brown,

stands at the head of the grave, and additional inscriptions record the names of John Brown and three of his brave sons, who died for the cause of freedom. It was the wish of John Brown that his name might thus be linked with that of his grandfather, who was a soldier of the Revolution. But long after this frail and ancient tablet has crumbled into dust, the giant boulder, with its classically beautiful inscription, will commemorate the name and fame of the Friend of the Oppressed.

"To the late Colonel Francis L. Lee, of Boston, Massachusetts, of the Forty-fourth Regiment of Massachusetts Volunteers, belongs the credit of establishing this imperishable memorial. For many years Colonel Lee had spent the summer months at his country home, 'Stony Sides,' on Lake Champlain, near Westport, New York, only about thirty miles east of North Elba, and had always entertained a high regard for the noble qualities of Brown, even before his exploits in Kansas had revealed to the world the stuff of which he was made. The year following the close of the war, 1866, Colonel Lee made a pilgrimage to North Elba, accompanied by some members of his family and the Hon. George S. Hale, of Boston, taking with him Mr. Andrew J. Daniels, of Westport, a skillful marble-worker. To Mr. Daniels Colonel Lee intrusted the task of cutting those large, deeply furrowed letters and figures in the flinty rock."

This cutting took many days, owing to the extreme hardness of the rock in which the letters are cut. This same hardness will protect the mighty boulder from the hand of the vandal relic-seeker for all time. I wish also to add my protest as a native of Essex County against putting any artificial monument over the grave of the rugged old man who lies buried among the surroundings of his own choice "with his face to the south." If there is to be a monument built from the accumulated funds spoken of in the letter, let it be at Harper's Ferry or some other place where it will suit its surroundings, but not on the old farm.

Chestnut Hill, Mass.

Francis W. Lee.

Recent Publications.

A History of Gardening in England. By the Hon. Alicia Amherst. London: Bernard Quaritch. 1895.

Miss Amherst's book is sure to be useful to any serious student of the history and literature of English gardening, and should also have a place in the library of every lover of gardens who takes an interest in the growth and development of an art which has a long past, since it started, we are told, in Eden. The History of Gardening gives evidence of long and careful preparation, and the author has grouped her facts so skillfully and with such a keen sense of historical perspective that the work is likely to become a classic of the craft with which it deals. Externally the book is attractive in its green cover, with the two quaint men digging and planting in an impossible garden, the sole decoration of which seems to consist in one or two microscopic twigs. The illustrations are less satisfactory, as in many cases the photogravure process has failed to reproduce the differences in light and shade of the actual scenes. The bibliography at the end is large and full, but, although there are some advantages in the chronological arrangement over one that is alphabetical, the latter is plainly more convenient. The short index of names, however, furnishes a much needed help to one who wishes to consult a given author. It would double the working value of this list if in another edition a little more information were given about the books on such points, for example, as whether or not they are illustrated, what is the best edition, etc.

The author begins by a few words on the probable want of gardens among the rough and warlike tribes which inhabited Britain before the Roman conquest, but passes on to the early Saxon times, when the monks, in their quiet communities, cultivated herbs and simples, while protecting learning and the refinements of life from the boisterousness of the mediæval world. An amusing part of the book is that in which Miss Amherst treats of the expenses of monastic gardening as shown in the pipe-rolls and chartularies of the period, where one may see from the charge "for labour of labourers in extracting 'mosse' from the

cloister green, 6d.," that weeds grew and had to be pulled up as much in the middle ages as they do now. The Hortulanus, or Gardinarius, was an important person in the Priory, since he had charge, not only of the garden, but of the orchard, vineyard, moat and fish-ponds, and it was also his duty to see that the church was decorated with suitable flowers.

As soon as England began to recover from the many wars which kept people shut up in walled towns and in castles, where want of space prevented any but the most necessary cultivation, gardens multiplied, and an association of gardeners became so powerful that they forced the Mayor and Aldermen of London to recall an order which had been issued forbidding them to hold a market in front of the church of St. Austin.

The literature of the fourteenth and fifteenth centuries is full of references to sweet-smelling flowers and green lawns, while some of the illuminations in old manuscripts of that time are views in gardens where ladies sit upon turf seats and weave "gerlonds" of roses or periwinkles. Later, in Tudor times, when houses did not need to be surrounded by high walls, and people had time to think of something besides fighting others and defending themselves, the pleasure-grounds began to be more elaborate, and the topiary artist, who in later times was to create such extraordinary objects in Yew, was called in to pleach alleys and hedges. Galleries and mounts also make their appearance, and flower-beds fenced with brightly painted trellises. In short, one feels that here is the fresh and fair beginning of the simple, hearty country life which has continued to grow until the present time. Miss Amherst also shows that in the reign of Elizabeth gardening did not lag behind the other gentle arts, since Bacon's well-known essay was only one of the many treatises on the subject which were written about that time. The garden became a part of daily life, insomuch that the architect, John Thorpe, designed the surroundings for his houses, thinking the plan of the garden important enough to require an artist for its proper and harmonious distribution. The author also glances at the humbler kitchen-garden, where the list of vegetables has constantly grown longer and the methods of cultivation more technical.

In the time of the Cavaliers and Roundheads the love of gardening grew steadily in favor, both with the working classes and the gentry, as shown by the well-known Royalist names of John Evelyn, the author of *Sylva*, and Lord Capel, whose famous garden was at Kew. Toward the end of the seventeenth century the influence of the pomposity of Versailles was felt in England, since Le Nôtre is said to have been ordered by Charles II. to make designs for the elaborate alterations at Hampton Court, which were afterward only partly carried out. It was natural when William and Mary were on the throne that Dutch gardening should become the fashion, and accordingly we see a great remodeling of old places going on, largely under the superintendence of Hollanders, who, doubtless, brought with them the taste for cultivating Tulips, which became a mania in their own country.

Miss Amherst's sketch of the rise of landscape-gardening is most interesting, since she shows how the reaction against the excessive formality of the later gardens created a style which, in its affected simplicity and naturalness, grew to be quite as artificial as the one it had superseded. The author also emphasizes the enormous amount of damage done to fine old places by the "improvers," who cut down avenues of grand old trees because they considered them neither "pensive, picturesque, nor sublime." A short account of the progress of horticulture in this century, with a few appreciative remarks on some modern gardens, closes this attractive book. Its mass of well-ordered and well-digested information, with constant reference to original authorities, gives it a genuine value, and it has the charm of being written in an easy, flowing style which is never dull. It is altogether the best existing treatise on the subject, and it is not likely soon to be superseded.

Notes.

The Puget Sound University owns what is called a residence park of some twelve hundred acres south-west of the city of Tacoma, and it is proposed to devote some two hundred acres of this, where the soil is most suitable, to an arboretum of such trees as will grow in the remarkable climate of that region. The amount of land available is so ample that room can be given for a large collection. Some ten thousand young plants of two hundred and fifty species, native and foreign, already form the nucleus of the proposed tree museum.

As a proof that more Olive-trees have been planted during the past season than ever before in California, a recent dispatch to the *Tribune* states that a single nurseryman in Pomona has sold 200,000 trees, that Mr. Andrew McNally, the Chicago publisher, is planting an Olive orchard of four hundred acres in Orange County, and Mrs. Adlai Stevenson is preparing 340 acres in San Bernardino County for Olive-trees. All the Olive groves in southern California were profitable last year and the demand for California olives constantly exceeds the supply.

Mr. William Falconer, editor of *Gardening*, has accepted the position of superintendent of the park system of Pittsburg, Pennsylvania, which has been vacant since the death of A. W. Bennett. Mr. Falconer has been in this country some twenty years, and during the latter half of this time he has had charge of Dosoris, the well-known estate of Charles A. Dana, Esq., on the northern shore of Long Island. He has had an unusually wide experience in the various branches of gardening, and the new parks of Pittsburg are sure to be managed with intelligence and skill.

A Farmers' Bulletin on Potato Culture has just been issued by the United States Department of Agriculture, which, while not intended as a complete treatise, contains many helpful suggestions in relation to a crop which is grown in every state and territory of the Union, and which amounts in value every year to a hundred million dollars. Such questions as when to cut tubers for seed, the quantity of seed per acre, the size of the pieces, the value of mulching, and the proper methods of harvesting and storing are discussed in the pamphlet, which contains twenty-three pages and is filled with useful matter.

An effort to explain the physical geography of one of those narrow but well-defined areas to which the successful cultivation of certain classes of fruit is often confined, is found in Bulletin 109 of the Cornell Experiment Station, and entitled the Geological History of the Chautauqua Grape Belt. This region is very plainly defined, and the inquiry was undertaken to determine, if possible, the reasons for the existence of this particular belt, and to ascertain whether its limits might be profitably extended. The work has been done by Professor R. S. Tarr, of Cornell University, and it contains much interesting research, both on the soil and on the climate of the Chautauqua Grape fields, and gives reasons why they are specially adapted to all the fruits common in this latitude. Altogether, it seems to be a peculiarly favored spot, and Professor Tarr suggests that even the Tobacco plant might be profitably grown there.

In a bulletin rather more than two years ago concerning Japanese Plums in North America, Professor Bailey stated that these Plums are the most important type of fruit introduced into North America during the last quarter of a century, and deserved to be carefully tested in all parts of the country. Of course, this did not mean that the Japanese Plums were superior to the European Plums of the *Prunus domestica* type, for, wherever these will succeed, they are still more valuable, although the Japanese can be added to give a variety. The advantages of the Japanese Plums are that they are adapted to a wider range of country than the European type, and among other desirable features which they possess in various degrees are earliness, productiveness, freedom from black-knot and leaf-blight, with long-keeping quality and beauty of fruit. Several of them compare favorably with the Lombard in quality, but it must be admitted that they are generally inferior to the best European Plums.

The first California grape-fruit of this season to reach this city was sold on March 3d and comprised a car-load, or 300 boxes. Much of it was small and below the desirable sizes of fifty-four and sixty-two to a box. The best realized \$3.00 at wholesale, a few boxes containing from 150 to 200 of the fruits bringing but \$2.00 each. Nevertheless, the entire lot averaged \$6.00 a box. The color was light and the weight not heavy enough to insure first quality. Some shaddocks, from the Barbadoes, are now forced into the market; these are of irregular

form, their uninviting lemon color marked with green. Altogether pleasing are the handsome Forbidden Fruits from Jamaica; these are large, spherical, the smooth skin a rich orange-color and of oily texture. The fruit is free from bitterness and exceedingly juicy. These have realized \$7.00 to \$8.00 a box. No Tangerines or Mandarins have come from California during the past fortnight, and the season for them is nearly ended. The limited stock on hand is offered at \$3.00 to \$4.50 a box. The supply of pears for the remainder of the season is now practically controlled by one firm. Winter Nelis are offered at \$5.50 to \$6.00 a box to wholesale buyers, Easter Beurre bringing a half-dollar less, and large russet P. Barrys \$4.50 to \$5.00.

The extensive mycological herbarium of Mr. J. B. Ellis, of Newfield, New Jersey, has been purchased by the Board of Managers of the New York Botanical Garden, and will be deposited in the fire-proof museum building of the Garden which it is proposed to erect in Bronx Park. The purchase also includes a considerable portion of Mr. Ellis' library, and the collection will be brought to this city within a short time and placed in a fire-proof storage warehouse until it is finally placed in the Garden. The herbarium represents the work of nearly fifty years devotedly given by Mr. and Mrs. Ellis to the study and accumulation of Fungi from all parts of the world. It is especially rich in North American species, being very nearly complete in that regard, and containing all or nearly all the types described either by Mr. Ellis alone or in cooperation with Dr. M. C. Cooke, Mr. B. M. Everhart, Mr. E. W. Martin, Professor W. A. Kellerman, Rev. A. B. Langlois, Mr. E. D. Holway, Mr. B. L. Galloway and others. It is put up in volumes, there being some 250 volumes of published exsiccati, including all but a few of the earliest distributed sets, and more than 150 volumes of a general collection, the whole completely indexed on a card catalogue. There are also more than 100 tin cans and boxes filled with fleshy fungi. This important acquisition will make the new institution a centre of interest for students of these plants, and with the other collections already secured will make a substantial foundation for a great herbarium.

An array of vegetables, such as may be seen any Saturday morning in our large markets and first-class green-grocers' stores, presents almost as wide a range of color as a collection of flowers. Besides this diversity of color there is the delightful freshness and crispness of stems and foliage and the beauty of plump roots with clinging soil, while the whole place is pervaded with the wholesome and satisfying earthy smell which reminds one of spring in the country. Green is, of course, the prevailing color, and is seen in many shades and tints now, especially in herbs for seasoning, and salads. The fine-leaved chervil, delicately fragrant tarragon, and the more pungent mint are abundant, while curled parsley, rank-growing chives in their native sod, forced dandelion, corn salad, spinach and kale, tight bunches of perfectly grown watercress and celery, heads of curled endive, escarolle, Romaine and other lettuces, each has its particular tint, and the so-called French salad is specially noteworthy for the white midribs and pale lemon-colored blades of its leaves. Excepting Sugar corn and Lima beans, all the summer vegetables may now readily be had in abundance, although prices have advanced recently, owing to cold weather in northern Florida and the other states of the south Atlantic coast. The main supplies now come from along the coast of southern Florida. New egg-plants, small, glossy and rich purple in color; snowy white cauliflowers, in their green envelopes; choice grades of asparagus in generous-sized bunches, and long grass-green peppers, with occasional splashes of red, are heaped among masses of golden pumpkins, rusty green okra and French artichokes and the earthy brown celeriac, long light straw-colored parsnips and pale green squashes. Neatly piled heads of imported cabbage, glossy and rich purple-red, are showy beside the dull red of beets. Russet-colored mushrooms and oyster-plants, the less well-known kohlrabi, waxy green cucumbers, fresh-looking well-filled pea-pods and yellow and green string-beans are in all well-stocked offerings of vegetables. New leeks and spring onions are shown, and full-grown onions, in all sizes, in satiny skins of silver, red and yellow. There are slender stalks of bright pink rhubarb, and field tomatoes lacking summer richness of coloring. Sweet potatoes, red-jacketed Bermuda potatoes, clear white and purple turnips and the dull cream-colored rutabagas are common enough. Perhaps no one vegetable makes so decided an impression on the eye as a lot of carrots, especially when these small clear lemon-yellow roots are lighted up by a neighboring gas-jet.

The Cascade Range Forest Reservation in Danger.

THE effort now on foot to restore to the public domain for entry and sale a large proportion of the land which makes up the great Cascade Range Forest Reserve, in Oregon, will cause little surprise. We wish it could be added that it causes no apprehension. The simple truth is that it is only one more evidence that these forest areas which have been reserved by Presidential proclamation will be attacked one after the other and again and again by powerful well-organized forces of men who have a personal interest in getting possession of them. Of course, so long as there is no specific legislation for managing these reservations, no provision for punishing skin-hunters, timber-thieves or sheep-herders, the forests will be open to these and other marauders. League after league of the finest timber in the world has been wastefully chopped down or burned over; league after league of young forest growth has been girdled and trampled to death by the millions of sheep that have been pastured on national property. These wounds, bad as they were, might heal over, at least partially, in the slow process of time, but attacks like the one on the Cascade Range mean the final and total destruction of the woods and the utter defeat of the purpose of the law which made the creation of these reservations possible—the one law in all the great mass of legislation relating to our public domain which had in it any immediate promise for the future of our forests.

The assault upon this particular reservation is wanton and selfish to the last degree, and it is to be hoped that the Secretary of the Interior will stand firm and refuse to turn this area over to private use and reverse the policy of holding it as the property of the people forever. Before this Cascade Reserve was created a long and careful investigation was made by competent members of the Geological Survey and others, so that its resources and possibilities are all well known. It embraces high mountain ranges where there is a large rainfall and snowfall, just the place where a forest cover is absolutely necessary to the adequate and equable water-supply of the plains below. Only limited portions of the region are fit for agricultural use and the rugged slopes are adapted to forest growth alone. Oregon has been inhabited for fifty years, and

yet but very few settlers have made their homes within this great area, a fact which of itself proves that it is not a desirable place of habitation. Very little mining land is included in it, and although much good timber is standing there, the lumbering on the Coast Range is better, so that there is no urgent need of felling the forests of the reservation. Of course, the wandering sheep-herders who gain a subsistence by preying upon the national property are clamoring for more land to devastate, and they are especially urgent now since they have been driven northward from the forests of California, which they have laid waste. Altogether, turning over these mountain forest lands to private use will only benefit a few individuals, and of that particular class whose very occupation it is to destroy the forest and break up those beneficent conditions which, in the end, will benefit the greatest number of people for all time to come.

We are glad to see that the executive committee of the American Forestry Association adopted vigorous resolutions at its meeting on March 4th against the opening of this Cascade Reserve either in whole or in part, and that they have addressed a memorial to the Honorable Hoke Smith, Secretary of the Interior, protesting against any action that threatens the integrity of the reservation or a reversal of the policy which has created them. We are glad to see, also, that they take broader ground than that of a mere protest against a special case for special reasons. They show very plainly that the mere reservation of public lands is not a policy with any life or force in it. They recognize, also, that even if the reservations could be kept rid of trespassers, either by the army or any other force, this alone would not give them their proper place in the national economy nor establish their proper relations with the people and the people's interests. The forests must be saved where they are needed to protect and enrich the plains, but they must be saved for use. The people have a right to demand that they shall be productive, and increasingly productive wherever this is possible. Beyond question, also, the settlers in regions adjacent to the Government forests ought to be able to draw from them the supplies that will in many cases be absolutely necessary to their existence. Some of them may contain land more suitable for agriculture than for the production of timber, and a wise national policy will not fail to provide that every acre can be turned to its highest and most fruitful use. In short, all the necessary and reasonable demands of the people which do not conflict with the essential permanence of these reserved lands as forests must be fairly and frankly met.

It is very plain that not an acre of the national domain which is now in forest, whether within or without one of the reserved areas, is safe until some comprehensive scheme of administration is put into active operation. There must be some authority to decide what part of the public forests shall be held under Government control, and which shall be allowed to pass into private hands; and then some broad scheme of managing these forests which will commend itself to the enlightened public opinion of the country must be adopted and enforced. Simply shutting up and fencing in large tracts of forest is no policy at all. The ultimate policy must clearly be conservative. The forests are first of all to be protected, but they must also be judiciously worked and used. They must be carefully husbanded and their productive power preserved, but they must furnish supplies to settlers and others, and, under proper restrictions, access must be had to all the resources of the region, whether agricultural, mineral or forestal. A wise forest policy is not opposed to any legitimate right of the people in the forest. It is really the only certain way to establish and perpetuate these rights.

We cannot protest too strongly against this assault on the Cascade Reservation, but we may as well face the certainty that if this attack fails another and a more violent one will soon be organized. No reservation will be secure until all of them, together with all the national domain

which it is intended to hold in forest, are placed under a wisely regulated forest service—a service which will be for protection primarily, but never for stagnation, and always for development and use.

AN Audubon Society has lately been organized in Boston, in the hope of arousing the community to the fact that the fashion of wearing feathers means the cruel slaughter of myriads of birds and threatens the extermination of some of the most beautiful of those which inhabit the United States. Its purpose is to discourage wearing and buying for ornamental purposes the feathers of wild birds and to further the protection of our native species. The circular of the society cites as an instance of the evil it would restrain the aigrette which is now so commonly worn by ladies, and which is made from the feathers of the Egret, or Snowy Heron, the plumes being obtained by killing the mother at the time of the year when she is hatching or rearing her young, so that, in nine cases out of ten, her death causes the death of her brood. The result of this has been that the Snowy Heron, one of the most beautiful of American birds once common in the southern states, has already become exceedingly rare, and its extermination must be only a question of a short time longer unless the fashion in aigrettes changes or their use can be discouraged.

A subscription of \$1 00 and a written agreement not to purchase or encourage the use of feathers of wild birds for ornamentation entitles any one to become a member of the society, which includes among its officers some of the most distinguished men and women of the commonwealth. The objects of such a society appeal not only to lovers of nature, but to every man, woman and child interested in the prosperity of the country, for birds are the farmers' and gardeners' friends, destroying annually countless millions of insects which, without their aid, would devour the profits of the husbandman. Such a cause should have the support of all civilized men and women, and such societies should be organized in every state to carry on an active campaign against the wickedness of a fashion which destroys beauty and life to gratify human vanity in one of its lowest forms.

Miss Harriet E. Richards, Boston Society of Natural History, Berkeley Street, Boston, is the secretary of the society, to whom applications for membership should be addressed. There is no annual assessment.

New Perfumery Products.

THE perfumer's art has not until recently availed itself of chemistry or strictly chemical operations. Primary articles have been the results of enfleurage, distillation, percolations, expression, decoction or similar operations. The basis of all good perfumes is, and probably always will be, the spirituous extracts which are produced from a few flowers, mostly rose, cassie (*Acacia*), jasmine, orange, jonquil and violet.

This extract is produced by washing the pomade or grease which has absorbed the molecules of odor from the fresh flowers, the latter process being known as enfleurage. Alcohol has a greater affinity for the molecules than the grease, and hence quickly robs it of odor. It is evident, of course, that a more direct process could not be used, as alcohol applied directly to the flowers would absorb detrimental organic compounds. This extract supplies a mellow floral body to compounds or perfumes which is not otherwise obtainable. Except the rose, none of the flowers mentioned above are distilled for their essential oil. This product in the case of the rose, reduced with spirits, has an entirely different odor from the enfleuraged product, and the same may be said of any flower which it is possible to treat both ways. The simple addition of essential oils to spirits produces a compound lacking in body and richness.

With a basis of these floral extracts the skillful perfumer undertakes to produce synthetically any desired odor, add-

ing, as his experience suggests, various essential oils or infusions of roots, leaves, seeds, resins and animal matters, the latter usually to insure permanency or to bind the somewhat various scents composing the combination. These scents all vary, according to their molecular arrangement, and have such differing evaporating points that an expert can analyze a complicated perfume by simply picking out the separate primary odors as they become successively prominent in the evaporation.

The perfumer's art has been brought to great perfection in the production especially of pleasant "bouquets," and, in a minor degree, simple floral scents are made, which, with nice labels and some imagination, are enabled to pass as fair representations of the odors of popular flowers. A delicate sense of odor is a rare gift, and few persons are familiar with the true scents of the most ordinary flowers, and the ordinary consumer is not critical, requiring only that the article be fragrant pleasing and lasting. Fashions change in perfumery, and it will be noticed in any assembly that the present taste is for pronounced odors of the most offensive type.

The chemist has lately had some rare successes in synthetical work and has given the perfumer some products which simulate floral odors with fidelity. One of the newest products of chemistry is ionone, or artificial odor of violets, with which in combination the perfumer is now enabled to produce an extract of violets which not only simulates quite perfectly the odor of violets, but is of remarkable permanency and, more important, has certain striking qualities which appeal successfully to the popular taste. Very perfect extracts of violets are made from the flowers, but if pure these are very delicate and evanescent. Ionone is an interesting chemical compound produced by starting from citrol (a constituent of oil lemon). It is impossible to accurately estimate the exact limits of the new chemical products as used industrially, but as they all seem to depend somewhat on oxidation to develop the full odor, their weak point would naturally be an eventual degeneration, unlike natural products whose oxidation is extremely slow.

Another commercially valuable odor is artificial musk, Musk Baur (or, chemically, trinitroisobutol toluene), which is successfully used as a base or binder in many perfumes where its presence would not be suspected by the layman. Terpinol (Laire) is a direct product of spirit of turpentine, which in combination reproduces the odor of Lilac blossoms perfectly. The old-fashioned extract of Heliotrope of the perfumer was, at the best, a fiction, and usually unstable and unsatisfactory also from its dark color, which stained linen. The Piperonal or Heliotropine of the chemist produces, with Jasmin spirit and coumarin, an extract perfect in odor and so colorless as to be known as extract of White Heliotrope.

Coumarin is the odorous principle of Tonka Bean, Wild Vanilla, Woodruff and Sweet Grass (*Anthoxanthum odoratum*). It is now prepared synthetically and is practically used as a substitute for the natural products, largely in scenting tobacco.

Vanilla is a minor article with the perfumer, being used most largely for flavorings, but, as it seems to be associated with the trade, it may be well to note that vanilline, or artificial vanilla, has proven a commercial success, and largely replaces the seed-pod of the Orchid.

There are various other synthetical products which are in a more or less forward state, notably those which seek to replace neroli and the rose, but they are scarcely out of the experimental state. For a long time the maker of soap has been using ethers and aldehydes, which are cheap sources of such odors as oil of wintergreen, oil of bitter almonds, etc. The chemist has now classified most flower odors into a few typical sections, as the indoloid, aminoid, parafinoid, benzoloid and terpinoid, according to the molecular arrangement of the odoriferous principle. These sections do not include the great number of flowers with the honey scent, as sweet pea, honeysuckle, etc., whose molecular arrangement has not been determined with cer-

tainty. With the constant progress in organic chemistry there does not seem any reason why any desired odor should not be artificially produced.

A Botanical Journey in Texas.—III.

ALPINE is a pleasant mountain-girt town of two or three hundred Americans, and, perhaps, of as many Mexicans. It is the county seat of Brewster County. This year it was plain that the town and surrounding country had been left out in the almost universal distribution of rains over Texas, still in damp places numerous plants were in blossom. The little *Zinnia grandiflora* and taller *Berlandiera lyrata* are common, and as both species are found in Kansas they were old friends. More gladly I found here, for the first time, the rather handsome *Martynia fragrans*, Toloache of Mexicans. Growsome tales are told of its vicious nature, and Mexican girls are said to use it to rid themselves of their rivals in love, since the plant, it is claimed, produces gradual insanity and finally death to the victim who eats it.

In our journey from Alpine to Marfa we crossed in the night the highest point reached by the Southern Pacific Railway between New Orleans and San Francisco, a distance of nearly twenty-five hundred miles. That point, Paisano Pass, is 5,082 feet, and Marfa itself is 4,682 feet above the sea. Its flora, therefore, may be considered alpine in its character. It is the highest mesa that we shall find in the state. The orography of western Texas, while neither grand nor sublime, is interesting and pleasant to see. We are now about seventy-five miles from the Rio Grande, and shall not again see it until near our destination.

There is a small arroya winding around Marfa. Its sands are not even damp, but along it grow large clumps of *Fallugia*, now white with its rose-like flowers; huge *Yuccas*, so tall that their flowers cannot be reached; the handsome *Willow Catalpa* and fragrant *Acacias*. A small solitary Hackberry (*Celtis*) grows near by, even to fruiting capacity. Its leaves are thick and hard almost as a board, but still doing the tree that bears them their natural service. Care has been taken to collect specimens of Hackberry from Kansas and Missouri to western Texas and New Mexico, to learn finally, if possible, what specific differences may be made of its largely variant forms.

Near the dry watercourse I found a few living individuals of a tiny dark red-flowered *Oxalis*, which botanists hitherto appear to have failed to notice and describe. *Microrhamnus ericoides*, a queer little thorny shrub, was growing in company with *Acacias*. It was out of blossom, but well loaded with nearly ripe fruit. Another species of *Zinnia* with purplish flowers grows here with *Z. grandiflora*. It looks as if it was here for its health. The handsome *Eupatorium* is commoner here than I have seen it elsewhere; so are *Perezia Wrightii* and the little *P. nana*, the last-named species being very small, but it has learned, with the other members of the genus, to deposit the brown wool at the roots. Dr. Havard's Evening Primrose, *Oenothera Havardi*, I met here for the first time. It is a handsome small-growing species. Just at close of day its bright yellow flowers pop wide open, and almost illumine the surrounding darkness. A low-growing *Asclepias* begins to appear at Alpine. It bears large clusters of purple flowers. We shall meet it more or less often to New Mexico.

Populus Fremonti, the commonest western Cottonwood, is now often seen either in cultivation or wild. It is a smaller tree than *P. monilifera*, with smaller leaves, which are usually truncate at the base, the basal portions being destitute of serratures. The pistillate forms are now loaded with fruit, which is dropping. The copious light down attached to the seeds is a fine plaything for the wind, which scatters them everywhere to the annoyance of the people, who should plant out only staminate trees, which bear no seeds. They might easily raise such trees from cuttings of trees of that form.

Hoffmannseggia stricta is the most abundant species of

that genus over the entire alkaline region of the south-west. Its tuberous roots are collected and eaten roasted by Mexicans. It is sometimes called "Wild Potato." Mexicans call it "Camote del Raton," which being interpreted is The Rat's Potato, alluding to the wood rat of this region, which loves this root as well as the natives and eats it as readily, and unroasted. This species is becoming shy in seed-bearing, perhaps because it propagates itself by its roots as well as by its seeds, and the two methods seldom long exist harmoniously in the same plant. *Lepachys Tagetes* is common along our entire route. It grows in the driest places if it is necessary, but, like all sensible plants, preferring more favorable conditions. It is a lower and more rigid plant than its congeners, with shorter rays that are often purple. The species extends northward to Colorado, and in Kansas to the Saline River.

Riddellia tagetina is one of the most common composites from the lower Rio Grande region to Colorado, and to south-western Kansas, where I have seen the prairies of Clark County yellow with its flowers. It often assumes a rounded conical form, with its yellow flowers half-hidden among the green leaves, when it is very handsome. The large-flowered *Lepidium alyoides* is found at this station, its clustered stems, when in full bloom, often presenting a mass of white flowers a foot or more in diameter. *Tribulus maximus*, a widely distributed species growing in Cuba and Florida to Mexico and California, and northward to Colorado, and in Kansas to the thirty-ninth parallel, is very abundant in all this region. It is a prostrate plant, often spreading three to four feet, with three to five pairs of leaflets, and bearing diurnal small yellow flowers, succeeded by a bur-like fruit; hence its generic name. Its south-western congener, *T. grandiflora*, has a more limited range in the United States. It is more erect in habit, with five to seven pairs of larger leaflets and large orange-red flowers. This species is very handsome when in blossom, and is sometimes seen in cultivation.

In the lowlands, as we have come up from the Nueces River, thousands of stately *Yuccas* grow. Their wand-like stems and large lily flowers gave, as we passed them, a scene of chaste beauty not soon to be forgotten by those who from the car-windows observed them. There are few more showy native plants in cultivation or wild, in Texas, or in the country, than the golden-flowered *Columbine*, *Aquilegia chrysantha*. It is found in western Texas and extends into New Mexico. The Tree Cactus, or Cane Cactus, *Opuntia arborescens*, enjoys the dry but mild and healthful climate of the elevated plains of western Texas, and of the region northward to Colorado. The abundant and, when ripe, yellow fruit of this species makes it almost as conspicuous in late summer as its handsome purple flowers do in early summer.

Among many rare and peculiar plants of western Texas is Dry Whisky, *Mamillaria fissurata*. Mexicans know it as "Peyote." This queer Cactus is said to be a powerful intoxicant. Nature gives us so many stimulants that it almost seems that they are made for use. The common Mistletoe, *Phoradendron*, is abundant and grows to a large size on the western Cottonwood from lower down the river to New Mexico. Its stems are sometimes two or more feet long. In Texas this species, including variant forms, grows upon Hackberry, species of Elms, different Oaks, Mesquit, Ash, Osage Orange, Cottonwood and *Forstiera*. I have never seen it growing upon Apple-trees, as it does in some more eastern states. It is sometimes so voracious as to kill all limbs upon which it grows above its point of union with them. Botanists are, doubtless, in error who think that this species comes into Texas from the west; it is much more common in central and eastern than it is in western Texas. It grows in the Indian Territory, Arkansas, south-east Kansas, Missouri and eastward across the country.

Houttuynia Californica is the name of a remarkably made western plant. It is not likely to be found so far from the river as Marfa, but it is common along the Rio Grande from Texas up as far in New Mexico, at least, as Abu-

querque. On the alkaline flats near that city it is the commonest weed. The species extends also to California. It is a semi-aquatic, growing one to two or more feet tall, bearing few leaves and a close spike of small white flowers, with a bract of the same color at the base of each flower, the whole inflorescence being surrounded by an involucre of petal-like white leaves. Its nearest relative here, but a remote one, is the Lizard's-tail, *Saururus cernuus*, of our north-eastern states, a plant also found in eastern Texas and westward to the ninety-seventh meridian or near it.

La Junta, Colo.

E. A. Plank.

Juniperus communis.

THE common Juniper, the *Paria* of the European coniferous trees, grows over wide areas, especially in the north, on barren, gravelly and stony soil, almost unavailable for cultivation. In a great number of varieties, from the dwarfed, procumbent forms of the higher Alps and the extreme north, to the small but handsome trees of the lower plains, this despised but bright and cheerful plant lends a great diversity and beauty to the landscape. In most regions it is associated with purple Heather and cross-leaved Heather, *Empetrum*s growing in immense tufts, and dwarfish Birches gnarled and twisted by high winds and starved into peculiar shapes. The Blueberry, the Cranberry and other ericaceous plants abound in the beautiful glades formed by these ever-varied trees. Under its sharp branches the young seedlings of Birch and Alder find protection against the destruction of browsing cattle, and so to some extent the more valuable trees in a young state are sheltered and guarded from injury. Unlike our Red Cedar, the Common Juniper is of a bright green color, particularly during winter and spring, but there are also more or less silvery or glaucous varieties intermixed, such as the Swedish Juniper, which, after all, is a rather unattractive plant. The more common conical, irregularly pyramidal or roundish forms of a bright green color, found all over northern Europe, are, on the other hand, very beautiful. The Juniper woods offer a peculiar irregular and varied aspect. Trees of large size, twenty to thirty feet in height, form the centre of numerous irregular groups around which the younger plants in many different sizes spring up in abundance. There are always wide vistas of Heather and Blueberry, patches of Eagle Ferns, and here and there, under clumps of Birch, Alder and Hagberry (*Prunus Padus*), many kinds of Ferns and herbaceous plants.

The Juniper is the advance-guard of the forest. It appears in masses where the forest has been destroyed; it nurses the young seedlings into trees, and when the shade of other trees in due time becomes too great, it disappears, to spread over more open ground nearby. The wood of the Juniper is hard, whitish and very fragrant. Many useful things are made of it, such as tankards and drinking-cans, which are often carved in beautiful and artistic designs, wooden spoons, paper-knives, pails and vessels of many descriptions, and handles for many different utensils. The wood is valuable in many ways, strong and durable, and when burned for fuel gives off a refreshing fragrance. It is often used in gardening for poles and stakes, beautiful and very durable fences for enclosing cottage gardens and many other purposes. The fruit, a berry of bluish color, is gathered and used in the preparations of drinks and liquors, particularly for the flavoring of the non-alcoholic home-brewed ale, so common in Scandinavia, which always stands on the table of the "Stuga" in a can of Juniper wood, ready for the thirsty traveler.

Because so common, it is not esteemed at its full value as an ornamental tree, but as such it possesses qualities far superior to many of the *Arbor Vitæ*s and *Junipers* commonly grown in gardens. Unfortunately, it is not easy to establish, unless raised from the seed or cutting in a nursery and frequently transplanted. Light gravelly, sandy and stony soils, and preferably moist positions, are the best. Here it retains its more pleasing characters—freshness and

brightness of color. Its most natural, and also most pleasing, associates in the garden, as well as in the woodland, are White Birches, Spruces and plants of the *Erica* family.

Newark, N. J.

N. J. Rose.

The Dauphin Chestnut.

CHESTNUT-TREES of stately proportions and dignified expression are of such frequent occurrence throughout the eastern states that mere size does not entitle any one tree to be singled from the many, but there are others, as, for example, the great Chestnut at Dauphin, Pennsylvania (see page 115), whose surroundings, as well as their appearance, give them a claim to distinction. Dauphin is a small town on the Susquehanna, directly above the water-gap in Second Mountain, and lies between the river and mountain, with a stream, Stony Creek, running through the town. The most attractive point for the visitor is a small and now apparently abandoned farm on a shoulder of the mountain, almost overhanging the river, less than five minutes' walk from the railway-station, and little farther from the town. In what is still rather open ground stands the great Chestnut, six feet in diameter, and of unrivaled dignity, and, although one of its limbs has been blasted by a stroke of lightning, there is no other tree in the vicinity that equals it in impressiveness. The land on which it stands is high enough on the mountain-side to possess forever an unobstructed view of one of the most beautiful reaches of the Susquehanna, which has cut far into the broad lateral valleys and spreads like a lake between the Dauphin water-gap and the next upper one, four miles above. The wild shrubbery growing along Stony Creek includes *Ilex opaca*, the only place it is found in this region, and on the mountain-sides are famous Laurel thickets, but the charm of the knoll where the Chestnut stands is in its far-reaching view.

Places like this shoulder, or promontory, assert the fact that people care less for mere beauty than for many other things. The place is a rest and refreshment, and to the casual visitor suggests itself as an ideal spot for a small park or reservation, and it is only one of thousands equally beautiful scattered through the country that might now, at very slight expense, become places of recreation for each growing town.

As a general thing, the only places of recreation now to be found in central Pennsylvania, with exceptions, of course (and notably at Reading and Harrisburg), are grounds leased by or belonging to railway and trolley companies. The trolley companies well deserve their dividends, for they have made accessible to the general public many points that were either kept as private grounds, or because of their distance from towns and cities could not be reached by women and children who now visit them daily by thousands in summer.

Leaving aside the larger centres, there is hardly a town of the type represented by Dauphin that has not close at hand some special point—a spot generally valueless for agriculture—such as this abandoned farm, with its primeval Chestnut. Sometimes it is a waterfall, and these are very rare in central Pennsylvania, or it is a grove of trees, or extensive meadows, or bluffs like Chiques Rock, but there is not a town or village that does not possess one spot worth reserving for public use.

Fifty years from now, when parks and playgrounds will be as much a feature of ordinary life as the water-supply and police are at present, our present apathy in providing for the helpless members of the community will be incomprehensible; but, apart from that provision, perhaps it will also be felt that the most valuable portion of a town or village is not that possessing the most expensive architecture, but that where some elements of natural beauty may be found.

Perhaps some time the original meaning of Pennsylvania (from the Welsh "Penn," for headland), the "head woodlands"* may be recalled, and the most distinctive feature

* Hazard's *Annals of Pennsylvania*, p. 500.

Fig. 12.—The Dauphin Chestnut.—See page 114.

of our Susquehanna scenery will be looked upon as something besides an obstacle in the way of railway enterprise, and receive full appreciation of its hygienic and æsthetic value.

Hardy Shrubs for Winter Flowering in the Greenhouse.

WHERE large quantities and a variety of flowers are needed, either for cutting or greenhouse decoration, many of the early-flowering shrubs are invaluable. But to flower these successfully, most of them need to be specially prepared for the purpose. We lift ours from the borders in the spring previous, selecting healthy, shapely specimens, and put them in pots or neat tubs. Any long or straggling roots are cut back, so that a ball of good fibrous roots may be made. The pots should then be plunged in ashes or other light material to protect them from the hot, drying winds of summer. The shrubs must not be shaded, but exposed to full sunlight in order to get well-ripened wood. Due attention must also be paid to watering. Toward the end of November or beginning of December we place them in a deep frame, admitting air on all fine days. About January 1st we bring into the greenhouse, where they are to flower, about one-third of the whole number. About the 15th of January the next lot is brought in and the remainder about February 1st. A succession of bloom through February, March and April is thus provided for. The greenhouse is kept at a temperature of fifty degrees at night, with a rise of fifteen degrees by day. A list of the hardy shrubs I have found excellent for this purpose includes *Forsythia suspensa*, every branch being loaded with its beautiful golden bells; *Spiræa Thunbergii*, *S. Van Houttei*, *Deutzia gracilis* and *D. scabra*, *Amelanchier Canadensis*, *Pyrus baccata* and *P. Japonica*, *Berberis Aquifolium*, *Prunus Cerasus*, *P. Sinensis* and *P. Persica*, *Xanthorrhiza apiifolia*, *Syringa Persica*, *Ligustrum lucidum*, var. *coriaceum*, and *Daphne Cneorum*.

These should all be potted in the spring. The following may be lifted in the fall, taking care to choose those plants well set with buds: *Rhododendrons*, both the evergreen and deciduous kinds; *Andromeda Japonica* and *A. floribunda*, *Erica Tetralix*, *Vaccinium vacillans* and *Leucothoe Catesbæi*. Of this last named we have some good plants in five-inch pots along the front edge of the stage, and their dark shining leaves with racemes of cream-colored flowers, sessile in the axils, have a particularly pleasing effect. *Daphne Cneorum*, with its rosy pink, sweet-scented flowers, is also useful for the front edges of the stage.

Many other shrubs besides those I have enumerated might be used for this purpose, and we intend to try a greater variety this coming season.

After the shrubs have finished flowering we replot them, removing as much as possible of the old soil and filling in with good rich soil. They are kept in the greenhouse until spring is well advanced, when they are gradually inured to the outside and again placed in their summer quarters. I ought, perhaps, to have mentioned that where these shrubs are flowered principally for cutting, it would be necessary to pot up fresh plants each spring, and those that have flowered, instead of being reotted, should be planted out for a year or two.

Botanic Garden, Northampton, Mass.

Edward J. Canning.

Imantophyllums.

BOTANICALLY, *Imantophyllums* are *Clivias*, and all cultivated kinds, according to competent authority, should be classed as varieties of *Clivia nobilis*. For gardening purposes they are distinct enough, and may be continued under the better-known name, which was given to them as descriptive of their long leathery leaves. Their characteristics are a root-stock reduced almost to a crown, shortly stoloniferous above the ground and hidden by the sheathing bases of the leaves. These are two inches wide, from two to two and a half feet long, and distichously arranged. Apparently from the centre, but slightly along one side, rises a stout umbellate scape about eighteen inches long, bearing from twelve to twenty-six tubular orange-colored flowers. In *Imantophyllum miniatum*, which is the handsomest and best known of the earlier introductions, the petals and sepals are nearly equal in size and spreading. The flowers measure between two and three inches across and are as wide as deep. In *I. cyrtanthiflorum* the sepals are much shorter than the petals, which are about two

and a half inches long. The flowers are pendulous, tubular, and scarcely half as wide as they are long, but they are brighter and more lustrous; the lower half of the petals is white, making a pretty contrast.

It is evident that nearly all the forms we now have are crosses between these two kinds. They can scarcely be called hybrids, as competent authorities declare only one species exists. Few of them are worthy the names bestowed upon them. Some are remarkable for vigor, with little or no compensating increase in size, form or coloring. Few have varied much from the type of *I. miniatum*, or are superior from a decorative point of view. August Van Geert and *Williamsii* are the best known of these so-called hybrids. The object of the raisers of new varieties, no doubt, has been to get the good coloring of *I. cyrtanthiflorum* infused into seedlings from *I. miniatum*, retaining the erect, spreading flowers of the latter. Mr. Harris, gardener to H. H. Hunnewell, Esq., states that out of forty or more seedlings raised by him none departed from the *I. miniatum* type. Mr. Harris called my attention a few days ago to one of the finest varieties either of us had ever seen. Every good quality of *I. miniatum* was evident, with the good coloring of *I. cyrtanthiflorum*. The upper half of the segments is glowing orange-scarlet, and under sunlight quite lustrous, while the lower half, forming, as it were, a throat (for the segments are distinct, though touching), is white. The filaments and anthers are yellow. This variety was sent to Mr. Hunnewell by James Veitch & Sons, London, as number thirty-three. Mr. A. H. Fewkes, of Newton Highlands, Massachusetts, exhibited a handsome variety a few years ago at Horticultural Hall, Boston. It is a handsome kind and similar to number thirty-three. The flowers are equally as large and the coloring quite as good, but in form it is not quite as well finished.

It is practicable in the United States to bloom *Imantophyllums* twice in a season. Those in bloom now can be forced into growth in a moderate temperature, stimulated with liquid-manure, and be ready to be placed out-of-doors in June in shady quarters, with less water, to ripen. They can be forced again in September or October. A full sun treatment has been recommended, but has not proved satisfactory with us. The leaves easily burn, even in winter, and as they are remarkably persistent and produced only at intervals, such disfigurement remains for a year or more.

Acanthus mollis.

THIS plant is now in flower in the cool temperate house, and though, perhaps, it might not be called pretty, it is stately. It is, properly speaking, an herbaceous plant, and not hardy in this climate, its native home being Italy. The flowers are arranged decussately on the spike. I counted thirty-four flowers and buds on one side. *Acanthus mollis* is the plant in which Goethe first observed the dissemination of seeds by projection when on a visit to Italy. *A. mollis latifolius* is also in flower now, and of the two this is much more robust. The leaves are large and handsome and of a deep shining green. They are heart-shaped, deeply and regularly incised and toothed; like those of *A. mollis*, they are all radical, and as beautiful as Palm leaves. This variety is a native of Portugal and is also known under the name of *A. Lusitanicus*. From the leaves of this plant architects have chosen their models. Its bold and graceful appearance makes it a good subject for an isolated position in the garden or lawn. Two conditions are absolutely necessary—a deep rich soil, and, like most plants with a large amount of respiratory surface, a good supply of water. In England these plants and also *A. longifolius* are used largely in rock gardens. The imposing effect produced by their use in the rock garden at Kew, in a prominent position, is impressed on my mind. They are propagated by seeds and by division of the roots.

Botanic Garden, Northampton, Mass.

Edward J. Canning.

Succulent Plants.

AN unusually attractive show of succulents now quite fills a small house in the Missouri Botanic Gardens, and one or two species appealed to me in a new way for supplying cut flowers and winter-blooming house plants. A mass of *Cotyledon (Echeveria) metallica*, with flower-stalks three feet high, was strikingly ornamental, and this would make an attractive plant for a small conservatory or the window-garden, where these can be easily grown. And nothing could be prettier for bouquets than large panicles of the delicate white and rose flowers of *Crassula quadrifida*. They last almost indefinitely when

cut, and their character fits them to replace such flowers as the tiny blue *Statice* and the lace-like *Gypsophila paniculata*, which are invaluable for furnishing the misty, delicate veil indispensable to good flower arrangement. Besides these two succulents, others in bloom were *Kalanchoe crenata*, *Mesembryanthemum heterophyllum*, *Cotyledon clavifolia*; *C. pachyphyllum* and another *Cotyledon* that was unnamed and seemed to be between *C. stolonifera* and *C. retusa*, *C. strictiflora*, *C. agavoides*, *Aloe variegata*, which is highly decorative when in flower, and *A. macrocarpa* in bud.

Among many fine species in this very complete collection the rare *Aloe elegans*, *A. umbellatum* and *A. brachystachys*, var. minor, with spines scattered all over the under side of the leaves, were noted. A pleasing feature of this unexpectedly satisfying house was the *Nasturtiums* trained along the rafters on the southern side, all in full flower. They seemed a happy choice, having themselves a succulent look, and they were sufficiently removed from the plants beneath to prevent an unpleasant contrast between the blue-green tone prevailing here and the less agreeable yellow-green of their own foliage. With varieties of *Nasturtiums* having blue-green leaves the effect would have been perfect.

Brighton, Ill.

Fanny Copley Seavey.

The Sundews.

A COLLECTION of *Droseras*, carefully grown, are not only highly interesting on account of their carnivorous habits, but they are beautiful plants to look at. The kinds most frequently seen in our greenhouses are principally natives of the northern hemisphere; these, while very showy, cannot compare in beauty with some of the species from the Cape of Good Hope, New Zealand and Australia. The leaves of all the species are closely covered with glandular hairs, the apices of which, while the leaves are in a healthy state, are continually covered with a thick fluid which serves as a kind of tanglefoot to gnats and mosquitoes. This fluid is liable to become dried up during the heat of the day if the plants are exposed to the hot burning sun, but next morning they are as heavily coated as before. If kept in an open place, where the insects have free access to the foliage, it becomes unsightly in a short period from the enormous numbers of insects entrapped; these insects are conveyed by the sensitive hairs to the middle of the leaf, in which position they are left to decay.

Drosera dichotoma, under favorable conditions, will grow over a foot high. It is the handsomest of all the Sundews, a well-furnished plant making a gorgeous display, owing to the reflected glitter from the innumerable little globules of fluid, especially when the plants are under the electric light. There is an allied form, whether or not a distinct species I am unable to say, which has leaves divided into two primary lobes, and these again into four. It is a stronger grower than the above, with the leaves not so highly colored. Both of these plants are propagated by the roots cut up into small pieces, covered with chopped sphagnum and placed in heat where they will sprout in a few weeks. *D. Capensis* is one of the showiest of the species in which the leaves are arranged in the form of rosettes. This plant has quite a stout stem above ground, and as it persists in sending out one or more thick strong roots from this stem yearly it must be lowered in the pot as the stem elongates. *D. spatulata* forms a very showy rosette of leaves. It keeps quite dwarf; in fact, it grows almost level with the material in which it is potted. All through the summer and late into the fall the hairs are bright red in color. If kept in too hot a place they will turn green. This kind is easily raised from seed, of which each plant bears annually an abundant supply. The flowers are pink, arranged at the ends of very long stems. A good way to grow this species is to pot the seedlings into thumb-pots, using very porous soil. After they have made a few leaves they should be top-dressed with live sphagnum and a number of them plunged in a large seed pan, with gravel between the pots, and the whole finished off with moss.

Botanic Garden, Washington, D. C.

G. W. Oliver.

Cuphea strigulosa.—This is one of an attractive genus, popularly represented by the Cigar-plant, *Cuphea platycentra*. All the cultivated kinds are natives of the New World, the majority belonging to Mexico. *C. strigulosa* comes from the Andes. It forms an attractive little bush and is an interesting addition to winter-blooming greenhouse plants. Our plants were raised from seed sown last spring and planted out for the summer. The plants grew about one foot high. The branches are wiry and clothed with opposite shortly petioled, ovate leaves about an inch long. Curiously, the leaves become alternate from the point

where the flowers appear. The flowers are orange-red, pendent, in short paniced cymes, and, though never in profusion, continue all winter long. The showy part of the flower is the tubular, spurred calyx. It is slightly labiate, with a curved, pouch-like lower lip, from which an uneven lot, or bundle, of purplish filaments and anthers protrude with pleasing effect. The petals in some species of *Cuphea* are abortive, or reduced to mere points. In the species under notice they are represented by two short maroon-colored limb-like appendages, which look like the standards of a papilionaceous flower. Cuttings root easily, and, no doubt, the plant will prove useful for outdoor decoration.

Correspondence.

A Home Acre in Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—It would, perhaps, be interesting to eastern readers to know how we treated the acre of land which constitutes our home grounds. We bought this little tract in South Pasadena, California, twenty-one months ago, being attracted to it by the great Live Oaks on and about it, trees that were not started in tin cans and set out with geometrical precision, but specimens which grew from chance acorns dropped fifty or a hundred years ago. Four of these great Oaks, standing just where they ought to be, give our place its name of "Four Oaks." One of these trees is especially dear to the family Druids for having mistletoe upon it. On the border of these Oaks, and partly in their summer shade, stands our comfortable dwelling-house.

As late as the middle of April we began tree-planting, there being only one late Peach and three large Apricot trees on the acre, beside a little leafless tree some three feet high, which we could not then identify. We set out twelve budded Orange-trees, four Lemon, four Olive, a Grape-fruit and a Citron-tree, fifteen deciduous fruit-trees, a hedge of Blackberry and Raspberry plants, a large bed of Strawberries, four Guava bushes and eight Grapevines, and laid out a general kitchen garden, including a large herb bed.

The returns of the first year were something marvelous. The Strawberries bloomed a little and fruited; the red Raspberries bloomed freely and surprised us with much fruit; the Blackberries fruited quite a little in the fall and winter. The next spring the deciduous fruit-trees, after being pruned, were three and four feet across and became white with bloom, and eight to ten fruits were allowed to set and ripen on each of the Peach-trees. The Orange and Lemon trees bloomed freely, and six to twelve oranges were left to set and ripen on two Washington Navel-trees. The Olive-trees are eight and ten feet high.

The Strawberry bed proved a failure when winter rains set in, as the crowns were set too low and rotted. Subsequently plants were set in slightly elevated rows, and in four weeks one single stem bore forty-eight berries, and many stems held up twenty-five. The fruiting of the Grapevines in their second year, seventeen months from planting, surprised us also. From two Muscat vines we gathered fully two pecks of fruit. The Mission vines did nearly as well, and all of them bore a little fruit. We give our vines long pruning to grow them over a trellis for want of room to grow them in bush form, as is common in California. In limited grounds the vines are trained over a trellis and the arbor in turn becomes useful as a substitute for a lath-house. In our climate, where the atmosphere is so dry, a great many plants require lath-house protection, and space must be spared for this shelter. The Strawberry Guavas fruited heavily during the second autumn after their planting.

In the ornamental grounds a Loquat-tree has not yet fruited, but has increased its size threefold since planting, and a Russian Mulberry-tree, forty feet high, has developed from the leafless and unknown withe, three feet high, when we bought the acre. It fruited heavily, but its fruit is so much coveted by the many beautiful birds that we did not try to harvest any. Other trees thriving are a *Persea gratissima* (Alligator Pear), an *Aralia papyrifera* (Chinese Paper-tree), a *Eugenia Mitchellii* (Suribam Cherry), a *Camphora officinarum* (Camphor-tree), a *Jacaranda mimosifolia*, a *Eucalyptus ficifolia* (Red-flowering Eucalyptus), and a *Ceratonia Siliqua* (St. John's Bread-tree).

In anticipation of ripe fruit the year around, we have planted Orange and Lemon trees. These fruits are always on the tree ready for use, if allowed to remain, the old fruit getting a little dry before the new is fully ripe. We have early peaches and apricots to ripen in June, and some later varieties. One peach (Pickwick Late) ripens in the latter part of November. Necta-

ries ripen in July, and many Plums. Our Plum-trees include Kelsey Japan, Burbank and French Prune; a Bartlett Pear-tree ripens fruit in August. Strawberries can be kept in fruit the year around. Blackberries come into fruit as early as latter April, and continue until the middle of December. There were green leaves and a little bloom scattered through the row during all of last year. Red Raspberries bear two crops, the first fruit coming the latter part of April, and the second bloom starting in September, making a continuous crop, with lessened vigor in August, until January. There have been scattered bunches of delicious fruit on our row during the entire year of 1895. Black Raspberries do not thrive here; they are very dry, and we were disappointed in our one plant. Our early Grapes came into fruit in August, not as early as our neighbors', and the late varieties lasted into December.

A high wire fence was arranged about the Citrus orchard, and a flock of Plymouth Rock fowls housed there. Four movable hen-houses are located wherever fertilizer is needed, and the orchard is cultivated every month.

In our vegetable garden a pretty effect is produced by a long row of Swiss Chard next to the dark green Alfalfa. We plant Lima Beans in March, and they bear prolifically until the latter part of July, when they rest some four or six weeks, and in September come up anew from the same roots, and bear quite as well until the slight frosts about New Year's. Spring Squash-vines cut off in August will become green at once and bear a second crop, as will also Melon-vines. We plant Peas in September and October for winter use, and in February for summer use, the frost not being heavy enough to damage them. Tomato-plants may be kept over, and do well the second year. Onion and herb seeds are planted in October. The herb-bed contains Sage, Peppermint, Thyme, Dill, Summer Savory, Sweet Marjoram, Lavender, Borage and Caraway, and, with the exception of Dill, Summer Savory and Caraway, these are green the year through. We have a bed of large and small Chilis and Lettuce during all the year. Lettuce is sown in a seed-bed, and some of it is always ready to transplant. A plant transplanted in February, with bottom-heat, will more than cover the largest dinner-plate by the last of March. Asparagus is ready for use in February, and the second year our bed furnished large fine shoots into June.

We have about fifty varieties of Roses, which bloom the year around, the flowers being most perfect from March to June or July. Grass is very tedious to grow in southern California, the least bit of shade from a shrub turning it yellow. We have no grass because our front yard is shaded by the Oaks, but we cultivate Violet-lawns instead—one of Swanley (white), one of Czar and one of Giant California. The lawn of Czar Violets gives bloom the year around, and all are green. We have besides other Violet plots. Our row of Freesias is in luxuriant bloom from February until May. Chrysanthemums flower from September to January, and can be coaxed to bloom on into March.

Our Palms are small now, but thrifty. Two plants of *Phoenix reclinata*, set out soon after our arrival, are six and eight feet across; they are in the open ground. Our Kentias are potted and kept in sheltered places from wind; we have *Kentia Fosteriana*, *K. Belmoreana* and *K. Canterburyana*; also a *Scaevola elegans*, potted. A *Washingtonia filifera* and *W. sonora* are thriving in the open, and so are plants of *Erythra armata* and *E. edulis*. Under one Oak is a rockery to make an exposure for Ferns, and here seven of the native sorts are doubling the size of wild ones. But a tale of the rockery flowers would make a book.

Outside of the labor of watering, a gardener can keep one acre in fine shape by doing two days' work each week, after the kitchen garden is planted. Watering is an item in this land of perpetual summer, with rain in only four months of the year, and is a daily necessity at twilight in many parts of the garden. To one who delights in this kind of a playground, considering that the skies in daylight are blue and cloudless eight months in the year, with never a horrible thunder-shower, the labor with hose and spray is not a heavy exercise.

Lincoln Park, Calif.

Jennie Kruckeberg.

The *Aspidistra* Scale in California.

To the Editor of GARDEN AND FOREST:

Sir,—In 1869 Signoret described *Chionaspis aspidistræ*, found on *Aspidistra* in cultivation in Europe. Maskell in 1891 reported the species from *Areca Catechu* in India. Mr. E. E. Green (in litt.) has detected a variety of it in Ceylon, and has been so good as to send me specimens. This Ceylon form is found on *Mussaenda frondosa*. Finally, Mr. Craw has found

the species on leaves of *Aspidistra lurida*, from Japan, examined in the course of his quarantine work.

It was believed that the insect had not effected a landing on our shores, but now Mr. S. A. Pease, Horticultural Commissioner for San Bernardino County, California, sends me some, mixed with *Aspidistis ficus*, on *Aspidistra*, from San Bernardino. So long as this scale is confined to ornamental plants in hot-houses or gardens it is, perhaps, to be considered as of comparatively small importance; but a form found by Takahashi on Orange, at Tokio, Japan, is extremely close to it, and may even be specifically identical. This latter, which I have named *Chionaspis latus*, seems to me to be a valid species, but Mr. Hubbard, of the Department of Agriculture, for whose opinion I have great respect, believes that there is only one species concerned. Should his view be correct, we must regard *C. aspidistræ* as rather a dangerous scale. The male scales of these insects are white and tricarinate; the female scales mytiliform, reddish brown. That of *C. latus* is much broader than that of *C. aspidistræ*, but individuals of the latter are sometimes quite broad, though not so broad as *C. latus*.

According to Mr. Pease, this *Chionaspis* was brought from Japan to San Francisco two years ago on plants which were fumigated, and then sent from there to Redlands. The original plants were used there for propagation after having been dipped in kerosene emulsion to insure disinfection. The scale must, nevertheless, have come from the original stock, and this well illustrates the necessity for destroying, not merely fumigating, imported plants infested by exotic scale insects.

New Mexico Agricultural Experiment Station.

T. D. A. Cockerell.

The Forest.

Forest Protection.*—III.

"DURING the present century," says Professor Hartig, in his *Diseases of Trees*, "and especially during the last few decades, the forests of Germany have been threatened with dangers of a magnitude formerly unknown. These have been occasioned by the gradual relinquishment of natural regeneration, and by the substitution of pure even-aged woods for woods consisting of trees of different species and of various ages, but most of all by the displacement of broad-leaved trees by pure coniferous woods. It is especially noticeable that enemies from the animal and vegetable kingdoms find favorable conditions for rapid development in our modern forests, so that the complaints of increasing devastation of woods appear to be by no means unfounded."

Of late years a vigorous reaction against the former methods of forest management has been taking place in Germany under the leadership of Karl Gayer, Professor of Forestry in the University of Munich. Among the reasons urged, the greater safety of mixed forests against the attacks of both insects and fungi is conspicuous. The danger of devastation from each of these sources is great in pure forests, especially if they are composed of coniferous trees.

The attacks of fungi never reach the extensiveness of insect depredations, a most fortunate circumstance, since the means of resisting them are almost entirely indirect, and very inefficient at the best. Such remedies as exist are prophylactic and disinfectant, and the most important of them is to avoid woods of a single species and to keep the forest in general good health. Measures against insects, on the contrary, are often direct and effective, where the relatively heavy expense can be borne. I may add that owing to a copyist's error the destructiveness of insect pests was not treated in my last paper with the emphasis which it abundantly justifies.

Among the conspicuous American fungi closely allied to the European species described in the volume under discussion are those of the genus *Aecidium*, to which the Witches'-brooms and other excrescences on various species of American Firs and Pines are due. *Polyporus sulphureus*, a fungus destructive to the Oak in Europe, also attacks

* *A Manual of Forestry*, by Dr. W. Schlich, C.I.E. Vol. iv, Forest Protection, by W. R. Fisher, B.A. London: Bradbury, Agnew & Co.

Oaks in the United States, and other species of the genus have been noted in this country by Dr. Mayr. The White Pine and several of the conifers of the Pacific slope suffer from injuries inflicted by members of the genus *Trametes*. In Europe, *T. radiciperda* is the parasitical fungus most dangerous to coniferous woods, of which it destroys the roots and the lower part of the stem.

In discussing means of protection against fungal disease, Professor Hartig says: "The best prophylactic measure against the occurrence and spread of an epidemic is the formation of mixed woods. Infection, both below and above ground, is least likely to occur when every tree is isolated by being surrounded by others of a different species. On ground which is infested by root-parasites, or which contains resting-spores whose vitality is preserved for many years, it may be advisable, under certain circumstances, to abandon the cultivation of some particular species of tree."

It may fairly be asked how these matters bear upon the forest questions that confront us here. Their value, to my mind, lies very largely in the emphasis they give to the good qualities of mixed forests. If we must plant forests, a remote contingency east of the Mississippi, but an immediate necessity in many places west of it, the question of what kind of forests requires an answer. To specify the kinds of trees is by no means a solution of the problem.

Mr. Fisher's discussion of the injury done by frost is unfortunately not clear; nor has he improved upon the usefulness of Dr. Hess's description, although he has brought to the subject the results of more recent investigations. A statement of the action of frost upon the tissues of plants, on the points of which both Hartig and Prantl agree, is somewhat as follows:

As the temperature of a plant descends pure water is separated from the cell-sap and withdrawn from the interior of the cells, which lose their turgescence. (Turgescence in a plant cell occurs when the cell is sufficiently supplied with water. It is the prerequisite of growth.) The concentrated sap remains in the interior of the cells, while the water freezes in the intercellular spaces outside of them. Rapid thawing, to which the major part of all injury from freezing is due, does harm because it allows insufficient time for the reabsorption of the water through the cell-walls. Consequently it either remains between the cells, where it stagnates and eventually discolors the plant and causes its decay, or it evaporates and the plant dries up. In either case the cells lose water. On the other hand, if the amount of water withdrawn from the cells is small, or if the thawing is sufficiently slow to allow reabsorption, the plant recovers. It is in this deficiency of water in the cells that the harm done to green vegetation by freezing always lies. In frozen wood, since for the most part intercellular spaces do not occur in woody tissues, the water separates from the sap and freezes inside of the cell. The effect of severe frost may be noted in the narrower annual rings found during the years when it occurs.

Rime or hoar-frost is a very dangerous enemy to trees of all ages. The damage done by ice-storms is at times most incredible. In the southern Alleghenies I have seen trees six or eight inches in diameter broken off short, and in many places the ground so littered with branches torn off by the weight of ice that progress on foot was a difficult matter. Snow is far less harmful to old trees than rime, while hail does serious damage only to the very young.

The process by which frost lifts young seedlings from the ground is somewhat as follows: When the moisture in the surface soil freezes it expands, rises and carries with it the young roots of the seedlings imbedded in it. As the ground sinks back to its original level when the thaw comes, the numerous fibres of the roots cannot drop back into the holes from which they were drawn, and the seedling remains at the height to which it was raised by the freezing. A repetition of this process finally lifts it so far above the ground that the roots lose their hold upon it and

the young tree falls over. This may be one of the most extensive causes of damage in nurseries, where the process of replanting often becomes extremely expensive. To guard against the evil effects of low temperature and storms many ingenious protective rules are laid down, but they need not be quoted here.

A curious form of damage to young growth mentioned by Mr. Fisher is from heat reflected by the trunks of old trees standing among seedlings in early youth. I have noticed similar damage in the vicinity of trees with large shining leaves, such as the Balsam Poplar. Such facts supply still another reason, where there are already so many, for keeping the leaf-canopy uninterrupted in the forest.

The matter of protection against winds, except in so far as it regards the planting of wind-breaks, and, perhaps, occasionally the maintenance of unbroken forests on the summits of hills, has very little application in the United States at present. The means taken to guard against it nearly all require for their execution a degree of refinement in methods which is still many years in the future. The danger and injury are here, but the remedies are out of reach.

The chapter on forest fires contains much interesting material from Indian experience, especially as regards measures of protection. It is more nearly adapted to the question of fires in the United States than any other similar treatment which I have seen. Indeed, Indian experience in this matter resembles that of the United States, at least in the enormous areas devastated and the enormous interests to which the fire is destructive. As a striking instance of the divergence in the European and American points of view and scope of experience, it is curious to note in a section entitled Register of Fires that the burning of 5,675 acres in the year 1800 in the Black Forest is still thought worthy of record, as well as that of 3,300 acres in Prussia in 1857, and of 3,250 acres on the Lüneburg Heath in 1880. On the other hand, our own fires of 1881 and 1894 are also mentioned, and the great destruction in Canada in the year 1863.

In happy contrast again is the statement that the average number of fires a year in Prussia from 1860 to 1880 was but twenty-nine, and the average area burned over only 1,335 acres. Here is a condition utterly beyond us at the moment, but for which we may look and work with confident hope. Thirty years ago the attempt at protection against fire was just beginning in British India. Now it is effective over more than 24,000 square miles, and at a cost per square mile of somewhat less than \$3.00 per annum.

One of the subjects which demand most earnest investigation in this country is the natural history of forest fires. Already some material has been gathered, such as an exceedingly interesting paper by Mr. Austin Cary in the report of the Forest Commissioner of the state of Maine for 1894, and certain articles by Mr. H. B. Ayres, of Minnesota; W. W. Ashe, of North Carolina, and John Gifford, of New Jersey; but, on the whole, the vast body of information which must exist in the minds of those who know the forest best has not been adequately formulated, nor have the investigations needed to give accuracy and completeness to such a statement been undertaken. Such a field is far too promising to be long neglected.

In conclusion one sentence must be quoted, for in it lies the gist of the whole matter. Speaking of countries like India, Mr. Fisher says, "More than half the battle against forest fires is won when the protection of the forest from fires meets with sympathy from the neighboring villagers."

New York.

Gifford Pinchot.

Notes.

At the exhibition of flowers at the Farmers' Club in this city a vase of Mr. Fisher's new crimson seedling *Carnation* attracted much attention. This variety commended itself to the experts at the late meeting of the *Carnation Society* for its size, form, fragrance and other good qualities.

Vol. i., No. 1, of a little ten-page monthly entitled *Horticult-*

ture, and published at Cuyahoga Falls, Ohio, has just come to this office. It is edited by M. Crawford, and it is full of practical instruction on the cultivation of fruits, vegetables and flowers. It costs twenty-five cents a year.

The stormy weather of the past week has made dull trade in the fruit markets, and shipments, too, have been interfered with. Oranges are commanding somewhat better prices, while lemons continue so cheap as to involve heavy losses to importers. About 110,000 boxes of oranges and 320,000 boxes of lemons are now on the way from Mediterranean ports. Coconuts are abundant, some 95,000 having reached this port during last week. The supply of Cape Cod cranberries is becoming small, and some fancy berries have recently sold at wholesale for \$11.50 a barrel.

The vacancy in the Department of Botany at Cornell University, made by the resignation of Professor A. N. Prentiss, has been filled by promoting to his place Mr. George F. Atkinson, who has been Associate Professor. Assistant Professor Rowlee has been promoted to the highest grade of Assistant Professor; Mr. E. J. Durand has been appointed Instructor, and K. M. Wiegand, Assistant. Under the reorganized scheme of study, courses in comparative morphology, mycology and algology are offered by Professor Atkinson and Instructor Durand, and courses in comparative histology, systematic botany and dendrology by Professor Rowlee and Mr. Wiegand.

Mr. F. E. Emory, Agriculturist of the North Carolina Experiment Station, has just issued an interesting circular on hillside terraces—that is, a succession of comparatively level benches arranged on sloping ground to prevent the soil from washing away. All who have seen the unsightly gullies in the rolling lands of the south and who appreciate the enormous loss of plant-food which is washed away every year will recognize the importance of any device which will arrest this waste. The method of constructing these terraces is carefully explained, and the value of the practice has been proved by ten years' experience. It is a misfortune that the bulletin is printed on such poor paper that the illustrations have little value.

The frost which came in California last week after the warm weather did considerable damage to Almonds, Apricots, Cherries and Peaches in Sonoma and other counties, but the fruit prospects in the state generally are said to be unusually bright. In spite of the freezing weather at the end of the year the shipments of oranges from Southern California have paid a better average, perhaps, than ever before. Over 2,400,000 boxes have been shipped eastward, and 800,000 boxes still remain; the price offered has averaged \$3.50 a box, of which the grower gets a clear \$2.00, or \$300 an acre. As it will be some years before Florida can actively compete in this fruit, investments made in Orange groves in Southern California are likely to continue profitable.

Kaffir Corn, one of the so-called non-saccharine Sorghums, has been found to flourish well in Kansas, Oklahoma and Nebraska, where the soil warms up early and where droughts are severe. It might flourish well in the east in dry seasons if it were not planted until the soil was thoroughly warm. Fifty, and even more, bushels of seed have been grown to the acre in Kansas, and frequent tests have shown that the seed is almost equal in feeding value to Indian corn, but it is principally useful as a forage crop. Kaffir Corn, Jerusalem Corn, Milo Maize, Brown Darra are all varieties of this group of Sorghums which are especially useful on account of their drought-resisting qualities; both as forage and for the grain which they produce they have been proved to be more desirable than the so-called saccharine group of Sorghums.

Professor Taft, of the Michigan Agricultural College, says that the Peach growers in that state who have sprayed their trees with the Bordeaux mixture, in order to prevent curled leaf and rot, have found a decrease in the number of their trees attacked by the yellows. Some of these orchards, where the disease had never failed to appear in previous years, have been entirely free from it for two seasons, while its ravages have been continued in surrounding orchards. This does not prove that the disease can be prevented by using fungicides, but since it is known that the yellows is highly contagious and that it probably is spread by germs of some kind, it is possible that trees kept covered with copper sulphate are protected against it. Peach growers who spray their trees just before the buds start in spring, and once or twice after the blossoms fall, will certainly find that this treatment will pay against rot and leaf-curl, even if it fails to arrest the progress of the more dreaded yellows.

In the absence of statistics relating to forestry in this country a circular of facts and figures regarding our forest resources, just issued by Mr. B. E. Fernow, Chief of the Division of Forestry, is an interesting little document. The data given are, of course, only approximations, but they give estimates as far as practicable on such important points as the extent of our forest area, the character of the forest growth in different regions, the amount of timber standing, the annual cut and value of these products, the amount of exports and imports and the extent of losses by fire. This is followed by a brief description of the principal centres of production of the leading commercial timbers, including the White pine, the Red pine, the Bull pine (*Pinus ponderosa*), the Long-leaf pine, the Cuban pine, the Short-leaf pine, the Loblolly pine, spruce and fir, the Douglas spruce, hemlock, Bald cypress, Red cedar, redwood, oak, hickory, ash, poplar, cottonwood and other hard woods.

Not long ago two men were convicted of plundering the lanes of Devonshire, England, of the Ferns which give them such beauty. Five hundredweight of Fern roots were found in their possession as the results of former raids, and it is not difficult to imagine how the banks and hedgerows will be changed in appearance after such wholesale pillage. In speaking of this case *The Gardeners' Magazine* says that if these plants should receive proper care, so as to lighten up the gloom of some city or town room with their foliage, the case would not be so bad. But these raiders select a time when the roots are least likely to survive removal, especially after they have been carelessly stored. These spoils of shady lanes are hawked about for sale, it seems, in open barrows, and are often nothing but rootless crowns, and as they are often baked in the glare of city streets for days together, not one in a thousand will ever survive to make a good specimen. Obviously many buyers are found, however, or the trade would not exist, and yet it is said that very few nurserymen in all the country find it worth while to raise or distribute even the most beautiful varieties which have been developed from the common British Ferns.

Mr. Theodore L. Mead, of Oviedo, Florida, writes an interesting note to the *Orchid Review* on the Vitality of Pollen. He has had success in hybridizing *Laelias* and *Cattleyas* with pollen which had been kept after removal from the flowers for two weeks, and in some cases even more than a month. On other occasions he has failed with pollen that had not been kept so long, and he well says that it would be instructive if other experimenters would state how many good pods they have secured from pollen which has been kept three weeks or more, and especially if they would specify the conditions as to dryness, darkness, ventilation and the like, which seem important in keeping the pollen alive. His own method has been to put the pollen in paper packets, and these are kept in tin boxes. He has found no advantage in enclosing it in gelatine capsules or other almost air-tight coverings. Mr. Mead thinks that the pollen parent has much to do with the length of time required for ripening seed, and gives many examples which show what he considers a tendency toward a mean between the normal time for ripening seed of each parent. It must be admitted, however, that the real cause of the variation of the periods of ripening between crossed and uncrossed capsules has not been satisfactorily determined.

The stock of apples to be depended upon for the remainder of the season is smaller than usual at this time of year, not many more than 100,000 barrels being held in the entire country. Since September 1st about 650,000 barrels have come to this city, 265,000 of which were exported. The *New York Tribune* says that the export trade has been large and fairly profitable, notwithstanding that transatlantic countries, as a rule, had full crops. The foreign apples, however, were mostly early ones, which were mainly consumed before New Year's, so that a good market existed for American apples. London, Liverpool and Glasgow, as usual, were the best markets, and some satisfactory shipments were made to Paris. Not a few apples have come east from Kansas and Missouri, and some choice Pippins are now on the way from Oregon, the fruits separately wrapped in paper and packed in boxes holding a bushel. These are intended for export. Altogether, this season, 750,000 barrels of American apples have been exported, including the Canadian output. As but few more will go abroad, the total foreign shipments will fall short of last year, when 1,438,155 barrels were exported, the largest amount ever sent out of this country in a single season, excepting only 1891-92, when 1,450,336 barrels were sent to foreign markets.

John Bartram.

THE facts relating to the preservation of John Bartram's garden, detailed on another page of this issue, stand for an expression of civilization which is pregnant with possibilities. John Bartram was a Pennsylvania farmer, possessed of good understanding, remarkable powers of observation, uprightness of character, courage, a strong will and much industry. His love of plants showed him his field for doing good in the world, and made him a traveler and discoverer at a time when no other American was interested in botany. Through his friendship with Franklin he made the acquaintance of many of the most distinguished men of science in Europe, and his correspondence stimulated his activity and increased his usefulness. For many years in the eighteenth century John Bartram was the principal agent for the interchange of plants between North America and Europe, and to his efforts can be traced the introduction of many American trees into the gardens of Europe, and the planting in this country for the first time of several of the inhabitants of Old World forests. The first garden established in America for the study of plants was made by John Bartram; and his example led to the formation of the second American botanical garden, that of his cousin, Humphry Marshall, the author of the first book on American trees written by an American and published in America. John Bartram's reputation as a botanist, his admirable character and willingness to impart the information he had gathered in his long journeys, and the fame of his garden, made his home by the Schuylkill the Mecca of plant-lovers in America and gave scientific importance to Philadelphia.

John Bartram's garden, judged by the standard of our day, was a very humble one, and the plants which it contained are now all perfectly familiar to us, but, in his time, they were familiar to no one, and had been gathered slowly and laboriously at the cost of dangers and hardships which we cannot now even picture to ourselves. The city of Philadelphia might have selected within its boundaries some other site which would have been more desirable in location and natural features for a park, but in honoring the memory of John Bartram in this manner it

has done something which is of far-reaching significance. As a people we preserve and sometimes even attempt to embellish places of historic interest, buildings which are famous on account of the events which have taken place within their walls, and objects which appeal to our patriotism—the old State House in Boston, Mount Vernon, the headquarters of Washington at Newburg, the Liberty Bell and battlefields of the War of Secession; but this is the first time in this country that the memory of a man who served his country by going into the forest and gathering trees and seeds and making them grow, and then sharing his discoveries with others, has been honored with a memorial like this, which will keep Bartram's virtues and his services in the minds of men as long as Philadelphia continues to be a city.

This Bartram memorial seems to us to mean a great deal, to be full of hopefulness for the future of this country; to mean that the whole science of rural life and the love of fields and forests is really to be a part of our national life. And, if this is true, it is the evidence that men and women are going to turn to the soil for rest and recreation; that the love of Nature and of growing things, which the Bartram memorial stands for, will gradually so enlarge and broaden us that life in this country will be fuller and better and more beautiful than it has been in the past; that public sentiment, stimulated by the love and knowledge of Nature, will make it possible to preserve our forests from ruin, to maintain urban parks safe from the inroads of greed and ignorance, to prevent the destruction of beautiful scenery, and to make this wide land fruitful and attractive for all time. John Bartram served his country well in his own generation, but his life in the influence it can now be made to exert has a power for usefulness which neither he nor any of his generation could have imagined.

LAST week we spoke of certain dangers which threatened the forest reservations in the wild mountain regions of the west, but it would be a mistake to suppose that land which is set apart for public use in the older-settled portions of the country is any more safe than it is in Oregon. A plan is now on foot to take the Niagara Reservation out of the control of the Board which has managed it so wisely, and the meaning of this seems to be that certain capitalists are anxious to obtain franchises so that they can speculate on the Falls as a water-power. Even if the people were suffering because this mighty force was running to waste, that would be no reason for giving it away to any private corporation. But, so far as we can see, there is no mechanical or material necessity for destroying the grandeur and sublimity of the great cataract which is recognized as one of the wonders of the world. Its uplifting influence on the minds and imaginations of thousands of visitors certainly ought to count for something. A spectacle which enlarges and educates the mind, and opens it to noble thoughts, may be as truly a potent force in a civilized community as the electricity which the plunging river may be made to generate. We apprehend that the enlightened people of the state and of the country would feel the obliteration of Niagara as a distinct and personal loss, even if every ounce of its force were utilized to run some machine to provide for man's material wants. A community which erects immense advertising boards, to shut out or mar some refreshing prospect, and allows objects of great natural beauty to be desecrated, is plainly on the road to savagery. It certainly is no evidence of thrift or progress in its highest sense that we are willing to sacrifice all the higher emotions of our nature for purely material results. It is not an evidence of civilization that we permit the banks of our great rivers to be scarred by cuts and fills in constructing railroads, when they could have been built equally well without such an offensive exhibition. It ought to be a matter of more than local concern that the rugged battlements of the Palisades are being blasted down for paving blocks and building stones. And yet a member of Con-

gress or of the State Legislature hesitates before he introduces or votes for a bill which is simply to protect natural scenery for his own sake. He seems so fearful of being sneered at as sentimental or unpractical, that he is compelled to manufacture some excuse for doing what is plainly dictated by enlightened public policy. Before any provision can be made for protecting the Palisades, Congressmen have to be assured that they have a military or strategic importance, which, no doubt, is true. It ought to be enough for the country to know that this wall of rock is the most dignified natural spectacle near the chief maritime city of the continent. A people, entrusted with a possession like this, deserve to be stigmatized as vandals

that he bought land on the west bank of the Schuylkill and built the main portion of his house (see pp. 122 and 123), and it is the second wife's name that appears on the panel in the south gable, "John and Ann Bartram, 1731."

The land lay along a beautiful reach of the Schuylkill, between Gray's Ferry and Point Breeze; the greater portion was rolling, other portions were marshy, but Bartram irrigated, drained and improved these swampy reaches, adding more land, until he possessed upward of six hundred acres. After his death this was divided and subdivided, but throughout all changes and divisions the greater portion of the Garden remained intact, and was owned by those who were either attached to it, or interested in it, so

Fig. 13.—John Bartram's House—east front.

if they do not transmit it unimpaired as a secure inheritance to their children.

It cost years of effort to wake the people up to the point of organizing some protection for Niagara; certainly there ought to be enough public virtue left in the state to restrain the Legislature from facing about to undo one of the best pieces of work ever accomplished.

Bartram's Garden To-day.

THE near approach of the two hundredth anniversary of John Bartram's birth should arouse a widespread interest in the work now in progress at his Garden, under the auspices of the University of Pennsylvania.

John Bartram was born at Darby, Pennsylvania, on March 23d, 1699; he received his early education in that vicinity, where his body now lies. He was twice married, and it was about the time of his second marriage, in 1728,

that in its life of more than a century and a half it has suffered less change than any other portion of the estate.

The original Garden comprised about five acres, beginning on the higher ground, a short distance west of the house, and extended beyond it toward the river. All of this land is included in the tract of about twelve acres, purchased some five years ago from the Eastwick estate by the city of Philadelphia. The city now owns, but has not yet taken possession of, land adjoining on the north, and it hopes shortly to acquire more of the Eastwick property adjoining on the south. The acquisition of the Bartram property, through the instrumentality of Mr. Thomas Meehan, the press, and the generosity of public-spirited persons throughout the country, is generally known. From time to time articles have appeared in the Philadelphia papers reflecting on the management. Many of these displayed a complete misunderstanding of the character of the place and its requirements, and most of them an ignorance of

affairs, legal and financial, which needed consideration. It has seemed curious that in Philadelphia so little general interest has been shown in this unique place, for there are some repairs which should have been made earlier if means had been available. But, on the whole, delay has not been a misfortune, for it has given those best fitted for the work time and opportunity to formulate plans whose value will become apparent with time.

Suggestions for "beautifying" have been made, the very thing to avoid, for it would destroy the air of antiquity which pervades the place, and which even the suburban squalor apparent in some portions cannot destroy. One

far as present conditions permit, of restoring the house and grounds to original conditions. In labeling specimens the historic ones will have brief histories attached, in addition to botanical and popular names. Apart from association, the buildings are well worthy of preservation as examples of the constructive methods of the first half of the eighteenth century. They stand about midway in the grounds, where the higher portion ends and the slope to the Schuylkill begins, and are reached, as in Bartram's time, by a private lane that runs in from Darby Road, and which is bordered by forest trees, among them some beautiful Willow Oaks.

The lane skirts the upper part of the orchard where

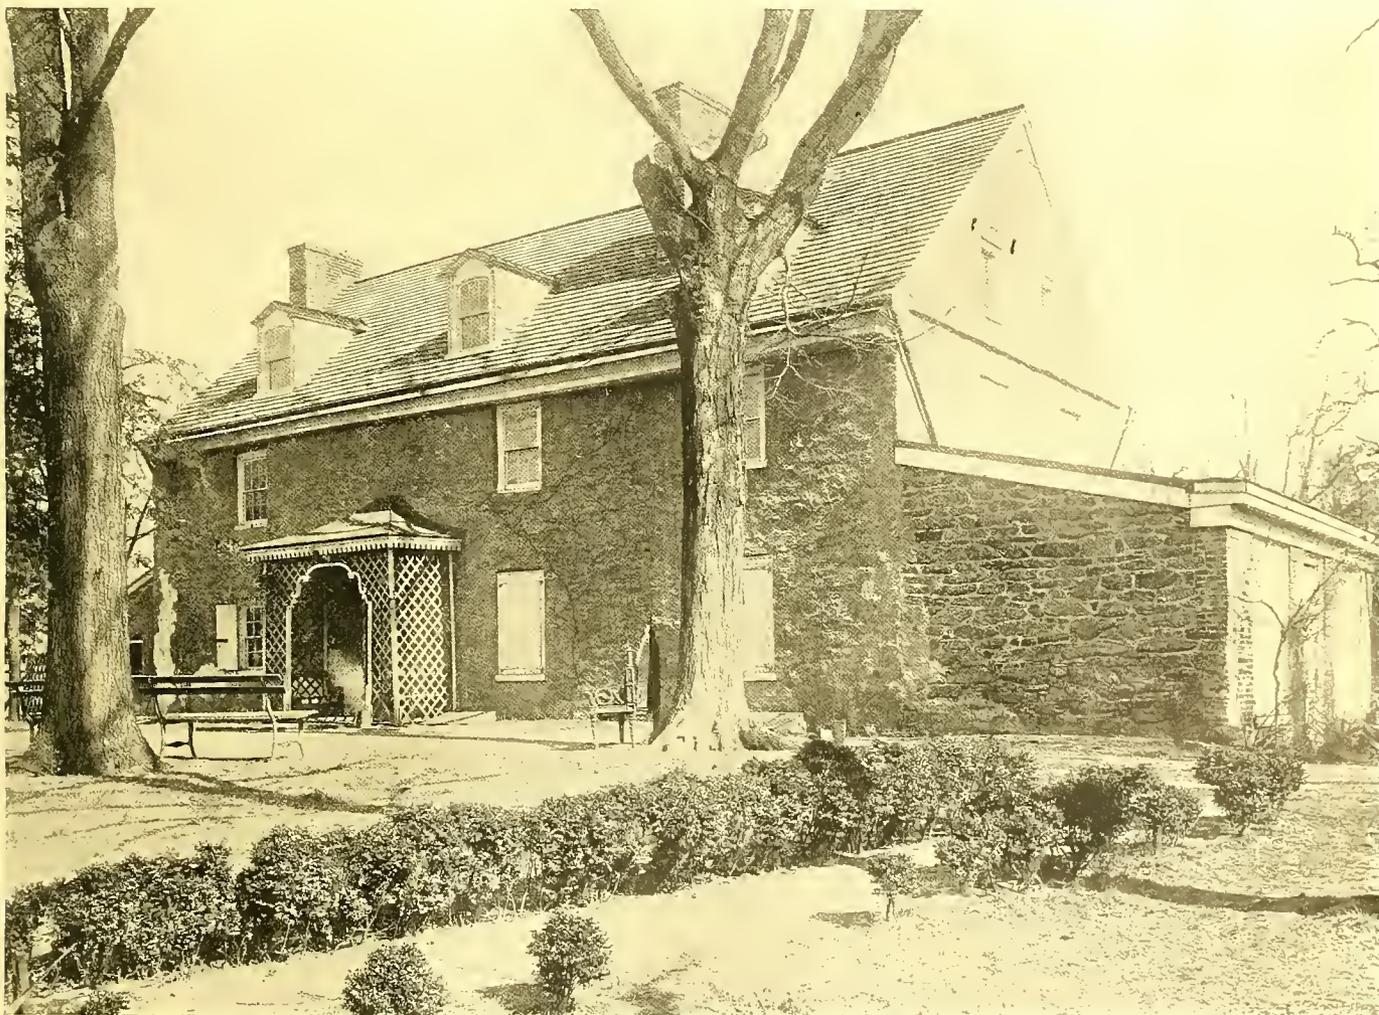

Fig. 14—John Bartram's House—west front.

enthusiast on the subject of beautifying shed abroad some quaint and curious botanical information. After stating that "the wild growth of underbrush has choked the rare shrubs that still survive, and none of these plants is still labeled so that the visitor may identify them," went on to describe one of the trees (Mossy Cup Oak, *Quercus macrocarpa*) as "a huge and spreading Oak which bears acorns with a fringed cup, the like of which no one to-day has ever seen, and whose original habitat is unknown." Besides this, there were "varieties of the British *Æsculus*, American Horsechestnut, Buckeye, Cottonwood, and several supposed to belong to the tropics, such as the Magnolia, Cypress and Chinquapin Oak." Glib ignorance of this sort will, it is hoped, be dispelled by the educational work, admirably planned by the University authorities, to follow their present practical work of retracing paths and boundaries, removing dead wood, giving crowded specimens light and air, repairing broken stonework, filling in washed-out places, and, so

Bartram experimented successfully with irrigation. Near a group of White Pines a diverging path runs diagonally from the lane across the orchard, past a fine Yew, and on to the west entrance to the house, where lane and path meet again at the doorway, after having passed through the oldest part of the Garden. Near the house they cross a railroad cut (really a picturesque feature, its rocky walls curtained with herbaceous plants and vines) that marks the site of the old kitchen garden; between this and the house was the flower garden, and portions of the beds are yet outlined by Box borders that were planted about fifty years ago.

The path is, perhaps, rather more attractive than the lane, but those who know their "Letters" will follow the lane. From its entrance into the grounds, across the bridge, past the barns and to the house-door it is like turning the pages of the earlier Collinson letters. First come the "narrow-leaved Oaks" and "noble White Pines":

close by the bridge is "that curious tree from the Jerseys" (Hackberry, *Celtis occidentalis*); near the west door a "Sugar-tree" and Horse-chestnut; the latter, perhaps, the one that Bartram believed to have been the first to blossom in America.

The house is built of heavy gray stone blocks, mortar-covered on the older western part and on the gabled ends. The front, which is of a later date, is built of still heavier blocks, and shows some attempt at ornamentation in the stone window-frames and bases and capitals of the porch columns. Still later, Bartram placed over his study window the panel with its inscription—

Tis God alone Almyty Lord
The Holy One by me adored
John Bartram 1770.

That a great part of the house is the work of Bartram's own hands we know from that letter to Jared Eliot, where he describes his method of quarrying and working stone, and says: "I had been used to split rocks to make steps, door-sills, window-frames, pig and water troughs. I have split rocks seventeen feet long and built four houses of hewn stone, split out of the rock with my own hands."

The woodwork over the porch and stone and brick addition on the south were added in this century. The western doorway was the original entrance, and through it one steps down into the house. The rooms are, with one exception, small, and are floored with the original heavy oak boards. In one of the rooms a cupboard in the wall beside the chimney is shown as the place where Bartram kept his seeds. This is doubtful, when the great quantity he kept on hand is considered, and, in spite of the thickness of the wall, this cupboard must have been a rather warm place.

The little "study" is an indisputable fact; from it one can pass out to the enclosed porch, with its stone floor, and have a good view of the grounds in front. The Box-trees planted about the house are of such enormous size that they interfere with all views, yet one would not have them destroyed. Near the upper corner of the house is the "Thorn" sent by Collinson, and near the south end is the Pear-tree of which Collinson wrote to Bartram almost a century and a half ago, "It has been thy pleasure to wait, but mine to hear of the delicious pear raised from Lady Petre's seed; but she, dear good woman, is gone to rest."

From the house to the river the land falls gradually, but directly in front of the house is a terrace, with remains of a Box-border along its outer edge, where it is upheld by a dry stone retaining-wall, pierced by two narrow flights of steps. From the terrace, paths originally led by circuitous routes through the ground and down to the river; one of them ran near the greenhouse, whose lines are still visible, a short distance from a very beautiful Yellow-wood, *Cladrastis lutea*. Further down, this path runs near the great Cypress, *Taxodium distichum* (see p. 125), brought from Delaware by Bartram, and now nine feet in diameter. Later on this path joins one along the river-bank. It is on this river-path that one finds the curious cider-press cut by Bartram in an outcropping ledge; and at the present southern boundary of the grounds there is an effective group of Beeches growing on another ledge that juts into the river.

In the southern part of the grounds are the fine Magnolias; one of them, *M. acuminata*, undoubtedly that brought from "up Susquehanna," and discovered on Bartram's journey with Conrad Weiser to the Five Nations' Council (1743). Near by grows the "Rose Bay," as they first called the Rhododendron, and a noble Mossy-cup Oak, one of the finest trees on the place.

Not many years before his death, Bartram, probably in acknowledgment of the courtesy of a life-membership presented him by the trustees forty years earlier, gave the "Philadelphia Library Company" some of his most valuable books, several of them presentation copies from the authors; among these latter is the fine edition of Dillenius' *Historia Muscorum*, of which he says, "I take this work to

be the completest of the kind that ever was wrote, for Solomon did not write of any plants lower than Hyssop, so we may conclude he knew as little of mosses as of America." It is the intention of those now in authority to collect, if possible, relics from their present owners and form a Bartram museum in one of the rooms of the house. As yet the precise lines upon which this will be formed are unknown, but a mere collection of relics will only be interesting to those who know something of Bartram's lifework. It is to be hoped that the collection will include copies of the "Letters" and the "Observations on the Inhabitants, Climate, Soil, Rivers, Productions (Animals and other matters worthy of notice) made by Mr. John Bartram in his travels from Pennsylvania to Onondago, Oswego and the Lake Ontario." Printed by J. Whiston and B. White, Fleet Street, 1751.

Then, if a collection of portraits (old engravings preferably) of Bartram's correspondents could be hung in one of the rooms, and a series of charts of his journeys arranged in chronological order, there would, no doubt, soon be an understanding and appreciation of the work of this remarkable man.

Of nearly forty correspondents, all were men of distinction in their time, and some of them for all time. His journeys began with botanical trips in his own neighborhood, grew in distance and wealth of observation, and culminated when he was nearly seventy, in the exploration of four hundred miles of the St. John's River, Florida. Out of his great but unfulfilled desire to explore the Mississippi Valley grew that idea of exploring the Missouri country, discussed immediately after the Revolutionary War, by Franklin, William Bartram and the Marshalls. This discussion and hope became almost a reality ten years afterward, when Dr. Wistar wrote to one of the Marshalls that "Mr. Jefferson and others are much interested . . . and think they can insure a thousand guineas to any one who undertakes the journey, and can bring satisfactory proof of having passed across to the South Sea. If thee can come to town and converse with Mr. Jefferson, I am confident no small matter will stop them."

Something happened, for ten years later, when the expedition started in 1803 that was to give us the Oregon country as proof of having reached the South Sea, we know it was led by Lewis and Clarke, but Jefferson's instructions to them read like extracts from Bartram's letters.

If some of this may be learned in the house where Bartram wrote and pondered it will lift the work of protection and restoration, now in progress, far above the plane of mere preservation of an historic place.

Foreign Correspondence.

London Letter.

PYCNOSTACHYS URTICIFOLIA.—Flowering specimens of this beautiful Labiate plant have lately been received at Kew from a garden in Rotherham, where they were grown from seeds imported from south Africa. The plants grew to a height of three feet in a year under greenhouse treatment and produced terminal spikes of rich blue flowers, of the same shade as the flowers of *Salvia patens*. The species was first described and figured in *The Botanical Magazine* in 1863 (t. 5365), where it is said to have been raised and flowered by Messrs. Backhouse, of York, from seeds sent by Dr. Livingstone, who collected it on Mount Zomba, near Lake Nyassa. It flowered with Messrs. Backhouse in January. It is well worthy of cultivation, and would probably thrive out-of-doors in summer. The genus is allied to *Plectranthus* and *Coleus*. *Pycnostachys urticifolia* has nettle-like green leaves, and the flower-spikes are from four to six inches long. Sir William Hooker anticipated for it great favor as a garden-plant, but it appears to have gone out of cultivation. Its reintroduction from Livingstone's country is therefore satisfactory.

PENTAPTERYGUM SERPENS.—This is a Himalayan ally of

Vaccinium which has been cultivated at Kew for the last fifteen years and has flowered every year in a greenhouse about this time of year (March). It is a beautiful plant; the arching stems, rising from a woody root-stock to a length of five feet, are partly clothed with shining, green, myrtle-like leaves and fringed for nearly their whole length with pendent tubular flowers an inch long and colored blood-red, with darker V-shaped lines. The flowers remain fresh

WELDENIA CANDIDA.—I noted this plant in 1894, soon after its introduction to Kew from Guatemala, where it occurs only on the crater of the Volcan de Agua. Since then it has improved under cultivation, and it has been in flower in a cold house along with Cape Heaths all winter. The stems, which are about nine inches long, are formed of the closely folded bases of the leaves, as in a *Crinum*, the leaf-blades forming a spreading rosette about eight inches in

Fig. 15.—Bald Cypress, *Taxodium distichum*, in Bartram's Garden.—See page 124.

upon the stems for about two months. Such a specimen as this at Kew takes about twenty years to grow, but, once acquired, it is a most valuable plant for the conservatory, practically looking after itself if only a little water be given to it now and then, and when it comes into flower it is universally admired. It can be multiplied from cuttings of the young branches. Mr. Elwes, who collected this plant in the Himalayas, found it growing upon trees with *Cœlogynes*, etc.

diameter. The flowers are developed two or three at a time from a central capitulum, each flower having a tube two inches long and a spreading limb of three ovate concave segments about an inch across; they are of the purest white, with a cluster of pale yellow anthers. The root-stock is fleshy, and during the autumn the plants are allowed to rest for about two months. The genus is monotypic and is allied to *Tradescantia*. It is propagated by division of the root-stock.

HYBRID ROCHEAS.—*Roclea jasminica* and *R. coccinea* are two well-known greenhouse plants, the former, with short crowded stems bearing small heads of erect, tubular, white jasmine-like flowers; the latter, often called *Kalosanthus*, with taller thicker stems and larger clusters of bright red flowers. These two were crossed a few years ago by a Belgian horticulturist, and the progeny were distributed by Monsieur Pynaert, of Ghent. They are now popular with some of the growers for market near London, large numbers of them being grown in the convenient "forty-eight" pot, and sold for about a shilling each when in flower. They form dense tufts of stems about nine inches high, each bearing an erect umbel of white, carmine, rose and bright red flowers. They bloom in early summer. No plants are more easily grown, a light frame or greenhouse, such as suits a *Pelargonium*, an open soil, plenty of water during the growing season and frequent stopping of the stems in the early stages being the chief of their requirements.

TECOMA SMITHII is still flowering freely here, so that plants have been in flower now for the past four months. They are single-stemmed plants, two feet high, clothed from base to top with healthy pinnate leaves and bearing at the apex a beautiful cluster of from twenty to fifty flowers, which are rich yellow, faintly tinged with red on the outside of the corolla. This is a greenhouse plant for the million. It can be grown as easily as *Chrysanthemums*, and it never fails to flower if the following directions are observed: (1) Cuttings to be struck in early spring in heat; (2) the plants must be limited to a single stem, all laterals to be removed as soon as they start; (3) when the buds show at the apex lateral shoots will push near the top, which must be removed, or they will prevent the buds from developing; (4) the plants should be kept in a cool airy house or frame from October till the flowers are over.

DAPHNE INDICA.—This is one of the choicest of greenhouse plants when it is successfully cultivated, but it has fallen into neglect because of its miffiness. I believe this is due entirely to the fact that the plants supplied by nurserymen hitherto were grafted and not grown on their own roots, *Daphne Mezereum* or *D. Pontica* being used as stocks. Messrs. Low & Co. have, however, discovered that cuttings of *D. Indica* will strike root readily if planted in small pots in a hot frame in early spring, and that plants thus rooted grow freely and flower profusely. A few plants of this *Daphne* placed about in conservatories when in flower give off a most pleasing odor. I have seen good specimens grown by setting the plants in a rich border in a sunny position in a conservatory. Several plants have survived the past three winters against a warm south wall out-of-doors at Kew. The species is a native of Japan.

PRIMULA IMPERIALIS, the Royal Primrose from the high mountains of Java, continues to thrive here in a cool house or frame. It is apparently a biennial, seedlings flowering when two years old and then perishing. Plants have been tried in various sheltered positions out-of-doors at Kew, but they have always succumbed to the first severe frost. In Cornwall, however, it can be grown out-of-doors permanently, for plants have lived in a garden at St. Austell for two winters, and the winter of 1894-5 was a record one. I believe this plant would sport freely and produce variety in color and size in places where the conditions were exceptionally favorable to its growth. It has, no doubt, considerable capabilities if placed in the hands of a clever breeder favorably situated. A *Primula* with a rosette of leaves nearly two feet across and erect spikes three feet or more high, bearing whorls of deep yellow flowers like those of *P. Japonica*, is essentially a plant to be looked after.

PERSIAN CYCLAMEN.—Growers of this plant in England have lately proved that although German growers are successful, English are even more so. Exhibits from some of our leading metropolitan cultivators of the *Cyclamen* were lately pitted against plants from the best of the German growers, and the English plants were better, both as to quality of strain and cultural excellence. I have lately

seen establishments where from ten to twenty thousand plants of this *Cyclamen* are raised annually. The seeds are sown in September and the seedlings are treated as stove plants till about the following June. By the end of the year they are bouquets a foot through of healthy leaves and from twenty to fifty expanded flowers. Two-year-old plants have been grown near Kew which measured twenty-six inches in diameter and bore a hundred and fifty expanded flowers; all this, too, in an eight-inch pot. Great improvement in the size and color of the flowers has been made in the last few years; a rich blood-crimson break being very much favored now.

SENECIO BOURGÆI.—This is a handsome winter-flowering greenhouse plant, a near ally of *Senecio cruenta*, the parent of the garden *Cineraria*, and a native of the same country—that is, the Canary Islands. Plants of it have been in flower for the past month at Kew; they are about a yard high, the leaves are pale green, the under surface clothed with soft white wool, and the petioles bear ear-like lobes, as if the leaf had attempted to be pinnatifid. The flowers are larger than those of *S. cruenta* and of a rich purple color. It is probably an annual. Breeders of *Cinerarias* may find it useful. A figure of it was published in *The Botanical Magazine* in 1853 (t. 4994) under the name of *Doronicum*, and it is there spoken very highly of as an ornamental greenhouse plant. We are indebted to the Cambridge Botanic Gardens for its introduction.

London.

Plant Notes.

CERCIDIPHYLLUM JAPONICUM.—We have lately received a photograph of one of these trees growing on the grounds of a correspondent on the banks of the Hudson, which represents a specimen some twenty-five feet high and of perfectly conical shape. The tree at this stage of its growth is certainly beautiful, and as it seems to be perfectly hardy and not subject, so far as observed in this country, to any serious disease, there is no reason why it should not take high rank among our ornamental trees. In Japan it becomes a large tree, and in moist, deep, rich soil it often attains a height of a hundred feet. Sometimes it grows with a single stem three or more feet in diameter and rising fifty feet without branches, but usually a cluster of stems unite together at the base into a stout trunk and then diverge gradually. The photograph of a tree of this kind, with a trunk circumference of twenty-one and a half feet, was reproduced in vol. vi. of this journal, page 53. When young the tree is fastigate, the branches hugging the trunk closely, with the apparent purpose of protecting it against the rays of the sun, which seem to injure it at early stages of its growth. At this early season the slender branches of the trees hereabout are plump with sap, the red-brown bark is bright, and the leaf-buds, apparently, are already beginning to swell. In fact, the *Cercidiphyllum* is among the first trees to show its leaves in spring. These are at first a bronzy red, with bright red stalks and narrow red stipules, and they present a striking appearance at this season. Neither the flowers nor fruit are conspicuous, but the foliage, which is abundant when the tree stands in rich soil, and rather thin in more sterile situations, is a dark green during summer and turns to a clear yellow in the autumn. The *Cercidiphyllum* is a valuable timber-tree in Japan, producing a wood which somewhat resembles that of the *Liriodendron*, to which it is closely allied, and the Ainos of Japan use it for canoes as the Indians of our own country once used the wood of the Tulip Poplar.

MAHERNIA VERTICILLATA.—This is a subshrub or woody perennial which has been cultivated for seventy-five years, and yet it is seen more rarely now than it was thirty or forty years ago. The bright yellow bell-shaped flowers are very pretty and abundant, and it used to be seen often drooping about vases and sometimes in hanging baskets, for it is not a compact upright grower, but rather spreads around in a straggling fashion. In Florida, where it flourishes out-of-

doors, in a single season it will creep over the ground so as to cover a space a yard across, and in a window at the north or in a cool conservatory it will bloom through the winter and spring, and it may also be flowered out-of-doors in the summer-time. After all, perhaps, the most interesting quality of this plant is its fragrance, the flowers being as sweet as Lilies-of-the-valley, so that, indeed, it takes rank with *Boronia megastigma* among the plants which are conspicuous for a distinct and pleasing odor.

Cultural Department.

Vegetable Notes.

THE weather experienced here during early and middle March has proved uncommonly severe, and the probabilities now are that the ground will not be in suitable condition for seed-sowing and planting until later than usual. We have taken advantage of recent severe weather, when there was no snow, to have manure carted or wheeled on all ground not dug in the fall. This work should on no account be left until the earth is soft, when the operation is both disagreeable and laborious. Pea-brush has recently been secured and pointed ready for use; also Bean-poles. These and other seemingly unimportant little duties performed now will materially lessen the strain when the busy season is in full swing.

Lettuces planted out in frames early in February are now well headed and ready for cutting. Plants set out in October gave us a constant supply until these came in. Later batches have recently been planted in a gentle hot-bed, while additional sowings are made fortnightly. We find no difficulty in having a constant supply of lettuce during all the winter. White-seeded Tennis Ball still proves the best all-round variety with us. A sowing of Radishes is made between the Lettuce rows. From February onward these are ready to pull before they interfere with the Lettuce. An early sowing of Carrots, of the French Horn variety, and Beets have recently been thinned out. We grow rows of Radishes between these crops, and they are ready to use before the Carrots and Beets are of much size. Our earliest batch of forcing Erfurt and Snowball Cauliflower are now in four-inch pots, and will be transferred to a gentle hot-bed about March 25th. A later sowing recently made will give us nice plants by the time they can safely be set outdoors in this latitude. Early Cabbage have just been pricked off in a frame. We have just made our first hot-bed for Cucumbers, having delayed it somewhat owing to the severe weather. This, and, indeed, all other vegetable frames, will need to be well matted up on cold nights, and careful attention must be given to watering and ventilation. This is a suitable time to make a sowing of Egg-plant and Peppers, and as greenhouse space is just now pretty well occupied, the seeds may be started in a Cucumber-frame. Parsley planted in frames last fall will now be making good growth; an occasional soaking with liquid-manure will improve it. Care should be taken at this season to use tepid water for all plants in frames. Soaking them with water of almost ice coldness drawn from a faucet outdoors chills the plants and checks growth.

Our earliest sowing of Celery is now almost large enough to prick off. We use equal portions of White Plume and Paris Golden for a first batch. We still have some good heads of Kalamazoo in the trenches outdoors, which will give us a supply until Easter. This winter has not been favorable for keeping Celery in the open, since there has been a succession of freezings, thawings and heavy precipitations. But we are more convinced than ever that it keeps best banked up where it is grown, while the flavor is vastly superior to the stored heads usually seen on the markets. Tomatoes for our main outdoor crop have just been sown. These make strong plants by the middle of May, which is quite as early as we can plant them out here with safety. An earlier batch has just been boxed off. These will be grown along and transferred to six-inch pots later in the season. By planting-out time they will have one or two bunches of fruit set on each plant, and under favorable conditions will give ripe fruit by the end of June or first week in July. The most satisfactory forcing kind we have grown this winter is Eclipse, a variety introduced by a Scotch firm of seed merchants two or three years ago. Plants in ten inch pots are carrying bunches with from six to ten fruits on each, averaging about a dozen bunches per pot. The fruit is uniform in size, fully as large as Chemin, but without the three-cornered appearance of that useful variety. Comrade, which we have grown a few pots of, gives some remarkably large bunches. Some have as many as fifteen fruits on, but the

fruit is more irregular in form than Eclipse. May's Favorite is a good forcing variety and sets well after February. It proves much better than President Cleveland. Nicholson's Hybrid as an early-winter forcer is excellent; it lacks size, however, and compares unfavorably with some other kinds after this season. Our tallest batch of plants for indoor culture are now in four-inch pots; an earlier lot is ready to transfer to fruiting-pots, and will be grown where space will permit in our cooler divisions. Artificial pollination is now unnecessary. Giving the plants a shake about the middle of a bright day will distribute the pollen. Laterals and decaying foliage must be removed each week and sufficient foliage cut away to give the fruit all the sunlight possible. The plants require copious supplies of water, and we scatter a handful of sheep-manure or Bowker's fertilizer on each pot once a week, in addition to liquid stimulants. That this treatment is appreciated the network of roots on the surface of the pots testifies. Where Mushrooms are grown wood-lice are apt to prove rather troublesome. We find that by placing a small wisp of straw in a dry corner of the bed most of them will congregate there, and they can be easily destroyed with scalding water. If not looked after they will do untold mischief to the crop. We find that home-made spawn gives us better results than English Milltraek, and gives us mushrooms two weeks ahead of the imported spawn.

Onions produce so much finer bulbs under what is sometimes called the new culture, although in reality it is a very old practice which has been adopted for the production of specimen bulbs, that even market growers find it pays to adopt it. Our seed was sown in shallow boxes about February 20th on the shelf of a cool house. In a few days these will be transferred to a frame and gradually hardened off. All varieties are improved in quality by being raised in this way and pricked out; some kinds, such as Giant Rocca, Prizetaker and Silver King, more so than others. All who have not given this mode of culture a trial should do so.

Sensitive Oxalids.

THERE are at least four species of *Oxalis* in common cultivation the leaves of which are sensitive to the touch. They are *O. (Biophytum) sensitiva*, *O. (Biophytum) dendroides*, *O. Ortgiesi* and *O. bupleurifolia*. The two varieties of *O. Biophytum* are, of course, closely related, and in appearance are pretty nearly alike, the first being the more sensitive and preferable as an ornamental plant for the conservatory or window garden. The flowers are almost stemless and produced in the heart of the pretty rosettes of leaves which terminate the branches. The leaves are pinnate, with from twelve to twenty pairs of leaflets. On being touched these leaflets close downward until those on opposite sides of the leaf-stem touch each other, just the reverse way in which the common Sensitive-plant, *Mimosa pudica*, closes its leaves when interfered with. From some cause this plant sets seeds poorly with me; although I have grown the same specimen for over ten years, it has never yet reproduced itself from seed. The upper part of the leaf is bright green, the under side of a reddish hue. It is quite an interesting plant to have in a greenhouse, as it will close its leaves on the slightest provocation. *O. dendroides* takes alarm less easily, and sometimes, especially when it is grown cool, it scarcely closes its leaves at all when touched. The reproductive qualities of this species are such that when introduced into a greenhouse it is not long in permanently establishing itself; the seeds set very freely, and it would seem as if they all germinated, for they come up in every conceivable place where it is at all possible for a plant to live. It is especially at home in the pots of other plants, and so pretty is it when growing in this way that one grudges to pull them out. Its flowers are on long stalks clear of the leaves. The rosettes are arranged in the same way as in *O. sensitiva*, and they are green on both sides. The plant does not have the same branching habit as *O. sensitiva*; the flowers of both are pinkish white. *O. Ortgiesi* is a well-known plant in our greenhouses, the whole plant, excepting the flowers, having a brownish metallic hue to it. The flowers, which are borne on long stalks, are bright yellow in color. The leaves are trifoliate, and when disturbed droop downward. The stem is of a succulent nature, and young plants are easily raised from cuttings. *O. bupleurifolia* is a dwarf shrub; it has leaves unlike any of the other four; when the plant is in a young state or in poor health the leaves are not developed at all, but, instead, there are leaf-like formations called phyllodes, which, when the plant is strong, develop trifoliate leaves at the extremities. This species has yellow flowers in the axils of the phyllodes. It is propagated from cuttings, and, apart from its sensitive nature, it is of little horticultural value.

Botanic Garden, Washington, D. C.

G. H. O.

Garden Annuals.

IT is now generally admitted that for the best and most continuous display of flowers during the whole of the summer season annual plants are essential. Perennials can be relied on for early flowers before tender annuals can be even planted out, and they will also furnish a late fall display after the advent of frost. The most approved practice, therefore, is to so combine the two that there be no intermission, and this is not difficult if a little care in selection and a little foresight in planting be exercised. We have this week made such sowings of the earliest annuals as may be deemed necessary, and at a later date, say at the end of this month, the general sowing of all such seeds as are planted each season will be made, and this will be found a good time if a hot-bed or a greenhouse be at hand to place them in after being sown. The old-time plan of sowing in a hot-bed is not to-day superseded. There is no better place to obtain the proper conditions that insure even germination and a sturdy aftergrowth than a hot-bed of moderate heat if an inch or two of earth be spread over the fermenting materials to prevent an excess of steam. This is also a good place for plunging the pots or pans, but a warm greenhouse is most generally used where it can be commanded, although it is not at all essential.

For the sowing of all seeds it is well to compound the soil in such a way that it will neither become hard on the surface so as to prevent the young cotyledons from pushing through, nor dry out too quickly. No mistake is more fatal to successful germination than allowing the soil to become dry just as the seeds are about to sprout, and to avoid this we set the pans or pots altogether in a warm place and cover them with paper until germination takes place, when they are taken out as fast as the cotyledons are well developed and set apart in a lighter position; this covering will prevent too rapid drying, will also tend to guard against extremes of temperature, and is altogether the best way to save labor in watering and get the best returns for work and care. Soil for seed-sowing must always be made light in texture as well as weight by the addition of plenty of leaf-mold, and if the compost from a spent mushroom-bed is available it is well to add at least one-third of this, sifting the whole well, and after the seeds are sown covering them with soil that has passed through a sieve with a mesh no coarser than one-eighth of an inch. A sprinkling of sand over the surface of the top will prove a good index as to state of the soil as to moisture, as it is then possible to see at a glance if water is needed. These little details may seem frivolous, but are in themselves the secret of success in getting good returns from seeds that are either slow to germinate or of weak vitality.

It may be well to name a few of the annuals that we have found to fill all the requirements for display in the garden and to be at the same time available to cut for house decoration; and it may be added here that if a plant does not produce flowers that are fit for this latter use it is hardly worth while to grow it. There are so many plants now that are good for both purposes that we have a sufficiently long list of these alone to choose from ordinarily. Zinnias we regard as indispensable to even the smallest garden; they have done more toward filling the place of the scarlet Geranium than all the other forces together; they are easily raised from seed, and give a profuse and abundant bloom for at least three months; we use the tall and dwarf strains—a double row, one of each, makes a fine effect in a long border, or if used in the mixed borders they may be planted in groups where other plants are likely to die down early in the season, as sometimes happens with early-blooming perennials, and they will cover the ground and give a bright effect just when it is most needed, during the early fall months. Good Asters are as essential as Zinnias, but we here also prefer the tall kinds with long stems, such as those known locally as Boston Market, for early use, and the new branching kinds which are admirable later. There are so many strains of Aster now on the lists that it is perplexing to know just which to select, but it is safe to add some each of the old standard kinds from the Peony and Victoria sections, for example, as these are as good as any for a display, and they also have a good length of stem.

There has been an amazing improvement of recent years in the Antirrhinums, and seed of good strains will produce flowers that would hardly be recognized as the old-time Snapdragon. They are continuous bloomers from the time they begin until after frost, and may be even taken up and put in the greenhouse for a winter crop if kept from flowering for a few weeks before lifting, when they will give a spring crop of bloom that is most acceptable. The annual Scabious are good, too, for cutting, and give a great profusion of bloom; these

may be sown outdoors when the soil is warm and will do best in this way, but a few started now will give earlier flowers.

The new Japanese Ipomœas are well worth a trial if a good strain is secured, but there are some that are inferior, and this has brought into bad repute a most interesting novelty among summer flowers, one of the best of its kind for a number of years. The flowers are of almost all shades of blue, purple, crimson, pink and many other intermediate shades, all of silkiest lustre; many of them, too, are double, and the foliage is in many cases beautifully marbled or mottled with silvery white, or golden bronze. These Morning Glories are perennials, but are better raised from seeds each year, unless some specially good variety is worth keeping over in the greenhouse. The seeds are hard-shelled and need to be scratched through the outer shell with a knife and put in water for a few hours till they swell, and if planted then they will germinate in a day or two. These plants are useful for fences, piazzas, arbors and any other place where a climber of quick growth is desired for the summer months.

The Celosias are worth trying; in fact, they have been successfully tried in some places as summer annuals in the border. We hope to make trial of them more extensively this year. Though they have generally been grown in pots, they will do much better in the open ground if strong when set out, and the season of bloom is so long as to make them specially valuable in the border. Care should be taken to save the weak seedlings, as these often carry the best plumes, the strong vigorous growers often making no plumes worth the name even in pots where root-room is restricted. Last summer I saw the new *Nemesia strumosa* splendidly in bloom in Mr. Chamberlain's garden, at Manchester, and when well grown, as these were, there are few annuals so showy for a sunny position. They have been somewhat disappointing here, but this was evidently due to a failure to understand all their necessities. The seed must be sown in pots to insure germination, they are so small.

In a dry, sandy, poor soil, which must sometimes be occupied, there are a few annuals that will do better than in richer compost; indeed, I have failed altogether to flower the scarlet *Salvia* in the ordinary border, where they never stopped to bloom, but kept on growing until frost cut them off. In dry positions, however, where the soil is poor, they will produce a blaze of color, and are not to be despised as cut bloom for house decoration. Petunias of the improved strains are also well adapted to such soil, where they grow rapidly and flower profusely, and a margin of *Portulacca* will complete a pretty effect in a spot not easy to make beautiful under other treatment. With Sweet Peas, as with Asters, it is a difficult matter to select the kinds to grow from such a long list, but, given the colors that are desired, they should be planted as soon as the frost is out of the ground and it is possible to work it conveniently. We do not like to plant in the same place year after year, but always take out the soil to the depth of at least eighteen inches, placing at the bottom of the trenches good manure, filling up to within six inches of the top and then sowing the peas. It is then possible to add a little more earth later on at staking-time, and still leave a trench to pour on water when it is needed. They are very thirsty in the flowering-time, and we leave the hose running in the trench all night, to their great delight. The annual sales of Sweet Pea seeds have come to be one of the most remarkable features of modern horticulture. They are grown by the ton in California, and no better samples are to be found. There is no excuse for foreign-grown seeds, and, indeed, we hear little of them now, compared with what we heard a few years ago. Even English novelties are now sent to California, where they are grown to secure stock for selling. The climate is well adapted to them, and their cultivation has been reduced to a profitable system. I find that other seeds grown in California as well as Sweet Peas are well acclimated, and thrive better here than those of European origin do.

South Lancaster, Mass.

E. O. Orpet.

Physianthus albens.—This is a pretty climbing *Asclepiadaceae* plant from Brazil. The common name, White Bladder-flower, is simply a translation of its botanical name. Although an old plant, and once quite common, it was not until last summer that I chanced to see it, when I was at once attracted by the large number of cutworm moths which the flowers had entrapped. For this reason it was named the Cruel-plant by the late Dr. George Thurber, of Passaic, New Jersey, who thus describes the contrivance: "The anthers are so placed that their spreading cells form a series of notches in a ring around the pistil. The insect, in putting its proboscis down for the honey, must pass it into one of these notches, and in attempting to withdraw it the end is sure to get caught

in a notch, bootjack fashion, as it were, and the more the insect pulls the more its trunk is drawn toward the end of the notch. Thus caught, the insect starves to death." The plant is quite easily propagated from cuttings. The usual plan of cultivation is to trim plants in, which have been blooming all summer, and keep them rather dry during the winter in an ordinary greenhouse. It is very effective trained to a post or trellis.

Wellesley, Mass.

Correspondence.

Shrubs which Flower in Early Spring.

To the Editor of GARDEN AND FOREST :

Sir,—Will you be kind enough to give a list of shrubs which flower very early in the spring? I have a lawn with a warm and sunny exposure, and I should like to border it with a shrubbery which will make some sort of floral display before the great mass of spring-flowering shrubs are in bloom.

Bordentown, N. J.

R. A.

[Perhaps *Chimonanthus fragrans* would survive the winter in our correspondent's latitude, though it is not reliably hardy much north of Washington. Its remarkably sweet-scented flowers appear very early. The long wands of *Jasminum nudiflorum* are covered with bright yellow flowers very early, also, but this, too, is doubtfully hardy except from Philadelphia southward. *Corylopsis pauciflora*, which was brought from Japan some years ago by Dr. Hall, is perfectly hardy. It belongs to the Witch Hazel family, and bears pale yellow flowers. *C. spicata*, a rarer shrub, is hardy in Philadelphia, and its flowers are more showy and interesting, of richer color and with an odor which reminds one of Violets. *Fothergilla Gardenii*, a native of our southern Appalachian region, is also a member of the Witch Hazel family, and, although it has been grown in English gardens for more than a century and a quarter, it is rarely seen in American gardens. It is perfectly hardy, and the flowers, which appear before the leaves at the end of all the branches, cover the plant with brush-like masses of long white stamens, which have a very curious and beautiful effect. It is a shrub of good habit all summer long. The old-fashioned Cornelian Cherry, *Cornus mascula*, with its abundant small yellow flowers, is a first-rate plant, and later in the season its cherry-like fruit is attractive. *Daphne Mezereum*, a stiff upright shrub with fragrant rose-colored flowers, should come in the list. Our native *Andromeda floribunda*, an exquisite shrub with evergreen leaves, and the Japanese *Andromeda*, a more spreading shrub with broader panicles of handsome white flowers, should both be planted. Two Chinese Bush Honeysuckles, *Lonicera fragrantissima* and *L. Standishii*, both display their odorous flowers before the leaves appear. The native Leather Wood, *Dirca palustris*, the Yellow Root, *Xanthorrhiza*, the fragrant Sumach, *Rhus aromatica*, all have inconspicuous flowers which appear very early, and the last two are useful for connecting the turf on the borders with the taller plants in the rear of the shrubbery. Some of the Currants, like *Ribes saxatile*, *R. alpinum* and the native *R. aureum*, have handsome and fragrant flowers. The little Heath, *Erica carnea*, rarely more than a foot high in this latitude, is very interesting in early spring on rockwork, and, of course, if there is a place for the Mayflower, *Epigaea repens*, this should not be neglected. Some of the bush Cherries, like *Prunus tomentosa*, *P. Davidiana*, and the Sweet Almond, *P. Amygdalus*, are very desirable, and they will be still in bloom when *Spiræa Thunbergii* opens its profusion of pure white flowers and the Forsythias are in the full splendor of their bloom. For full descriptions of all these shrubs and for figures of several of them we must refer to back volumes of GARDEN AND FOREST.

A place like one of the small openings in the Ramble of Central Park, if bordered with shrubs of this sort, might be made especially attractive. Into the border some of the Hazels and other plants with conspicuous catkins could be admitted, and behind the border would be a suitable place

for early-flowering trees, among which the Swamp Maple and the Red Bud and tall shrubs, like our Spice Wood, could be made prominent. Shrubs, like *Magnolia stellata*, with very showy bloom, perhaps, might be discarded from a quiet nook like this, and even Forsythias might be too glowing in color. But, certainly, such a lawn would be most interesting just after winter has relaxed its hold. —Ed.]

Recent Publications.

The Spraying of Plants. By E. G. Lodeman, Instructor in Horticulture in Cornell University. With a preface by B. T. Galloway, Chief of the Division of Vegetable Pathology, United States Department of Agriculture. New York: Macmillan & Co.

The literature of horticulture must more and more from this time on fall into the hands of professional men and students. There is so much of science attached to the art of horticulture, so much detail, such an accumulation of experimental facts and methods, that it is now beyond the powers of the layman to digest and collate these stores. The coming literature may not be in all respects better than the old, but it will be different in type, and it will certainly gain in freedom of treatment and in the breadth of its mission, and it will be freer from provincialism and dogmatism and hereditary errors. Mr. Lodeman's book on spraying is a noteworthy illustration of the modern horticultural treatise. Ten years ago spraying against insects and fungi was practically unknown as an important, or as even an accredited, operation, and yet here is a volume of four hundred pages devoted to the subject. All the practice has been developed since Downing, Barry and Thomas and other authorities wrote or revised their books, and the special literature on the subject is now so extensive that only a specialist can master and classify it for use. Two hundred and thirty closely printed pages are given to the history and principles of spraying, in which the gradual advancement of our knowledge is set forth, together with the principles which underlie the practice. The remainder of the book is taken up with specific directions for the spraying of cultivated plants, with descriptions of the most important insects and fungous diseases affecting them and the method of treating each. Mr. Lodeman has gathered the results of an immense amount of experiments, both in Europe and America, and his book can be trusted, not only as a manual of practice, but as a true and well-classified record of our knowledge on this subject at the present time.

We have received the interesting *Hand List of Orchids Cultivated at Kew*, and find it a very useful little manual for all who have to deal with these plants. The brief preface contains many interesting historical facts in relation to the growth of the collection there, and the list comprises nearly two thousand species and garden hybrids. Wherever possible there is a reference made to a figure, and as the list is only printed on one side of the leaf there is abundant room for annotations. There are many collections where Orchids which bear the fashionable and popular flowers are more largely represented than they are at Kew, but this one is particularly strong in the so-called botanical Orchids, which are absolutely essential to the student who wishes to gain a complete knowledge of the family. Of course, dried specimens of the botanical Orchids can be had in herbaria, but a living plant is better for purposes of study than a dead one, and it is by an examination of living plants alone that we can observe the contrivances for cross-fertilization which so interested Darwin and many other naturalists.

Notes.

One of the most striking features in some of the florists' windows now are exceptionally long and full-flowered spikes of *Gladiolus*, probably the variety Shakespeare. The large flowers are white, with light stripes of carmine or rose color

at the base of the petals. Trailing *Arbutus* is also becoming quite abundant. The greater proportion of it now comes from North Carolina.

According to a correspondent of *The Gardeners' Chronicle*, the most interesting collection of *Coleus* ever made has been on exhibition this year at the Royal Botanic Garden, in Portici, Italy. The plants are of the most varied dimensions, from dwarf forms a foot high to the gigantic varieties six feet in height, with branches covering a circle ten feet in circumference and stems five inches in girth. The leaves of some of the plants are as much as eighteen inches long and thirteen inches wide, and they have broken into a wonderful variety of colors.

At the recent Fruit-Growers' meeting at Worcester, Massachusetts, complaint was made that the Japanese Plums were short-lived and not hardy, and that the cold this winter had killed all the fruit-buds and many of the limbs on some of the trees. To this it was replied by Mr. Hale that when these Plums were first sent out they were budded on Peach stocks, and this may be a reason for their lack of hardiness and their liability to disease. Nevertheless, it is not wise to plant these Plums very largely in central and northern New England until more thorough tests of their value have been made.

In a list of 106 varieties of Sweet Peas tested at the Cornell Experiment Station last year the few classified as "very good" are said to have some superlative merit—that is, they are better in some points than those which have attained the accepted standard of excellence in the modern improved Sweet Pea. The varieties in this list are these: Adonis, Apple-blossom, Blanche Ferry, Boreatton, Butterfly, Captain of the Blues, Cardinal Wolsey, Countess of Radnor, Duchess of Marlborough, Emily Henderson, Empress of India, Improved Painted Lady, Isa Eckford, Lemon Queen, Mrs. Gladstone, Tangier Scarlet.

The prices of California oranges have advanced somewhat with the greater scarcity of the West India fruit, and Navel oranges from the Pacific coast sell readily for \$3.00 to \$4.00 a box at wholesale, seedlings commanding \$2.50 to \$3.25. Jamaica oranges bring \$9.00 to \$10.00 a barrel, repacked, and the few now coming from Havana sell for \$5.00 to \$6.00 a barrel, in original packages. Of oranges from the Mediterranean, Catanias now bring \$3.00 to \$3.50 a box, and Valencias \$4.75 to \$6.00 a case. The stock of California Navel oranges, it is estimated, will be exhausted by about the middle of April. A small lot of Florida oranges which arrived here the latter part of last week sold for \$5.00 to \$6.00 a box.

In the new Hand List of Orchids, published at Kew, after some preparatory statement as to the modern practice of cultivating these plants, the writer adds that after all a considerable number of species submit to horticultural conditions with great reluctance. Among these are *Cattleya citrina*, *Dendrobium Maccarthiæ* and many species of *Oncidium*. That the proper method of cultivating these plants will be discovered in the future there is little doubt, since species which are generally difficult prove amenable to treatment in special cases, as, for example, *Diacrium bicornutum* is generally found intractable, and yet it is grown at Kew with little trouble, while it seems impossible to grow *Disa grandiflora* there with anything like the success attending its cultivation in Edinburgh and Chatsworth.

The Gardeners' Chronicle gives a picture of a new hybrid *Rhododendron* which has been raised at Veitch's Chelsea Nurseries and named Eos (The Dawn), perhaps because it is the forerunner of a new race of warm greenhouse *Rhododendrons*. It differs from the beautiful race obtained by crossing *Rhododendron Javanicum* upon *R. jasminiflorum* in the bright carmine and scarlet color of its flowers, as well as in their form, their profusion and their persistency, since they last from three to four weeks in perfection. The pollen parent is *R. Malayanum*, a species widely distributed over Malaysia. Besides the three species already named, the new hybrid has among its ancestors on the female side *R. Lobbi*. From the table of its pedigree given, it appears that besides the four species named, there are four hybrids among its progenitors, and since all these plants are in cultivation, an interesting opportunity is offered to trace the influence of each in the successive crossings.

A bulletin on *Chrysanthemum* from the Cornell Experiment Station is interesting, not so much from its choice of varieties among the older sorts or its test of novelties as it is for certain suggestions for reformation in classification, nomenclature and the like. Everybody agrees that no flower should receive a vulgar or a bombastic name, and the naming of plants after Mrs. Judge This or Field Marshal That should be

discontinued. Particularly interesting is the study of variation in the forms of florets and some attempt to get rid of the confusion in catalogues about the way they are described. For example, it is important to know whether these florets of a given variety are ligulate or whether their margins are incurved, because single, intense, vivid colors are best displayed by a ligulate floret. In the variety *Crimsona* the general effect is red, but in *Miss Helyett*, which is of a similar shade, the margins are turned in so as to show the under side, and this produces a different effect altogether. There is an interesting discussion on problems of color, with notes about cultivation, and, altogether, the pamphlet is a neat monograph, which, while it contains nothing that is new, will encourage observation and study on the part of growers and lovers of these flowers.

The efforts of Secretary Morton to stop the shameful waste of money in the distribution of seeds have been brought to naught by a joint resolution of Congress which directed him to go on, as in former years, and spend \$150,000 for the purchase and distribution of seeds, bulbs, plants and cuttings through the various members of Congress. In accordance with this, Secretary Morton has sent out a circular to seedsmen, giving directions about putting up the seeds, which must be true to name and up to a certain standard of purity and germination, and free from smut, ergot, eggs and larvæ of insects, and seeds of certain specified weeds. The seeds will altogether weigh some 300 tons, and they are then to be divided among the members of the House and Senate into 450 separate packages. A few of the items are 1,300,000 packets of Lettuce, 130 packets to the pound; 1,200,000 packets of Radish, 60 packets to the pound; 1,040,000 packets of Beets, 400,000 packets of Cucumbers, 460,000 packets of Tomatoes, 320,000 packets of Garden Peas, 1,000,000 packets of flower seed of not less than seventy-five choice varieties, averaging 300 packets to the pound, with full cultural directions and description of growth to accompany each variety. The joint resolution became a law without the President's signature so late in March that it was not possible to undertake the dissemination of certain kinds of seed. The list selected includes such kinds only as could probably be purchased and distributed in time for planting throughout the country. With each item a percentage of purity and germination is given, and the seed will be tested by some employee of the Division of Botany in the Department of Agriculture, and Secretary Morton reserves the right to reject any lot which falls below the standard.

The cost of the seed is but an inconsiderable fraction of the cost of a vegetable garden, but the quality of the seed is a matter of too great importance to be neglected. It may look bright and plump and yet be worth little for planting. As a rule, our seedsmen are as particular as other tradesmen, but, after all, the planter is too often disappointed in his seed. In older countries legal restrictions have been thrown around this business, and in Germany alone there are forty seed-control stations, and many more in other European countries, and the quality of seed is said to have improved steadily since these stations were established. In order to obtain a clear idea of the actual condition of the garden seeds sold in Rhode Island, the Experiment Station of that state made some careful studies on the subject last year, and the report of the tests made appears in a bulletin just issued. A standard variety of each of thirteen common vegetables was selected and a sample of each was bought of nineteen different dealers in March last. The seed was generally clean and there was no indication that impurities had been intentionally introduced. In nearly two-thirds of the samples these impurities amounted to no more than one per cent. The seeds were then subjected to sprouting tests to ascertain their germinating power. In sixty-four out of 233 samples only five per cent. or less of dead seed was found, but in twenty-three others half of the seeds failed to germinate, and in twenty, three-fourths of the seeds were useless. This shows that some seeds are much better than others, and the buyer has no means of knowing the quality of the article he is getting, while the dealer who sells seeds of standard vitality and purity gets no advantage in price over his careless or conscienceless competitor who sells seed which is comparatively worthless. In several of our states the quality of commercial fertilizers is tested, and buyers now are more likely to secure the worth of their money in plant-food than they were before chemical manures were subject to inspection. Honest manufacturers, too, get the benefit of a state guarantee. It seems possible that some official guarantee of the quality of vegetable seeds could be devised which would protect the buyer and the careful seedsman in the same way.

to have flowed in midsummer at least twenty-five miles lower than it does at present, being now dry almost to its source, 8,500 feet above the sea-level. Living springs once abounded on the ranches in the White River valley, which now all run dry in midsummer. There is hope for those who desire the preservation of the Sierra forests in the fact that the valley rancher detests the sheep-herder, whom he regards as a foreigner and a parasite, who intends to return sooner or later to France, or Portugal or Ireland, carrying with him his gains pilfered through sheep-raising on land not his own.

The condition of the woods on the reservation was often such as to cause Professor Dudley the greatest concern. Fires some time in the past have swept over a large part of it; not an old Sequoia has escaped fire, and most of the Pines and Firs bear evidences of the ravages of the flames. In the region south of Nelson's Fork of the Tule River the number of overripe or decayed Fir-trees is enormous, and these trees, dying apparently from old age, in falling are carrying down young trees and furnishing the best possible material for destructive forest fires. Professor Dudley was everywhere reminded of the lamentable contrast between America and Germany. The latter has forest schools and trained foresters, who cull out the ripe timber, remove and sell it for the Government. In America, whose forests are unexcelled in variety, beauty or value, we have no efficient system for preventing their destruction by fire, no schools for training a class of men to husband and develop the enormous forest resources of which we are the spendthrift heirs.

As a relief from this gloomy picture it is pleasant to learn from the testimony of ranchers and hunters that last summer there were probably not more than a third as many sheep in the Sierra Reservation as had invaded it the previous year, a decrease accounted for by the presence of the United States soldiers in the adjacent Yosemite National Park, which had alarmed sheep-herders and scattered their flocks.

In concluding his address Professor Dudley called the attention of the club to the fact that there are still large tracts of Redwood-trees standing in the coast-range region of California, and urged the establishment by the Government on unsurveyed lands of a Redwood reservation. This should be done, and done speedily, as we have more than once insisted. The Redwood is only inferior in size and interest to the Sierra Sequoia. Its value as a timber-tree and its accessibility doom it to destruction, and if the demand for Redwood lumber increases in the future as it has in the past, another generation will see the destruction of these peerless forests. The Redwood grows only on the California coast-ranges, and unless the Government will create a Redwood reservation, as it has a Sequoia reservation, the majestic trees which have been growing for two or three millenniums will be swept away forever.

We commend a careful study of this number of the Sierra Club's bulletin to all who are interested in the national forests and in the welfare of California. The address of the Secretary, Mr. Elliott McAllister, from whom probably copies can be obtained, is Academy of Sciences Building, San Francisco.

It is an unpleasant truth that, in spite of all that has been written and said on the necessity of forest protection in this country, the great mass of people still need to be instructed on this point, and since no comprehensive and efficient forest policy can even be devised without a more cultivated public sentiment, and since the best of laws would fail to be enforced without the quickening of the public conscience, every effort to arouse interest and disseminate knowledge on the general subject of forests, their uses and their management, is an occasion for gratitude as well as encouragement. We, therefore, commend, as an example to similar bodies, the action of the New Jersey State Federation of Women's Clubs at its recent meeting in Trenton. A prominent place in the programme was given to an

address on the "Forest Interests of New Jersey" by Mrs. Edward D. McCarthy, of Plainfield, who explained in a clear way the different forest conditions which prevail among the mountains in the northern part of the state, in the Pine plains of the south and on the shifting sands of the seashore, together with descriptions of the special beauties and uses of the woods of each region; and then gave convincing reasons for the adoption of a conservative forest policy in each. The history of the steady growth of sentiment in favor of good forestry throughout the country was graphically sketched, and then practical ways were pointed out in which women could reinforce the propaganda. Work was suggested through schools, libraries and public discussions; by offering prizes to school children, and having in every district exhibits of maps and photographs illustrating the results of wanton forest destruction and scientific forest management; by joining forestry associations; as clubs and classes by taking up a systematic study of the forest in its economical aspect, and, more than all, by the cultivation of a sympathetic love of trees and of natural beauty and order out of which will grow village improvement societies with forestry committees and the like. There is no doubt that Mrs. McCarthy was justified in the statement that if the women of New Jersey took hold of this matter in earnest, "within a year a State Forest Commission would be organized, a radical and practical fire policy would be so enforced throughout the state as to save the remnants of our forests, and courses of instruction would be founded which would teach us to value them and use them aright."

In connection with this address, and illustrating it, was an admirable exhibition in an adjoining chamber. This consisted of a series of maps, showing the forest reservations in the west and the forest area of New Jersey; large photographic views of the Palisades, in which nature and nature's defacement were contrasted; views to show the desolation wrought in various parts of the country by criminally careless methods of lumbering; pictures of the expensive engineering work in southern France, made necessary by stripping the mountains of their forest cover. Besides these, pictures of noteworthy trees and attractive landscapes and the instructive leaf charts of Grace Anna Lewis were disposed in an artistic way about the walls, while on the tables were pamphlets on tree-planting, forestry and village improvement, sample copies of periodicals devoted to forestry, a sheet for the registration of names of all who wished to enroll themselves as taking an interest in the subject, and a circular for distribution containing a brief list of books relating to forestry, village improvement and rural life. The arrangement of this exhibit was so effective that it seemed a pity that it must be transient, and the suggestion that every library and schoolroom should have something of this kind as a general help in the education of public sentiment was felt by all who saw it.

What Would be Fair Must First be Fit.

A CONSTANTLY increasing number of Americans are desirous of securing some measure of beauty in the surroundings of their every-day lives. These people are not content with things as they are. They want more and more of pleasantness in and around their own houses and about their village, town or city as well.

To these earnest and inquiring people come a numerous company of writers and would-be missionaries, who, however, preach strangely differing gospels. First to appear are the gentlemanly agents of the commercial nurserymen. These bring many books of pictures of more or less lovely and rare plants, shrubs and trees, and say, "Look, you can make your surroundings beautiful if you will plant some of these interesting and lovely things. You ought to screen that ugly fence with Roses, scatter 'specimen ornamentals' about your grounds and put a bed of Cannas before your door." Next come the more pretentious

landscape-gardeners, who prescribe curves for paths and other approaches as being more "natural" than straight lines, and then propose plantations to fit or account for the curves. These gentry talk much about Nature and affect to consider formal treatment of ground and planting a sort of profanation. They are of many schools, for some will urge the planting of Purple Beeches, Blue Spruces and all manner of exotics, while others say, "You will do well to use few but wild native shrubs. What can be lovelier than this wayside group of Red Cedar, Bayberry and Wild Rose?" Thirdly, come the modern American architects, whose technical training has been acquired at the Parisian Ecole des Beaux Arts. These hold up their hands in holy horror at the landscape-gardeners of all schools, and say to the inquiring public, "Let us show you how wrong these men are! What you really need to make your surroundings beautiful are straight avenues, terraces and balustrades, a 'rampe douce' at your door and a sun-dial in an old-fashioned garden."

This is no fanciful picture of the strange conflict of modern doctrine concerning beauty in the surroundings of daily life. It is no wonder that the inquiring public is bewildered. Controversial papers and books are continually appearing. Bad language is employed by all parties, but the modern architects appear to be decidedly the most skilled in its use. Such adjectives as asinine, silly and ridiculous are not uncommon in the writings of Messrs. Blomfield, Thomas and Seddings, who, however, are English and not American controversialists.

How absurd all this quarreling seems when once a moment can be obtained for sober reflection. Is beauty, as a matter of fact, often won by following shifting fads or fashions, by heaping up decorations, by gathering architectural or botanical specimens, however remarkable or even lovely? On the contrary, it is by wrong-headed attempts to win beauty in these impossible ways that the ignorant rich and their imitators so often succeed in putting pretentious ugliness in place of simple loveliness and charm; witness the greater part of Newport and many another once pleasing region now sophisticated and destroyed.

Little or no thought being given to the fundamental arrangement of lands and buildings for convenience and beauty, an attempt is often made to retrieve the situation by adding decorations, such as statues, fountains and bridges, or, more generally, a selection from the marvelous products of modern nursery gardens. In those rarer cases where some real attention is devoted to the all-important fundamental arrangement, the design is apt to be strictly limited by the supposed requirements of the particular style of treatment which may be selected. The picturesque, the gardenesque and the formal styles are soberly discussed; but selection is apt to be made according to fancy merely, and the results, as in the first-mentioned class of cases, are generally amusing or striking rather than beautiful. A house scene filled with irrationally curved paths is seldom lovelier than one which is decked with a collection of contrasting specimens. A private country house approached by an unnecessary triple avenue and fitted with steps and terraces broad enough for a state capitol is equally amusing in its way.

The cause of the failure to attain to beauty in these and all similar cases is doubtless the same; it is (is it not?) the common lack of rationality at the foundation.

How is it that so much of the natural scenery of the world is beautiful and that so many myriad kinds of living things are lovely? The fact may not be explicable, but "it is one of the commonplaces of science that the form which every vital product takes has been shaped for it by natural selection through a million ages, with a view to its use, advantage or convenience, and that beauty has resulted from that evolution."

How is it that so much of the humanized landscape of the world is lovely? Is not the same natural law at work here also? The generations who by their arduous labor made

the scenery of Italy, England and the valleys of New England what each is to-day

wrought with a sad sincerity,
Themselves from God they could not free,
They builded better than they knew,
The conscious (earth) to beauty grew.

In New England, for example, the hard-worked men of the last century cleared and smoothed the intervalles, left fringes of trees along the streams and hanging woods on the steep hillsides, gathered their simple houses into villages and planted Elms beside them, for "use, advantage and convenience" merely, and yet beauty is the result. Truly,

this is an art
Which does mend nature, change it rather;
But the art itself is nature.

The moral to be taken to heart by the sophisticated and self-conscious seekers after beauty in our present day is obvious. Success in achieving the beautiful is to be hoped for only when we bow to the law of nature and follow in the appointed way. Special purpose is the root, and fitness for purpose the main stem, of the plant of which beauty is the flower. As William Wyndham wrote to Humphrey Repton, "lands should be laid out solely with a view to their uses and enjoyment in real life. Conformity to these purposes is the one foundation of their true beauty."

Thus, the right planning of the arrangement of lands for private country-seats or suburban houses, for public squares, playgrounds or parks, for villages or for cities, is not a question of "the gardenesque" or "the picturesque," "the artificial" or "the natural," "the symmetrical," or "the unsymmetrical." Whoever, regardless of circumstances, insists upon any particular style or mode of arranging land and its accompanying landscape, is most certainly a quack. He has overlooked the important basal fact that, although beauty does not consist in fitness, nevertheless all that would be fair must first be fit. True art is expressive before it is beautiful; at its highest it is still the adornment of a service.

The modern practitioners of renaissance architecture need especially to be reminded that they have not a monopoly of the lovely. "Symmetry is beautiful, but so, also, is the unsymmetrical relation of the parts to a whole in Nature." Since all natural landscape, save that of the plains and the oceans, is unsymmetrical, it follows that humanized landscape is also generally and fittingly informal. Such landscape properly becomes symmetrical or formal only occasionally and for good reasons. The roads of a hilly park rightly curve to avoid obstacles or to secure easy grades; but a particular spot within that park, intended for the gathering place of crowded audiences at band concerts, is rightly graded evenly and symmetrically and shaded by trees set in rows. Again, the fields and woods of a country-seat are rightly disposed picturesquely, while those outdoor halls and rooms of the mansion called the terrace and the flower-garden are just as rightly treated formally and decoratively. The naturalists are justified in thinking formal work often impertinent and out of place. The formalists and the decorators are justified so long as their work is rooted in usefulness and adaptation to purpose. "Each has its proper situation; and good taste will make fashion subservient to good sense," wrote Humphrey Repton. It is to be hoped that our quarreling faddists may take to heart this saying, and may turn themselves to the advancement of Repton's real and much needed art of arranging land, vegetation, buildings and the resultant landscape for the use and delight of men.

Brookline, Mass.

Charles Eliot.

Salt and Sugar in *Washingtonia filamentosa*.

RECENTLY, while examining this Palm for tannin, I was impressed by the sweet and salt taste of the fresh tissue. Less than one per cent. of tannin was found, but, as the specimen contained 68.97 per cent. of moisture, this raised the amount of tannin to 2.73 per cent. when calculated for absolutely dry substance. The quantity is too

small, however, to give the tree any value on account of its astringency.

Attention was then directed to the sugar content of the specimen with better results, for the amount found, when calculated for dry substance, was 15.50 per cent. Since this amount was not materially increased by first treating the infusion with acid, it was probably a glucose sugar.

The ash in the absolutely dry specimen was found to be

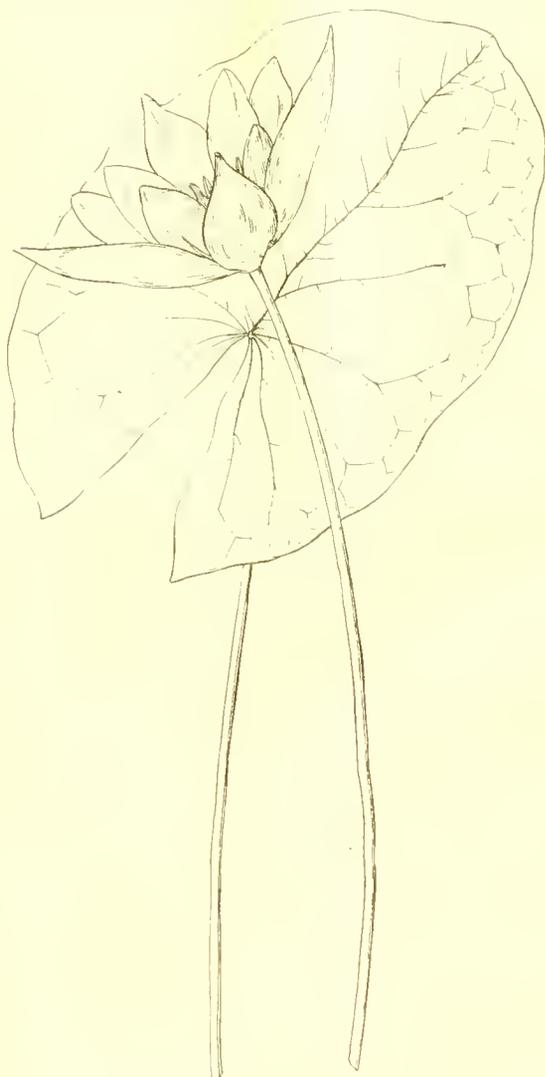

Fig. 16.—*Nymphaea tetragona*.

11.86 per cent., over one-fourth of which was sodium chloride (common salt), the actual amount of salt being 3.09 per cent. of the dry substance of the Palm. The locality in which the tree was grown might have had something to do with the amount of salt present.

The specimen analyzed was a cross-section of the trunk at the base of the leaves, and in the fresh state was sufficiently fleshy to be easily cut with a knife, but in drying it became hard and woody.

It was received through the kindness of Dr. F. Franceschi, of Santa Barbara, California.

College of Pharmacy, Philadelphia, Pa.

Henry Trimble.

New or Little-known Plants.

Nymphaea tetragona, Georgi.

PROBABLY the earliest figure of this small but attractive Water-lily is that of Gmelin in his *Flora Sibirica*, iv., t. 71 (1769). The woodcut which he gives as *Nymphaea alba minor*, although rather stiff and crude, is unmistakably of this plant. Georgi's name, *N. tetragona*, used in 1775 in his *Bemerkungen einer Reise in Russischen Reiche*, i.,

220, is apparently the first published binomial for the species, although from Sims (*Bot. Mag.*, xxxvii., under t. 1525) we learn that Pallas had found the same plant in his Siberian travels, and called it tetragonanthos, a name probably unpublished until mentioned by Sims. Both specific names allude to the quadrate form of the floral receptacle or even of the flower itself.

In his *Paradisus* (t. 68) Salisbury named and figured a *Castalia pygmæa*, a native of China. This was later transferred to *Nymphaea* by the younger Aiton as one of his unnamed collaborators (*Hort. Kew*, ed. 2, iii., 293 [1811]), and Sims, who in the *Bot. Mag.*, xxxviii., t. 1525, gives an excellent representation of it, admits in his synonymy that the Chinese plant is identical with the older Siberian *N. tetragona*, to which it is now generally reduced.

Our knowledge of *Nymphaea tetragona* as an American plant is comparatively recent, dating from 1888, when Dr. Morong characterized and figured (*Bot. Gaz.*, xiii., 124, t. 7) as *Castalia Leibergi* what he regarded as a new species from northern Idaho. The types had been secured by Mr. John B. Leiberg in a small pond near Granite Station, on the Northern Pacific Railway. It requires, however, no specialist in aquatic plants to see from Dr. Morong's plate, above cited, that he had before him the flowers of a *Nymphaea* with the pinnately veined leaves of a Nuphar. A careful study of some of his type material not only confirms this view, but shows that the *Nymphaea* is identical with the Asiatic *N. tetragona*, Georgi. In 1890 Professor Macoun stated (*Cat. Canad. Pl.*, v., 300) on the authority of Professor Britton that *N. tetragona* had been found in the Misinaibi River, in northern Ontario, by Dr. Robert Bell, and in ponds along the Severn River, Keewalin, by Mr. James Macoun. These plants appear to be the same which Lawson (*Trans. Roy. Soc. Canad.*, ser. iv., 1888, 113) erroneously referred to *Castalia odorata*, var. *minor*.

With our present knowledge of its distribution, *Nymphaea tetragona* (see figure 16 on this page) appears to be rare and local in America, but between its widely separated occurrences in north Idaho and north Ontario future and more careful exploration may well show a number of intermediate stations.

Gray Herbarium, Cambridge, Mass.

B. L. Robinson.

Canna Italia.

ON page 520 of vol. viii. of this journal we quoted from an article by Monsieur Edouard André an account of a new race of what he called Italian Cannas, which had been produced by Messrs. Dammann at their grounds near Naples. It was said that a member of the firm, having concluded that he could produce nothing novel by continual interbreeding of the large-flowered varieties, determined to introduce some new blood and began to experiment with *Canna flaccida* as one of the parents. This species is a native of the southern United States, of medium height, with large flowers, in which one of the petals is specially developed. The first success was achieved from seed of Madame Crozy with a fine variety of *C. flaccida* as the pollen parent. The result was a plant named Italia, the flower of which was said to be of unusual size, of a golden vermilion color and peculiarly opened or flattened so as to resemble the flower of Kämpfer's Iris. One of the flowers of Italia figured in *The Gardeners' Chronicle* was said to have been five and three-quarter inches across.

This new *Canna* has recently flowered with F. R. Pierson & Co., of Tarrytown-on-the-Hudson, and although the color of the flower does not exactly coincide with Monsieur André's description, the plant is certainly most interesting, and the flowers have a singular and striking beauty. An illustration of a truss of these flowers from Mr. Pierson's plant, reduced to less than half the natural size, will be found on page 135. It will be seen that the petals are unusually broad, and that two of the inner ones are held above the three outer ones a trifle, thus producing something of the effect of a double flower. In this arrangement it differs from that of any other *Canna* with

which we are acquainted. The general color-effect is rather yellow than vermilion, the outer petals being almost entirely yellow, with a pleasing shade of carmine at the centre, and the inner ones almost entirely carmine, with a narrow margin of yellow, while a distinct satiny lustre adds to the richness of the combination. The flowers when fully open are about six inches across, larger than those of the best of the American seedlings. Perhaps the truss will not be as large and full as those of some of our seedlings, but the second trusses of Mr. Pierson's plants were considerably larger than the one in our illustration, and held well up on a long stem. The flowers of *Canna flaccida* are rather frail, and it is therefore possible that this hybrid may lack substance, but this is only conjecture, as it has not yet been grown here out-of-doors. The foliage is a light green, and the plant seems to be of taller habit than most of the Crozy seedlings.

Plant Notes.

North American Plums.

THE value of some of the North American Plums as ornamental plants is hardly appreciated yet by the planters of parks and large gardens. Of the species of the eastern and northern parts of the country the Canada Plum, *Prunus nigra*, is the earliest to flower; this is a tree which, under favorable conditions, occasionally attains the height of thirty feet, with a short stout trunk separating into a number of upright ridged branches armed after their first year with short, lateral, spur-like branchlets. The fragrant flowers appear in New England late in April or early in May, before the leaves, and completely cover the head of the tree; they are about an inch and a quarter across, with pure white petals, which turn reddish purple as they fade, and are borne on slender dark red pedicels. This is the native Plum which is so often planted as a fruit-tree in Canadian gardens, and is sometimes found naturalized by roadsides in northern New England, where it is supposed to have been introduced by the Indians.

Even more beautiful is the Wild Plum of the middle states, the *Prunus Americana* of botanists, which is distinguished from the Canada Plum by its long, slender, pendulous branches, which form a wide, graceful head. This tree does not expand its flowers until after the petals have fallen from the Canada Plum, and the flowers are smaller and often do not fade until after the young leaves have begun to unfold. A well-grown specimen of this tree covered with flowers is an object of extreme beauty, and the only objection to it is the rather disagreeable odor which the flowers emit. Left to itself the Canada Plum produces numerous suckers, so it is usually found in dense broad thickets of many stems, but with the aid of a little judicious pruning and attention it can be made to grow into a shapely tree, often more than thirty feet high. It is most ornamental, too, in early autumn, when the branches are borne down with its abundant crops of small fruits, which, after they have attained their full size, are orange-color, with bright cheeks, later becoming bright red.

Very useful, too, as an ornamental plant is the Beach Plum, *Prunus maritima*, which, in cultivation, grows to a much larger size than it often attains in its home, close to the sea; as a garden plant this shrub covers itself early in May with innumerable small white flowers, which wreath the branches from end to end and have the merit of lasting in perfection for a considerably longer time than those of many other Plum-trees. The fruit, too, varies much in size, in edible quality and in color, being occasionally a clear amber, instead of the usual purplish red.

These three Plums can be easily raised from seeds; they grow rapidly and are perfectly hardy and not very particular about soil. Among the early-flowering trees in the shrubberies of the Arnold Arboretum none have excited so much admiration during recent years as a number of large specimens of *Prunus Americana*, which flower with remarkable profusion.

Cultural Department.

Cyclamens from Seed.

THE Cyclamen may be grown to perfection in an ordinary window without bottom-heat, and with as little trouble as would be given to a seedling Geranium, and those who never have grown it from seed have no idea of the ease with which it may be brought to flowering size. Success with these plants is possible if a seed is put here and there in the soil where other window plants are growing, and the young seedlings are removed as soon as they are large enough to bear transplanting.

If it is desired to bring the plants to blooming size as early as possible, the seed should be sown as soon as ripe—which will be in late winter or early spring—in shallow seed-pans or boxes, in a soil composed of leaf-mold, well-decayed stable-compost, and somewhat coarse sand in about equal parts and thoroughly mixed. Glass may be laid over the top of the box to assist in keeping the surface of the soil moist. The seeds will germinate in from fifteen to twenty-five days. The first leaves are nearly round, dark green above and of a dull reddish hue on the under side and cannot easily be mistaken for anything else. The later leaves are heart-shaped, and are mottled or marked on the upper side with grayish green.

Fig. 17.—Hybrid *Canna Italia*—reduced.—See page 134.

As soon as the seedlings have made the third leaf they should be transplanted into other pans or boxes of similar soil, disturbing the roots as little as possible, and they may be moved again, if necessary, before September or October, when they should be placed in the pots in which they are to bloom. The seedlings should have plenty of light, but when

young they should be shaded from the direct rays of the sun. The bulbs should be set with the crown or upper part even with or a little above the surface of the soil. In all transplanting or repotting of this bulb the roots must be disturbed as little as possible.

For the first six months the bulbs grow slowly, but afterward they increase in size more rapidly, and will bloom—if it is their season of bloom—when about one inch in diameter; and will increase in size and blooming power as they grow older. A mature bulb, say three inches in diameter, will bear hundreds of flowers in a season, producing from twenty-five to fifty at once, and continuing to bear thus lavishly for about three months each season.

The Cyclamen comes into flower in January or December, though seedlings at their first blooming season may be somewhat later than this, and they will bloom if they have been well cared for when a little less than a year old. The plants require considerable moisture, but the soil should not be kept wet,—that is, not saturated with water. Excessive moisture would be fatal to the seedlings. Neither must they be allowed to become dry, or their growth will be checked. They do not require great heat. An even temperature of about sixty degrees will produce the best results. During the summer the seedlings may be kept upon a porch, or on the north side of the house where they will get the morning sun only. They should be washed or sprayed occasionally to keep down the red spider, which sometimes attacks them.

The plant has a neat, dwarf habit of growth, and bears its flowers, which are white, pink blush, red, or striped and mottled, on slender stems well above the foliage. After blooming, the bulbs require a season of rest, and water should be partially, but never wholly withheld, until it is time to repot them, in late summer, for winter use.

This plant is best propagated from seed, though some have succeeded in growing it from large leaves. The stem of the leaf is placed in water in a sunny window, and after a time a small bulb may form on the end of the stem, which is then transferred to suitable soil and treated as a seedling.

Seedlings do not always resemble the parent plant in the color of their flowers, and often new and valuable varieties are produced. It is this element of chance that helps to make the growing of bulbs from seed such a fascinating pastime.

Considering the number of its flowers the Cyclamen does not seed freely. When the seed is ripening the stalks bend or curl down until the seed-pod rests on the soil.

Beth Day.

Hippeastrums.

SOME new Hippeastrums, now in bloom in the greenhouses of H. H. Hunnewell, Esq., Wellesley, Massachusetts, are remarkable for immense size and fine coloring. They came from Messrs. Veitch, of London, and the selection being left to them there is no doubt they represent the highest attainment of the hybridists' art up to this time. They are certainly great improvements on the older kinds. These novelties are altogether free from the green lines and reticulation on the petals so commonly seen in the earlier hybrids. Messrs. Veitch grow their plants in houses specially constructed for them. They are potted or top-dressed, as need be, immediately after the flowers fade. They are continued in a fairly high temperature, with abundance of water—manure-water alternating frequently, until the annual growth of leaves is fully matured. After this less and less water is given; but it should never be altogether withheld. The leaves will fade away, but may not do so entirely. Some hybrids remain with considerable green all the year round, and common sense suggests that these have slightly more water. Hippeastrums respond to artificial hybridization so freely that several gardeners hereabout are growing large numbers of them with pleasing results; for while they may get few which come up to the highest standard, there are, nevertheless, many highly decorative varieties which are useful at all times in winter. These seedlings are grown without rest until they bloom. The majority will bloom at two years, but probably the better varieties will need to be grown three years before they flower. Where a special house is provided, cocoanut fibre or litter is used as a plunging material. These imported varieties had made roots over the edges of the pots during last season's growth. In houses specially constructed for them it makes no difference whether the roots are in the pots or outside, for the plants bloom where they grow. With our facilities it is different; where no general collection is grown no special culture can be given.

Hippeastrum Johnsoni is one of the earlier hybrids. Although the flowers are small, by comparison, it is still a

handsome kind. A neighbor who grows it largely for market succeeds well by plunging the deep flats in which he grows them out-of-doors for the summer. This suggests the idea that raising Hippeastrums might become part of the bulb industry proposed for the south. Some few are already offered by Californian growers, but, as far as I have seen, they are quite common kinds. A few of the choicest types should be imported as a basis to work on. My experience with the few I have is that they are hardier than is generally supposed. By an oversight some pans were left out last year until the middle of November. What few leaves remained were cut off at once, but the bulbs were uninjured, and they have flowered well this winter.

Mr. F. L. Harris, gardener of Mr. H. H. Hunnewell, exhibited a collection of Hippeastrums at a recent meeting of the Massachusetts Horticultural Society, and received honorable mention for them. The most noteworthy were Calabar, scarlet, with orange shading and crimson reticulation. The flowers were eight inches across and finely recurved. Olympia resembles Calabar, except that the markings are better defined. The flowers are equally as large, but not so finely formed. Madonna is a most chaste and beautiful variety. It is creamy white, with light scarlet pencilings. The petals are wavy and finely revolute. Fresca is crimson, with maroon lines and reticulation. It is the best of all the dark-colored varieties. The flowers are eight inches across and beautifully formed. Cupid is the gem of the group. The flowers are creamy white, with a heavy reticulation of crimson. They measure six inches across and are finely formed. The habit is dwarf, and the plant bore two large scapes of four flowers each, in a seven-inch pot, showing high culture.

Wellesley, Mass.

Seasonable Suggestions.

ALTHOUGH April is close at hand, winter still reigns, and practically nothing has been done in the garden. We might attempt some pruning, but, with the exception of Grapevines, which should be pruned before the frost leaves the ground, it is better to leave shrubs until the weather is settled. Especially where the ground is heavy, much harm may come from treading on it. Roses of the Hybrid Perpetual kind will need cutting below the frozen growth. In varieties such as La France and other hybrid Teas it is best to leave on as much sound growth as possible, and Paul Neyron, Ulrich Brunner, Marie Baumann and the majority of sparsely thorned varieties also. As a rule, the heavily thorned varieties will bear harder pruning. The Prairie Rose, Scotch, Persia, Dawson and rambling Roses, such as the Multiflora group, need no more pruning than is required to clean off decayed growth. Hydrangea paniculata and all other flowering shrubs which bloom on the current year's growth may be spurred well in, and Yellow-barked Willow and Red Dogwood will be brighter in the autumn if pruned yearly; but spring-flowering shrubs should not be touched until past blooming, beyond clearing away dead growth, and, in fact, this is all that is necessary at any time. Climbing plants need looking over and bare spaces covered. Wistarias which have covered their allotted space should not be allowed to develop useless canes. All slender spiny shoots with light-colored bark must be cut away. Clematis paniculata may be cut back to within five or six feet of the ground and tied into shape. This yearly pruning keeps the vines well clothed below, where there would be only congested growth from the live tips. All planting of trees and shrubs should be done early, as drought too often quickly follows the breaking of winter. There should be at least a yard of good loam to every plant, and this can only be counted upon to last a year or two, before the area of deep soil will need extension. If herbaceous borders need replanting or filling from the reserve garden this work must be done at once. The common practice of digging borders in spring is objectionable. It is a work needing extreme care, and is seldom done in a satisfactory way. We only clear away leaves and litter remaining from the top-dressing of manure laid over winter. The rock-garden is still frost-bound and covered with pine-needles, but as soon as practicable it will be cleaned and receive a top-dressing of lawn fertilizer. This mixture we have found to answer perfectly, having discarded barnyard-manure in its favor. The latter carries too many weed-seeds, and as only hand-weeding is practicable, the work of keeping the place clean is quite tedious.

Spring-bedding must be prepared for. Pansies, Forget-me-nots, Silene pendula and Daisies are used in masses with better effect than in mixed beds. Dutch bulbs have been used, but these are short-lived and seldom satisfactory, as it is hardly

possible to get a perfect bed. Later we have special effects in nooks and corners of the shrubberies, with Foxgloves, Canterbury Bells, Sweet Williams, Larkspurs and Hollyhocks.

Wellesley, Mass.

T. D. Hatfield.

Dendrobiums at the Harvard Botanic Garden.

DENDROBIUM SECUNDUM deserves mention as the most distinct species of this showy genus, in bloom here at present, although its flowers are not as gorgeous or as delicate in color as those of many other species. It is an erect plant, its stoutest stems being about twenty inches high and three-fourths of an inch in diameter. The young stems of last summer's growth are clothed with ovate leaves three or four inches long and an inch and a half in breadth. The flowers are produced in racemes, are four inches or more in length, from the upper part of the leafless one or two-year old, or even older stems. The small rosy purple flowers, about fifty or sixty in number, are arranged thickly along one side of the rachis. The sepals and the slightly smaller petals are ovate, the lip a lighter shade of color than the other parts of the flower, with an orange blotch at the apex. The spur is long and rather broad and blunt. A plant carrying several racemes is very striking, and, although the flowers are small, they last in good condition for several weeks. It does well planted in a pot, using fern-root and sphagnum as a compost. During the summer it is grown in the stove, and when its pseudo-bulbs have grown their full length water is withheld by degrees and it is shifted into a cooler and drier house, suspended near the roof-glass, and with only enough water to keep it from shriveling. When the racemes begin to slow on the upper part of the stems it is taken back and treated more liberally. If it needs shifting into another pot this is done after the plant has flowered.

Another distinct species in bloom now is *Dendrobium aggregatum*. It is a dwarf evergreen plant, growing some four inches high, with oblong-ovate pseudo-bulbs two inches in length. The loose pendulous racemes of yellow flowers, produced from the side of the pseudo-bulb, are six inches long, and made up of ten or twelve flowers. When the plant blossoms well the light and graceful racemes hide the sides of the basket. The flowers are golden-yellow when they open, but in a few days they turn to an orange-yellow. This *Dendrobium* is usually cultivated on a bare block of wood, but here we grow it in a small shallow basket, using fibrous peat for a compost. It is kept during summer in the warmest house and needs liberal watering and frequent syringing. When the pseudo-bulbs are full grown less water is needed, and late in the fall it is removed to a cooler house, where it rests until the flowering season. With the above treatment it produces an abundance of flowers every year. It was introduced into English gardens from India more than sixty years ago.

The handsomest yellow-flowered *Dendrobium* in bloom is *D. fimbriatum oculatum*. This is a strong upright grower, its long cane-like pseudo-bulbs attaining a height of nearly three feet. The upper half of the stout stems when young is clothed with green leaves, which are six inches long. The flowers are produced from the ripened stems in drooping racemes, which contain from half a dozen to a dozen blossoms. The individual flowers measure two inches or more across and are of a rich orange-color, with a deep maroon-purple spot at the base of the lip. The lip is the most conspicuous part of the flower; it is margined with a deep golden-colored fringe. If the flowers are kept dry and not too much moisture in the house they last two or three weeks. This *Dendrobium* is planted in a deep basket in fern-root and sphagnum and suspended near the roof-glass. When it is making its new growth it requires stove-heat and abundance of water. After it has completed its season's growth it requires to be kept dry and in a slightly cooler temperature until it begins to show flowers.

Dendrobium superbum is a fine species, easy to grow and flowers freely every spring. It does best in the stove, in a basket suspended near the roof-glass during the summer months. After it has completed its growth it needs a good rest in a slightly lower temperature, and in a position where it can get all the light possible. This is a strong-growing, drooping, deciduous plant, and has stout pseudo-bulbs nearly a yard long, with oblong lanceolate leaves five inches in length. The pale purple flowers are large, measuring three to four inches across, and are produced in pairs from the joints of the new growth. They last well and the plants are handsome for some time.

Some of our plants of *Dendrobium chrysanthum* are in bloom now, but on a number of them the buds are just beginning to show on the long pseudo-bulbs. This *Dendrobium* is treated differently from the other species mentioned in these

notes. It is grown in the stove the year round, as it rejoices in heat and moisture. When the pseudo-bulbs have finished growing less water is needed, but at no time is the water withheld long enough to permit the compost to become quite dry. It is one of the easiest species to grow when properly treated. Some of the pseudo-bulbs are nearly four feet long and a mass of golden flowers. The only deficiency the plant has is that its flowers do not last long. It does best when grown in a basket suspended from near the roof, where its long graceful stems will show to the best advantage. The beautiful golden-yellow flowers are produced on the young leafy stems and they measure about one inch and a half across.

The most useful and the best-known species is the old *Dendrobium nobile*. Even the smallest collection can boast of plants of this handsome Orchid. Among a number of plants of this showy species in bloom here, the variety named *D. Sanderiana* stands out conspicuously and seems one of the most distinct. It has magnificent flowers, large and very brilliant in color.

Botanic Garden, Harvard University.

Robert Cameron.

Caladiums.

IT is not surprising that bulbs and other tuberous-rooted plants occupy so prominent a place in decorative gardening, for without these there would be a great loss of decorative material. Plants which accumulate nutriment for another year in bulbous or tuberous roots can be stored away during their resting season in a very small compass, and the advantage of this is obvious. It is necessary to prepare each year for considerable summer decoration, and at the same time provide space in the greenhouses for the growing of cut flowers. No plants are more useful for summer decoration than the fancy-leaved Caladiums. There has been quite a revolution in this class of plants since their cultivation was taken up in Brazil by skilled operators under the best possible conditions. At the World's Fair in Chicago an education was afforded by the fine examples of Caladiums seen there, and which showed brilliant colors and excellent cultivation, the fine effect being obtained in but a few weeks and continuing throughout the season. The newer kinds, to that time practically unknown to us, were made familiar, and these are no more difficult to grow than the older kinds of less brilliant coloring. We have fairly tested this new Brazilian set of Caladiums for several seasons. The cost is reasonable, and they are very effective. A set to be found in English nurseries surpasses them in one respect, that of dwarf habit. I am told that this habit was brought about by crossing the larger high-colored varieties with the dwarf red variety *Caladium minus erubescens* that we grow as a companion to *C. argyrites*. The resulting progeny is superb in coloring, dwarf in habit, and excessively high in price at present, but some day we hope they will be obtainable. Among other things we have noticed that the varieties that have foliage of pale color and thin texture, often without a trace of green in their composition, are also very sensitive to sunlight, and practically of no value for general decoration such as we need for terrace or piazza, and are of little use except in the greenhouse, owing, perhaps, to the lack of chlorophyll. But as conservatory plants they are very beautiful; the transparency of the leaves, through which it is possible to read a newspaper, gives them interest in a collection. The varieties of higher color are all that one could desire, and there are, I think, as many as sixty in all. We had the set complete at the start, but many of them were practically identical, and more were undesirable owing to the dull tints, and the original number is reduced consequently. But the distinctive character of the collection is due to the influence of this Brazilian strain. It is to be desired for us that are not Portuguese scholars that the raiser in future give to his infants names that could be pronounced by an Anglo-Saxon tongue. I shall not attempt to put the names in type here, for they can be seen at a glance in lists of Caladiums, and there is the consolation that the plants are at least as distinct as their nomenclature.

A few remarks about their cultivation to those who wish to try them: Caladiums are distinctly tropical, being found directly under the equator, and cannot be treated to too high a temperature, as we understand this particular in greenhouse work. It is in the manner of resting the tubers that many fail, but we always shake the tubers out of the pots in autumn and place them in the warmest part of the boiler-room, each kind being provided with a new label and placed in dry sand in small pots, or in such as are large enough to accommodate the tubers. In this way a large number may be stored in small space without the loss of a single individual, care being taken

when they are shaken out to clean all decayed portions away and to rub on a little charcoal-dust if there is any sign of decay. Since we have taken the precaution to place a handful of sand under the tubers at potting-time they have almost entirely escaped from the rot that used to give a great deal of trouble at their bases. To be of the most use to us *Caladiums* must be started early in the season, so that they shall be well grown in the early summer months and the foliage well developed and in a condition to stand exposure at that season. We start them early in the year for this reason, and this makes it possible to store them away under the benches at the time in fall when all plants must be got under glass, and the space occupied by a collection of *Caladiums* is needed for winter-flowering plants. This early start, therefore, gives us a twofold advantage. But those who have not a warm house commanding at least a temperature of sixty-five at night had better wait until later in spring, when it is attainable, for a good brisk heat is necessary to get a free growth of large well-colored foliage. *Caladiums* like a light rich soil. We add a large proportion of spent mushroom-bed material to a compost of leaf-mold and loam, made porous with plenty of sand, and later in the season, if necessary, liquid stimulant is given. The aim is to produce the greatest leaf-development, and, on the whole, it is easy to accomplish.

I am glad to find that there is an operator at work in Florida on this family of plants, and we have now in course of trial some two dozen or more varieties raised in that state, where they thrive outdoors with great vigor. It is not too much to expect that we may have in the near future a race of American *Caladiums* equal to those we have hitherto received from abroad.

South Lancaster, Mass.

Plants for Conservatory and Window Garden.

Chorozema ilicifolium.—This elegant leguminous plant bids fair to become one of the most popular of its class. It forms a dwarf, globular bush when well trained, producing numerous few-flowered racemes of bright yellow flowers, tinted red, from March until late in summer. The leaves are about an inch long, dark green and leathery, with wavy, spiny-toothed edges, not unlike Holly leaves, but smaller. The branches are very slender; young plants should, therefore, be well pinched in order to form compact specimens. The variety "nana" is naturally dwarf and compact. The genus contains several other extremely showy and attractive plants, all of which flower later in the season than the preceding kind. One of the most beautiful of these is *Chorozema cordatum*, a species not uncommon in cultivation; the flowers are yellow, with reddish keel and produced in great abundance in drooping racemes; the leaves are cordate and spiny-toothed. *C. Henchmannii* is a rare scarlet-flowered species with acicular, spiny-pointed leaves. It flowers early in summer. *C. diversifolium* is a very showy plant with bright orange-colored flowers in numerous nodding racemes late in spring. *C. varium* has erect racemes of bright red and yellow flowers and cordate, somewhat spiny, leaves. The *Chorozemas* are easier to grow than most other New Holland plants; they will thrive in any moderately light and warm greenhouse or conservatory. In the conservatory they may be trained on pillars near the glass, in sunny positions. They are excellent house plants, too, rivaling *Cytisus racemosus* in usefulness for this purpose. Propagation by means of seeds is the simplest method of increasing them. The seeds should be sown as soon as ripe, in shallow boxes, in a compost of sandy loam and leaf-mold, which should be kept in a light but comparatively cool place in summer. The young seedlings must be transplanted early and pinched frequently during the first season. Older plants may be plunged in a cool frame in summer in a half-shady position. In potting the soil must be pressed firmly down around the roots, as a loose potting often proves fatal. Watering and spraying must be carefully attended to in summer, and the roots must on no account be allowed to become dry.

Imantophyllum cyrtanthiflorum.—This is a very valuable and floriferous spring-flowering plant of the *Amaryllis* family. Like the more common *Imantophyllum miniatum*, it has quite beautiful and attractive foliage, the leaves being long, dark green, slightly curving and distichous. The flowers are almost bell-shaped, of a very bright salmon color, produced in large, many-flowered corymbs, on scapes from two to three feet high. This is considered a hybrid between *Clivia nobilis* and the above-mentioned *I. miniatum*. It is best grown in large pots or tubs in which it is allowed to increase and form large masses of foliage. The compost should consist of rich fibrous loam, with a liberal addition of cow-manure and some

sand. During the growing season plenty of water is needed, but the plants should never be allowed to dry as much as *Hippeastrums*, as they are ornamental throughout the year. The roots are fleshy, the plants form no bulbs, but increase readily by means of side-shoots or offsets which may be used for propagation. All *Imantophyllums* form ripe seeds if fertilized, and they may, therefore, be propagated with the greatest ease by this means.

Wellesley, Mass.

T. D. H.

The Climbing Hydrangea.—We often hear complaints that *Hydrangea scandens* is tardy in starting to grow. The usual way of raising it is by layering. Numerous roots push out wherever the shoots touch the ground, in the same way as they do from the English Ivy, but when the layers are severed from the parent shoots and set out by themselves they scarcely grow at all for a year or two. Its near relative, *Schizophragma hydrangeoides*, behaves in the same way. It is becoming the practice to pot the layers when taken from the parent plant, and keep them in frames or in a cold greenhouse for a season; after this they may be set out with more certainty of thriving. Both of these vines are gross feeders, and they should be abundantly supplied with manure, especially when well started. It must not be forgotten that all climbers grow much faster when they are supplied with supports. The Climbing *Hydrangea* needs a rough surface, and when it once attaches itself it grows rapidly. *Decumaria barbara*, a closely allied climber, is not at all like the *Hydrangeas* in habit of growth, but from the start pushes on rapidly. Though a native of our southern states, it is perfectly hardy in Philadelphia and much farther north.

Germantown, Pa.

Joseph Mechan.

Correspondence.

Ericas as Market Plants.

To the Editor of GARDEN AND FOREST:

Sir,—The festivals of Christmas and Easter are now two events of the first importance to the commercial florists, for at these times the demand for plants and flowers reaches its highest mark. Especially at the latter festival does there seem to be an almost unlimited outlet, especially as then the range of choice is much greater than it is in the dull weather of the early winter.

Naturally there are many would-be gleaners at the harvest, and every grower at this season exerts himself to produce his specialty in its finest form and greatest abundance. For the modern flower grower for the market is a specialist in very few plants. Competition has driven him to grow only those plants which he best understands and can grow to the greatest perfection or most economically.

Among the choicest plants grown for the market are the *Ericas*, or Cape Heaths, but often sold in the city shops as Scotch Heather. Not so many years ago Heaths were driven out of private greenhouses by the Orchids, and those beautiful plants are seldom or never seen in collections. As is well known, they require cultural skill of a high order, and only the softer-wooded kinds are now grown as market plants by a few specialists. Among the best growers of these plants in this locality is Louis Dupuy, a young Frenchman, whose houses are located on a warm southern slope in Whitestone, Long Island. There I found the other day Heaths in all stages, from cuttings to three-year-old plants, the mature ones ready for the Easter market in hundreds and, perhaps, thousands. Judging from the health and thriftiness of the plants here one might suppose them as easily grown as *Geraniums* if he did not know to the contrary. Like all good growers of plants, Mr. Dupuy has no cultural secrets. Learning his business on the Continent, Mr. Dupuy found, in undertaking the culture of Heaths here, that, like many other plants, they required different treatment in their environment, and he has broken away somewhat from the traditional practice so rigidly adhered to abroad. In the first place, they are potted in none of the fancy soil mixtures usually recommended in the books, but simply in good light soil, with plenty of sand, the local article, in fact. Of course, the successful culture of Heaths is a matter of careful, unremitting attention as to air and watering. I suppose the secret of Mr. Dupuy's success may be summed up in the sympathetic culture of each plant as an individual. I learned, also, that a tight greenhouse is a poor place for Heaths. According to Mr. Dupuy's experience on both sides of the ocean, he gets as much growth from a cutting in one year here as is secured abroad in two, and his two-year-old plants are as large as European ones at three years old. The one-year-old plants here were very bushy and about nine inches

high, and in four and four and a half inch pots. This is the most popular size. Those unsold are cut down after flowering and grown on in six-inch pots, and make plants about eighteen inches high and as much through. This, of course, refers to the varieties now in flower, which are mostly *Erica persoluta* alba for white, and *E. Mediterranea* for pink. For Christmas there are grown here *E. Wilmoreaana*, one known as *E. nigra* and *E. gracilis vernalis*. Even earlier there is a form of *E. gracilis autumnalis*, a favorite English variety. There were a few plants of *E. cylindrica* just coming on, which have large tubular corollas of a beautiful coral-color. According to recent investigations, Heaths and a number of plants naturally growing in soil rich in humus have their roots much modified, and flourish most successfully when their roots are covered by fungoid growths. This is given as an example of most important plant association, or the so-called symbiosis, as the mycelium of the fungus is said to act as the absorber of nutriment from organic matter instead of the usual root-hairs, which fail to develop in such cases. It will be noticed that Mr. Dupuy's potting-soil is not favorable to fungal development, but I brought a specimen plant away for examination of the roots. Under a microscope of high power it was seen that no parasites infested the roots of the plants, and the root-hairs were very abundant. This proves nothing against the scientific theory, but it does seem to prove that the *Ericas* have an adaptability not always suspected, and will grow perfectly in what might be considered unnatural conditions. The same painstaking care shown in the culture of Heaths was evident in all the plants on the place. There were fine dwarf plants of *Hydrangea Otaksa*, well-grown Lilies, *Genistas* (*Cytisus*), *Azaleas*, *Spiræas*, Daisies and a number of beautifully flowered *Acacia armata*, a plant of great distinction, leading to covetousness. Mr. Dupuy also grows Carnations and hybrid Roses—Ulrich Brunner at the moment. Sweet Peas were grown cleverly in pots, a device rather novel, but useful, as they can be shifted about as space permits when the plants now crowding are cleared out.

Elizabeth, N. J.

J. N. Gerard.

Farming on Vacant City Lots.

To the Editor of GARDEN AND FOREST:

Sir,—On reading your editorial on the cultivation of the vacant lots I was struck with the humanitarianism and practicability of this plan to help the now almost helpless poor. Apart from scientific aspects of the case, with which GARDEN AND FOREST chiefly has to do, the economics of such questions, particularly the relation of men to the soil, is a matter of supreme importance, on a proper adjustment of which the weal or woe of a country largely depends.

This might be illustrated by the almost uniform prosperity of settlers in new countries, where civilization barely begins, but where land is easily accessible, contrasted with the constantly recurring seasons of depression in the more densely settled countries where civilization attains highest development, but where land is not to be had except at exorbitant prices.

I would, therefore, urge the further discussion of this matter in the hope that, by a free exchange of opinion, a simple and, therefore, practicable plan may be evolved whereby the needy masses may be enabled to get access to the idle lands on terms which, without recourse to charity, will afford a proper recompense for their labor, security for their crops, and work no injustice to the owners of legitimate investments.

New York.

Luther G. Sand.

To the Editor of GARDEN AND FOREST:

Sir,—Your editorial, "Farming on Vacant City Lots," is timely and interesting. The educational side of the scheme has a special interest for me, but chiefly in its politico-economic aspects, for it will help to explode Malthusian fallacies about overpopulation, restricting immigration, regulating hours of labor, limiting apprenticeship, and the like. The earth is large enough and fertile enough for ten or twenty times its present population, and the bringing together of idle hands and idle lands will alleviate this horrible poverty that festers in our great cities.

The assertion that "anybody who wants work can find it" is utterly false; I have "been there" myself. The Detroit plan proves that a large number, at least, of the very poor will work if they are given a chance at the land. This opportunity will be worth infinitely more to them than all the charity that wealth can offer. It will put them on their mettle and infuse into them the independence of true manhood.

Brooklyn, N. Y.

Stephen Bell.

To the Editor of GARDEN AND FOREST:

Sir,—It seems to me that had the writer of the editorial in GARDEN AND FOREST given the same careful thought to the suggestion regarding the cultivation of vacant lot gardens that has generally marked the discussion of technical subjects in that paper, his conclusions would have been different.

There is danger in this proposal; the scheme in my opinion is the entering wedge for land confiscation. Let the masses once realize that with free access to land they can make their own living; give them that free access in the name of charity, and it will not be long before the philanthropic features of the case will be forgotten, and access to land will be demanded as a matter of right, and questions of title between the state and the individual will be subjected to the same remorseless scrutiny and review as similar questions between individuals are decided now.

You see the danger to property owners? Even now the right of the landlord to ground-rent is being questioned, that right which may be roughly defined as a privilege to appropriate a part of the earnings of the labor which must use the land. Suppose lot owners allow the use of their land for a few years without recompense—in other words, charitably donate the rent to their tenants—a time must necessarily come when rent will have to be collected or the lots vacated. Is it likely that the people who have "squatted" on the property for years will pay or quit without trouble? Besides their unwillingness to give up part of their earnings to the landowner, is it not probable that their husbandry, presupposing it successful, will have created a powerful public opinion antagonistic to the landowners, as such?

While it cannot be denied that some beneficial results have to be credited to the experiment at its present stage, there can be little doubt that these are due to exceptional circumstances. I believe it is not claimed by its originators that the "potato-patch plan" is a panacea; and their moderation in this respect is justified by every feature of the case. Nothing short of renting the land at a fair valuation will enable the tenants to maintain their self-respect; and in case advances are made for seeds, living expenses, etc., the security usual in such cases should be given to the lender. No other plan will meet the exigencies of the case and remove all fear in the future of a dangerous spirit of independence among the classes whose necessities are now the object of philanthropic solicitude.

New York.

Gregory Smith.

Exhibitions.

Boston Flower Show.

AT the exhibition of spring flowers given in Boston last week by the Massachusetts Horticultural Society the three most interesting features were, first, a collection of Persian Cyclamens from the gardens of Mr. N. T. Kidder, of Milton. The plants were exceptionally well flowered, with abundant foliage and large clear-colored flowers of good substance. Better-grown and more beautiful plants, perhaps, have never been produced, although a large and evenly grown collection of the same plants were shown by Mrs. B. P. Cheney, of Wellesley. Second, a plant of the Japanese Crimson Rambler Rose, two years from a graft, grown by Mr. Jackson Dawson, of the Arnold Arboretum. The plant was five feet six inches high and almost as deep through, covered to the pot with healthy foliage and with more than a hundred clusters of flowers. Whatever may be said of the beauty of this variety, which some people think less attractive than the single white-flowered *Rosa multiflora*, from which it has sprung, or than the hybrid Dawson Rose, this specimen shows its possibilities as a pot-plant for winter or spring decoration. The flowers are of a glowing color, which outshone that of the Indian *Azaleas* near it, and under electric light it was still more lustrous. The society's silver medal was awarded to this plant. The third striking feature was a well-grown plant of the Australian *Acacia Drummondii*, about eight feet high and five or six feet through, exhibited by Dr. Charles Weld, of Brookline. This also received the society's silver medal. Other noticeable exhibits were the Catherine Mermet Roses shown by Mr. William H. Elliot, of Brighton, and the fine hybrids by David Nevins, of Framingham, and a collection of hardy shrubs forced at the Bussey Institution and exhibited by Mr. Charles Dawson, who is exceptionally successful in the management under glass of early spring hardy flowers. Among these were *Andromeda Japonica*, *A. floribunda*, *A. polifolia*, *A. speciosa*, *Daphne Cneorum*, *Leucothoë Catesbæi* and a peculiar Gorse, *Genista Germanica*.

Notes.

The *Ceylon Forester* gives the dimensions of a Banyan-tree at the Admiralty House at Trincomalee, the girth of whose central trunk is nineteen feet six inches at three feet from the ground, the full height of the tree being sixty-six feet and six inches, and the circumference of the circle shaded by its foliage being 541 feet.

At the recent meeting of the Massachusetts Fruit-growers' Association at Worcester it was stated that the canning of good apples was constantly on the increase in obedience to a steadily growing demand for them, especially abroad, Great Britain alone last year having taken 20,000 dozen. The canned product is so attractive that the demand for evaporated apples is diminishing.

Some experiments made in Belgium recently tend to throw doubt upon the truth of the assumption that insects are guided to flowers by the brightness of their colors. Brilliantly colored Dahlias were covered so as to expose only the disks, and butterflies and bees sought these flowers with the same eagerness and frequency as those which were fully exposed. The conclusion by Plateau was that the insects are guided more by their sense of smell than by their perception of the bright colors.

A Buffalo correspondent writes that he finds *Linum* (*Reinwardtia*) *trigynum* one of the best of the few window plants which flower in early winter—that is, before ordinary bulbs are brought forward. Beginning with the last of November the *Linum* will rival the Chinese Primrose in profusion of bloom, and if the two are placed together in a cool window where the temperature is kept above actual freezing the golden yellow flowers of the *Linum* will appear to admirable advantage among those of the Primroses, and both will keep on flowering until late in February.

Mr. Joseph Meehan writes to confirm what we have stated about the shy way in which *Magnolia Kobus* blooms when young. He speaks of a beautiful specimen in Germantown with a trunk four feet in circumference at a foot from the ground, just below its separation into several large limbs. The tree is twenty-two feet high, with a spread of twenty feet across, and very symmetrical in shape. This tree has flowered as yet but very little, although it is doing so more freely every year. Large as it is, he thinks it carries no more than a hundred flower-buds this spring, while a tree of *M. conspicua* of the same size would have thousands. The flowers are not large and the buds at present are not more than one-third the size of those of *M. conspicua*.

Green peas have recently been shipped from Florida in comparatively large quantities, this vegetable, with mint, being in more especial demand as an accompaniment to spring lamb. Seventy-five cents a half-peck is the current price. Tender and fresh-looking string-beans, also from Florida, sell for twenty-five cents a quart, and some late okra, from Louisiana, costs ten cents a dozen. But little cauliflower is coming from Florida, and the dependence has been on the California supply, which finds ready sale at twenty-five cents a head, a limited quantity from France selling for sixty cents. Boston hot-house cucumbers sell at fifteen cents each, and mushrooms from Long Island and New Jersey at ninety cents a pound. Large stalks of asparagus, as fine as any grown in northern gardens later in the season, are now coming from South Carolina, and sell for sixty-five to ninety cents a bunch. Egg-plants from Florida and Cuba cost twenty-five to thirty cents each, and celery, from Florida and California, \$1.25 for a dozen stalks. Beets are coming from Florida and the Bermudas, and other field crops arriving from these islands are kohlrabi, carrots, onions, potatoes, parsley and Romaine lettuce. Tomatoes from Florida and Key West cost twenty-five cents a pound, and the near-by hot-house product thirty-five to fifty cents. Other new-crop vegetables now in market are white squashes and cabbage from Florida, and lettuce from Florida, Louisiana and South Carolina. Some of the first-class fruit and vegetable stores now include in their varied stock yams, from the Bahamas. These rough-skinned, irregularly shaped tubers find not a few curious purchasers, fifteen cents a pound being the price asked for this popular food of the West Indian negroes.

The sales of cut flowers during the Lenten season, which closes with this week, have been more satisfactory to the dealers than in former seasons, and informal dinner and theatre parties have made considerable demands until now, in Holy Week, when but few flowers are sold. While there have been not a few muggy days during the weeks when plants and

flowers have been forced for Easter, the weather, altogether, has not been unfavorable, and the quality of flowers is, perhaps, higher than ever before. To growers whose stock is developed to the point of hardening off sunless days are now comparatively harmless, though a hindrance to any whose plants are belated in development. The uptown flower-stores began on Monday to receive their Easter stock. Lilies, as usual, are most conspicuously associated with the season, and after these azaleas are most abundant. Acacias are among the most popular plants, as are Heaths, the light-colored *Erica gracilis* and the rich pinkish lavender of the more densely flowered *E. globosa* being varieties frequently seen. Among the newer and rarer offerings of this season are *Asparagus Sprengeri*, luxuriant drooping plants of which, in ten-inch pots, are offered at \$4.00. *Spiraea compacta* is evidently supplanting the old *S. Japonica*, the larger and denser flower-trusses of the former proving much more durable. Genistas are somewhat less generally grown than formerly, due to the fact that the flowers fall so soon, a complaint also made against the still less popular Hydrangeas, which are specially susceptible to injury from lack of water. In cut flowers carnations are remarkably fine this season, and it is said by expert buyers that ten good flowers are obtainable this year for one a season ago. Helen Keller is just now the most expensive variety, costing one-third more than William Scott and other standard sorts. In roses, Meteor, Bridesmaid, Bride, American Beauty and Mrs. Pierpont Morgan are the favorites in this order, and Baroness Rothschild, Merveille de Lyon and extra-fancy buds of American Beauty have a demand of their own at prices as high as \$18.00 a dozen. The greatest novelty is, perhaps, Moss Roses, dainty plants appearing in one of the Broadway window displays, while small sprays, each carrying a delicate bud, are more frequently seen. Sweet peas, lilacs, Poet's narcissus, forget-me-nots, gardenia and Cape jessamine appear in all the collections.

Firm, well-grown and richly colored strawberries are now quite plentiful, a well-packed quart box costing sixty-five to seventy-five cents, while the more delicate berries from hot-houses near Hackensack, New Jersey, cost \$1.50 for the same quantity. Grape-fruits from Jamaica, carefully carried over in cold storage, bring fifty cents each, and selected Navel oranges from California sell for \$1.00 a dozen. New limes from Jamaica, small and not fully colored, cost \$2.50 for one hundred, and the first new-crop Jamaica oranges have already followed upon the old crop. While not fully matured, these are in demand at \$4.50 to \$8.00 a barrel in wholesale lots. A few tangerines are still shown in collections of citrus fruits. Fresh-looking Catawba grapes, covered with bloom, cost so late in the season but thirty-five cents for a three-pound basket, and heavily shouldered bunches of Almerias, with rich pink coloring, sell at fifty cents a pound. The first native-grown Black Hamburg grapes, from Pennsylvania graperies, now command \$5.00 a pound, and large bunches of immense berries of Gros Colman, cut with a piece of the woody vine, are a luxury at the same high price. These come from the Isle of Wight. The staple apples seen in the wholesale markets are Roxbury and Golden Russets, Baldwin, Ben Davis and Greenings, these ranging in cost from \$2.50 to \$4.25 a barrel to dealers. In fruiterers' collections Ben Davis apples sell at sixty to seventy-five cents a dozen, and Newtown pippins at seventy-five cents to \$1.00. A showy red apple, known as Willow Twig in the trade, is of more delicate coloring than the Baldwin and resembles Northern Spy in its crisp and juicy quality. A few bright-checked Lady apples are carried over for use in making up fancy baskets of fruits. Winter Seckel, Winter Nelis, Forelle, Easter Beurre, P. Barry and the large Acme pears are offered at seventy-five cents to \$3.00 a dozen. The best shops include, besides fresh fruits, attractive and varied displays of nuts and of preserved fruits. Among many sorts of nuts that may now be had are large Pecans from Texas, American filberts, English cob nuts in their hulls, Paradise and Souari nuts from South America, large Italian chestnuts and the so-called Lychee nuts, besides the commoner domestic nuts, whole and skillfully shelled. The array of preserved fruits is almost endless, and olives of many sorts and sizes, from tiny, bean-shaped Crescents to large oval Queens; maroons, crystallized ginger, crystallized fruits from France, and crystallized semi-candied fruits from California; layer and pulled figs and the candied product, the familiar Fard dates, besides a section of the stem thickly set with this fruit, each in a fancy box, and dates stuffed with Pecans; German prunes, in pound boxes, costing sixty cents, and large, meaty French prunes, in jars holding two pounds, for \$1.00; Guava and other domestic and imported jellies, including Japanese and Indian preserves, are a mere suggestion of the tempting and wholesome stock.

Dangerous Enemies of Street Trees.

HOW much the beauty and comfort of public highways, and especially of streets in towns and cities, are increased by a border of thrifty and symmetrical trees can be appreciated by those who have driven under the avenues of Live Oaks and Laurel Oaks in some of our southern towns and cities or beneath the long arches of Elms a century old which can be found occasionally in New England, and yet not one town or city in a hundred, take the country through, is able to show a row of street-trees of any considerable length which are what they ought to be. As we have often explained, mistakes are made at the very outset by selecting short-lived trees like the Sycamore Maple, or those which lack vigor like the European Ash, or others with brittle branches like the Ash-leaved Maple, or Poplars whose trunks are soon riddled by borers. And even when the proper kinds are selected no adequate care is taken to insure anything like wholesome growth by a proper preparation of the ground in which they are to stand, although there is no more excuse for planting a tree in imperfectly prepared soil than there would be for sowing wheat on an unplowed field. If the young tree has abundant food for its roots and room for its branches to spread, and is properly anchored until it gets firmly set, it probably is left unmulched, and therefore exposed to drought and changes of temperature, or it has no guard against the teeth of horses, no opening in the asphalt about its base to receive water, or it is mangled by some ignorant tree-trimmer and its wounds left bare to invite the rot fungus. The hopeless part of the case is that its natural protectors, the people about it, have no affectionate interest in it. They see it languish without any attempt to revive it. They do not consider one who wounds and bruises it a public malefactor.

No doubt, the way to insure satisfactory street-trees is to put the whole business in the hands of a skilled commission. There is no reason why a man should be allowed to select the tree to plant along the street before his house, or to plant it in his own crude way, any more than he should be permitted to build his own sewer or his own sidewalk to suit his personal whims. Where there is a commission of men who understand their work like those

in Washington every tree is inspected before it is planted, so that specimens of even growth and similar shape are secured. They are then scientifically planted and cared for, and, more than that, they are systematically pruned, an operation which street-trees need above all others. Until the planting and care of these trees is considered an important municipal matter, like providing a water-supply, and one which as truly demands expert ability, the trees in our streets will be likely to excite commiseration rather than pride. Reformation in our city practice as to street-trees will come like other reforms, only after a strong public sentiment is enlisted in its favor.

Because there is no such sentiment—that is, because the trees have no active friends—they suffer from another cause which is one of the most serious dangers at present threatening them. Since the increased use of electricity, wires for telephones and trolleys are run through every village and almost every country road, so that no tree which stands on the public highway is out of danger from the axes of linemen. Occasionally some indignant citizen has mustered courage to bring these vandals into the courts, and in some cases exemplary damages have been secured, but the destruction seems to go on unchecked all over the country. In a late number of the *Michigan Cyclist*, Mr. Charles A. Garfield writes that a gang of telephone men utterly destroyed, with no apparent reason, the most beautiful Maple-tree in the southern part of the city of Grand Rapids. It had been trained and pruned into comeliness and had become a delight to every one who passed it, but in five minutes its beauty was destroyed forever. These marauders unloaded poles upon shrubbery and dug a hole for a post in the midst of a group of shrubs by the roadside, and when remonstrated with they replied that they thought this was wild brush which ought to be cleared away. This pole with its weight of wire stood at a street corner, and to make it steady, guy wires were wrapped about a noble Walnut which had been cherished for more than fifty years; its branches were cut and its trunk half-girdled. Professor Beal added that his experience corroborates entirely that of Mr. Garfield. Two fine White Oaks near him had half their tops cut away and the limbs were left where they fell. A thrifty young Elm and an elegant Beech, trees with trunks more than a foot in diameter, had most of the branches on one side cut away and reduced to stubs from one to six feet in length. Reports of this kind come from all parts of the country, and it is time that some associations like village-improvement societies or forestry associations should unite to try their rights before the law.

What is primarily needed in all such cases is a public sentiment which appreciates the value of a tree, for when the use and beauty of these wayside trees are thoroughly understood their owners will defend them as they will any other property. Meantime, the natural enemies of trees are increasing. The imported Elm-leaf beetle has become a pest of the first magnitude, and although we may expect that its ravages will be checked by natural causes after a time, this may not happen until many of our finest trees are killed, for certainly no tree can endure defoliation for several successive summers without loss of constitutional vigor and early death. Science has taught us how to meet these attacks as well as those of the tussock-moth, the bag-worm and other pests of this sort, and the matter has seemed so important that the Division of Entomology of the United States Department of Agriculture has issued a special circular on the subject in advance of a more complete article which is prepared for the Year Book of the department. There is no need of repeating here what has been frequently said about the necessity of spraying, the proper material to use, and the time of application. The serious question to be dealt with is the spraying apparatus, especially where there are large trees which are infested. Hand pumps have been used by the Gipsy-moth Commission of Massachusetts for trees in streets and parks, but since it is necessary to work rapidly to get over the trees just when the remedy will be most effectual a steam

apparatus would be altogether preferable. The most approved apparatus is described, but the special suggestion which will be most valuable for towns and cities is that an old steam fire-engine can be readily arranged for this spraying work among the shade-trees. Indeed, a steam fire-engine without any modification is a valuable aid against many kinds of insects which can be washed from the branches and foliage by the simple force of the water. But in cities of any size a fire-engine is occasionally retired, and a little work by a competent steam-fitter would transform it into an admirable insect destroyer.

If the city authorities refuse to do this work, coöperation by citizens can accomplish much. Private individuals cannot invest in an expensive apparatus for the few trees on their own grounds, and, therefore, combination is essential, and here, as this bulletin points out, is an opportunity for the new business of spraying at a given price for each tree. Mr. W. S. Bullard, of Bridgeport, Connecticut, has constructed several cart sprayers, and during the months of June and July he sprays the trees on the grounds of private individuals and along the streets in front of them under contract, guaranteeing to keep them in fair condition during the season. His work has been directed solely against the Elm-leaf beetle, the only insect of importance in Bridgeport, and last year any one driving through the streets of that city could easily pick out the trees which had been placed under his care. These were green, while others were brown and nearly leafless. Of course, if every owner of property or resident would agree to employ a tree-sprayer there would be no need of the coöperation of the city authorities, but some might be unwilling to do this.

After all, as we have repeated, the ultimate protection of the trees rests upon public opinion, and it is to this end the circular suggests the banding together of citizens in a tree-protectors' league. Last summer one of the Washington newspapers in every issue through the summer contained a coupon reciting briefly the desirability of protecting the shade-trees and enrolling every signer as a member of such a league, pledging him to do his best toward destroying the injurious insects upon the city's shade-trees adjoining his residence. If every household could be made to take a proper interest in this matter the work would be half done. What is needed is intelligent work at the proper time—the burning of the webs of the fall web-worm in May and June, the destruction of the larvæ of the Elm-leaf beetle about the bases of the Elm-trees in late June and July, the picking of the eggs of the tussock-moth in winter and equally simple operations for other insects when they become especially injurious. The subject is one worth the attention of the Agricultural Department, and we hope this paper prepared by Professor L. O. Howard will be widely read and heeded.

In a recent issue of *The American Cultivator*, Mr. J. D. Lyman, of Exeter, New Hampshire, describes a plantation of White Pine made about forty years ago in Enfield, Connecticut, by Omar Pease, one of the colony of Shakers which settled in that place toward the end of the last century. A sandy plain, which had been cropped with Corn and Rye until what little fertility it had ever possessed was exhausted so far as the production of profitable farm crops was concerned, was planted with the seeds of the White Pine. Two quarts of the Pine seed were mixed with rye or buckwheat sufficient to sow an acre of ground, the seed being scattered as if the crop of grain was the only object of the sowing. In this way from year to year, as Pine seed could be obtained, rather more than two hundred acres were sown. After the death of Omar Pease one of his fields, about forty acres in extent, covered with Pines a foot high, was plowed up in the belief that it would produce Rye more profitably than Pine-trees. Nothing has been done to the land since the seed was sown, and nothing has been done to the trees, which now cover something over one hundred and sixty acres. Omar Pease's good work ended with sowing the seeds. Neither he nor any of

his successors have ever thinned the plantation, and Mr. Lyman finds many Pines growing in a space where there should be only one, and his belief is that the trees have made less growth than they would have, had the plantation been properly thinned from time to time. He adds:

In one place, selecting what appeared an average growth, I found ninety trees on four square rods, or 3,600 to the acre. Cutting what I thought an average tree I found, as nearly as I could judge by counting rings in stump and rows of limbs, that the tree was forty-three years from the seed. It was forty-nine feet high and seven inches in diameter at the stump. In another part of the plantation I found eighty-four trees to the square rod, or 13,440 to the acre. An average tree was here 28-10 inches in diameter at the stump and twenty-nine and one-half feet in height; as it had twenty-seven rows of limbs I concluded that it started from seed about thirty-one or thirty-two years ago. Properly thinned from time to time there would have been of these trees some four hundred to the acre and they would have been about eight inches in diameter at the stump and, perhaps, four or five feet taller. The first trees, instead of being seven inches in diameter, would, by proper thinning, have been about one foot.

It is a prevalent idea, supported by the results of many experiments, that it is a difficult matter to raise White Pines from seed sown in the open ground, the young seedlings of this tree being very susceptible to exposure to the full sun. Omar Pease, by demonstrating that poor, sandy land in New England can be seeded with White Pine as successfully and easily as it can with the far less valuable Pitch Pine, has rendered the country a service, and his plantations can, perhaps, be made to serve a valuable object-lesson for demonstrating the necessity of thinning young White Pine forests in order to secure the largest results in the shortest time.

Proposed Plan for Madison Square, New York City.

ON another page are reproduced the plan of Madison Square, in this city, as it is to-day, and a plan for its rearrangement which was shown at the recent Architectural League Exhibition, by Messrs. Bell & Langton, landscape-architects.

Sixty years ago few buildings, except rural ones, stood north of Union Square, and the area now called Madison Square was an open tract some ten acres in extent, in the centre of which stood a House of Refuge for unruly boys—an altogether neglected and unsightly tract, of which the only useful feature was a little pond used for skating in the winter. When the House of Refuge burned in 1839, efforts were made to improve the place, but nothing substantial was accomplished until the mayoralty of James Harper, between the years 1844 and 1847. This was some ten years before Central Park was thought of, and although Downing had already done some of his best work, he had not yet laid out those urban squares in Washington which first showed American eyes what might be accomplished in this direction.

When studied on paper the plan of Madison Square shows the working of design, not of accident; yet its treatment is so petty and monotonous, so wanting alike in broad unity, in effective variety and in conspicuous points of interest, that, we believe, few New Yorkers realize that it has any plan at all. When seen from the encircling streets it has a pleasantly verdurous and shady look, and it contains some very good trees, an Elm which stands near its north-easterly corner, opposite the University Club, being the most symmetrical and beautiful tree which New York possesses south of Central Park. But its trees are not properly grouped—they are simply scattered about. Its lack of shrubs permits the surrounding houses to reveal themselves too clearly from all points of view, and deprives it of that charm of mystery, contrast and surprise which may be achieved even within very narrow limits if shrubberies are artistically employed. It affords no proper place for the display of flower-beds, and none for the proper placing of statues. The one virtue of the design is that those who wish to cross the park diagonally may do so with reason-

able directness. And its chief defect is that its many minor paths cut up its lawns so pitilessly that the eye nowhere rests upon a quiet, reposeful stretch of green.

Truly naturalistic schemes of park design are, of course, more difficult to manage well on a small than on a large scale; and they are not as appropriate as others when the architectural surroundings of the pleasure-ground are of an obtrusively urban sort. Therefore, Messrs. Bell & Langton have sensibly conceived their rearrangement of Madison Square upon semi-formal lines. It may appear that in drawing their main paths anew they have made diagonal circulation less direct; but measurements show that, if anything, they have shortened the diagonal courses. By suppressing the minor paths they have won space for wide lawns. Yet the accommodation for strollers and for playing children, and for rows of seats as well, which is lost in

rightly been removed to a less conspicuous station and discreetly screened by foliage on all sides.

In explaining their design Messrs. Bell & Langton say that the improvements they suggest would be accomplished with "no sacrifice worth mentioning of the existing trees," while those that would necessarily be removed would be compensated for by their new central avenue. They point out that "the careful planning of the shrub-planting has isolated the formal centre" of their design from the noisy streets on all sides, although particular care has been taken to avoid interference with the cooling breezes so grateful in summer. "It would probably prove advisable in execution," they add, "to follow the accepted rule of utilizing a number of species, though we propose so to concentrate these as to make effective masses of one or two kindred species which blossom or fruit at the same

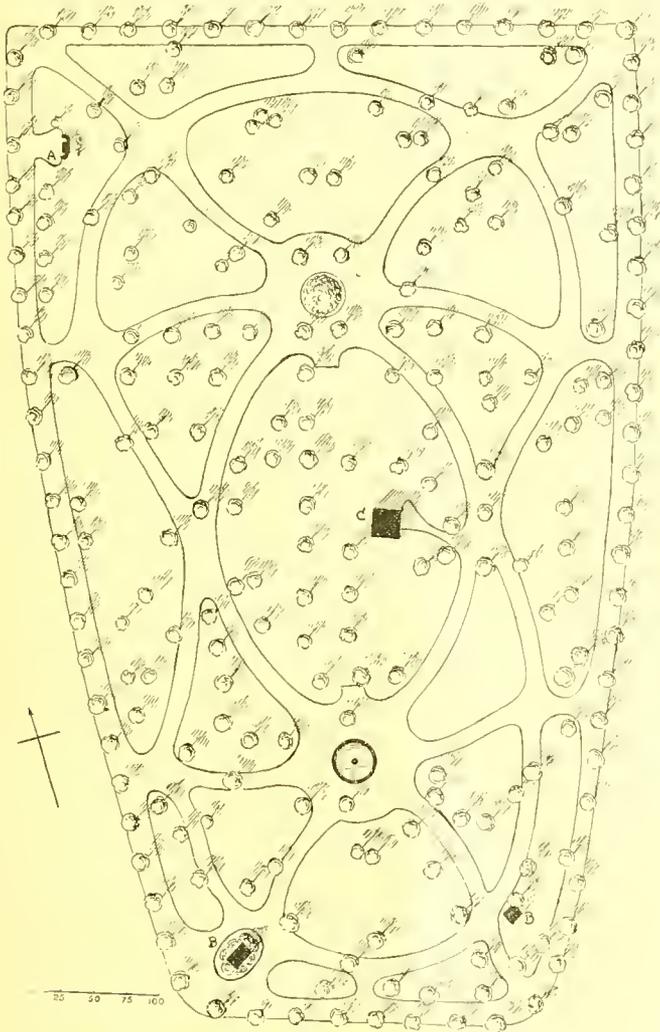

Fig. 18—Present Arrangement of Madison Square, New York.

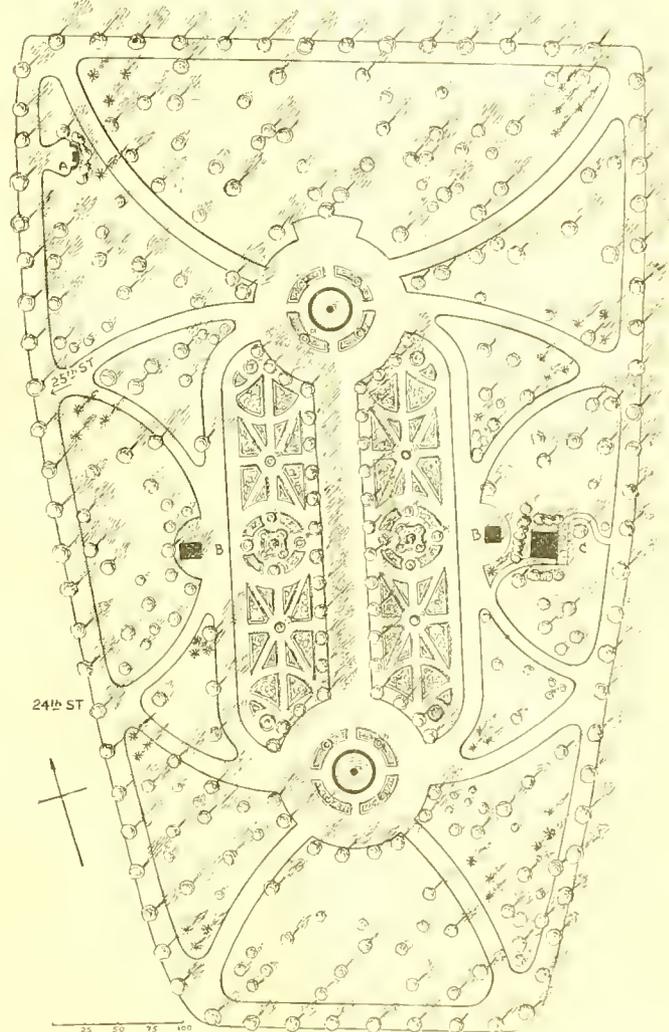

Fig. 19.—Suggestion for the Improvement of Madison Square, by E. Hamilton Bell and Daniel W. Langton.

this way, is more than made good by the broad mall which forms the central feature of their design, the two parallel paths which lie beyond its flanking flower-beds, and the large open circles which surround the basin that now exists, and the one which they indicate as balancing it toward the north. The formal flower-beds, thus properly conceived as important parts of a formal scheme, would be effective and delightful in themselves and would increase that beauty of general effect which they ruin when they are intruded into a purely naturalistic scheme. The Farragut Monument (A) is left in its present place, while its back is screened by shrubs, as was intended when it was built. The statues of Seward and Conklin (B, B), which now look as though they had been dropped down by accident, are properly incorporated with the more formal part of the pleasure-ground. The kiosk (C), a necessary convenience, has

season, thus providing a constant succession of attractive blossoming throughout the year. But a more satisfactory and artistic proceeding in a city like New York would be to treat the entire park as a unit, filling it with trees and shrubs all of which reach their prime of beauty at the same season. Thus, if Madison Square were so planted as to blossom in May, it might be made an object of enjoyment and pilgrimage not only to New Yorkers, but to the residents of the entire neighborhood. When this blossoming season was over, the flowers in the formal garden, set in the green park, would take up the succession and carry it through the year. One of the other parks might be so planned as to bloom later in the summer, and yet another to be at its prime in the autumn."

This is an interesting suggestion, yet there are some reasons against its adoption in a large and busy city like New

York. The pleasure of the majority should be chiefly considered. The majority of those who enjoy our small parks are the persons who have the habit of frequenting the same one day by day, or who pass it perforce in their daily round to and from their places of business, or whose windows look out upon it. And these people might—I do not say that they would—prefer to have their park display as many as possible of the beauties characteristic of each season in turn rather than to find it supremely attractive at any one season.

But, be this as it may, Madison Square would be improved for all seasons if it were rearranged according to Messrs. Bell & Langton's plan. This does not mean that the plan is faultless. In the first place, its authors were obliged to accept the trees as they stand instead of conceiving their plantations as an harmonious whole. Then, this fact puts difficulties in the way of shrub-planting: for, while many shrubs grow well under trees if they are planted when the trees are, and become well established before the ground is shaded, it is harder to induce them to thrive when set after the associated trees have attained their growth. And, finally, an actual mistake may be pointed out in the new plan: lawns which run to sharp points are undesirable in public pleasure-grounds because unruly feet are almost certain to trample upon these points, and also because the grass will dry out and the lawn-mower does not easily reach them. Nevertheless, considering the attendant difficulties, the plan is interesting. It is published here less with the idea that Madison Square may actually be renovated according to its indications than in the belief that a comparison of it with the existing state of the Square will be instructive to those charged with the arrangement of new small parks in this and other cities. Sometimes, even in small urban parks, conspicuous features may prescribe a naturalistic method of treatment. This was the case, for example, on Mount Morris Park, in Harlem, where the existence of a bold rocky hill, as tall as the surrounding houses, inspired the reservation of the tract around it. But such instances are very rare. As a rule, a formal or semi-formal manner of treatment, resulting in a pleasure-ground which is properly to be called a large garden rather than a park, must be most appropriate for restricted areas in the heart of a great city. And Messrs. Bell & Langton show that such a manner of treatment need not exclude variety in design, abundance of shade, the reposeful effect of wide green lawns, or even such seemingly unstudied, yet artistic, arrangements of trees, shrubs and grass as may produce pleasingly naturalistic impressions and illusions.

New York City.

M. G. Van Rensselaer.

Foreign Correspondence.

London Letter.

LISSOCHILUS CRISTATUS.—This is a beautiful terrestrial Orchid in the way of *Lissochilus Krebsii*, and evidently as likely to thrive under artificial treatment as that species, hitherto the only one of the thirty species known that deserves to rank with good garden Orchids. *L. cristatus* was named by Mr. Rolfe on its first flowering at Kew in September, 1892, having been received from Uganda, where it was collected on the hills by Mr. Buchanan. It has lately flowered also in a garden in Liverpool and the scape has been sent to Kew. The pseudo-bulbs are ovoid, the leaves narrow, lanceolate, thick and somewhat fleshy, and about a foot long. The scape is erect, thirty inches long, and it bears ten flowers, each one and a half inches across; sepals small, dull purple; petals broadly oval, nearly an inch long, flat, purplish crimson in front, bright yellow behind; lip saccate, with a distinct spur; the mouth wide, the front lobe short, with prominent ridges, bright yellow, with a maroon-colored tip; column short, purplish, with a green apex. *L. Krebsii* grows and flowers freely at Kew in a warm greenhouse, and *L. cristatus* promises to do equally well under similar treatment. It is an Orchid

which, if a few hundred plants were placed on the market, would secure ready buyers.

CYPRIPEDIUM SANDEKÆ.—One thousand plants, recently imported, were sold by auction here last week under this "provisional" name. The description states that this is the best *Cypripedium* for cutting purposes ever introduced, and that from photographs and measurements received with the plants this species is believed to be far and away the largest of the genus yet discovered. Here is a description of the flower:

Dorsal sepal broadly spear-shaped, the basal portion, median line and veins a warm crimson-maroon, the central portion a clear canary-yellow tinged with green and with a broad margin of pure white. The lateral petals, disposed at right angles to the pouch and dorsal sepal, are of great breadth, much broader than in any other *Cypripede* we know of; most distinct and beautiful in color, the upper half of each petal is of the same color as the basal portion of the dorsal sepal, the lower halves being a clear yellow, slightly shaded in some instances with maroon. The pouch is unique in shape, being much narrower and more elongated than any other in the genus; in color it is yellow shading into ochre. Most beautiful and quite novel in shape.

I cannot identify this vague description with any known species of *Cypripedium*, unless it be an ally of *C. villosum*. The plants were in excellent condition, and we shall, no doubt, soon be in a position to judge whether it deserves all that the venders say of it. At the same time protest must be made against this growing practice with Orchid dealers of giving new names to plants on the chance of their proving new when they flower.

An importation of "a new and magnificent *Cypripedium* from the Malayan archipelago" was sold by auction this week. Is it likely that this is identical with the preceding? The collector in this case states that he discovered the plants in an island devoid of civilization, and that this "is certainly the grandest *Cypripedium* I have ever seen, and should prove one of the most sensational productions of late years." In this case the vender has omitted to give the plant a name.

CÆLOGYNE VIRGINALIS is still another "provisionally named" introduction of which a hundred plants were sold in London this week. It is described as a new species with large, well-shaped pure white blossoms in the way of *C. cristata*, and deliciously fragrant. They are produced in great abundance during the winter months. The exigencies of trade may justify this kind of proceeding, but it is utterly bad in a botanical sense.

ZYGOPETALUM PERRENONDI.—This is a beautiful hybrid which has been raised by Monsieur A. Peeters, nurseryman, Brussels, from *Zygopetalum intermedium* and *Z. maxillare Gauteri*. It was exhibited last week and was awarded a certificate by the Royal Horticultural Society. It bore a stout scape of five flowers, each nearly three inches across, the sepals and petals lanceolate, spreading, with recurved margins, colored green, with bands of dark brown, and the lip of the same shape as *Z. Mackayi*, colored intense violet-blue, with reticulations of a darker shade.

MILTONIA BLEUANA AUREA is a variety of this remarkable hybrid, in which the flowers are four inches across and the white labellum is conspicuously marked with yellow at the base. It was shown last week by Monsieur Peeters and received a first-class certificate.

ANGULOEA UNIFLORA.—An importation of this well-known Orchid, the type of the genus, in fact, was sold in London a few weeks ago under the "provisional" name of *Anguloea albo-magna*. Some of the plants have flowered lately and prove to be identical with the plant figured in *The Botanical Magazine*, t. 4807. The flowers are of medium size, white, tinged with rose and spotted with pale red.

EPIDENDRUM ELEGANTULUM is a new Veitchian hybrid in which there are two parts of *E. Wallisii* and one of *E. Endresii*, the two species named having been first crossed and the product crossed again with *E. Wallisii*. It was shown in flower last week and obtained a first-class cer-

tificate. The flowers, which are in terminal panicles on leafy stems, are one and a half inches across, the sepals and petals ovate, concave, fleshy, dark brown, with reddish eye-like spots, and the flat, fringed lip is white and yellow, with rose-colored spots.

CYMBIDIUM LOWIO-EBURNEUM.—Sir Trevor Lawrence has emulated Messrs. Veitch & Sons by crossing *Cymbidium Lowii* and *C. eburneum*, but reversed the parentage. The result is a hybrid of superior merit to that raised by Messrs. Veitch, the flowers of Sir Trevor's plant being ivory-white, with plane segments and a labellum conspicuously marked with a V-shaped blotch of crimson. It was shown in flower last week and was awarded a first-class certificate.

6,000 feet. I think they would thrive with you if fastened onto the south side of a tree trunk in a sheltered spot out-of-doors. I do not say that the plant would safely pass through a winter like that of 1894-95, but I think it would live outside through an average English winter. Ten to fifteen degrees of frost are often experienced where I gathered these plants, and the winds are often cold and cutting. You might make the experiment, and the result would probably be interesting."

CONIFERÆ.—A hand-list of *Coniferæ* and *Taxaceæ* grown in the Royal Gardens, Kew, has just been issued, and may be obtained from the curator, price threepence. It comprises 227 species, with 340 varieties, belonging to thirty

Fig. 20.—*Quercus Californica*, in Oregon.—See page 146.

LELIO-CATTLEYA DORIS, a hybrid between *L. harpophylla* and *C. Trianae*, raised simultaneously by Messrs. Veitch & Sons and Mr. Norman Cookson, is an enlarged *L. harpophylla*, the lip only bearing distinct evidences of the *Cattleya* in its size, shape and tinge of purple. It received a certificate last week.

CÆLOGYNE CRISTATA.—We grow this plant either in a stove or a warm greenhouse temperature, but, according to a correspondent in Saharumpur, in the north-west provinces of India, it is found wild under conditions which seem to indicate a hardier constitution than is commonly attributed to it. He writes: "The plants I send were collected from the face of exposed rocks at Mussoorie at an elevation of

seven genera. The arrangement of the genera differs in a few particulars from that followed by Bentham and Hooker in the *Genera Plantarum*, and the species are referred to the genera under which they have been placed by the latest authorities. Dr. Masters, F.R.S., the acknowledged authority on the nomenclature of conifers in this country, has assisted in the preparation of the list, which is prefaced by an interesting historical introduction by Sir Joseph Hooker, who has always taken a peculiar interest in this group of plants, and to whose exertions, when Director at Kew, the extent and richness of the collection of *Coniferæ* at Kew is largely due. In 1877 Sir Joseph's interest in conifers was one of the main influences which induced

him to undertake an extensive journey in western North America, and the collection of cones, etc., which he then formed is now in the Kew Museum. The synonymy of *Coniferæ* revealed by this list is appalling. Cultivators of these plants will find the list valuable.

Plant Notes.

Quercus Californica.

KELLOGG'S Oak, a western representative of the Black Oaks, is found distributed throughout the length of California in the coast mountains and on the western slopes of the Sierras, and in Oregon as far north as Eugene, ten miles north of that city being its most northern limit.

This tree, a photograph of which is reproduced on page 145, is one of large dimensions and of fine, open, widely branching and symmetrical habit. The trunk is rather short, but is thick and stout. The bark is dark in color (whence the popular Oregon name, Black Oak), one and a half inches thick and rather deeply fissured longitudinally. The twigs and leaves when young are clothed with a dense white pubescence, which, however, soon disappears. The dark twigs are then smooth, straight and more slender than those of the Garry Oak, giving the tree a cleaner, more open appearance. The leaves are oval in outline, the lobes cut moderately deep, and these and the lobules pointed with delicate spines. The petioles are short and slender. The scales of the cups are thin, ovate, obtuse, flat and imbricated and light brown in color.

The wood of this tree is especially worthy of notice. The heart-wood has a reddish hue, the sap being darker and lacking the red color. The pores of the wood are numerous and slightly wavy; the medullary rays are well marked and not broad, but thick and pronounced in the tangential and radial cut. Samples of the wood, even in an unpolished state, are always admired. The tangential cut is noticeably rich in figure, and the waviness of the vessels, too, is more marked than in the radial or quartered cut. It ought to be a great favorite for decoration and interior finish. It is, however, a little-known and still less appreciated wood.

The bark is said to be rich in tannin and brings about twice as much in the market as Hemlock bark.

The tree here reproduced is an old landmark standing in Eugene, Oregon. It is something more than four feet in diameter and is known in that locality as "Henderson's Big Oak."

Pacific University, Forest Grove, Oregon.

Francis E. Lloyd.

ANDROMEDA MARIANA.—A correspondent sends to this office a branch of *Andromeda Mariana* in flower, with the inquiry whether this shrub is ever planted for ornament. Whether the branch was cut from a plant forced under glass or whether it had merely been cut from a wild plant and brought into flower by placing it in water, we are not informed. We have never seen the latter method tested, although, without much doubt, this *Andromeda*, like many other plants whose flowers are produced on last year's wood, would open its buds if treated in this way. The flowers themselves, however produced, ought to be sufficient evidence as to the desirability of this shrub for planting, at least in certain situations. It is found along the coast as far north as Rhode Island and is abundant in the Pine region of New Jersey and in Long Island in moist and sandy situations. It is a comparatively low shrub, rarely four feet high, with shining, leathery, deciduous leaves, and large, white, waxy, bell-shaped flowers clustered along the branches of the preceding year's growth. It thrives without any special care, if planted in deep loam, particularly if some peat is mixed with it. It is one of the handsomest shrubs of a genus which includes such excellent native plants as *Andromeda speciosa* and the ever-green *A. floribunda*. In autumn its long wand-like branches retain their foliage late, when it turns to an in-

tense scarlet color. It is said to poison sheep which browse upon its leaves, and this gives significance to its common name, the Stagger-bush.

IRIS ASIATICA.—This is hardly to be classed among the winter-flowering Irises, although it was flowering in a cool house with Mr. Gerard a few days ago. It is an attractive plant, akin to *I. pallida*, but inferior to good forms of this species in the size of its flower and in distinction of habit. The flower is of fair size, dark purple, and under artificial light shows a reddish hue. There is a quite distinct blotch of darker purple on the lip of falls. The scapes are four-flowered. In a cool house, however, there are no winter-flowering Irises as satisfactory as *I. stylosa* and its varieties. If well cared for during the summer they make strong growths and flower continuously during the winter under any protection secure from frosts. The plants are fairly hardy in this latitude, but the usual weather conditions are too rigorous to admit of good flowers in the open. This plant seems a favorite in the open in southern England, but the latitude of Richmond, or possibly Washington, would probably be as far north as they could be grown with any satisfactory result in the garden.

KNIPHOFIA PAUCIFLORA.—This is a distinct species of what is generally a showy genus, and it will flower very early with little encouragement but only a botanist would recognize this as one of the Red-hot Poker plants. The tubular flowers, slightly less than one inch long, are borne sparsely on one side and at the top of a thin scape some eighteen inches long. They are of a light straw-color and pretty, rather than striking. The leaves are very narrow and deeply channeled.

Cultural Department.

The Earliest Spring Flowers.

WITH the flowering of the first Daffodils one feels that the spring has fairly arrived now at the end of March. Nature has broken no promises this season, for the weather has been uniformly bad, for the garden at least, as the temperature has been at all times low, with little chance for the winter-flowering plants to progress, and only a rare flurry of snow to protect green foliage.

The impatient Snowdrops even have been discouraged this year, and though they have been peeping since the holidays they have waited for March. Some belated snow, melting quickly, with less rigorous weather, has reminded the alpine bulbs that it was time to waken; and for the last fortnight the garden has been rapidly gaining cheerful bits of color. Of course, those early plants will vary in their flowering time very much from year to year as the weather permits, but there are other influences also at work each year. For instance, the vigor of a plant at flowering time depends on the growth made after flowering the previous year, and a weak growth one year will retard its flowering time the year following.

A number of new Snowdrops received from Mr. Whittall, who had collected them in different locations, are not found to be specially distinct from those already known, but those which last year were found in flower on Mount Taurus in May were here among the earliest to open. *Chionodoxas* are becoming plentiful, but the brightest blue effect in the garden is made by the early Squills, *Scilla Sibirica*, which also came from Asia. These *Scillas* are not only earlier than the typical *S. Sibirica*, so long grown in gardens, but they are brighter in color. They are now (April 1st) in full flower, though the ordinary ones are scarcely started. The white variety, however, is rapidly advancing, and is rather earlier than the white form of *S. bifolia*. Yellow Crocuses, *C. aureus*, have been flowering bravely for some weeks, and very cheerful their color is. Early spring and late fall Crocuses suffer many persecutions from the weather, which they do not withstand very well, and natural selection does not seem to have been very active among them.

At present *Iris Rosenbachiana* is the handsomest individual flower in the garden. This hardy plant from Bokhara has the largest flowers of any of the early Irises, and they are somewhat variable in color, the ones now open being a rich vinous red. A few Irises of the *Reticulata* class have flowered, the dainty *I. Kolpakowskyana* and a nice form of *I. Krelagii*, and there are a few collected ones in the corner, which, aside from being wildings, are interesting since they came from Mrs.

Barnum, of Harpoot, only a few weeks before the troubles broke over the American Mission.

The forerunner of the Daffodils is *Narcissus minimus*, which is as bright as it is dainty. It is a very miniature Ajax, quite small enough to serve in the corsage of a fairy.

J. N. Gerard.

Orchids at Langwater Gardens.

PLEUROTHALLIS ROEZLI was among many new and rare Orchids in bloom recently at the gardens of Mrs. F. L. Ames, North Easton, Massachusetts. It is really more curious than beautiful, and valuable rather on account of its rarity. The Langwater plant is probably the finest specimen in cultivation. It bears eighteen spreading scapes of pendent, irregularly globose flowers of deep wine-color. It is here grown in a basket in the Masdevallia house, and, apparently, is quite at home. It has also been noted by Mr. Watson, in his London letter (GARDEN AND FOREST, No. 420).

The Masdevallias in this collection have frequently been referred to in GARDEN AND FOREST. Seedlings and hybrids multiply with great spontaneity. A small specimen of the strangely curious *M. muscosa* is in a six-inch pan, the plant being not more than ten inches in diameter and six inches high, but it carries thirty-six hairy scapes of yellow flowers. It is chiefly interesting on account of the sensitive character of the lip. Watson, in his book on Orchids, says: "At Kew, in 1887, a small plant of *M. muscosa* flowered for the first time in England. It had short thick leaves, erect, hairy flower-scapes and flowers half an inch across; the lip was hinged and had a concave blade one-fourth of an inch long, in the middle of which was a raised yellow disk. On touching this disk the lip moved upward and closed with a jerk, and it was found that any small insect on alighting on the lip was at once trapped and held for twenty minutes, when the lip opened again. Charles Darwin, who regretted never having seen a sensitive Orchid, would have been delighted had he seen this."

It is difficult to trace the parentage of many of the natural hybrids originating here. What they are may be generally surmised. The majority are evidently between *M. Lindenii*, *M. ignea* and *M. Harryana*. Rebecca, named in honor of Miss Ames, is a brilliant orange, shaded with crimson. Another unnamed kind is a most beautiful violet-purple. *M. Lowii* is very rare. It is remarkable for the violet papillæ covering three-fourths of the length of the sepals, their bases being bronzy, and tips, or tails, white. In *M. Hincksiana* the sepals are yellow, deepening toward the tips; the centre of the flower is white. This lovely hybrid is a cross between *M. ignea* and *M. Tovariensis*. The flowers of *M. bella* are most curiously formed; the long tails cross over the triangular-shaped flowers in such a way as to suggest some large insects; and flowering as they do, from willow baskets suspended above one's head, the effect is heightened. The specific title would suggest beauty, but in this respect the flowers were not to be compared with many others.

Wellesley, Mass.

T. D. Hatfield.

Bomareas.

THESE remarkable twining plants are nearly related to the *Alstrœmerias*. They are natives of the mountain regions of Central America, Colombia and Peru, and have been known in gardens some twenty years or more. As yet they are rare in America, although especially adapted to a bright, sunny climate like ours. They thrive well in moderately warm greenhouses in the north, and are probably quite hardy farther south. All are very floriferous and deserve to be grown for the sake of their large, gorgeously spotted flowers, which are generally very brightly colored. Some flower in early spring, others throughout the summer, the flowers being produced in large umbels or cymes on terminal or lateral shoots. The leaves are more or less lanceolate, with parallel veins. The stem is slender and grows from a fleshy root to a height of twelve or fifteen feet, and even higher under favorable conditions. Among the several species cultivated the most common, as well as the most attractive, are the following: *Bomarea Carderi*, a magnificent Colombian species, with broadly lanceolate leaves six or eight inches long and very large bell-shaped flowers on long peduncles, collected in loose, many-flowered pendulous cymes. The three outer segments of the perianth are rose-colored and three inner ones paler, and all spotted near the apex with numerous dark purple spots; *B. Schuttleworthii*, another very showy species, with flowers two inches long in drooping umbels, with the outer segments orange-scarlet and inner ones yellow, all greenish and spotted near the apex; *B. oligantha*, with very much smaller

but very attractive flowers, about an inch long, funnel-shaped, with the three outer segments sepal-like, reddish green and smaller than the inner ones, which are broader, tawny yellow and but faintly spotted.

The Bomareas delight in a rich, fibrous soil and require plenty of water during the growing season, which commences early in spring. Late in fall the stems are cut down to the ground and the roots are kept in the soil in a dry state. They do best planted out in an open and sunny position in a cool conservatory or greenhouse where they may have plenty of air in summer. The propagation is best effected by means of seeds, which germinate quite easily when fresh, and if sown in shallow pans in a warm propagation-house, but as this method is somewhat slow they may also be increased by a careful division of the fleshy roots.

Newark, N. J.

N. J. Rose.

Seasonable Flowers in the Cool Greenhouse.

IT is not difficult to have cool greenhouses attractive at this season, even where but few rare and expensive plants are available. Just now our own houses are gay with *Cinerarias*, and the individual blooms seem to increase in size each year, some of them being three and a half inches across. *Primula Sinensis* is nearly over, having been flowering since the second week in December. *P. obconica* is at its best, and our largest plants, in eight-inch pots, each carry from fifty to seventy flower-scapes. *P. floribunda*, a pretty little yellow species from the western Himalayas, deserves to be grown more extensively. We sow our *Primula* seed early in April, and as soon as the seedlings are large enough they are pricked off into boxes four inches deep, with a soil composed principally of leaf-mold. They remain in these boxes in the greenhouse, or in a well-shaded frame, till August, when they are potted. They grow very rapidly during the fall and are shifted on as they require it into larger pots. Treated in this way they are very little trouble and very satisfactory. The later species of *Narcissus* are now in flower, and one of the very best is the variety of *N. bicolor*, commonly called Grandee. The perianth segments are a pale sulphur color, which contrasts beautifully with the rich golden corona. The flowers are about three and a half inches in diameter, and each bulb produces two and often three. Of course, the fragrant *Poet's Narcissus* is good for late bloom. *Ixias* and *Ornithogalums* are just coming into flower. English Daisies, in four-inch pots, are useful for the front edge of the stages. The varieties Longfellow (pink) and Snowball (white) are very good when they come double, but a great many seedlings are apt to come single or semi-double. *Myosotis alpestris*, besides being a good spring bedding plant, does well in a cool greenhouse. *Schizanthus pinnatus* has been flowering profusely for the last two months; its beautiful sprays of white and lavender-colored flowers last a long time when cut. *Calendula pluvialis*, the Cape Marigold, is another annual which does well in the greenhouse, but it unfortunately closes its flowers early in the afternoon. *Aquilegias* are useful where a varied supply of flowers has to be kept up. Last September we lifted some clumps of *A. Canadensis* and *A. atrata*; these were potted and kept in a cold frame till the end of January, when they were brought into the greenhouse, where for the past three weeks they have made a fine show. The double-flowered pink *Lychnis flos-cuculi* is just now at its best.

In the warm temperate greenhouse stocky plants of *Fuschia speciosa* and *Rose of Castile*, in five-inch pots, are flowering profusely. *Torenia Fournieri* and *Impatiens Sultani* have been flowering all winter and are very beautiful, though of no use for cutting. *Swainsonia galegifolia*, with its beautiful sprays of pea-shaped flowers and pinnate foliage, is one of the best winter-flowering plants we have, and *Abutilon*, Golden Bells, is proving an excellent free-blooming variety. Some cuttings of a double-flowered form of *Tropeolum Lobbianum*, received here last fall, are now in flower, and though to many the flowers are not as attractive as the single kind, it is the most profuse blooming *Tropeolum* I have ever met with.

Botanic Garden, Northampton, Mass.

Edward J. Canning.

Clianthus Dampieri.—It is thirty years since this plant was first brought from the deserts of Australia, and, though extremely beautiful as well as interesting, many persons have never seen it in flower. Its common name, the Glory Pea, is a translation of its generic name, and since it belongs to the Pea family and bears flowers of the brightest scarlet it well deserves the title. It is also called at times the Parrot's Beak, from its sharply curved and pointed keel. The lower part of

the standard carries an almost black-purple boss. These handsome flowers are borne on five-angled stems proceeding from the axils of the leaves in clusters of four or five, and they are individually four inches long by one inch wide. The pinnate foliage is pale green, covered with a silvery down. The plants should be propagated by seed sown singly in four or five inch pots, which should be well drained. The soil is better if prepared of about equal mixtures of loam, leaf-mold and sand, with a little charcoal to prevent its becoming sour before the roots have filled the pots. If sown in smaller pots the roots are liable to be hurt in transplanting, and any injury happening to them while young means sure death to the plant. Neglect of caution in this particular has given the Glory Pea the reputation of being difficult to cultivate, but when treated as recommended above it is not a very untractable plant. Seeds sown at this season will germinate in a temperature of sixty degrees, and if properly cared for the plants flower well in the greenhouse late in the following winter or spring.

Northampton, Mass.

E. J. C.

Hippeastrum Ackermanni.—The *Hippeastrum* are especially adapted to the American climate. Whether grown indoors as conservatory or house plants, or in the open ground in the southern states, they grow and flower very profusely. The above old-fashioned species is one of the most common plants now seen in windows and apartments. The plants are generally large and robust, with two or three scapes, each bearing several very large and showy crimson flowers, which last in perfect beauty for several weeks, if kept in a moderately cool place. The culture of this species is so simple that anybody ought to succeed in growing it with very moderate attentions. The growing season begins early in spring or late in winter, and from that time until September abundant watering is necessary. Afterward water should be given more sparingly, and in the bright autumn months the bulbs will ripen thoroughly. The leaves should not be allowed to die for want of water, even when stored away beneath the benches in a greenhouse. *H. Johnsoni* is a less common species with a white band down the middle of each segment of the perianth. It is of equally easy culture. All species require a rich, fibrous soil.

Wellesley, Mass.

I. D. H.

Hardiness of *Aspidistra lurida*.—Some remarks on *Aspidistra lurida* which I recently saw in GARDEN AND FOREST remind me to say that it is quite hardy in Philadelphia. Your correspondent, Mr. E. J. Canning, found it hardy when living in this vicinity, and I have recently seen a large number of plants used in a narrow border, close to a building, and they have withstood the winter perfectly. It may be hardy much farther north than this, and if so it will prove a most useful dwarf evergreen, and quite unlike any other which we now have at command. It is a Chinese plant, and possibly plants from seed gathered in the extreme northern part of its natural range might endure New England winters.

Germantown, Pa.

Joseph Meehan.

Correspondence.

Nurseries at Bay Ridge, New York.

To the Editor of GARDEN AND FOREST:

Sir,—A visit to the nurseries at Bay Ridge, an outlying suburb of Brooklyn on the Bay shore, cannot fail to be interesting to the flower lover and highly instructive to the practical cultivator at this season. Here, in the three large establishments of John Dean, James Weir's Sons and John M. Keller, seventy-five glass houses were last week closely filled with Easter plants. Many of these structures are 200 feet long, a few stretching 230 feet, with a span of twenty-two feet. As much as 60,000 square feet of glass and four acres of ground, perhaps, is in use in each one of the places. The enormous trade in cut flowers and plants in cities the year through can scarcely be conceived by the occasional buyer of a corsage bouquet or a plant in the holiday season. At Weirs', for example, there are twenty-five greenhouses. For the Easter trade these were largely planted with Lilies, as many as 2,600 pots of this seasonable plant extending 200 feet through the middle of several of the houses. A house of equal length was a continuous bed of the delicate Maiden-hair Fern, *Adiantum cuneatum*, the plants in five-inch pots. Another was given up to climbing Asparagus, one to Smilax, another to Palms, Araucarias, Rubber-plants and the like, and the most brilliant effect of all was a house of General Grant Geraniums, some 2,200 of the plants being in full glow. Besides 30,000 bulbs of the Bermuda Lily in different stages of forcing, some being

brought on for use as late as Decoration Day, there were immense collections of Azaleas and Hydrangeas, at least 1,000 plants of each being covered with bloom, the latter very fully flowered and with unusually thrifty foliage. On the side benches in these houses were bedding-plants for the spring-planting trade, as Geraniums, Coleus, Ageratum, Vinca, Lantanas and rosy stretches of *Alternanthera*. One house was given over to propagating. Marguerites occupied 100 feet of space, and Spiræas as much more, while there were 5,000 Hyacinths forced into flower. This great establishment is exclusively devoted to plants for the Easter trade, to spring-bedding plants and Chrysanthemums. An idea of the quantity of stock handled in the city retail flower-shops may be had when it is realized that in the two stores of the Messrs. Weir in Brooklyn, besides all that is grown at Bay Ridge, as many as 5,000 to 20,000 roses alone, and some thousands of other cut flowers, are each day bought in New York City, and also during the planting season a great van-load of bedding stuff.

In each of these great nurseries Lilies were in greatest abundance, Azaleas following in numbers. In Mr. Keller's twenty-eight houses *Genistas* of both the two common market varieties, *Cytisus racemosus* and *C. Canariensis*, were conspicuous, and, besides the standard plants of the season, there was a large and interesting variety in which were forced *Rhododendrons*, Lilacs, the beautiful broad-leaved *Kalmias*, *Andromeda speciosa*, with its dainty bell-shaped white flowers, which are disguised by retail dealers under the name of Canterbury Bells; *Metrosideros*, the striking Bottle-brush plant, and beautifully berried plants of *Ardisia crenulata*. In one large space, fifty by eighty feet, obtained by the removal of the dividing-walls of three houses, seven broad benches of Hydrangeas gave an impression of rude vigor, the roof being utilized for baskets of *Cattleya Triana* and *Oncidium*s.

In Mr. Dean's houses Azaleas were the most striking feature. The best specimen plants were comprised in about a dozen selected sorts, Niobe, a large double white flower, with lemon tinge at the base of the upper petals and almost bud-like centre, was the best white shown, while Bernhard Andrea alba, of snowy whiteness, was also attractive. Dr. Moore was the best pink, a single flower with closely twisted centre, of clear bright solid rose-pink and satiny sheen. Another good flower of this color was Madame Van der Cruyssen, less even in tint, the upper petals distinctly splashed with crimson, and the flower more open at the centre. Empress of India was a delicate true pink with a white edge. The richest color in the entire collection was that shown in the clear rich crimson of the flowers of Le Flambeau. These were rather small, single, almost entirely free from spots, with only a faint marking of a deeper shade. *Vervæneana* showed immense flowers with the inner petals twisted, the outer edge of the petals white, the middle a bright splash of pink. Other notable sorts were Mademoiselle Marie Vervæne, distinct red and white stripe, resembling the Helen Keller carnation; Czar Alexandre III., brick-color, splashed with red; Souvenir du Prince Albert, clear medium shade of pink, irregularly edged with white, double, small; Hermione, rich deep pink, very double; Versicolor, a large single flower of most distinct effect, the petals greenish white, boldly striped and splashed with brick-red, this color sometimes occupying a solid quarter of the flower. Besides these, varieties having special merit were Simon Mardner, Louise Pynaert, Sakuntala, Comte de Chambord, Madame de Grevé, Antigone and Etandard de Flandre. These varieties were all free from unpleasant tints, the 3,000 plants having an average size of fifteen inches in diameter and eighteen inches in height, in six-inch pots. Of course, there were specimens of much larger size. Easter being a movable feast, the same sorts are not the best for all years, but these were the best kinds this year.

This season of trade, the largest of the entire year, preceding, as it does, the regular spring business, needs long preparation. Indeed, the work for Easter laps over more than a year. The Lily-bulbs are ordered immediately after Easter and delivered from Bermuda in July, when they are at once potted and placed out-of-doors; in the fall, after the Chrysanthemums are removed from the houses and severe frost is threatened, the Lilies are brought indoors and kept in a night temperature of forty to forty-five degrees until Christmas or New Year's, when they are urged forward in a higher temperature. One bulb is planted in a six-inch pot, and beautiful effects are produced by grouping five or six plants in twelve-inch pots. These masses are three to four feet high and carry thirty-five to forty flowers, the rich foliage being almost as strikingly decorative as the flowers. The Bermuda Lily is grown in preference to *Lilium longiflorum*, because its flowers are more easily produced in abundance under less favorable treatment, and they last longer. This Lily is sometimes called

soft, not because this is its real character, but because it has been forced too hard. *L. longiflorum* fails entirely under too severe urging, the buds coming blind, or not appearing at all. The two sorts potted on the same day will show flowers on the taller-growing and more spreading Bermuda Lily by Thanksgiving Day, while the older *longiflorum*, of more sturdy and upright habit, cannot be flowered before February. An important and exacting detail of cultivation is the examination of every lily as soon as it expands, for the removal of the pollen before it is ripened and has been shed and made its yellow stain on the pure white flowers. This is done by hand and requires going over the stock once and even twice a day. It may be worth while saying that no Ascension Lilies or Callas were seen in any of these collections. While the regular stock of Lilies is each year produced from freshly imported bulbs, in some of these large nurseries the Lily plants, when returned, are dumped out-of-doors and picked over later in the season. The best bulbs are planted in July or August in frames and protected over winter. These plants bear, during the next spring, one or two flowers each, for the six to ten of the first efflorescence, the blossoms being useful for funeral orders.

The stock of Azaleas is imported from Belgium in October, and these, with the Lilies, Spiræas, Genistas, Hydrangeas and other Easter plants, are started indoors at the same time and under the same general conditions. They are all carried along in gentle heat, Lilies being pushed forward about the beginning of Lent, the general idea being that it takes six weeks to get them into bloom from the forming of the bud. Azaleas, as a rule, need a shorter time to be brought into flower, though there is considerable difference in this respect in different varieties. Hydrangeas, which are propagated from cuttings made at the beginning of March a year ago, need longer forcing, and are started on in December. These are usually planted out in the open ground in summer, but Messrs. Weir last year kept them in pots and plunged them. The plants of Genistas are carried over from year to year, and when new ones are propagated it is from cuttings which require several years to bring them into flowering condition. Genistas are not often sold, but loaned for the Easter season. When returned to the cultivator they are repotted and pruned and plunged out-of-doors until autumn. The stock of Spiræas comes from Belgium, and its treatment is not unlike that of the other plants noted. Besides the old Spiræa, *Astilbe Japonica*, and the increasingly popular *A. compacta*, there are this year some of the old-fashioned Spiræa palmata, with bright rose-colored trusses and handsome, deeply pinnate raspberry-like foliage. Bulbous plants, as Narcissus, Tulips and Hyacinths, are, of course, profusely grown in pots and pans for dressing up in baskets, and many cut blooms are sent to the stores.

After the stock is sufficiently advanced the temperature of the houses is reduced from the forcing heat of sixty-five or seventy degrees to fifty degrees, to harden off the plants. On Monday following Palm Sunday the work of removal of the plants begins, and during frosty weather the carting over muddy roads in immense padded wagons and heated vans is of itself an enormous undertaking.

Protection for a Public Interest.

To the Editor of GARDEN AND FOREST :

Sir,—The bicycle has been taking people into the country of late and setting them in touch with nature, teaching them what they have never known before—that a landscape could be beautiful or interesting or inspiring. As the exuberant wheelman, who has just pulled himself up the hill, lifts his feet from the pedals and comfortably settles himself for a coast down the other side, he is peculiarly susceptible to the view from that hill-top. If he finds the coasting good he is likely to come to that hill again; and it is not long before he feels, and justly feels, that he has a right to the enjoyment of that prospect, with all its inspiration and refreshment. Imagine his feelings, then, when some day, as he pauses out of breath for his usual eye-feast, he finds a huge board curtain drawn across the landscape, and on it a screaming advertisement of the virtues of somebody's "germ destroyer." He knows that he has been robbed of what is his by right. If a painted landscape by Turner or Corot has a high money value, why shall we not estimate the real thing as worth something, and why should not its wanton destruction be counted a crime? If some man in the pursuit of his private business should blow up the Smithsonian Institution or an art museum he would meet with prompt punishment, yet the anarchist who paints signs does the same thing all summer long in the rural and suburban districts, and never hears a whisper of reproof.

Why not legislate against such an evil? It is a mistake to suppose that the venders themselves delight in this method of advertising. They are driven to it, perhaps, by competition, but by a competition which they would gladly evade. The advertising and bill-posting agency preys upon the dealers on one side, and inflicts itself on the public on the other. The agency alone would have to suffer if this unpleasant species of advertising were suppressed.

Could legislation reach this evil? Probably. The most feasible plan is, perhaps, that proposed in the Rural Advertisements Bill, which was brought before the English Parliament at its last session. The proposition was to tax all publicly displayed advertisements by the square foot. Such a tax could be easily levied and apportioned, and there would be no one but the bill-poster to lament if this tariff should be made prohibitory. This would be protection in a proper sense—protection in the enjoyment of one of our natural inheritances and against a nuisance. Suppose the patent-medicine man should follow me all day crying out in my ear that his nostrum was just the thing I needed to make me young again, would not the police interfere in my behalf? And why should a man assail his fellow-citizens' eyes with greater impunity than he assails their ears? All that such a plan of taxation would need anywhere would be some one to draft the bill and watch it through. Even the sign-painter would rather look for new employment than hire a lobby to defeat it.

Plant Breeding. By L. H. Bailey. New York: Macmillan & Co.

This little manual belongs to the Garden Craft Series, of which the excellent Horticulturist's Rule Book was the first number. It consists of five lectures setting forth those principles of evolution upon which any successful efforts at improving domestic plants must be based. There are few subjects upon which popular knowledge is so imperfect as the origination of new vegetable forms, and a compact treatise on its essentials is evidently needed, for until the horticulturist ceases to regard each novelty as a chance phenomenon without looking at the laws under which these organisms vary, there can be no sustained progress in the development of plants in any desired direction. The first lecture in Professor Bailey's little book treats of plant-variation and its philosophy, and after stating the fact of the individuality of the seed and of the bud, the principal causes of individual differences are explained, and then the reasons for choosing certain varieties and methods of fixing these, so far as these can be fixed, are discussed. The next lecture treats of the crossing of plants with reference to their improvement, after which a few concise rules are laid down for breeding domestic varieties, with specific examples. The book concludes with a practical chapter on the structure of flowers, and especially of their essential parts, with directions for manipulating them in crossing. This last topic is carefully illustrated and shows the simple tools needed, with such plain directions for using them, that any person of ordinary skill can do the work. There is an intermediate lecture, which consists of extracts from Verlot on the varieties of ornamental plants, Carrière's account of the varieties of ornamental plants with a list of bud varieties and Focke's interesting discussion on the characteristics of crosses. This little manual, with a glossary and complete index, comprises nearly three hundred clearly printed pages, and it ought to be in the hands of every studious horticulturist. If it does nothing else it will show him the limitations of his field and warn him against attempting impossibilities. But, besides this, it will point out the directions in which he can hopefully experiment and give him the assurance that he is working in the realm of law and not in one of chance.

Notes.

Another Canna, named Austria, and of the same strain with Italia, which was described and figured in our issue for April 1st, has flowered with Mr. Pierson at Tarrytown. We have not seen the flower, but, according to reports, it is even more

beautiful than the first one. It is very large, of a perfect yellow, with pencilings of scarlet on the two inner petals so faint as to be hardly visible. Whether these flowers will have sufficient substance to be valuable for out-of-door bedding remains to be proved, but, beyond all question, they are superb when grown under glass.

The blanched tops of Swede turnips are much used as a vegetable in England, but when they are grown with offensive surroundings, as is occasionally the case in old mushroom beds, of course they are inferior. A correspondent of *The Gardeners' Chronicle* writes that untrimmed turnips placed close together in a box, the bottom of which is covered with a few inches of damp sand and then loosely covered with a mat, will soon show a small forest of shoots of perfect flavor and free from the objectionable "turnipy" taste. Many persons consider them quite superior to the best grown sea kale.

Linseed-oil meal is rich in plant-foods, and if these were rated at their cost as obtained from nitrate of soda, dissolved bone-black and muriate of potash a ton of linseed-meal would have a fertilizing value of \$18.00, and would be worth for fertilizing purposes about \$26.00 as the ordinary mixed fertilizers are sold. A late bulletin from the Ohio Experiment Station calls attention to the fact that inasmuch as this meal is now selling at \$16.00 a ton the farmers who are buying fertilizers can get plant-food in this way at reasonable cost. The oil meal is so rich in nitrogen that fertilizers containing considerable phosphoric acid and potash should be mixed with it. By actual experiment in the Ohio station it was found that half a ton of oil meal worth \$8.00 gave as much increase on an acre of Wheat as a compound commercial fertilizer which cost \$11.00.

The Association for the Improvement of the Condition of the Poor in this city, under whose auspices the system of vacant-lot farming was conducted last year, have arranged for a series of lectures and object-lessons in different parts of Westchester County, of this state, with the view to the improvement in methods of horticulture and agriculture. Professors from the different agricultural colleges and experts in dairy practice and cultivation of different crops speak in the different towns on such subjects as Strawberry-culture, Apple-culture, Insects Injurious to Fruit, How to Suppress Epidemic Diseases among Plants, etc. This is practically an extension of the institute work and schools of horticulture which have been conducted in other parts of the state with signal success, and it is hoped that this new venture will prove equally helpful as an educating force.

At a late exhibition of flowers before the New York Farmers' Club, Mr. W. A. Manda, in connection with an interesting display of Orchids, delivered an address in which he said that many of these plants do not require so much moisture as is commonly supposed, watering once or twice a day and syringing the leaves daily being sufficient for them. He added, that at least twenty-five species and varieties could be grown as easily as Palms, and that a good place for some of the cool Orchids in summer is out under an Apple-tree. He named *Dendrobium nobile* and *D. Wardianum*, *Cypripedium insigne*, *C. villosum* and *C. Boxallii* as varieties which could be grown in any window. Even *Dendrobium Calceolus*, of which he had on exhibition a magnificent specimen, he pronounced a plant which could be perfectly well grown in an ordinary window. The cardinal point in Orchid culture is that they must certainly have a season of growth and a season of rest, which are in their homes seasons of rain and seasons of drought, and this indicates the proper treatment. The more growers learn about Orchids the more fresh air they give these plants.

The past week or ten days has probably been the most disastrous term of the season to fruit merchants, owing to unfavorable weather and dull sales. The prices of Mediterranean oranges fell twenty-five to fifty cents a box, and of lemons ten to twenty-five cents. California oranges were affected by this decided drop, and some car-loads of Navels were withdrawn from sale toward the end of last week on account of unsatisfactory prices. Lighter receipts of the Sicily fruits are expected, and delayed spring weather hoped for, when better prices are anticipated. Sicily oranges of the highest grade and desirable sizes sold last week to wholesale merchants for \$2.50 to \$3.00 a box, Valencias at \$2.75 to \$4.00, and California Navels at \$1.20 to \$3.50. A small shipment of Cayenne pineapples, large and of extra quality, came from Florida during the past fortnight. They were grown under glass, near Orlando, and sold at \$1.50 apiece in the fruit shops. It is between seasons now for this fruit, the first of the new crop, some 350 barrels, being due to-day from Cuba, but there will be no regular shipment

of this fruit from Havana for two weeks. The season for Bahama pineapples opens about the middle of May, and for those from Florida in June. The first pineapples from Cuba in 1894 arrived here April 10th, and last year April 15th. It is feared that shipments from Cuba will be interfered with by the war there, although importers depend upon more general forwarding from all over the island, so that any deficiency from particular sections usually depended upon will thus be made good. Even a more serious drawback is the injury to the crop by storms over a year ago, and more recently by lack of winter rains and unusually cold weather and strong winds during March, conditions which have prevailed generally throughout the West Indies, and which have made the crop late. The season for strawberries in Florida is nearing an end, and the best berries now coming from that state, smaller and less luscious than the perfect fruit of a week ago, cost forty-five cents for a quart box at retail.

The flower-stores of this city made a meagre sidewalk display, in comparison with that of former years, on the day before Easter, owing to windy and cold weather. Some of the best establishments made no outside sign of the great floral festival. Occasionally a line of pyramidal Box-trees stood out in wind-break fashion, but even double rows of these gave way before the sharp blasts. Indoors the plants were more fully and perfectly flowered than ever before in this market, though to an onlooker buyers seemed very few. Among the most beautiful and satisfying effects were plants of Lilac just beginning to open, the light and graceful thyrses singularly dainty in the untolding of the flowers above the tender foliage. Genistas abounded in small plants a foot high for house use, and in tall, spreading specimens for church decorations. The long drooping wands of the closely flowered clear yellow *Cytisus Canariensis* was particularly satisfying in contrast with the muddy color and more rigid form of *C. racemosus*. Lilies and Azaleas were, of course, foremost in quantity, and there were Hydrangeas and Spiræas, the old form with its open and airy habit being more attractive than the newer variety known as compacta. There were strong shrubby little plants of *Kalmia*, bright and striking dashes of color in spikes of *Metrosideros*, fruiting Otaheite Oranges, plants of *Andromeda speciosa*, the branches thickly strung with the delicate white bells; vigorous large bushes of *Acacia*, the straight thick spikes often a foot and a half long and densely covered with globe-shaped feathery clear lemon flowers to within four or five inches of their extremities. Heaths were more abundant than ever before, while occasional forced specimens of *Spiræa Cantonensis* and *S. Thunbergii* were seen, covered with snowy bloom. *Cinerarias* were happily missed, with their usually decided and coarse colors; although not yet common, the new dwarf *Bougainvillea* is proving that it is a good plant for Easter flowering. Vigorous plants of *Magna Charta* Roses in promising bud and dainty pots of Moss Roses were among the scarcer plants. With the usual display of bulbous flowers gay and cheery beds of Pansies were pleasing and appropriate, and an occasional pot of well-flowered Primroses came as a pleasant relief to the more striking colors. Among the less common cut flowers there were Orchids in unusual variety, considerable quantities of anthuriums, spikes of gladiolus, stems of white snapdragon and tight bunches of trailing arbutus from the south. The real phenomenon of the Easter trade in this city was the hideous attempt at decorating the flower-pots with crêpe paper and ribbons. The result was more than grotesque—it was absolutely vulgar. In one window off shades of red, blue, purple, pink and yellow, besides white and parti-colored papers, with ribbons of conflicting tints, and arranged with no reference to the colors of the flowering plants, made a most offensive display. Presumably well-grown plants were disguised in crimped and ruffled swaddling clothes, which reminded one of the attempts of a rural dressmaker to revive the full-skirt style of 1860. A few color combinations noticed were Genistas in bronzy-yellow paper, with pea-green ribbon shown against the glaucous foliage; pink Azaleas surrounded by broad ribbons of the bright shade known as American Beauty, and dull purple-flowered *Rhododendrons* shrouded in long gowns of white crêpe secured by belts of dull purple ribbon. Occasionally the better taste and deft hand of some woman was seen, as where long boxes containing single yellow narcissus with rich blue-green foliage were simply covered with a band of yellow paper and a spare use of yellow ribbon of the same shade to match the flowers. Carnations were in meagre supply, one dealer, for example, being able to secure but 7,000 flowers to fill orders amounting to 10,000. Prices for these flowers ranged from \$1.00 to \$2.00 a dozen for the ordinary sorts, \$3.00 being asked for the popular Helen Keller.

The Tree Palms of the United States.

A NUMBER of Palm-trees live on the southern borders of the United States, adding special interest to the forest flora of this country, which, rich in many forms of the common trees of the northern hemisphere and in many special and peculiar types, is extraordinary in the variety of its composition and in the size and beauty of its individuals.

Of these Tree Palms of our country the best known is the Cabbage Palm, or Cabbage Palmetto (*Sabal Palmetto*), of the coast region of the south-eastern states, where in the immediate neighborhood of the sea it ranges from an island off the mouth of the Cape Fear River in North Carolina to southern Florida, and along the Gulf coast to the Apalachicola. This tree is interesting to botanical geographers as the most northern arborescent Palm in the world; and probably nothing so delights and instructs northern travelers in the south as their first introduction to a grove of these plants. The large terminal leaf-bud of this tree and of many other Palms is cooked as a vegetable—a fact to which it owes its common name. The custom is an extravagant one, as the removal of the bud, which is never replaced, kills the tree, and as young vigorous trees produce the most succulent buds it is rather remarkable that the species has escaped extermination in a region abounding in negroes who are credited with a special fondness for cabbages which can be had without agricultural forethought or labor. But if it has survived the vegetarian it will not long survive the maker of scrubbing-brushes, who now uses the fibres of the sheaths of the young leaves in his industry. To obtain his material the top of a young plant with its bud is cut off, trimmed down to a disk of about eight inches in length, and then, after the soft edible core has been removed, boiled to separate the fibres. The removal of the top kills the plant, as we have already said, and as one concern in Jacksonville, Florida, alone consumes 7,500 buds a week, the time is not very far distant when the *Sabal Palmetto* will become a rare tree. The buds, which are now mostly procured from the west coast of Florida, where the Palmetto is most abundant, are worth at the mill only six or seven cents each, and it is not probable that the extravagance and wastefulness of this brush

industry is exceeded by that of any other in the United States.

A rude stockade made of the stems of the Palmetto on one of the islands in Charleston harbor, and manned by less than a hundred Americans under Moultrie, repulsed, on June 28th, 1776, Sir Peter Parker's British fleet and decided the fate of the Carolinas. A year later South Carolina placed on her official seal, in memory of this victory, a Palmetto erect, emblematic of its strength, and below it an Oak-tree torn from the ground and shorn of its branches to recall the fate of the oaken ships of her oppressors; and the Palmetto state took her place in the Union. In these days the trunks of this Palm are found as serviceable against the attacks of the teredo as they were in withstanding British shot, and make excellent wharf-piles for our southern coast.

A second arborescent *Sabal* enters our territory. This is *Sabal Mexicana*, a tree which is widely scattered along the Gulf-coast of Mexico and, crossing the Rio Grande, follows its Texas bank for a distance of some thirty miles from the coast, growing to a height of fifty feet on the rich bottom-lands of the river, where it is associated with the Texas Elm, the Texas Green Ash, the Mimosa and other trees peculiar to that region. In habit it resembles the Carolina Palm, but the leaves are rather larger, the flower-clusters are three or four times longer, with stouter branchlets, and the seeds are more than twice as large and much darker in color. In Texas the leaves of this tree are cut off almost as fast as they appear, being highly prized as thatch for buildings. It is occasionally planted as a street tree in the towns along the lower Rio Grande, and in some of the Mexican states this *Sabal* is regularly cultivated to produce leaves from which cheap straw hats are made in great quantities.

The third of our arborescent Palms inhabits the Colorado Desert in southern California. Found by the Jesuit missionaries, who settled in California, on the low shores of the depression of the desert which once held the waters of a great arm of the sea, the *Washingtonia* was taken to decorate the gardens of their southern missions. Some of these mission trees have now grown to a great size, and not long ago two of them standing near an old well in San Pedro Street, Los Angeles, were nearly one hundred feet in height, with trunks nine feet in diameter at the base. Specimens of such a size are rare, and on the desert and in the dry mountain cañons which this species selects for its home, and where it is subject to the constant hardship of drought, wind and fire, it is rarely more than fifty or sixty feet tall. Nature, in thatching the trunk with a thick cone of dead pendent leaves extending from the base of the living crown of foliage nearly to the ground, has furnished *Washingtonia* with the best possible protection against the drying winds of the desert. But, unfortunately, this thatch, which becomes as dry as tinder, is very inflammable, and usually falls a prey to the fires of Indians who find that it prevents them from climbing the tree to gather the fruit, or of untaught white men who enjoy the sight of the mass of dead leaves disappearing in a flash of flame. The tough outer rim of the trunk, fortunately, does not burn easily, and through uncounted ages *Washingtonia* has survived hardships of environment and the vandalism of man from a time, perhaps, when its broad and splendid crown of foliage was reflected in waters which have disappeared with its less robust and enduring forest companions. But, whatever may have been its history and its hardships in the past, the lines of *Washingtonia* have at last fallen again in pleasant places, and, nourished by the waters of limpid mountain streams, it is growing now in countless thousands in all the gardens and parks of southern California; and in all the countries of southern Europe this lonely denizen of the desert has become a rival in stately beauty of the Palms of every semitropical country.

Washingtonia is now known to contain a second species, an inhabitant of western Sonora and Lower California, and very like our California tree, except in some unimpor-

tant botanical characters and in its more slender habit and smaller size. First considered a species of *Pritchardia* by Wendland, the German authority on Palms, our California Palm was afterward made the type of his genus *Washingtonia*. Some later students of the Palms have now united *Washingtonia* again with *Pritchardia*, but the structure of the flower with its free stamens, the armed petioles, and its geographical distribution appear sufficient grounds for considering *Washingtonia* generically distinct.

The two Sabals and the *Washingtonia* are the only Palms which belong to the flora of North America, and one of the Sabals, which only just enters our territory, is really Mexican. The other arborescent Palms in the United States are all tropical species and are confined to the shores and keys of the extreme southern part of Florida which are covered by a purely tropical vegetation, and where three genera are represented.

The first of these is *Oreodoxa*, an American genus of about four species. Three are lofty trees, the loftiest, perhaps, of all the American Palms, and true princes of the vegetable kingdom, while the fourth is a humble inhabitant of the high slopes of the Andes of Ecuador, only remarkable as one of the most alpine of all Palms. The largest species, *Oreodoxa oleracea*, the Cabbage Palm of the Antilles, sends up a slender trunk nearly two hundred feet in height, surmounted by a long, green, polished cylinder of petiole sheaths and a crown of long, arching, graceful, pinnate leaves frequently twenty feet long and six feet wide. Its tall pale stem and beautiful head make this Palm a favorite in gardens, and it is planted in all tropical countries and often in long and stately avenues, as in the Botanic Garden of Rio de Janeiro, which owes its fame to its Palm avenue. Economically, *Oreodoxa oleracea* is one of the most useful of the American Palms. The bud of young leaves, like that of the Palmetto, is eaten as a vegetable; the sheathing bases of the leaf-stalks, which are eight or ten feet long, are used by the negroes as cradles, and are split into surgeons' splints; from the inner coat of these sheaths vellum-like paper is made, and mats are manufactured from their fibres. A kind of sago is obtained from the pith of the stem, and oil is pressed from the seeds. The long stems are split longitudinally and, freed of the spongy interior, are used as gutters, while from the hard rind-like exterior rim beautiful canes and many small objects are made. Another West Indian species, *Oreodoxa regia*, the Royal Palm, is a tree often one hundred feet high, with a trunk which is often largest near the middle, but otherwise generally resembles the Cabbage Palm and is equally graceful and beautiful. This species, which is common in Cuba, extends into southern Florida, where it inhabits two or three hummocks on Rogue's River, about twenty miles east of Caximbas Bay on the west coast, Long's Key and the shores of Bay Biscayne near the mouth of Little River. The presence of a lofty Palm in southern Florida was hinted at more than sixty years ago, and the fact is mentioned in the preface to Nuttall's *North American Sylva*, but it was not until 1859 that this Palm was known to be *Oreodoxa regia*. In that year Dr. Cooper found it on Bay Biscayne, and twenty years later Mr. A. H. Curtiss established the fact of its presence on Rogue's River and Long's Key.

The portrait of a young tree of this species near the shores of Bay Biscayne appears in our illustration on page 155 of this issue. It is made from a photograph for which we are indebted to Mr. James M. Codman, of Brookline, Massachusetts; and, although it does not display the loftiness of the full-grown tree, it shows the slender stem and graceful head of the most beautiful of the Palms of the United States.

The next genus, *Pseudophoenix* (see vol. i, p. 353, fig. 55), is monotypic and confined to two of the southern keys. It is a small and not particularly handsome tree, with long, arching, pinnate leaves and large orange-scarlet, usually three-lobed, fruits. The flowers of this species, of which there are probably not more than two or three hundred

individuals in existence, unless it grows elsewhere than in Florida, are still unknown.

The last of our genera, *Thrinax*, is exclusively West Indian and Floridian, with a few species of small trees and shrubs distinguished by large handsome fan-shaped leaves often silvery white on the lower surface, minute flowers, with calyx and corolla confluent into a short cup, and small fleshy or dry fruits. The Florida species are not well known, and there are probably four arborescent species on the keys, although at present no other North American trees are so little known as this group of Palms.

At a recent meeting of the West Virginia Academy of Science a committee was appointed consisting of Dr. A. D. Hopkins, Chairman; Dr. J. L. Goodknight, President of the West Virginia University; Dr. J. A. Myers, Director of the West Virginia Agricultural Experiment Station; Judge Okey Johnson, Dean of the Law Department of West Virginia University, and L. C. Corbett, Professor of Agriculture and Horticulture, West Virginia University, to inquire into the subject of forest protection, and draft bills for the establishment of a system of forestry reservations in the middle Alleghenies; the bills to be submitted to Congress and the state legislature.

The committee state that by referring to a map it will be seen that there is an area in the middle Allegheny Mountains, principally in West Virginia, but extending through a portion of Maryland and Virginia, and into Pennsylvania and North Carolina, in which the sources of a number of important rivers are found, namely, the Monongahela, with its tributaries; the Elk, Gauley, Guyandotte and Big Sandy, all of which belong to the Ohio River system; the principal tributaries of the Potomac and James, and also the source of the Tennessee River. In addition to this important system of river sources, the region embraces possibly a million and a half acres of virgin forest, with a considerable area of cut-over brush and waste land. Much of the continuous forest area lies in large bodies, and consists largely of Black Spruce, Hemlock, White Pine and valuable hardwood timber, making it a region of extreme importance, not alone to the states in which it occurs, but to the entire region drained by the several rivers mentioned, embracing a large portion of the United States east of the Mississippi River.

It is, therefore, evident that the protection of the forests in this region is a matter worthy of consideration by the Secretary of the Interior, the Forestry Inquiry Commission of the National Academy of Science, the Rivers and Harbors Committee of Congress and the Representatives in Congress from West Virginia, to whom resolutions have been sent reciting the dangers to the forest and recommending prompt action.

The committee further states that it will hold itself in readiness to furnish, as far as may be, any information regarding the region embraced in West Virginia, and will gladly cooperate with other academies of science, scientific and forestry associations and individuals, in obtaining and presenting facts bearing upon the subject. We need hardly add that we are in full sympathy with this movement. This journal has repeatedly advocated the establishment of a reservation to preserve a portion of the southern Appalachian forest, so rich in the variety and magnitude of its trees and so incalculably valuable from its position.

Some Native Ornamental Grasses.—I.

IN the temperate zone grasses are, next to forests, Nature's chief decorative material. With them she covers the dark earth and colors half the landscape. But apart from their aesthetic value when growing together in meadow or greensward, individual grasses have a beauty that is not half appreciated. For grace of form and delicacy of coloring many of our native grasses are full worthy of cultivation, although but few of them have received the

attention of the horticulturist. To many gardeners *Arundo Donax*, *Miscanthus Sinensis* (*Eulalia Japonica*) and Pampas-Grass, all foreigners, represent the sum total of what is beautiful among these plants. Ribbon-Grass, *Phalaris arundinacea picta*, is occasionally seen in old gardens. Hair-Grass, a species of *Aira*; Quaking-Grass, a species of *Briza*; Sea Oats, *Uniola paniculata*, and Hare's-tail, *Lagurus*, are still sometimes grown for "winter bouquets." Some small grasses are now and then used for edgings. With these the list of widely cultivated ornamental grasses is practically closed. But any one who keeps his eyes open may find about him, in field and swamp and woodland, species quite as handsome as any of these and as worthy of a place in garden and lawn.

There are some strikingly ornamental species of Crown-beard or Broomsedge, *Andropogon*. The Silvery Broomsedge, *A. argyræus*, common in dry fields in the south-eastern states, is one of these. With its heads of silvery white bearded spikes, it is a very showy grass. Indian-Grass, or Wood-Grass, *A. nutans*, is another species that might, with cultivation, lend itself to decorative purposes. It is often met with in glades and along the edges of woods. In autumn the tall, straight stems bear handsome open panicles of silky brown spikelets. These grasses are relatives of the Indian *A. squarrosus*, whose root-stocks furnish the aromatic perfume, *vitivert*. None of our native Broomsedges appear to have this quality, although a member of a related genus, *Elionurus tripsacoides*, found in low Pine-barrens along the Gulf coast, has the *vitivert* fragrance. Another species of *Elionurus*, *E. barbiculmus*, is a pretty grass, native of the arid uplands of the far south-west. It has fine thread-like leaves in tufts and slender bright white hairy spikes.

Nearly all the species of *Erianthus*—a group related to the sugar-cane—are handsome plants. The Old World *Erianthus Ravennæ* is sometimes seen in cultivation. There are several in the south Atlantic and Gulf states, growing mostly in swamps. *E. alopecuroides* is the largest of these, while *E. contortus*—so named from its twisted awn or beard—is, perhaps, the most beautiful. It is a tall grass with a dense, pinkish panicle, which has a silky lustre due to the soft hairs on the spikelets.

Gama-Grass, *Tripsacum*, is a large plant of the eastern United States, more common southward. It has tall culms or stems and broad, ribbon-like dark green leaves resembling those of Indian Corn, to which it is close akin. It was formerly much esteemed as a forage-producer. The "head" is rather curious than beautiful, consisting of one to three spikes, which are very hard when ripe and break up into several joints. In the southern states it is often planted in cemeteries.

Indian or Tuscarora Rice, *Zizania aquatica*, sometimes known as Water Oats, is common on the muddy banks of tidal rivers near the Atlantic and about lakes and ponds in the north-west. The fruits are much relished by water-fowl of various sorts, and the seeds are on that account often sown. As it is a large showy grass, and of a decidedly odd appearance, it is very suitable for planting about artificial lakes. Another grass worth cultivating in such places is the Catch-fly Grass, *Leersia lenticularis*, a near relative of rice. It is a native of deep swamps in the south-eastern states. The broad leaves are often striped with white, as in Ribbon-Grass. The round, flattened spikelets are fringed with stiff bristles like those on the leaves of Venus' Catchfly. To this resemblance, rather than to any ability of its own to capture insects, it doubtless owes its popular name. Carolina Water-Grass, *Hydrochloa*, inhabits pools and streams in the Pine-barren region of the south Atlantic and Gulf states. The slender stems root in the mud at the bottom, while the short leaves, purplish underneath, float on the surface. At flowering time the whitish spikelets are thrust above the water. This grass has flowered in the ponds of the Fish Commission at Washington and might be grown in ornamental pieces of water, though it would probably not prove hardy much farther northward.

As one of the few purely aquatic grasses it is something of an oddity.

The Triple-awn Grasses, *Aristida*, are often of very attractive appearance. One of the showiest is *A. spiciformis*, a denizen of Pine-barren swamps near the coast from North Carolina to Florida. It has a conspicuous spike-like head, densely bearded with pale green awns. *A. purpurea*, abundant in the prairie region, is a handsome plant with very long purple awns. The related Feather-Grasses, species of *Stipa*, are nearly all of them ornamental. In New Mexico and Arizona occurs a variety of the Old World *Stipa pennata*, the true Feather-Grass, which has its long bent awns beautifully plumed, like the tails to the fruits of *Clematis*. *S. Kingii* is a singularly delicate little grass, and *S. Richardsoni* is remarkable for the grace of its panicles. The best known of the Feather-Grasses is the Porcupine-Grass, *S. spartea*, whose long-awned, sharp-pointed seeds do great injury by working into the flesh of sheep. *S. viridula robusta*, a tall plant with a long greenish panicle, is widely known in the west as Sleepy Grass, and is said to act as a narcotic poison upon stock eating it.

Department of Agriculture, Washington, D. C. T. H. Kearney, Jr.

Alpine Plants and some of their Peculiarities.

THE vegetation which thrives on high altitudes, whether on the Swiss Alps, the American Andes, the Himalayas or on the mountains of Oceanica, shows a distinct personal character, noticeable even to the most indifferent of travelers. These plants are usually stunted, short-stemmed or stemless, with flowers relatively exaggerated in size, whereas on the plains, tall herbs with highly developed and luxuriant foliage bear insignificant blossoms, generally smaller than the leaves. On the mountain tops everything is different, the large flowers are almost sessile, with scarcely apparent and only slightly developed foliage, which at a very high level is often clothed with a fine close down, so as to better withstand the effects of cold nights. In many cases the foliage is glabrous, when it is also usually coriaceous (with tissues especially adapted to resist the frosts of alpine climates), and the leaf of a firm, close, thick texture is provided with a solid epidermis and covered with a waxy coating which enables it to withstand the effects of the sun as well as those of an excess of humidity.

Species that grow in the shade and in well-protected spots show neither the one nor the other of these characters. Their foliage is soft and delicate, whereas such woolly plants as the Edelweiss, several species of *Senecio*, *Artemisia*, etc., as well as species having smooth, generally thick and glossy leaves, as, for example, the Alpine Azalea, *Azalea procumbens*, and the Alpine Rose, *Rhododendron ferrugineum*, are usually encountered on arid, unsheltered slopes. Another fact soon noticed is, that while the flora of altitudes exposed to the heat of the sun generally produces large, brilliantly colored flowers, that of shady situations on the contrary shows very small, pale blossoms, often entirely out of proportion to the size of the plant. The influence of the sun and its effect on vegetation is here more striking than elsewhere.

Annual species, so abundant at lower levels, are but rarely met with on alpine zones. There the very short summer granted to them will not permit of their accomplishing the complete cycle of their existence in a single season. The only alpine species that are not perennial are a few species of *Pedicularis* and some of the *Gentianaceæ*.

Alpine plants are always branched from the base, with perennial root-stock and stems spreading on the ground, from which the plant seems to seek the much required protection against the inclemency of the nights and the severe days that are but too frequent during the short summer that is accorded to them. Species that on the plains form shrubs, and even majestic trees, are represented on the mountains by dwarfed ones, which decumbently spread, often rise only a few inches above the ground. *Salix*, *Azalea procumbens* and *Betula nana* are good illustrations of the stunting effect of alpine climate. The presence of curiously constructed little plants is often noticed along the fissures of rocks, small round cushions, composed of a multitude of tiny rosettes closely crowded together and covered with minute imbricated leaves that perish through the winter, and during the flowering season are so densely covered with a profusion of sessile corollas that the foliage entirely disappears under the wealth of flowers. In the clear light of our Alps these tufts of brilliant blossoms produce a marvelous effect, enlivening the rocks and arid sands

and giving a unique aspect to the vegetation of our mountain summits.

All the activity and energy of the plant is brought to bear on the development of the flower with its reproductive organs. It is easy to understand, considering the conditions under which they thrive, that alpine plants should require sometimes several years to accomplish the cycle of their existence and that they need more than a single season in which to produce flowers and seeds. I have devoted much time and care to the study and observation of the gradual growth of alpine plants, and I am sure that certain large tufts of *Androsacé Helvetica* and *A. pubescens*, for example, have had more than a hundred years of life. It is not hard to realize that the difference of climate should materially alter vegetable forms. Our humid, relatively short and warm winters, with the slow intermediary spring season, followed by a hot dry summer, admits of the gradual development of stems and leaves, and forms a violent contrast to the climate of higher regions. There the winter lasts nine months, or often more (as in certain narrow valleys which are filled with snow frequently for years at a stretch), and is followed suddenly by a short summer that is in every way entirely favorable to rapid vegetable growth. As soon as the snow melts, owing to the influence of the foehn, the sirocco or other warm currents of air usually prevalent in the mountains, the tawny color of the old decaying vegetation changes rapidly in a few days, sometimes in a few hours, to a brilliant green. As if by enchantment, the fields and rocks become animated, are clothed with verdure, and everywhere the beneficent fertilizing insects busy themselves over flowers which, without their friendly interference, would remain sterile. Some plants are so impatient to unfold their blossoms that they cannot wait for the melting of the surrounding snow, but push their flowers up through it, piercing it easily, thanks to the dark color of their stems. This is often observed on alpine pastures in the cases of *Soldanella* and of the *Crocus*. But one question how can that be if the plant has remained dormant for eight or nine months. To which the answer is, that the plant has been far from inert during the winter, because, if it were so, it could not survive. Life and action continue, sap and juices move, but slowly, and the plant undergoes a gradual growth, the proof of which is as follows: On the eastern slope of the Jura I have studied a tuft of *Soldanella* for some successive seasons. My first observation was made during the last of October, as the winter was about to set in, and the next day snow was falling rapidly, preparatory to covering the ground for six long months. The little plant had reached maturity, its sap was retreating into the roots and it seemed about to die. At the first note of spring-time I returned to the locality and carefully brushed the snow from the spot noted the preceding fall, and found the plant alive, showing flower-buds, though still very small, in the centre of the little tuft. It had developed its buds in the same way that the trees on the plains do theirs even during the most rigorous of winters. The life of the plant is not reduced to as dormant a state as is generally supposed to be the case, which the breaking through of the snow by the early flowers of the *Soldanella* and the *Crocus* readily goes to prove. As is well known, the activity of the roots (and those of alpine plants are very numerous) is concentrated almost exclusively on the reproductive organs. The development of the foliage, which contains the organs of respiration, is generally remitted to the latter part of the summer, during and after the maturity of the seeds. After the long winter's rest the plant enters into a prodigious and astonishing activity. The summer days are of fourteen or even of sixteen hours of consecutive duration of intense pure light; the sun is hotter there than at lower levels and water is plentiful, whether in liquid form or in that of vapor. An abundance of light, an adequate amount of humidity and a profusion of roots and rootlets are the sources of life that keep these little plants in action.

Let us now examine the conditions that cause the dwarfing of alpine plants. In the first place, physiological experiments have proved that it is during the night that the lengthening of tissues and the gradual expansion of the plant occurs. In the daytime, the greater the insolation, the less growth they accomplish, and the alpine night being so extremely cold, there can scarcely be a question of nocturnal development of mountain plants. It is under the influence of attenuated solar rays and during the warm dusks that the plants are able to increase. The powerful, exceedingly hot sun of high altitudes causes the brilliancy and size of the corollas, but also prevents the equal expansion of stems and leaves. These latter have only the very short space of time between the setting of the sun and the beginning of the glacial night for their growth, and consequently they also profit by the short, cloudy, moist and tepid

days that precede the setting in of winter to put forth new leaves and buds. This is the general rule, though there are scattered exceptions to it.

The flora of polar countries has a very different aspect from that of our mountains, though it has many species common to both. There the sunlight is less intense, as well as more constant, lasting as it does for half of the year, but it is also more diffuse, the solar rays being forced to pierce a much thicker atmospheric stratum, and consequently the stems of plants are more highly developed, floral colors are paler, the foliage is less rigid and thick, and the blossoms are smaller.

I have preserved in my herbarium some specimens of plants common to both arctic and alpine regions, and the same species show a very different form as found growing in the Swiss mountains and in the boreal zone. *Silene acaulis* with us is truly stemless and the flowers are sessile, while in Lapland the name no longer applies, as there the much smaller flowers are borne on peduncles measuring as much as ten centimetres. There are also other causes that go to explain compression of form in the vegetation of higher altitudes. Extreme violence of storms and winds would destroy anything that did not cling close to the soil, and icy nights force the plants to seek shelter from the earth, which retains more heat than the air. Later the extreme dryness of the atmosphere again obliges them to look for protection from the ground, as the heavy dews that provide the necessary amount of humidity required for their existence are preserved in its light and porous soil. This same mountain soil is entirely different from that of the level country, and is light, very porous and composed of decayed vegetation and the pulverized rock common on the mountain. That rock, whether calcareous or granitic, gives a chemical character to the earth that greatly influences the plants which thrive on it. There is a flora of granitic regions, another of calcareous or siliceous regions, and that especially so on high mountains, as the alluvial soil of the plains is too great a mixture for any appreciable influence to be felt.

London Letter.

CALPURNIA AUREA.—This is the Natal Laburnum of residents in south Africa, with whom it takes the place of the common Laburnum of gardens in more temperate regions. It has been in cultivation in a sunny greenhouse at Kew for the last ten years, and is now a small tree about nine feet high, with the habit, foliage and flowers of the common Laburnum, the main difference being in the smaller flowers of the Natal plant. For countries where the temperature is too high for the common Laburnum the *Calpurnia* would be valuable. It grows freely from cuttings.

CYTISUS PROLIFERUS is a shrub indigenous to the Canary Islands, of which seeds were distributed from Kew in 1879 to Australia, India, etc., on account of its leafy branches being useful as fodder. "Its great value is manifest from the fact that it requires no irrigation, that it can grow in comparatively barren land and that its branches can be cut off three times during the year, resisting perfectly well a long dry summer." Sheep are said to be very fond of it and to thrive well when fed upon it; it is also reported to be good for and relished by cattle and horses. In Australia it is said to feed animals into condition more rapidly and in a greater degree than any other food except corn, and it grows rapidly in any kind of soil, growing to a height of twelve feet or more in four years from seed. It flowers freely from May to September and is a favorite with bees. Dr. Schomburgk wrote in 1891 that he "considered it to be one of the most valuable trees ever introduced into Australia." Plants of it are grown at Kew for the decoration of the conservatory. Here it forms a copiously branched elegant shrub six feet high, not unlike the common *C. racemosus*, except that the branches are longer and stiffer and they are clothed in spring with paper-white flowers.

CAMELLIAS as hardy shrubs are receiving attention in the south of England, where they are proving as hardy as the common Laurel and as floriferous as the Pontic *Rhododendron*, so that the leading nurserymen in Devon and Cornwall are working up large stocks of them. At Kew they are hardy, and this year they are flowering well. C. re-

ticulata, the Pæony-flowered species from the mountains of Hong Kong, is thriving in the open against a wall. We have only lately awoken to the value of *Azalea Indica* as a hardy shrub, and the *Camellia* bids fair to accompany its coun-

time in our southern states. The white *Azalea Indica* has proved hardy, with proper care, in the latitude of this city.—ED.]

RHODODENDRON, OTTO FORSTER.—This is a hybrid between

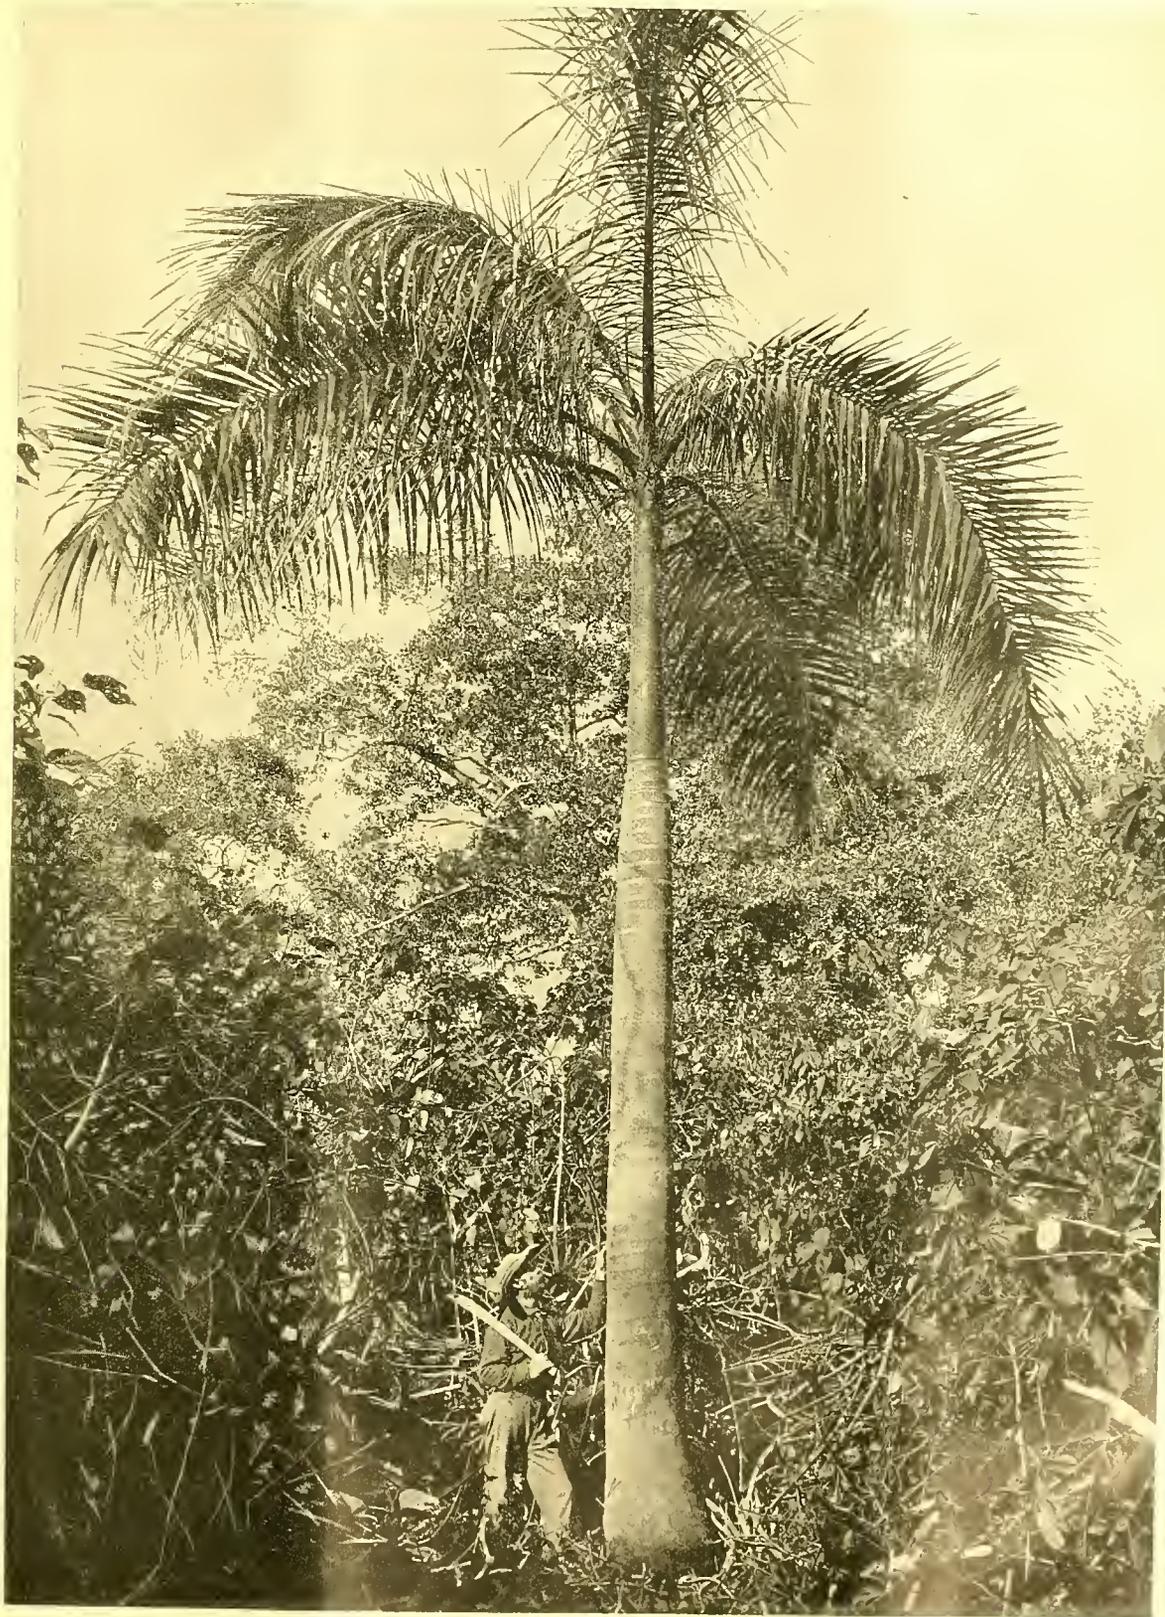

Fig. 21.—*Oreodoxa regia*, in Florida.—See page 152.

tryman in its migration from the greenhouse to the open air.

[Those who have seen the great *Camellias* in the old gardens at Drayton Manor, near Charleston (see vol. ii., p. 129), can realize the splendor of these trees at flowering

Rhododendron Veitchianum and *R. Edgeworthii*, two of the most distinct of the Himalayan species. It was raised a few years ago by Mr. O. Forster, of Lehenhof, Austria, from whom plants of it were secured for Kew, where it is

now in flower in the temperate house. It has inherited all the good qualities of the flowers of both of its parents and none of their bad qualities of habit. It forms a shapely shrub four feet high, clothed with dark green, wrinkled ovate leaves, and bearing loose clusters of large elegant pure white fragrant flowers. Among the hybrid Rhododendrons grown for the greenhouse I should place this by the side of Countess of Haddington, Henryanum, Kewense and fragrantissimum.

RHODODENDRON NOBLEANUM.—This and its near allies, *Rhododendron altaclerense* and *R. Russellianum*, all three hybrids between the Himalayan *R. arboreum* and forms of *R. Catawbiense*, have been beautiful here since the middle of January. They were raised in England more than fifty years ago, and for a long time they were in great favor, but they have long been supplanted by later-flowering hardier sorts. In a mild winter, however, such as the past has been here, they are a most attractive feature of the Rhododendron garden, the Kew plants, for instance, having been so full of beautiful flowers that horticulturists generally have wondered why such handsome winter-flowering shrubs are not in every garden.

RHODODENDRON FULGENS.—This is one of the most beautiful of the Himalayan Rhododendrons and one of the hardiest. It forms a somewhat scraggy bush, six feet high at Kew, sixteen feet in the Himalayas, with smooth purplish bark, elliptic rounded leaves dark green above, the under surface covered with rust-colored tomentum. The young growths are enclosed in strap-shaped imbricating dark red scale-leaves. The flowers, which are bell-shaped, are in dense heads six inches across and each flower is about an inch across and of the brightest glistening blood-red color, unequalled in brilliancy by any other Rhododendron. I am informed that on the high mountains of Sikkim the effect produced by the numerous bushes of this Rhododendron when in flower is indescribably brilliant. There are several big bushes of it in full flower out-of-doors now at Kew. Unfortunately, there is a close resemblance between this species and the comparatively worthless *R. campanulatum* (*æruginosum*), except in the flowers, and this resemblance has led to the latter being generally grown for *R. fulgens*. So far as I know, this species has not been used by the breeders of garden Rhododendrons, although in its hardness, rich color and time of flowering its claims are superior to other species which have.

RHODODENDRON PRÆCOX.—In favorable springs, such as that now being experienced in England, this Rhododendron is exceptionally effective, producing in great abundance its compact heads of rosy-lilac flowers in February and March. The habit of the plant is not unlike that of the Swamp Honeysuckles, and it resembles them in being practically deciduous. It is a garden hybrid between *R. Dauricum* and *R. ciliatum*, and was raised about thirty years ago by Isaac Davies, of Ormskirk, in Lancashire, to whose skill as a breeder of Rhododendrons we are indebted for some of the best in cultivation. *R. præcox* is as hardy as the hardiest of shrubs, and it a handsome bush when clothed with its glossy green Myrtle-like leaves. Its only drawback is its early-flowering habit, the buds unfolding in February, when they are often destroyed by frost. Where it cannot be grown out-of-doors permanently it is worth a place among greenhouse plants, a few bushes grown in pots in the open air during the summer and protected from severe cold till midwinter, when they may be started in a little heat, being very useful for the decoration of the conservatory in February.

PRUNUS MUME.—This plant, said to have been introduced from Japan into France twelve years ago, but as yet scarcely known in gardens here, is this year very attractive at Kew, the flowers being as large as those of the Almond, of the same color and deliciously fragrant. It is distinguished by the pale green color of its twigs, the long pointed Apricot-like form of its leaves, and its globose, slightly velvety fruits, containing oval convex stones. When in flower the shoots are quite leafless. It is quite

hardy and flowers a fortnight earlier than its ally, *P. triloba*. The flowers are semidouble. It was distributed by Messrs. Baltet Brothers, Troyes, under the name of *P. myrobalana flore roseo plena*, and it has also been called *P. cerasifera*. The Japanese nurserymen offer named varieties of it, with flowers varying from white to rose-purple. It is said to force well.

PRUNUS DASICARPA, the Black Almond, is also flowering freely this year. It is supposed to be a garden hybrid. The twigs are black, and the flowers, which are an inch across, are white, with rose-tinted stamens and reddish calyx lobes. It seems to be a good, early spring-flowering tree.

PRUNUS TRILOBA.—An old plant of the double-flowered form of this grand Plum has, for many years, been one of the principal attractions among trees which blossom in early spring at Kew. It is trained against a south wall, where it makes hundreds of wand-like shoots every year, each about a yard long and clothed from base to apex with clusters of rosy pink flowers over an inch across, double, beautiful both in bud and when fully expanded, their beauty being enhanced by the bright green of the budding leaves. It is impossible to speak too highly of this plant as a shrub for a south wall, for, although it is quite hardy and flowers freely when treated as an ordinary bush or tree, it is never so beautiful as when grown against a wall. The Kew plant is on its own roots. After flowering all the shoots are cut back hard, and this induces the plant to make long new shoots as above described. We have no more beautiful Plum from the east than this. It was introduced from China in 1857 and has been known in gardens as *Amygdalopsis Lindleyi*. Plants of the single-flowered form are also in cultivation, having been introduced from Japan by Professor Sargent a few years ago.

SPRING-FLOWERING SHRUBS.—The exceptional mildness of the past winter, followed by an unusually warm and sunny spring, has made gardens here more attractive than I ever remember to have seen them. Shrubs of all kinds have flowered profusely and earlier than is their wont, while the spring-flowering herbaceous plants have been wonderfully good. That grand shrub, *Forsythia suspensa*, has been wreathed in golden flowers everywhere; *Hamamelis arboorea* has been equally prolific in bloom. All our first comers, which generally get nipped in the bud with frost, have been a success, such as *Rhododendron Dauricum*, *R. præcox*, *R. Rhodora* (now beautifully in bloom), *Corylopsis spicata*, *Magnolia stellata*, *M. Soulangeana*, *M. conspicua*, Plums, Almonds, Peaches of all kinds, *Prunus Davidiana*, which is better than ever. Roses are in full leaf, and the Lilac bushes promise to be in bloom in a few days. With bright sunshine all day and a temperature of seventy degrees in the shade on several occasions and the entire absence of frost, such a state of things in the garden in March is not to be wondered at.

Pruning Shrubs.

THIS is the season of frequent inquiry as to when and how deciduous shrubs should be pruned. To this it must be answered that the knife ought to be used at different times and in different ways, according to the object to be served, and that no branch should ever be cut away unless an intelligent reason can be given for removing it at that particular time. Every one ought to know that shrubs which bloom early in the spring form their flower-buds on the wood made the previous year, and that if this wood is removed now it will to that extent curtail the production of flowers. With a view, then, to the production of more flowering branches it is evident that such shrubs as the early *Spiræas* and *Forsythias* should be pruned as soon as the flowering season is over, and this will induce the growth of new wood, which will produce flowering buds for next spring. On the other hand, shrubs like the late-flowering *Tamarisks* and *Hydrangeas* should be pruned at once, if this has not already been done, in order to insure flowering wood for late summer and autumn, since these

plants blossom on the wood of the current year. But a shrub is more than a flowering plant. It is beautiful in summer for its foliage, and in the winter for its form and the tints of its branches, and it should be pruned, therefore, with a view to its continued use and beauty. Altheas and Tamarisks cut back to bare poles in the autumn have no beauty until midsummer of the following year. Severe pruning, as a rule, leaves a disfigured plant. Pruning shrubs to the form of a globe or a cone, or to a single level like a hedge is a horticultural atrocity. Remembering what has been said about the relation of the time of flowering to the time of pruning, it is best not to remove large branches to the extent of interfering with the typical outline of the plant. It is as good a time now as any to thin out the weaker and overshaded branches and those which interfere with each other. Of course, this will not supersede the necessity of summer pruning. Suckers and surplus wood can be removed in the growing season, when the wounds will heal more quickly than in cold weather or when the plants bleed. When the flowering wood is shortened in after the bloom is over the overstrong shoots can be stopped in midsummer without injuring the shapeliness of the shrub, and this will hasten the development of the flower-buds and help to ripen the wood into good condition for the winter. This is especially true in wet seasons. If the luxuriant growth is then stopped the vital energies of the tree will be turned toward developing buds and fruit.

Growing Tomatoes.

ON page 37 of the present volume of GARDEN AND FOREST will be found a most instructive article on cultivating the Tomato, by Mr. W. W. Tracy, of Detroit, in which he called attention to the habits and surroundings of this plant in its native tropics. Under natural conditions, from the time the seed germinates until the plant is exhausted by bearing fruit, there is not any check in its growth from chill or other untoward circumstances, and it has consequently acquired a constitution which resents any check. When, therefore, the plants are exposed to a temperature of forty-five degrees they not only stop growing, but they lose vigor and vital energy, even although they are not killed. This indicates the true method of cultivation which was clearly described by Mr. Tracy—that is, a thorough preparation of the ground beforehand by frequent stirring; sowing the seed as late as from the first to the tenth of April; keeping the plants growing steadily in a good cold frame and not setting them out until cold storms are over, which is not much before June 1st in his latitude.

In the current issue of *The Rural New-Yorker* Mr. Tracy cites some instances to show that this most reasonable theory works well in practice. A field of Tomatoes in Oakland County, Michigan, treated in the usual way—that is, with the seed sown in March, planted in rich ground in such a way that they were checked for about ten days, after which they commenced a rapid growth, so that they soon surpassed in size the plants in an adjoining field from seed sown three or four weeks later and set out in ground that had been cultivated several times in such a way that they received no check. In spite of the vigorous growth of the stalks and leaves, the first field yielded less than three hundred bushels to the acre, and the second yielded about eight hundred bushels of excellent fruit. Of course, there were differences in cultivation. For example, the second field was cultivated every week, and sometimes oftener, and care was taken to stir the surface only, while the other field was cultivated three times, as deeply as the implement would run. Nevertheless, this will not altogether account for the difference in the yield, and it appears plain that Mr. Tracy's suggestions will be found very useful to all who study them so that they can adopt the practice understandingly.

Asparagus.

NO early vegetable is looked for more eagerly than the first dish of asparagus. A bed of Asparagus once established is permanent, and it is essential, therefore, that the work of preparing the bed should be done thoroughly. A well-drained sandy loam is best. Our location is a dry one, but we have never known the bed to suffer even in the driest season. In heavy soils some artificial means must be adopted to relieve the soil of excessive moisture. Where Asparagus is grown in the lowlands it is customary to cultivate it on ridges six feet wide, three rows to a ridge. The intervening hollows, or trenches, are filled during summer-time with the litter gathered from the manure which has lain on the ridges all winter. When

thoroughly decomposed this is thrown up again, with an additional dressing, and the trenches again left open during the winter. This plan will be a good one to follow in all heavy soils, and in such cases there is another advantage, that of having earlier Asparagus than could be grown in beds on the level. The beds being permanent, the ground must be deeply trenched with good loam to take the place of poorer soil. Six inches of good manure should be worked in deeply, as Asparagus-roots penetrate the ground for fully two feet, and this also is a safeguard against drought. It is not, however, recommended to make the plantation deep. Our original bed is now twenty years old, but it is equal in bearing and quality to plantations six years old. It is later, and this may be accounted for by the fact that crowns are yearly formed below, or behind, the main one, so that now the original roots, once near the surface, are from fifteen to eighteen inches deep.

Travelers in Europe often remark on the succulent quality and delicate flavor of asparagus as served in Paris, comparing American-grown as stringy and coarse-flavored. The French method of culture, to which alone is ascribed the excellent quality of the vegetable there, is described in Robinson's *Parks and Gardens of Paris*. A planting was made here six years ago according to the instructions given in this book, and with most interesting results. Trenches four feet apart were dug to the depth of six inches and the soil well pulverized. All along these, at three feet apart, mounds were made a foot in diameter and six inches high. The young plants were placed with their crowns on the top of the mound, and the roots spread in all directions along the sides, and finally banked up even with fine soil. This method of handling the roots is of considerable importance, and may be followed to advantage in any case. Regular development is insured, and the results in our case were surprising. It certainly is a more rational way than bunching the roots or squeezing them into holes that are not large enough for them.*

Each season the stems have been stayed with stakes to prevent the unavoidable injury from wind, liable to unprotected plants. In a closely planted bed this would not be necessary. Care was taken that these stakes were inserted far enough away not to injure the crowns. All seed capsules were picked off and everything done to secure the fullest development of the crowns. One, two, three years passed, and the hills were banked with fine soil to bleach the pushing shoots. But something was wrong, for the grass was stringy and tasteless, and the French method was abandoned. Nevertheless, for private gardens, whether one wants it blanched or not, finer and better asparagus can be grown in this than in any other way, and we would recommend it to all.

When the cutting season is past, which is usually when peas come in, we have given an additional coat of salt with no injury to the growing plants and with advantage in destroying millions of small weeds. There is an excellent artificial manure, specially prepared for top-dressing. In city gardens this will be preferable to barnyard manure.

Asparagus roots are sometimes lifted in the autumn and forced under benches in the greenhouse during winter. The results are seldom satisfactory, and the shoots are at best weak, stringy and tasteless. The plan adopted at the place of H. H. Hunnewell, Esq., and now in good practice, after several years' preparation, is to mark a bed out, which can be framed over when ready to force, and cover it with hot-bed sash. The bed is enclosed in the autumn, well matted and shuttered and banked, so as to exclude frost. When February comes, sunlight and air are allowed on all bright days, so that by the middle of March good, natural-looking heads push through, and these are as well flavored as any we get at any time. Cutting is continued until the open-air crop is well in, and then the bed is allowed to take its natural course.

Wellesley, Mass.

T. D. Hatfield.

Hovea elliptica.—New Holland plants are unfortunately little known or they would be very highly appreciated, and none more so than this one. The *Hoveas* are much like *Chorozemas* in many respects, but differ generally by having intensely purple or blue flowers. *H. elliptica* is of a rather straggling habit that can be improved under cultivation by means of pinching and pruning. The leaves are rather small, alternate, rounded-lanceolate, mucronate. The intensely blue and very beautiful flowers are produced in short axillary racemes in great profusion from March until early summer. The stems are very slender, with somewhat hairy branches, and grow a couple of feet high only, under cultivation. *Hoveas* are generally propagated by seeds, which grow freely when fresh. They

* The method of cultivating Asparagus in France was explained with great fullness by Monsieur Henri L. de Vilmorin, in GARDEN AND FOREST, vol. III, p. 557.

should be sown in shallow pans in a compost of fibrous peat, loam and sand and kept in a warm and shady position until germinating. Watering should be attended to regularly and with great care, as the young seedlings are apt to damp off if the roots are kept too dry and the top too moist. The seedlings should be pinched frequently to form bushy plants, and kept in a moderately cool and light place in summer. In winter they thrive best in a warm greenhouse or conservatory.

Washington, D. C.

O.

Mahernia glabrata.—This is a very desirable greenhouse plant, flowering from March until early in summer. It has a rather straggling habit, but can be grown into a neat and compact specimen by proper pinching and training. The Oxalis-like flowers are yellow, nodding, very fragrant and borne in pairs on long axillary or terminal peduncles chiefly on lateral branches; leaves lanceolate, pinnatifid, or coarsely toothed, and the stems are slender and wiry. The plants when well grown are very floriferous, and, although not among the showiest, they are, at least, among the sweetest greenhouse and window plants of this season. After flowering they should be allowed to rest and ripen, and any long and straggling shoots may then be pruned back. They should afterward be repotted and plunged during the growing period outside in a cool frame. Plenty of water is necessary in summer. In winter they should be kept quite cool until February or March, when a warm and light place near the glass is preferable to any other. Mahernias are generally increased in summer by means of cuttings of soft-wooded lateral shoots, which will strike in a cool propagating-bed in a temperature of about sixty degrees.

Kennedyia (Maryattæ) prostrata major.—Few twining greenhouse plants can surpass this showy species, which flowers very freely in March and April in a cool conservatory. It is the only really valuable and floriferous greenhouse climber among the Leguminosæ, and it deserves wide and general cultivation for its graceful habit and beautiful flowers. Like all *Kennedyas*, it is a perennial herbaceous twiner, a native of Australia, where the genus is indigenous. It differs from *K. prostrata* in having lighter-colored and larger flowers, in the more rounded and hairy leaflets, and in being profusely floriferous. The trifoliate leaves are very handsome, with roundish oblong wavy-edged leaflets about two inches long. The slender stems often grow as long as twenty feet and carry numerous axillary clusters of intensely deep scarlet flowers. All the green parts of the plant, stems and branches, as well as the foliage and stipules, are very hairy. All the *Kennedyas* are readily propagated from seeds, which ripen in any moderately warm and sunny position. They should be sown as soon as ripe in a light compost, and may be grown out-of-doors during the first season. They grow very rapidly and require an abundant supply of water in summer, but may be kept considerably drier in winter. They are best planted out in prepared beds in sunny positions in the conservatory, where they can be trained on pillars and rafters, producing the most beautiful effect in spring and early summer.

The Plans of Madison Square.

To the Editor of GARDEN AND FOREST:

Sir,—All persons interested in park-making will certainly be grateful for the two plans of Madison Square in your last issue and the study of their comparative merits by Mrs. Van Rensselaer. Perhaps still further discussion may be helpful, and I therefore write to say that it is hardly correct to classify the old plan as belonging to the naturalistic class. I draw a heavy line (see fig. on this page) to show how symmetrical it is except where it has been distorted in two or three places. Curved lines are not necessarily natural. Of course, the building (C) ought to be less conspicuous than it is, and the revised plan corrects this. Plainly, too, the statues are introductions of a later date, and the original designer is not responsible for placing them where they are. They might be well removed to the points (NN). If this were done I do not discover any great superiority in the proposed plan over the old one. The area is so small that the insertion of a bit of rectangular treatment surrounded by a curvilinear treatment seems incongruous. Nor is it large enough for a "variety of design, abundance of shade, an effect of wide green lawns with seemingly unstudied, yet artistic, arrangement of trees, shrubs and grass, which produce pleasingly naturalistic impressions and illusions." An attempt to accomplish all this in so contracted a space must result in confusion. Let us have symmetry

where this is needed, but curvilinear symmetry and rectangular symmetry ought not to be mixed up in so small a place.

Mrs. Van Rensselaer has noted one serious mistake in the new plan—that is, the sharp points in the grass-plats—and she might have added that the few conifers introduced tend to

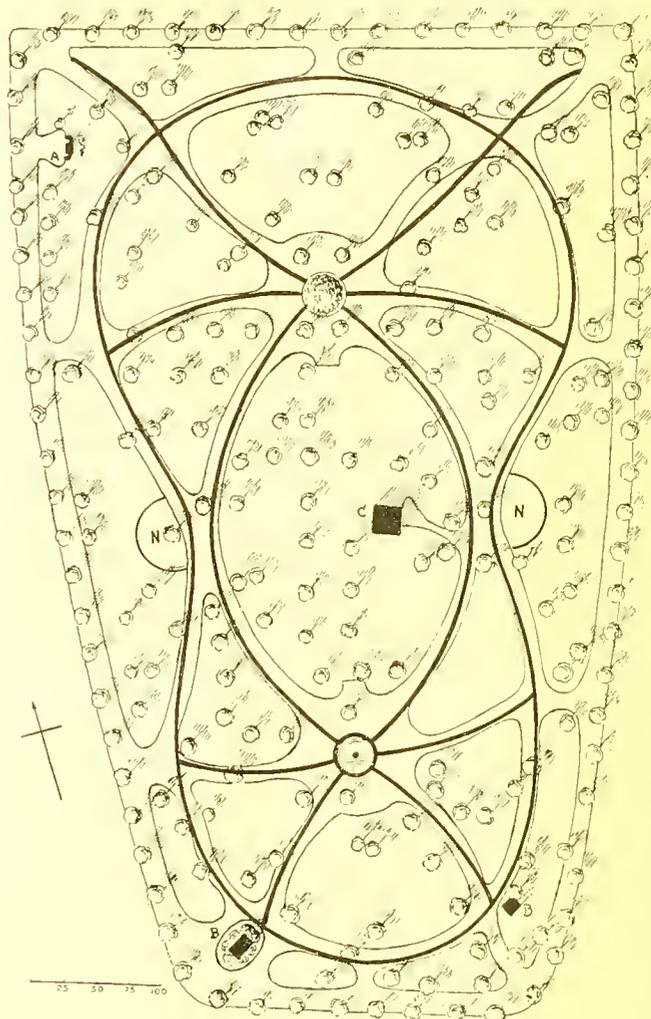

Fig. 22.—Plan of Madison Square, New York.

spottiness. Again, instead of dividing the rectilinear garden by a short straight avenue of trees running from circle to circle, would it not be better to surround and frame in the flower garden with them rather than bisect it? Perhaps trees are not needed at all, for the flowers need all the sunshine they can get. Mrs. Van Rensselaer is certainly right when she states that parks in restricted areas had better be formalized. But the central oval of the original plan might be adorned with flowers as advantageously as the central feature of the proposed plan, and the trees about this oval might be placed symmetrically and at even distances if it was thought proper to emphasize the symmetry of the centre of the place; and this would be advisable if the monuments were placed at the points (NN). Undoubtedly the trees in the old plan should be better grouped, or set in some symmetrical relation, and some symmetrical shrub arrangement is needed especially outside the central oval. With proper grouping of the trees symmetric places might be found for formal flower-beds and balanced sites for statues. Altogether, if there could be some rearrangement in the planting to make the symmetry of the present plan more evident, it strikes me as better than the new ones.

I should be greatly pleased to hear some other opinions on these points, and trust that some artist will furnish you with other plans designed without any regard to the square as it now exists. Messrs. Bell & Langton have been hampered by their efforts to save standing trees, so that they were allowed very little freedom of treatment, and it is not fair to criticize their plan as an original work.

New York City.

S. A.

To the Editor of GARDEN AND FOREST:

Sir,—I observe that in both plans of Madison Square, published in your issue for April 8th, the paths which converge at

the circles are very inaccurately centered—that is, the axes of the paths do not point to the centres of the circle, and if the designs were executed as shown on the map the result would be disastrous. This, however, may be simply carelessness on the part of the draughtsman. I should add that both plans ought to show greater seating capacity. Seats ought to be recessed so that the feet of those using them will not be in the way of pedestrians, because the paths as wide as those in the plans give no more than the necessary walking space.

New York.

Meetings of Societies.

Forestry in Pennsylvania.

A NOTABLE event was the spring meeting of the Pennsylvania Forestry Association and Arbor Day celebration, which occurred in Philadelphia on Friday, April 10th, with the coöperation of the trustees and faculty of the University of Pennsylvania and the trustees and faculty of the Drexel Institute. The planting ceremony comprised afternoon exercises in the chapel of the University of Pennsylvania. Perhaps so enthusiastic an audience never before assembled in the interests of forestry in America. The Governor of the commonwealth, Mayor of the city, Provost and faculty of the University, chief of the National Forestry Division, the State Forest Commissioner, the president of the Pennsylvania Forestry Association and other public officials, the members of the Pennsylvania Forestry Association and friends of forestry and of the University made up part of the audience, but the impressive feature of the great gathering was the hundreds of earnest young men, students of the University. The spontaneous ringing applause when telling points were well made by the speakers was doubtless inspired by patriotism sometimes as much by protest against the wasteful destruction of forests or the proposal of forest reform, but the effect in the direction of wiser forestry policy was none the less strong on the minds of the audience.

Provost Harrison, in opening the meeting and giving it into the charge of Mr. John Birkinbine, President of the Pennsylvania Forestry Association, said that Pennsylvania once had the greatest relative forest area of any of the colonies north of Virginia, and now has the least relative forest area of the states north of Virginia, excepting Connecticut. Mr. Birkinbine explained that his interest in forestry was aroused in connection with the hydraulic and metallurgical factors in railroad building. Governor Hastings was then introduced, and spoke, among other things, of the far-seeing wisdom of Penn, who aimed at the planting and preservation of the Oak-trees for ships and of the Mulberry-trees for silk; of two rows of trees along every street of the city, and the clearing of only five out of every six acres of forest by the settlers. Mayor Warwick's fancies and facts completely captured the audience. He said much of Shakespeare's poetry was due to his having yielded to the influence of nature in the Stratford and Coventry country.

Professor Rothrock, State Forest Commissioner, then read a letter from General Paul A. Oliver, of Wilkesbarre, giving a history of the scion of the Penn Treaty Elm, to be planted in connection with these exercises on the University campus, as a memorial to William Penn. Some account is already recorded in GARDEN AND FOREST, vol. v., p. 312, and vol. viii., p. 240. The little tree to be planted now was taken from a shoot of the Oliver tree on the 1st of March, 1893. Nathan C. Schaefer, Superintendent of Public Instruction, made an effective address, and, describing the love of German students for trees about their alma mater, called upon the loyalty and care of the students of the University of Pennsylvania for this historic grandchild of a great tree.

Mr. Fernow, representing the National Government, said that the American people had made two great mistakes, one moral, the other economic; one in the treatment of the Indians and the other in the treatment of the forests, and that Penn, in whose memory this tree is to be planted to-day, made neither of these mistakes. He said the planting would be a memorial of moral rectitude and advanced national economic thought.

The planting of the trees on the campus facing the main hall then followed, Governor Hastings doing the actual planting. In the name and by the authority of the commonwealth of Pennsylvania, the Governor commanded Provost Harrison and the University generally to care for the tree. The Provost accepted the trust, and promised also that trees would soon be planted along the entire three miles of streets surrounding the University, the plans for the work being already in hand.

At the evening meeting, in the Drexel Institute, the first address was that of Governor Hastings, who spoke on the necessity of preserving the forests of Pennsylvania. After sketching

graphically the original extent and wealth of our unbroken Appalachian forests which stretched from Maine to the Gulf, he showed how rapidly these had melted away before the axe of settlers, whose descendants were continuing this destruction while other nations had been taught by a disastrous experience to begin with infinite pains and cost the work of forest restoration. Leaving aside the broader economic and sanitary value of our forests, he quoted figures to show that the annual product of our forests was fifteen times as great as that of all our gold and silver mines, and more than double that of all the minerals as well as the natural gas, and slate and building stone which are dug from the earth in a year. Coming to his own state, he said that during the last ten years the timber crop of Pennsylvania had aggregated more than two hundred millions of dollars. Three-fourths of the timber in the state had already been marketed, the railroads had invaded the woods where streams were not large enough to float the logs, and the portable sawmill was making havoc with the smaller growth on the hills and the wood-lots on the farms. He gave Commissioner Rothrock as authority for stating that if the land in Pennsylvania unfit for farm purposes, and now worth not more than \$1.00 an acre on an average, could be protected from the axe and the brand, the value of the timber crop on this land at the end of fifty years would be a billion and a half of dollars, or an average of thirty million dollars a year, and this estimate makes no account of the saving of life and property from frequent floods, or of the improvement to agriculture and other industries and the promotion of the public health, which would certainly follow. He asserted that these tremendous interests make it the essential duty of the commonwealth to restore and protect the forests on the highlands of Pennsylvania wherever this is possible. This great waste forest area should be under proper guardianship and no interest of such public importance should remain in private hands. It was the welfare of the people at large, pure water, public health, which forest destruction threatened. Altogether the Governor made a strong and reasonable plea for state action in the interest of the state at large.

In the course of a very instructive paper, Mr. B. E. Fernow, head of the Forestry Division of the Department of Agriculture, said that there are two points of view from which we may look at the forestry movement: first, the one which a thinking lumberman and forest-owner ought to take when he considers only the perpetuation of supplies of useful material which the forest can yield, and, secondly, the broader one which the statesman and every patriotic citizen is bound to take in addition to the first—that is, he must consider the rôle which the forest plays as a factor in our civilization, as a general condition of the country which, if irrationally altered, must lead to the misery of the whole community. The influence of the forest upon the conditions of river-flow, climate and health can rarely concern the private owner who is interested only in the profit which he can draw from his property, and this is the reason why the state, which alone is as long-lived as the forest, should guard the essentials of its future welfare. The questions relating to our forest are not those whose adjustment can be deferred without detriment. Whether our currency be of silver or of gold, whether our tariff be high or low, whether our products are carried across the sea by English ships or by our own merchantmen, are matters which can be decided in the future; but whether fertile land shall be turned into deserts, forests into wastes, brooks into torrents and rivers changed from means of intercourse and power into forces of desolation—these are questions of immediate importance which must be solved at the proper time. Mr. Fernow went on to show the particulars of the devastation of the French Alps and of the efforts to recover them. He explained that the same processes are wasting the fertility of our own territory, where vast regions are doomed to impoverishment unless we begin at once to arrest the loss. He advocated strongly the passing of the McRae bill, now before Congress, which, although crude and primitive, is, at least, a definite and reasonable attempt at a rational forestry system for the property of the General Government.

Dr. Rothrock, State Commissioner of Forestry, followed with some well-selected lantern views illustrating the conditions of the naked hills and water-sheds of the state. One of these showed a scene in Sullivan County where ridge stretched beyond ridge for miles covered with an unbroken forest, making a natural sanitarium, and this was contrasted with another which was a scene of absolute desolation where the hills had been first lumbered over and the remaining trees destroyed by fire. Two beautiful pictures from Centre County showed the sources of streams in timbered regions where water was saved for the state use, and two others from Clinton County showed scenes of ruin, where the water had rushed off in a

deluge from the naked hills, destroying life and property in its course. Instructive, too, were the contrasting illustrations of what a street-tree ought to be, and of an actual scene in one of the Philadelphia squares, in which trees unsuitable for a city planting had been selected and then butchered by an ignorant pruner.

All the addresses were wise and temperate, and the exercises throughout were instructive and stimulating, just such exercises, indeed, as are needed for popular education in all parts of the country.

Notes.

Plums proved the least satisfactory of all fruit crops in western New York last year, and the reason assigned was that the crop of 1894, the largest ever known, proved such a drain on the vitality of the trees that they did not have strength enough for a crop the succeeding year. A marked exception to this rule was found in trees of the old variety Reine Claude, which gave a full yield of as large and fair fruit as ever.

Of the vegetables imported into New York during last week, Bermuda sent 14,068 crates of onions and 1,346 crates of other vegetables; Cuba, 2,366 crates of onions and 440 crates of other products; the Bahamas, 871 crates of tomatoes. Other receipts from the south were 4,600 barrels of kale, 12,700 barrels of spinach, 7,750 crates of cabbage and 5,100 crates of other vegetables, while 8,500 packages came over the Pennsylvania Railroad. Of course, this is only a partial record of the supply.

Strawberries from Florida have been quite abundant, but the fruit is of irregular size and quality, though in fair condition. Some Hoffman seedlings of extra grade have come packed in ice boxes and sold at fifty to sixty cents a box, at retail. In other grades those carried in refrigerator cars have shown the best average quality, and prices have been thirty-five to forty-five cents a box at retail. Other methods of transporting this perishable fruit are in freight lots in small ice boxes and by express in open crates.

Bananas are in plentiful supply in this city and sell rather slowly. During last week 49,900 bunches were imported here, against 63,500 bunches during the corresponding week a year ago. They sell for eighty-five cents to \$1.35 a bunch on the docks in truck-loads. Coconuts, also, are plentiful—a cargo of 398,000 from St. Andreas having arrived a few days ago, besides the large stock on hand. San Blas, St. Andreas, Baracoa and Kingston are the forwarding ports, and prices here range from \$24.00 to \$30.00 a thousand.

A very complete handbook on Indian Corn is contained in the report of the Kansas State Board of Agriculture for the quarter ending March 31st of this year. It fills more than one hundred pages, and has been written by experts in the various fields, and contains a surprising amount of information upon such points as cultivating and handling the crop, harvesting and storing the fodder, the merits of different varieties, the feeding value of the meal, diseases of the plant, etc. This is followed by a briefer treatise on the Sorghums and their use both for grain and for forage as estimated by Kansas growers. It is a useful little pamphlet, and yet the Secretary of the Board of Agriculture has not found it worth indexing.

Some time ago we gave a brief description of *Physalis Franchetti*, a near relative of *P. Alkekengi*, often seen in old gardens, where it is called the Winter Cherry or the Strawberry Tomato, on account of its well-flavored fruit enclosed in the swollen calyx. The new species was brought recently from Japan by Mr. Veitch, and from a colored plate of it in the last number of *The Garden* it must be a striking plant. The calyx is about seven or eight inches in circumference and of singularly glowing colors—a mingled orange and scarlet of varying tints. A group of these plants grown in deep soil would give a rich and bold effect, and when cut the inflated envelope of the fruit lasts for a long time. A correspondent of *The Garden* says that some of these fairy-like balloons are still bright, although they have been cut more than a year.

Along some of the more public business streets of Philadelphia, on market day mornings especially, interesting little collections of woody herbs are offered for sale by colored folks from out of town. One such little sidewalk-stand last Saturday offered bunches of the spicy leaves of the Creeping Wintergreen, or Checkerberry, which lacked the gloss, but were almost as varied and brilliantly colored as Galax leaves. Calamus, slender Sarsaparilla roots and the thicker Dandelion roots, with the bark of Wild Cherry, Sassafras and Prickly Ash,

all sold for some asserted medicinal value. Then there were fresh Catnip, clumps of the grassy young foliage and roots of Star of Bethlehem, leaves of Dandelion for salad, little nose-gays of Trailing Arbutus, and plants of the same well rooted in the glistening sand of The Pines of New Jersey, and patches of moss. There were plants of Peppermint, too, the straggling, nearly bare, stems showing little green and purple leaves on the ends.

We have alluded to the danger which threatens Niagara Falls since several great corporations, eager to secure power for nothing, are struggling for the privilege of taking water for their private use from what is now a public stream. Attention has also been called to the fact that surveys by the Government Engineer seem to show that the level of the Great Lakes has fallen within the past twenty years, and is still falling, and it is interesting to inquire, therefore, what will be the effect of the great Chicago drainage canal in the same direction. The Niagara is the outlet of the lakes, and any lowering of their level will, of course, be felt at the Falls. *The American Architect* doubts the propriety of draining a navigable lake for the purpose of floating the sewage of a city down upon the people of southern Illinois and the states below. But, besides this, the whole country has an interest in the Falls of Niagara, which will be affected, no one seems to know how much, by the Chicago canal.

According to a recent publication of the Department of Agriculture on Nut Culture in the United States there are about 250,000 Coconut Palms of all ages on the eastern coast of Florida, some 25,000 of which are bearing. On the shores of Lake Worth some 50,000 trees, old and young, are now growing, and nothing can be more picturesque or graceful than the soft, yellowish green leaves of these groves. Many of the leaves are as much as twenty feet long and as perfect throughout as an ostrich plume. Florida growers bury the nuts until they sprout, and then plant them in holes some two feet deep and twenty feet apart. The sprouted nuts are covered with good earth, and as the plant grows the earth is filled about it until it is level with the surface. The tree is fruitful near the salt water in Florida south of Lake Worth on the east, and Charlotte harbor on the west, including the keys. It begins to fruit in from five to seven years from the planting of the nut, but when removed inland it is not fruitful and does not thrive. On Key West there are some trees over fifty years old.

In Bulletin No. 40 from the Oregon Experiment Station, we learn that for commercial purposes there are practically only seven varieties of Apples grown in that state. Of these the Spitzenberg is the most generally planted and the best liked, and this is followed in the order of their acreage and reputation by the Ben Davis, the Newtown Pippin, the Baldwin, the Red-cheeked Pippin and the Northern Spy. The first orchards which were planted as minor appendages to farms where the fruit was only grown for home use have been allowed to be preyed upon by various pests until they are nearly valueless, so that the orchard area has actually decreased in recent years. New orchards are now being planted on a considerable scale, and organized efforts have been undertaken to combat the insects, of which the San José scale, the green aphid and the woolly aphid are the most serious pests, and the latter can hardly be annihilated since it lives both at the root and the top of the trees. On the branches the woolly aphid can be controlled by caustic washes, and it is to be hoped that some variety of Apple will be found with roots that can resist its attacks.

It has long been a common opinion among farmers in this country and in Europe, that where seeds are produced in pairs one of these will germinate the first year after ripening, and the other will not germinate until the second year. Experiments with the seed on a spikelet of Wild Oats, *Avena fatua*, and the Sandbur, *Cenchrus tribuloides*, have shown that there was no foundation for this belief, but with the Cocklebur, *Xanthium Canadense*, it has been discovered that the germination of both seeds in a pair in one season is exceptional. Very interesting are the details of some studies by Professor J. C. Arthur as given in a paper read at Springfield, Massachusetts, at the last annual meeting of the Society for the Promotion of Agricultural Science. He proved that neither of the two seeds had the advantage over the other in any physical protection, but he discovered at last that there was a constitutional difference in the character of the protoplasm of the embryos, so that one seed has a short resting period and the other a very long one—that is, the seeds are distributed in time, one of them germinating a year, at least, later than the other, instead of being scattered in space.

The Obliteration of Public Parks.

THE consolidation of three great libraries of this city has revived the project of erecting a monumental building to contain them in Bryant Park, where the reservoir now stands. Whether the reservoir ought to remain where it is or be taken down depends, of course, on its usefulness. It ought to stand as long as it is needed for the water-supply of the lower part of the city, and while it serves this purpose it will continue to be a dignified structure with a distinct æsthetic value. If, on the other hand, it is of no real use, it should be torn down, for, however well proportioned its lines, a mass of stone like this can have no real beauty unless it means something. If its removal is once determined, arguments for erecting the library on its foundations are something like these: It is the duty of the city to erect such a building somewhere; the location is central and accessible; the city will have to pay nothing for the land; no park space will be curtailed, because the library will occupy fewer square feet than the reservoir does, and Bryant Park, which adjoins it, will be enlarged rather than encroached upon.

On the other hand it is argued by a large and influential class of citizens, some of them trustees of the consolidated libraries, that if the city acquires a block of open ground it should by all means retain it for park purposes. Under a mandatory law the proper officers of the city have within a few weeks condemned two areas larger than that covered by the reservoir, one on each side of Broadway in thickly settled districts, and they will soon begin to tear down the buildings now occupying this land and convert it into parks. This has already been done at Mulberry Bend. Another block will be condemned within a year, and the city is authorized by law to spend a million dollars per annum for this purpose. It would seem, therefore, a singular inconsistency to continue the purchase of park land in the heart of the city every year and then to cover up park space which is already owned by the city.

At a recent public meeting in behalf of free libraries, Mr. Andrew Carnegie asserted that he would never advocate the surrender of a foot of park land for any other purpose than for a library of the particular kind which he favored. And this is precisely what makes these repeated attacks

upon public parks so dangerous. The reasons for each proposed infringement seem overwhelming to the promoters of this particular movement, and in general these are projects which in themselves are highly praiseworthy. Rapid transit was a crying need, and therefore the city gave a railroad corporation permission to invade the Battery and to make a blackened ruin of a large portion of that beautiful green. Now equally strenuous advocates are asking for the confiscation of a still greater portion of this park for a loop for the same railroad. When the city wished to give land for a great federal building a large portion of City Hall Park was sacrificed in the same way, another piece was covered over by the Tweed Court House, which also was called a public necessity, and now, "for this purpose only," some friends of this library wish to cover up another possible park. The trouble is that next year there will be other reasons quite as cogent for using some other park for some other purpose. Mr. Carnegie would be willing to give a park for a library, but for nothing else. There are other people who hold that the city owes a debt of gratitude to the Academy of Design which it can only liquidate by giving this institution a building place in one of the parks. In the name of charity another association may soon demand park room for a hospital, and even now some enterprising citizens are asking for a section of Central Park to be devoted to a permanent exhibition for the glory of the metropolis.

The only safe rule is to refuse absolutely to divert a single foot of park space from its legitimate use. If the city can afford to give any of its public land it can still better afford to give money. Why is it not wiser to give the library enough to buy the land it needs than it is to give away park space and then pay a million dollars for a park of the same size somewhere else? If the reservoir is torn down, this will be the only open space along Fifth Avenue from Twenty-third Street to Central Park, and every foot of the land is needed for a pleasure-ground. The policy of demolishing solid blocks of buildings to secure open spaces shows that the people have begun to realize that these are essential to their health and comfort. Having learned this, they should be educated to consider every encroachment upon the park space of the city as an invasion of their rights, which they should be prepared to resent as they would resent the destruction of any other public property.

We have received a circular from the Royal Horticultural Society, London, in which special prizes are offered for dessert apples and pears. These are called the Veitch Prizes for Flavor, and they are offered at every fruit and flower meeting of the society for the coming year, with a first and second prize for the best-flavored apple and a first and second prize for the best-flavored pear. Six fruits of each variety must be shown, and the judges are at liberty to cut any three of them. The exhibitor must guarantee that the fruit exhibited has been grown entirely out-of-doors, and he must state on the name-card whether it was grown on a wall, bush or standard, together with the aspect of the tree and its geographical location, the nature of the soil in which it stands, and when he knows it, the stock on which the scion was grafted. The fruit is judged by points, twelve being the maximum, and these points are distributed in the following proportion: For flavor, six; for quality, three; for appearance, two, and for size, one. It is explained that "quality" is intended to mean the degree of smoothness or meltingness of the flesh (the absence of grit), or in the case of early apples, crispness and juiciness of the flesh may be considered. Quality, therefore, refers mainly to the texture of the flesh. Appearance, of course, includes color and beauty of form; but size, which counts only one-twelfth in the estimate, does not mean that the largest fruit receives the highest marking. There is a type size which invests the fruit with its greatest value for table use, and this is counted perfection. Enormous specimens are not preferred, since beyond a certain point size is a defect in dessert fruits.

We have seen oranges in Florida judged somewhat in this strict fashion, but certainly it is not common in American exhibitions to lay such a stress on flavor and quality as is indicated in this schedule. Every one will admit that in our exhibitions great size and showy appearance count for more than they deserve. For dessert fruit, a beautiful appearance is certainly an advantage; but, after all, quality, if we use the word to include flavor, ought to be the controlling element of its value. In our home market it is true that a beautiful apple or pear will find a readier sale than one which is less attractive in appearance, although it may be better in quality. We apprehend that this condition of affairs prevails to some extent in England, and yet these prizes would seem to indicate that English horticulturists lay more stress on quality than we do here. If it is true that the English market demands high quality and that it will demand it more urgently in the future, it is worth while to inquire how long it will be profitable to ship Ben Davis apples to Great Britain. This variety has keeping qualities and appearance, and the trees are very productive, but it is inferior in flavor to many other sorts, and it is well for those who are raising apples for export to consider whether more attention should not be given to the quality of the fruit. No doubt, the time is coming when quality will count for more at home than it has done, and the growers who select varieties for the good texture and high flavor of their fruit will probably make no mistake, even for the home market.

Thrinax in Florida.

IN 1875 Dr. A. W. Chapman found growing on the Florida keys one of the West Indian Thatch Palms, *Thrinax parviflora*, Swartz, a tree twenty or thirty feet high, as it grows in Florida, with a slender stem not more than five inches thick, orbicular leaves three or four feet in diameter, bright green above and pale below, and a short slender-branched spadix with coriaceous sheaths pubescent above the middle and often ciliate on the margins at the apex. The flowers open in the autumn and are raised on stout spreading pedicels; the perianth is obscurely six-lobed; the six or nine stamens are composed of slender filaments and introrse anthers, and the large funnel-formed stigma is oblique at the apex. The fruit, which ripens in the spring, is globose, black, a quarter of an inch in diameter, with thin dry flesh closely investing a membranaceous endocarp. The seed is tawny brown and marked by deep vertical furrows caused by the enfolding of the seed-coat into the ruminate albumen. The pedicellate flowers, the thin dark flesh of the fruit and the grooved seeds with ruminate albumen are typical of *Thrinax* as the genus was first described, and plants with these characters are now grouped together in a section, *Euthrinax*.

In 1879 Mr. A. H. Curtiss found on No Name and Boca Chica keys another *Thrinax* which has been referred to *Thrinax argentea*, Desfontaines, but it now turns out to belong to another section of the genus (*Porothrinax*), and appears to be undescribed. In *Porothrinax* the flowers are nearly sessile; the fruit is yellowish brown, with a crustaceous pericarp, and the seed is dark brown and lustrous, without grooves, much depressed at the base, and the uniform albumen is penetrated by a deep broad basal cavity. The size of the fruits suggests the name of *Thrinax microcarpa** for this species. It is a tree rarely

* *Thrinax* (*Porothrinax*) *microcarpa*, Sargent, n. sp. Flowers solitary, ebracteolate, articulate on broad disk-like pedicels; perianth cupular, white, six-lobed, the lobes broadly ovate, acute, half as long as the ovary; stamens six, inserted on the base of the perianth; filaments broad and flat, slightly united below, slender and terete above, exserted; anthers oblong, emarginate, attached on the back, versatile, reflexed and extrorse at maturity; ovary ovate, sessile, one celled, orange colored, gradually narrowed into a short stout style dilated into a broad funnel-formed truncate stigma; ovule solitary, basal, erect. Fruit pisiform, one-eighth of an inch in diameter, tawny brown, short-stalked, bearing at its base the enlarged persistent perianth of the flower, tipped with the remnants of the style; pericarp crustaceous, of two coats. Seed subglobose, depressed at the base; raphe obscure; hilum basal, pale, conspicuous; testa membranaceous, bright chestnut-brown. Embryo apical in uniform albumen penetrated by a broad deep basal cavity. A slender tree; twenty to thirty feet; leaves terminal, orbicular, coriaceous, pale green above, silvery white below, more or less coated with young with hoary tomentum, especially on the lower surface, plicately multifold, the divisions induplicate, with thickened ribs and margins; rachis short, slightly convex, gradually narrowed and

more than thirty feet in height, with a trunk eight or ten inches in diameter covered with smooth pale blue rind, flowering in the spring and ripening its fruit late in the autumn. The leaves are from two to three feet across and split to below the middle or near the base of the leaf almost to the rachis into divisions which are an inch wide at the middle of the leaf, and rather less than a quarter of an inch wide at its base. *Thrinax microcarpa* grows on dry coral soil on No Name Key, Bahia Hunda Key and the shores of Sugar Loaf Sound, Florida.

On the Marquesas keys and on some of the small keys east of Key West there is another *Euthrinax* whose flowers are still unknown. It is a low tree with a short thick trunk raised above the surface of the ground by a cluster of stout roots, large orbicular leaves with blades longer than the petioles, and fruit which differs from that of any of the described species of *Thrinax* by the thickness of the fleshy succulent pericarp. Portions of a leaf and a few fruits of another *Porothrinax*, to be distinguished by its much larger fruit, were collected by Dr. A. P. Garber at Cape Sable in October, 1879, and are preserved in the Gray Herbarium.

The flowers, fruits and leaves of these two trees, with information as to their distribution, size and uses, are specially desired. C. S. S.

The Tannin Value of Some North American Trees.

TANNIN is found in the bark of nearly all trees, yet little attention is paid to the economic possibilities of this constituent. When timber is cut for lumber the bark is usually wasted.

There appears to be no record indicating the amount of tannin in many of our native trees. No doubt, all of them have been tried at various times in the tanning industry, and the barks of a few of them are used at the present time. The following list of results recently obtained will indicate in a certain degree the value of a number of barks, but, as nearly all of them were collected during autumn or winter, the percentages of tannin given probably indicate the minimum amount contained therein:

Barks.	Locality.	Moisture.	Ash in absolutely dry bark.	Tannin in absolutely dry bark.
<i>Taxus Canadensis</i>	Pennsylvania	10 80	5.64	20.46
“ <i>baccata</i>	Bengal, India	14.38	6.19	22.83
<i>Libocedrus decurrens</i>	Oregon	6.17	2.24	7.14
<i>Thuya occidentalis</i>	Philadelphia.	5.61	6.46	6.13
“ <i>gigantea</i>	“	6.93	6.10	8.16
<i>Cupressus thyoides</i>	New Jersey..	34 75	2.88	4.44
<i>Juniperus Virginiana</i>	Philadelphia.	8 64	6.30	7.30
“ <i>Californica</i>	California	5.57	9.23	8.10
“ <i>occidentalis</i>	Oregon	7.72	5.60	5.17
“ <i>communis</i>	Philadelphia.	5.95	6.49	5.66
<i>Taxodium distichum</i>	Alabama	6.61	3.88	4.28
<i>Sequoia sempervirens</i>	California	7.99	0.64	1.63
“ <i>gigantea</i>	“	6 45	0.37	2.77

Taxus baccata can hardly be considered a native tree, but the foregoing results are given for comparison, and they indicate a close relationship in the constituents of the two species, although growing in widely different parts of the globe. The amount of tannin found in these specimens indicates that the bark of *Taxus* would make an efficient tannin material.

Libocedrus, *Thuya occidentalis* and *gigantea* and all the Junipers contain sufficient tannin to make them valuable in the absence of richer material. *Taxodium* and *Cupressus* under some circumstances would also be valuable. The column headed “locality” in the foregoing chart indicates the place where these particular specimens were collected, and not in every case the place where the trees are native, for it was necessary to get a few of the samples from nursery stock near Philadelphia.

My thanks are due to Miss Alice Eastwood, of San Francisco,

rounded at the apex; ligula orbicular, thick, concave, lined with hoary tomentum; petioles slender, flexible, biconvex, unarmed; vagina elongated, light brown, the fibres slender. Spadix elongated, interfoliar, compound; primary branches short, slender, compressed, erect and spreading; secondary branches flower-bearing, slender, pendulous; spathe coriaceous, elongated, acute, deeply divided at the apex, tomentose above the middle; bracts acute, scarious, caducous.

No Name and Boca Chica keys, Florida, A. H. Curtiss, 1879.

California; Mr. A. E. Wild, Bengal, India; Mr. E. I. Applegate, Klamath Falls, Oregon, and Dr. Charles Mohr, Mobile, Alabama, for specimens kindly furnished by them.

Grape-fruit and Shaddocks.

DURING my recent visit to New York I was much interested to notice the considerable demand that existed there for grape-fruit,* from the West Indies. It appears to be very strongly recommended by the medical faculty for its refreshing and tonic properties, and, in con-

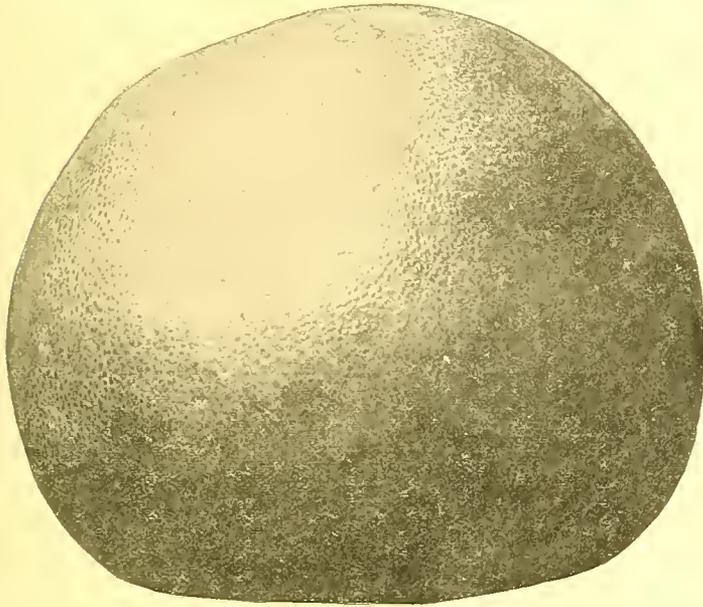

Fig. 23.—Pumelow or Shaddock, globular fruit. Diameter, 6 inches; weight, 49 ounces; flesh pink, with good flavor.

sequence, the use of it has become an important feature in the diet in American cities. The fruit I saw in New York called grape-fruit consisted of various sorts and qualities, and there is little doubt that much confusion exists as to what is really grape-fruit as distinct from the allied Citrus fruits passing under such names as Pumelow, † Shad-

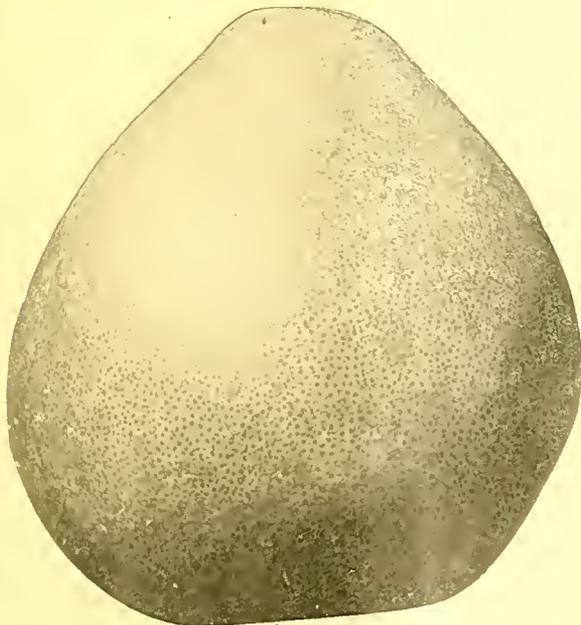

Fig. 24.—Pumelow or Shaddock, pear-shaped fruit. Diameter, 5 inches; length, 6 inches; weight, 32 ounces; flesh pinkish, flavor fairly good.

dock, Forbidden-fruit, Paradise-fruit and others. The chief characteristics of all these fruits distinguishing them from

the different varieties of the Orange are associated with the size and color. They are all, or nearly all, larger than the largest orange, and they are uniformly of a pale yellow color. In texture the rind may be smooth or even polished. It is seldom rough, nearly always firm and not very thick.

Fig. 25.—Grape-fruit, as sold in New York. Diameter, 5 inches; weight, 31 ounces; juicy, thin-skinned, excellent flavor.

The pulp is pale yellow or greenish white, sometimes pink or crimson; the vesicles of the pulp (juice bags) are more distinct than in the orange; very juicy, somewhat sweetish, with a distinct, but agreeable, bitter flavor. The pith surrounding the segments possesses more of the bitter than the pulp, but is less agreeable, and on that account is never eaten. In shape these fruits vary a good deal. Some are quite globular, others somewhat flattened at the top and tapering below, forming a pear-shaped body. Even in the globular fruits the top is more or less flattened. There are none, I believe, pointed at both ends.

Having indicated the general characters of this class of Citrus fruits I may venture on a brief sketch of their origin and history. It is agreed by all authorities that these fruits are quite distinct from the other groups of the Orange

Fig. 26.—Forbidden-fruit, as sold in New York. Diameter, 3 1/4 inches; 4 inches long; flesh pale pink, skin thick.

family, such as the true Oranges and the Citrons. They have, therefore, been kept apart and ranged under the giant Citrus, *Citrus decumana*. In this species the tree is twelve to eighteen feet high, with a flat crown and spreading branches, usually with no spines. The leaves are elliptic-rounded at both ends, emarginate (that is, with a notch at the apex) and crenulate (having the edge marked with small depressions); the under side of the leaf is softly hairy, with the wings broad, crenulated as in the leaves and bordered with fine hairs. The flowers are in clusters of from three to nine, large, white and fragrant. The fruit is either globose or pear-shaped, forming many seedling varieties without distinct names. This is supposed to be a native of the islands of the Pacific, whence it had been brought

* It is so called because the fruits grow in clusters like a bunch of grapes.
 † It is invariably spelled Pomelo in the United States.

to southern China, Japan and India. It was introduced to the West Indies, according to Macfadyen, from China by Captain Shaddock, whose name has since been given to it. The term Shaddock may be correctly applied to any of the larger members of the giant Citrus and is equivalent to the French pomelmouse, which is another form of the Dutch pomelmoes. The word Pomelow, so widely used in India and Ceylon, is supposed to be a contraction of "pomum melo," the melon apple. The largest Pamelows in India are said to reach "two feet in circumference and weigh ten to twenty pounds." The best sort, according to Bonavia, is "the thin-skinned red pomelow of the Bombay market." This is of a globose shape, juicy and "of the color of raw beef internally." There are, however, numerous grades in size, some being almost as small as oranges. In India the varieties do not appear to have recognized names. Elsewhere the smaller fruits have been variously called Paradise apples, Forbidden-fruit and Grape-fruit.

As regards the proper classification of the West Indian varieties, I cannot do better than record that put forth by Dr. James Macfadyen, the learned author of the *Flora of Jamaica*, which, however, he never lived to carry into more than one volume and part of another. Referring to the large-fruited sorts, he states: "There are two varieties of Shaddock. In var. A. maliformis the fruit is globose, with the pulp of a pale pink color, approaching to a very light yellow. In var. B. pyriformis the fruit is more or less pear-shaped, and the pulp is of crimson color, more or less intense. The second of these varieties is the more esteemed, being sweet and juicy, and having only in a slight and palatable degree the acidity which abounds in the first. I may remark that I have always found the pear-shaped variety good, whereas it is seldom the case with the round-shaped fruit. There cannot be a doubt but that if budding, as is done in China, were more generally practiced, instead of trusting to propagation by seed, that the fruit would be much improved."

The smaller Pamelows or Shaddocks are ranged by Macfadyen under a distinct species which he calls *Citrus Paradisi*. The tree is described as thirty feet high, of handsome appearance, with suberect branches and sharp at the apex. The leaves are oval, rounded and smooth on both sides. The flowers have linear petals and the stamens are twenty-five in number. The differences between this and *C. decumana* appear to consist in the more erect habit of the plant, in the rounded (not emarginate) leaves, and in the linear rounded (not oblong-obtuse) petals. With regard to the fruit he remarks: "There are also two varieties of this species: var. A. pyriformis, Barbadoes Grape-fruit; var. B. maliformis, Forbidden-fruit. The pear-shaped variety, as the Shaddock, possesses most of the sweet principle, and is, on the whole, a preferable fruit." This classification was made by Macfadyen nearly sixty years ago, therefore, long before these fruits were so widely distributed as now in other parts of tropical America. He was so accurate and skillful an observer that, as far as the New World fruits are concerned, we cannot very well improve upon it. It is doubtful whether the small-fruited sorts he places under *C. Paradisi* really deserves specific rank, but that point does not affect the main question with which we started, namely: What are the differences, if any, existing between the Shaddock and Grape-fruit? In summing up the results of the investigation we may say that all the larger-fruited sorts may be called indifferently either Pamelows or Shaddocks. These are merely the eastern and western names for the same thing, and are perfectly interchangeable. No distinction appears to have ever been made between them. There are two well-marked varieties, one being globose, with the flesh of a pale pink color, and the other pear-shaped, usually with a deep pink or crimson pulp. As regards the small-fruited sorts, these, according to Macfadyen, may be either globose, when they are called Forbidden-fruit, or pear-shaped, when Grape-fruit is the older name. The name Forbidden-fruit (from a fancied connection with the Garden of Eden)

is tolerably old in the West Indies. Tussac, in the *Flore des Antilles*, published in 1824, gives a good figure of the typical Shaddock, which he translates into the French *Chadec*. In vol. iii., pp. 73, 74, he states: "J'ai eu occasion d'observer a la Jamaïque, dans le jardin botanique d'East, une espèce de Chadec dont les fruits, qui n'excedent pas en grosseur une belle orange, sont disposés en grappes; les Anglais de la Jamaïque donnent à ce fruit le nom de 'Forbidden-fruit,' fruit defendu, ou smaller shaddock." Later on he refers to the same fruit in the following words: "C'est une assiette de dessert très distinguée et fort saine" (p. 74). In the illustrations here given are shown the various fruits as known in the New York market. The names attached to them do not, however, correspond to Macfadyen's classification. In the case of the Forbidden-fruit and grape-fruit they are exactly reversed. As usually happens when a name has become familiar in commerce, it is eventually applied in a much wider sense than the original one. Thus, the term grape-fruit has become so general that any moderately large fruit, provided the skin is pale yellow, thin and smooth, and the pulp of a delicate flavor, is designated by it. The fruit commonly called grape-fruit in New York is really the Forbidden-fruit of the West Indies. The true grape-fruit is pear-shaped, and, according to Macfadyen, when obtainable at its best, is preferable to the Forbidden-fruit. The fruit shipped from the Bahamas as grape-fruit is usually round, with a polished yellow skin of a silky texture and very heavy. This is probably one of the best of its class, and quite equal to Macfadyen's pear-shaped variety. Next comes some excellent fruit from Jamaica, no doubt that already referred to by Tussac under the name of Forbidden-fruit, a smaller shaddock. According to the New York estimation, this would be almost a typical grape-fruit, supplying "une assiette de dessert très distinguée et fort saine."

New or Little-known Plants.

Lavatera insularis.

FOUR species of *Lavatera* have been described from the islands situated off the western coast of North America. *L. assurgentiflora* was described by Dr. Kellogg from cultivated specimens raised from seed said to have come from the small rocky island lying south of Santa Barbara, known as Anacapa. This species is commonly cultivated in western California as an ornamental plant or as a wind-break. It grows very rapidly and thrives well, but must be protected from cattle and rabbits, which are very fond of it and would soon kill it. Californians of Spanish descent claim that the seed of this species was brought from Europe by the padres and raised by them about the old missions. There is a very similar form in the Mediterranean region, where many species of *Lavatera* grow. *L. assurgentiflora* has been found on San Miguel, Santa Rosa and small rocky islets about Santa Catalina Islands.

Another species is known only on Guadaloupe, an island far out in the ocean west of Lower California, and another is peculiar to San Benito, a group of islets nearer the Mexican mainland and north of Cedros Island.

Lavatera insularis (see figure on page 165) is supposed to be a native of the Coronados, small rocky islands belonging to Mexico, situated near the mainland in plain view of San Diego. The distribution of this species must be extremely limited, for, according to Mr. A. W. Anthony, the well-known ornithologist, to whom I am indebted for my information, it grows only in one cañon of the largest island. A great part of the year, from lack of water, it is in a dried-up condition, but cultivated plants well watered bear leaves and flowers throughout the entire year. Plants growing in my garden at San Diego, nearly two years old from seed, are quite attractive in appearance, and seem very different from any of the cultivated *Lavateras* of California.

The cultivated plant, already as large or larger than

those of the island, branches from the surface of the ground and grows into a perfectly hemispherical shape about four feet in diameter, and shows a disposition to increase in breadth rather than in height.

The flowers are yellowish white, striped and tipped with purple, and would not be conspicuous even if they were

Cultural Department.

The Water Garden.

THE Water Soldiers still lie quietly at the bottom of the tank, but the hardy *Nymphaeas* have suddenly awakened and are unfolding their leaves, though yet their leaf-stalks have not

1. A flowering branch, natural size.

Fig. 27.—*Lavatera insularis*.—See page 164.

2. Vertical section of a flower, natural size.

not completely hidden by the leaves. Although full of flowers and fruit, they are completely concealed by the almost unbroken hemispherical covering of soft green leaves.

San Diego, Calif.

T. S. Brandegee.

lengthened. Some other hardy aquatic plants need even less encouragement, and *Aponogeton*, the beautiful and fragrant Cape Pond Weed, has already ventured to float a leaf at the surface. It is, perhaps, not well enough known that hardy *Nymphaeas* are among the most reliably hardy plants, pro-

vided that they are established and have a covering of water, if only a few inches over their crowns.

A few of the species and varieties have been well tested here for several years, being completely frozen in ice each winter without injury. Last winter all the Pond Lilies were left exposed in the shallow water of the tanks and were frozen up for most of the season, and none were at all injured. It seems that the rhizomes of these plants having comparatively large air cells are not injured by the temperature of ice, and this being formed around them is a protection from excessively low temperature. We had, as usual, a temperature under zero several times during the winter.

As it is about time to prepare a water garden it may be well to again call the attention of flower fanciers to this most attractive, fascinating and still novel specialty of gardening. Of course, if one has a natural pond the growing of *Nymphaeas* is too obvious a decoration and too simple an operation to talk about, but in a common every-day dry yard the water garden charms, if only with its unexpectedness, and the modest owner of a few feet of water surface need not envy a broad expanse where the muskrats would probably eat up his good tubers. My first water garden, composed of three *Nymphaeas* in three sunken washtubs, backed and edged with subaquatic plants, was much prettier in effect than anything possessed since in more ambitious tanks which are more practical than æsthetic, and I should advise any one to whom expense was an object to commence the culture tentatively in the same way that I did. Of course, this is a very modest beginning, and the plants do not have much chance to expand, but it is sure to give satisfaction to any one really fond of seeing things grow. It is only with aquatics that one discovers the full effect of warmth and moisture on plant life. *Nymphaeas* are, of course, the first choice for water gardens, and one should be careful not to introduce other plants, especially in large gardens, unless they are tender and will disappear in winter. Hardy aquatic plants have a wonderful capacity for growth and increase, and are very difficult to eradicate if once established. One finds many curious life habits among the water plants, as the Water Soldier, *Stratiotes aloides*, which will soon rise from the bottom, and, floating at the surface, flower and sink, again to form a colony of young plants spread around the parents in the familiar "hen and chickens" style. There is another plant, interesting to the botanist and biologist, *Spirogyra*, which is often sent out by the florist with the *Nymphaeas*. This is a great pest in a pond, and new plants should be examined and all traces removed. This appears in dark green threads, which increase so quickly in warmth that it is difficult to eradicate from among other plants.

Elizabeth, N. J.

J. N. Gerard.

Cannas.

THE freedom with which Cannas can be grown makes them everybody's plants, and it is not uncommon to see them growing thrifflily in the backyards of crowded portions of the city. They are effective in every stage of their growth, and a mass of them in bloom is always pleasing.

After a rest of a month our last season's plants were gradually started and kept rather dry until active growth commenced. They began to bloom again in March, and after resting for a couple of weeks during May, which can be brought about partly by withholding water, they will be planted out again and will bloom for the remainder of the season.

Since the production of the Crozy type of *Canna* this has been the standard by which others have been judged, and nothing better, at least in form, was looked for, although new colors have been expected. These we have had in abundance, but as the type has always been so well defined it has been easy to decide on the merits of a novelty, and no introducer of any standing would risk his reputation by sending out inferior varieties. Now we have a new type, said to be a hybrid between *Canna flaccida* and the Crozy strain, one of which, Italia, has already been figured and described in GARDEN AND FOREST, and another, Austria, has also been noticed as bearing still larger flowers of similar form, pure yellow, with the exception of scarlet pencilings on the centre petals.

The introductions for the year of the Crozy type show an advance principally in larger flowers of symmetrical contour, full, and turned out on all sides of the stem so as to show a vertical face. Collectively, therefore, when best developed, they form a pyramidal spike. In beauty of outline and in the regular arrangement of its flowers, F. R. Pierson, a magnificent crimson with a golden throat, is the best of its type, and it is not likely soon to be excelled. Flamingo approaches it, although the short side spikes give the whole cluster a slightly more rounded appearance. As an element of beauty a head made

up in this way is not so attractive as one bold spike. For bedding purposes it will be superior on account of the long time one flower-stem will remain in good bloom. Trilby claims favor as the Orchid *Canna*, and under glass it is exceedingly beautiful. It is bright yellow, with clearly cut scarlet markings in the centre, and the large flowers have more substance than many of its color.

Pierson's Black Beauty is a seedling from President Carnot. This old variety is conceded by all who have grown it to be the best of all the bronzy-leaved varieties which have also attractive flowers. No doubt, J. D. Cabos and J. C. Vaughan, bronzy-leaved varieties, with handsome salmon-colored flowers, were both derived from this. Black Beauty eclipses them all in the color of its foliage and is equally effective in bloom.

Among yellow-banded Cannas of the Crozy group, Queen Charlotte, of last year, took a leading position. But the specialist has been at work in the mean time, and will introduce Little Billee as an improved seedling from Queen Charlotte. It is dwarfer and said to be superior for massing. Under glass it certainly is a most attractive variety, and, compared with Queen Charlotte, it is slightly deeper in tone. Madame Alphonse Bouvier is another so-called Orchid *Canna* of singular beauty. The ground-color is scarlet, with an irregular orange band continued into the throat. Souvenir Antonin Crozy remains the best of all the true Crozy type, and it is doubtful if any of this year's introductions will equal it in beauty. Ami Pezeux competes with F. R. Pierson among maroon shades. All through the flower are scattered dots of a deeper hue in the same way as the so-called yellow Cannas are speckled with red. Madame Rozain is a deeply toned Madame Crozy, with the addition to the characteristic yellow band of a yellow throat, which rather increases its effectiveness. Côte d'Or is described as strikingly effective for bedding, with saffron-colored flowers. It is compact and dwarf.

Among older varieties, Alphonse Bouvier stands at the head. It is not of the ideal form; the terminal spike per-versely droops. While flowers continue to expand on this, others take its place later, also spreading out. They continue to open in large effective clusters for a long time. Its lustrous maroon-colored flowers are unsurpassed by any variety known. Another of exactly the same type is Helen Gould, and this is bright amber. It was one of the most striking varieties in a large group here last summer. Although introduced several years ago, Paul Bruant is as yet little known. It is one of the best of crimson-flowering Cannas for pot-culture. On a plant in a ten-inch pot are three well-developed flower-stems carrying good heads of bloom, which would make this an effective decorative plant in any grouping. Florence Vaughan has been a surprise this season as a pot-plant, being the earliest to bloom and the most floriferous of any of the so-called yellow-flowered varieties.

T. D. Hatfield.

Greenhouse Climbers.

VISITING not long ago the greenhouses of the Massachusetts Agricultural College, at Amherst, I was much impressed with the luxuriant display which was made there by well-grown specimens of common climbing plants. They were in every case planted out in the borders, which is, no doubt, the best way of treating climbers, which are, in most cases, impatient of having their roots restricted. There are two large octagonal houses, in addition to a number of others. In one of these *Asparagus plumosus* is trained up the pillars which support the roof, and is festooned from pillar to pillar with particularly graceful effect. In the other octagonal house a fine plant of *Plumbago Capensis* occupied one pillar and was covered with its beautiful blue flowers. A handsome Cherokee Rose, a plant often commended and described in GARDEN AND FOREST, occupied a considerable portion of this house. Growing with it as a companion plant was a very fine specimen of the climbing *Perle des Jardins*, which was carrying great numbers of its lovely yellow flowers. Another pillar was occupied by that excellent climber, *Jasminum revolutum*, with its compound corymbs of bright yellow flowers and dark green pinnate leaves. This is one of the few vines which insect pests do not take to readily. In another house was a large plant of *Passiflora princeps*, with pendulous racemes of red flowers. *P. quadrangularis*, var. *acubifolia*, was also growing in the same house, and, in my opinion, this is the best of all the Passion flowers. The stem, as its name indicates, is four-angled; the alternate leaves are cordate, six to eight inches long and four to five inches wide and mottled with yellow, resembling the *Acuba* leaves very closely. The flowers are white outside, and of a dull reddish color within, and very

odoriferous. A good plant of *Aristolochia Siphon* was also showing its usefulness as a greenhouse climber as well as being a hardy one. *Cobæa scandens* occupied the end of another house and was bearing hundreds of its purple, cup-shaped flowers.

In a house devoted to Cacti and other succulents, was a large specimen of *Pereskia aculeata*, the Barbadoes Gooseberry, which covered a space of about ten feet by fifteen. *Pereskias* belong to the Cactus family, but this species is so unlike any of the other members, that, except for the flowers, which are of a creamy white color, one would almost fail to see the connection. It produces true leaves in abundance of a bright green color, and the stem is round and woody.

A good specimen of the noble *Cereus triangularis* was also doing well in this house. These greenhouses have been built several years, and the climbers have become so well established that they are now displaying the best effect which can be produced by intelligent cultivation, persisted in for a series of years.

Botanic Garden, Northampton, Mass.

Edward J. Canning.

Ouvirandra fenestralis.

THIS plant has been too long regarded as an aquatic freak difficult to grow and apt to die without any apparent reason. This is not true. Like many other plants, when their peculiarities are understood, the cultivation is simple, and this singular and interesting plant ought to be found in every collection of stove plants, and, of course, no aquatic house is complete without it. It grows in Madagascar on the borders of streams, the leaves being merely a network of vascular tissue resembling lace, or, as its specific name implies, a lattice window. In well-grown plants they are from twelve to eighteen inches long and about one-third as broad, oblong, with an obtuse apex, and spreading out almost horizontally beneath the surface of the water. When young they are light green, but they change to a deeper color as they mature, when the midrib is a bright yellowish green. The plant grows freely at a temperature of from seventy to seventy-five degrees, Fahrenheit, or from a little lower in longer days. During a cold spell, when the temperature is likely to fall below the minimum, warm water can always be added, and the top of the tank covered with shading material, or even paper, to retain the heat. Little shading is needed during the winter, although some may be needed after the first of March. There is no necessity of covering the water with such plants as *Azolla* or *Salvinia*, because they grow densely and would hide the plant, even if too much shade, with high temperature, did not weaken its growth, so that the leaves would become drawn, narrow and soft.

The *Ouvirandra* is not particular as to soil. I have grown it with success in different composts, and it surely will thrive in any mixture consisting of fibrous loam, rotted manure and sand. My preference is to have the soil rather heavy; in fact, the greatest success I have achieved has been with soil like that used for *Nymphæas*—that is, turfy loam, well-decayed manure and a little sharp sand. Any wooden tub or kerosene barrel cut in two makes a good receptacle, only, of course, this latter should be burned out before it is used. Glass aquariums are well adapted to the cultivation of these plants, and they afford the best opportunity for inspecting them. When the tubs or other receptacles are clean there is no need of changing the water when any scum arises or dust settles upon it. Pure water can be added with a hose to flush the tub, and the plants themselves will keep the water clean as they are good furnishers of oxygen. They do not suffer from insects, and they are no more difficult to grow than the well-known *Apongeton distachyon*, with which genus *Ouvirandra* is now included.

Riverton, N. J.

William Tricker.

Cyanide of Potassium as an Insecticide in Glass Houses.

AN interesting series of experiments has lately been carried out at the Department of Agriculture, under the direction of Professor Galloway, Chief of the Division of Vegetable Pathology, in the way of checking the ravages of the black-spotted mealy bug, *Orthezia insignis*. This pest is a native of South America; it was first noticed, I believe, in some greenhouses in the state of New York about five years ago. Since that time it has spread in all directions, and is getting to be quite as troublesome on certain plants as the mealy bug and green fly are on others. It was described at length in a bulletin issued last year by the Hatch Experimental Station. Some time ago Professor Galloway was impressed

with the idea that the method in use in Florida and elsewhere, whereby the Orange-trees are fumigated under tents with this cyanide, could, with certain modifications, be utilized in checking the devastations of the *Orthezia*, and the results, as seen in an exhibition at the propagating-gardens last week, have proved highly satisfactory. A house containing 15,580 cubic feet of space, which is used at present for storing *Coleus* for bedding purposes, was selected for the work. The *Coleus* is one of the favorite plants of the pest, although it is frequently found on a number of others, among which are the *Chrysanthemum*, *Lantana* and *Alternanthera*. The plants in the house selected were infested to such an extent that they were considered almost unfit for use this summer. The fumigation of the house took place after seven o'clock in the evening, as the presence of light nullifies to a certain extent the influence of the liberated gas. The ingredients used were three pints of water, the same quantity of sulphuric acid and five and a half pounds of cyanide of potassium; this was divided into three equal parts and placed in three two-gallon jars placed at equal distances along one of the side benches and close to the ventilators; the water was first poured in the jars, then the sulphuric acid, and through the open ventilator from the outside the cyanide was added. In less than two minutes the gas had evidently reached to all parts of the house. Twenty minutes later the ventilators, both top and bottom, were raised from the outside, provision having previously been made for this, as the presence of the gas after that period among the plants is considered hurtful to them. After careful inspection that evening and next morning not a live *Orthezia* was to be found, and after strong sunshine not a leaf appeared injured; even tender fronds of *Adiantum cuneatum* were uninjured. The common mealy bug and one or two species of scale insects were also killed.

Botanic Garden, Washington, D. C.

G. H. O.

Kæmpferia rotunda.—Although a very old and well-known plant, this is usually grown for its foliage, but its exceedingly beautiful flowers are really its greatest charm. The flowers are borne in spring or summer before the leaves, which should be allowed to die down late in fall, and the plants may be kept in a dry state until January or February, when they should be placed in moss in flat pans with the roots but slightly covered. Or they may be planted and grown from year to year in an ordinary light compost and allowed to rest in winter. When brought into a brisk heat the leaves and flowers soon begin to grow. The flowers, not unlike Meadow Saffrons in form and color, are almost sessile, and produced directly from the root in great profusion. They are sweetly fragrant and of a bright rosy red color, or sometimes paler, each one lasting only a day, but succeeded by new ones for a long period. *Kæmpferias* look best in masses when a number of flowers show at the same time. The leaves when fully developed are about two feet long, erect, broadly lanceolate and narrowed to a broad petiole at the base. The color is a dull olive-green, with one or two brownish longitudinal bands, so that the plant is quite effective even when out of flower.

Eranthis hyemalis.—There is, perhaps, no brighter and hardier spring flower than the little Winter Aconite, which flowers here much later than in Europe. It is a very dwarf perennial with fleshy tuberous roots which produce a couple of peltately divided leaves each and a solitary flower of a bright yellow color early in spring. *Eranthis* is nearly related to the Hellebores. The flower is about an inch across, with six petal-like sepals and inconspicuous petals and nice little bunches of yellow stamens in the centre. The flowering stem is simple, and has three deeply lobed involucre leaves. It is much used in Europe in rough places among trees and shrubs, especially on sunny southern slopes; unfortunately, it is not always easy to naturalize in such places here. When growing and flowering in masses in early spring the effect is very rich and beautiful. It will grow in any moderately rich garden soil, but prefers one that is light, loamy and well drained.

Adonis vernalis.—This is one of the early spring flowers that ought to brighten every garden, whether large or small, at this time of the year. It is, however, hardly known, and the country homes which should now be gay with flowers have hardly a bud to show that spring has come. *Adonis vernalis* is not unlike a large *Anemone* in shape, but the color is a very bright yellow. The flowers are set off by light feathery foliage. The species grows to a height of eight or ten inches and forms masses of foliage and flowers as early as the latter part of March in favored localities. It is a very desirable plant for naturalizing in bare places in shrubberies and among rocks. As it is perfectly hardy, it will generally look out for itself,

once established. It thrives best in a rather moist position where it is partially sheltered from the sun, but will not grow well in too deep shade. It is easily propagated by means of seeds or divisions and requires no special culture.

Correspondence.

Buckleya Again.

To the Editor of GARDEN AND FOREST:

Sir,—Three years ago, in May, I visited Wolf Creek, a small hamlet consisting of some half-dozen scattered houses, about five miles below Paint Rock, the original locality of *Buckleya distichophylla*. The post-office is situated at the mouth of a stream of the same name that rises in the high mountains near the North Carolina line, and, after winding among the hills for some seven miles, empties into the French Broad. Here *Buckleya* was found at several points along the river, from about two miles above to a half-mile below the creek. In only one spot was it found away from the river-bank, and there not more than an eighth of a mile distant. In the locality in question some two or three dozen plants grew on the steep wooded bank of a small pond—half water, half quicksand—among Cherry Birches, two or three Oaks and the Big Laurel, *Rhododendron maximum*. The presence here of Hemlocks, *Tsuga Canadensis*, makes it probable that at some not very distant time this colony was also growing on the river-bank, for Hemlocks are almost entirely confined to the banks of the larger watercourses in the Alleghanies. The probability is increased by the fact that only a stretch of low bottom-land intervenes between the pond and the river.

About two miles above Wolf Creek the largest number of individuals found in any one place were discovered on an abrupt rocky bluff overhanging the river. In this sheltered spot there were probably 120 specimens growing under the shade of various large trees, along with Yellow-wood, *Cladrastis lutea*, and the Sweet shrub, *Buettneria fertilis* (*Calycanthus laevigatus*). Between these two stations the plants were scattered along the river—a half-dozen or so here and there—near the water's edge, usually growing with the Sweet-shrub, *Leucothoe recurva*, Hemlocks and Red Birches. All the specimens found were on the left bank of the river; none were discovered on the right bank. *Buckleya* is said to have been found on a bluff on Wolf Creek, about half a mile from its mouth, but I did not come across it there.

The largest specimens grew on the bluff two miles up the river, where they attained a height of ten or eleven feet, but the average shrubs are only six or eight feet high, with a stem diameter of about one inch at base. In habit *Buckleya* is more like a small tree than a shrub. It prefers a rich shaded soil, but sometimes grows in almost pure sand. It is a handsome plant in every part. The foliage is light and graceful. The female flowers, drooping at the ends of short twigs, with their crown of four sepal-like bracts, are much more conspicuous than the small staminate blossoms. The bark, reddish brown in color, with conspicuous lenticels, somewhat resembles that of the Cherry Birch. The wood is white and has a beautiful fine grain. A quantity of the nuts, or rather drupes, were sent to me during the following autumn by Master Harry Allen, who wrote that they are produced in great abundance. The largest ones are nearly an inch long. When dry they are light brown in color and deeply furrowed lengthwise. Although rich in oil, they are not unpleasant to the taste, being quite sweet and with a flavor somewhat like that of filberts. The shrub is well known at Wolf Creek, but has received no more distinctive local name than that of "the bush with queer nuts."

There seems to be no great danger of its immediate extinction. Its occurrence in several different places is one security against this. Then it is usually confined to places rather difficult of access and unfavorable for agricultural purposes. In spite of the apparent disadvantage of a separation of the sexes in so rare a plant, it matures a great quantity of fruit. In May I found numerous vigorous seedlings among the older plants, especially in the two larger colonies. Moreover, it is highly probable that further search along the banks of the French Broad, between Paint Rock and Wolf Creek and below Wolf Creek, may discover other stations. As far down the river as Newport the conditions are very similar to those about Wolf Creek, so that its absence, rather than its presence, there would be surprising. At any rate, it is pleasant to know that this rare and handsome shrub is not quite as near extinction as has been supposed.

Department of Agriculture, Washington, D. C. T. H. Kearney, Jr.

Calochortus in Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—*Calochortus Weedii* is found in great abundance about the foot-hills of Pasadena, but the plant does not flourish equally well in all places. The finest flowers I have found are on the north-eastern slope of the highest hill near the summit, where another hill to the north cuts off the cold mountain winds. The plants appear in early March among the Sage-brush, where the soil is red and loose, and it may interest your readers to know that the very sturdiest of them come out of the gopher-holes, where the bulbs are at least eighteen inches deep. In some former year a seed chanced to fall into one of these holes, and the dust sifting over it neatly buried it, where, perhaps, it found more moisture than its neighbors nearer the surface. At all events, the plants in gopher-holes grow with unusual vigor and their flowers are exceptionally large and brilliant. The terminal flowers are largest, and they are seen scantily in the early part of April, while the lateral buds follow until the middle and the upper part of the slopes are luxuriantly covered with the white flowers. I have often gathered twenty of them in the space of three square feet, the tallest being on stems three feet long. The seed-cups open by July, when the ground is literally alive with snakes. Few of the seeds reach the ground, however, as the small birds relish them and often pick into the three-cornered capsule before it is ready to open. *C. Weedii*, with pink flowers, is found on the bench-lands of the Cañon La Cañada, where it may be the color is modified by unusual exposure.

The mauve-colored flowers of *Calochortus purpurascens* are found in a few places on the bench-lands which look over Arroyo Seco. These are very large, and the yellow pubescence extends from the centre of the flower fully half the length of the petals, making a most beautiful combination of color. These flower later than the ordinary white ones. They are not as tall and less branched. *C. claratus* bears a beautiful canary-colored flower, and is found on the high hills overlooking the Cahuenga Pass.

The Evolution of Horticulture in New England. By Daniel Denison Slade. Putnam's Sons, New York and London. 1895.

Dr. Slade's lifelong services to the art of horticulture are gratefully acknowledged by all lovers of the art in this country; and this little book, published just before his death, will be welcomed as a memorial of its author no less than for its own sake. It is somewhat overweighted by its title, for it is an attractive sketch rather than a scientific history of the progress of horticulture in New England since the time when the first colonists landed; but its delightful typographical dress and its simple pretty binding are entirely in accord with its character.

The volume begins with a brief sketch of the history of horticulture in the mother country, and then takes up the main subject from the very outset. It is impressed upon the reader that, in the early seventeenth century, New England was a forest-clad country, as regards its islands no less than its mainland, "the only exceptions to this condition being the salt marshes, the bogs and the higher ranges of mountains." An old chronicler relates that "the salvages are accustomed to set fire to the country in all places where they come and to burn it twice a year—that is, at the spring, and the fall of the leaf. The reason that moves them to do so is because it would otherwise be so overgrown with underweeds that it would be all a coppice wood, and the people would not be able in any wise to pass through the country out of a beaten path. This custom of firing the country is the means to make it passable, and by that means the trees grow here and there, as in our parks, and makes the country very beautiful and commodious." Nevertheless, much of the work of the early settlers was in clearing away the forests which obstructed agriculture and horticulture—how much it is hard for those who know eastern New England now to imagine until they have read many such notices as that which speaks of "a necke of land called Nahant" as being "well wooded with Oakes, Pines and Cedars." Their first

efforts in planting are carefully followed from year to year and from place to place by Dr. Slade, and the quotations from old writers, which show what plants they brought with them from the old country, are not more interesting than those which reveal their estimate of those which they found indigenous in the new. Their optimistic descriptions of the native fruits and berries certainly reveal that determination to look on the bright side of painful new conditions and to make the most of comparatively unattractive novelties which must always mark the successful colonist. Of course, Old World names are so often applied to different New World things that the task of interpretation is not always easy. For example, Wood, writing in 1629, says: "The Hornebound tree is a tough kind of wood, that requires so much paines in riving as is almost incredible, being the best for to make bolles and dishes, not being subject to crack or leak." The tree in question which, Wood explains, grows "with broad speard armes," was probably the Tupelo, the wood of which was used by the Indians for the purposes he notes, and which, along the Massachusetts shore, is still popularly called the Hornbeam. Growing wild, says the same writer, were "Strawberries in abundance, very large ones, some being two inches about: one may gather halfe a bushell in a fore-noone. In other seasons there be Gooseberries, Bilberries, Resberries, Treackleberries, Hurtleberries, Currants, which being dried in the Sunne are little inferior to those that our Grocers sell in England. This land likewise affords Hempe and Flax, some naturally and some planted by the Indians, with Rapes if they bee well managed." The local Walnut-tree, says Wood again, "is something different from the English Wallnut. . . . These trees bear a very good nut, something smaller but nothing inferiour in sweetnesse and goodnesse to the English Nut, having no bitter pill. There is likewise a tree in some parts of the Countrey that beares a nut as bigge as a small peare"—the Butternut. And, he continues, "the White Thorne affords hawes as bigge as an English Cherrie which is esteemed above a Cherrie for his goodnesse and pleasantnesse to the taste." But of the native New England Cherries even Wood could not speak in praise. "The Cherrie trees yeeld great store of Cherries, which grow in clusters like grapes; they be much smaller than our English Cherrie, nothing neare so good if they be not very ripe: they so furre the mouth that the tongue will cleave to the rooffe, and the throate wax horse with swallowing those red Bullies, as I may call them, being little better to the taste. English ordering may bring them to be an English Cherrie, but yet they are as wilde as the Indians. But the Plummes of the Countrey be better for Plummes than the Cherries be for Cherries; they be blacke and yellow, about the bignesse of a Damson, of a reasonable good taste."

But, despite their readiness to be pleased with their new possessions, the settlers were lavish importers of products familiar at home. For example, among the articles ordered to be sent to New England by the Massachusetts Company in 1629, were "Vine-planters, wheat, rye, barley, oats, a hogshead of each in the ear; beans, pease, stones of all sorts of fruits, as peaches, plums, filberts, cherries; pear, apple, quince kernels; pomegranates, woad seed, saffron heads, liquorice seed, madder roots, potatoes, hop-roots, hemp seed, flaxseed, currant plants and madder seeds." It is interesting to trace as far back as this the importation of the Woad-waxen which now so beautifully covers parts of Essex County; but Pomegranates certainly have not acclimatized themselves so well in New England.

More or less extensive orchards were early established. The first is believed to have been that of William Blackstone, to whom, in 1633, were granted "fifty acres . . . near his house in Boston, to enjoy forever." In 1765 this orchard was spoken of as still producing fruit, and its existence at even later dates is recorded. Blackstone himself afterward removed to Rehoboth and planted the first orchard within what are now the borders of Rhode Island.

Wood, writing between 1629 and 1633, mentions many

fruitful gardens in the regions about Boston, where, in his time, Boston itself was not the largest town. "The greatest Towne in New England," he says, was Dorchester, and a mile away lay "Roxberry, which is a faire and handsome Country-towne, the inhabitants of it being all very rich." And Boston is described as being "two miles North-east from Roxberry," and "although it be neither the greatest nor the richest, yet it is the most noted and frequented, being the Center of the Plantations where the monthly courts are kept. Here likewise dwells the Governour: This place hath very good land, affording rich Corne-fields and fruitful gardens." Brookline is noticed as a place called Muddy River, two miles from Boston, where the inhabitants of that place "for their enlargement have taken to themselves Farm-houses; where is good ground, large timber, and store of Marsh-land and Medow"—a description which is not out-of-date to-day.

In 1632, Conant's Island, in Boston harbor, was granted to Governor Winthrop, and was thereafter called "The Governour's Garden." Josselyn, writing in 1639, reported that he had received from there "half a score very fair Pippins . . . there being not one Apple tree nor Pear planted yet in no part of the Countrey but upon that Island."

But it was not long before the town of Boston was filled with such trees, and Mylne Street (now Summer Street) was especially a street of gardens. The one owned by Gamaliel Wayte was planted in 1692, and long remained famous; and in the eighteenth century this and neighboring towns were well entitled to boast of their horticultural products. Paul Dudley, writing of Roxbury in 1726, said, "Our apples are without doubt as good as those of England and much fairer to look upon, and so are the pears, but we have not got all the sorts. Our peaches do rather excell those of England, and then we have not the trouble or expense of walls for them; for our pear trees are all standards, and I have had in my own garden seven or eight hundred fine peaches of the Rareripes growing at a time on one tree. Our people of late years have run so much upon orchards that in a village near Boston, consisting of about forty families, they made near three thousand barrels of Cyder. This was in the year 1721. And in another town of two hundred families, I am credibly informed, they made near ten thousand barrels."

Many of the fine ornamental gardens laid out in Boston in the eighteenth century were preserved until comparatively recent days—for example, the one attached to the Faneuil mansion, nearly opposite King's Chapel, with which, Dr. Slade relates, he himself was intimately acquainted.

But it is impossible to follow his account of the progress of New England horticulture down to the present day; nor is his book of the sort which lends itself well to the reviewer's ordinary process of condensation and exposition. We have preferred not to attempt this, but, instead, to quote a few paragraphs from its earlier pages, which may suggest to our readers the interest of all the others.

As he reaches more recent times, Dr. Slade speaks of the great good done by the Massachusetts Horticultural Society, founded in 1829, and notices many of the charming suburban country places for which the environs of Boston have long been famous—places which, alas, must for the greater part soon perish before the steady advance of the city's streets. Nor does the volume lack some pages devoted to the consideration of gardening as a fine art—as an art of arranging surfaces of ground so that they may please the artistic sense—which are instructive as well as agreeable reading.

Notes.

One of the prettiest early yellow flowers is that of *Iris orchoides*, which was introduced into cultivation by Dr. Regel from the mountains of Turkestan. It is perfectly hardy and flowers with the early *Daffodils*. These flowers are not very large, but they are a pure rich yellow, with small blotches of olive or purple on the fall. The leaves at the time of flow-

ering are hardly six inches long, but the flower-stems are a foot or more in length, and each one bears in succession three to six flowers. The bulbs increase rapidly, and a colony of the plants at this season is one of the most interesting features of the herbaceous garden.

A circular has been sent out by the Division of Forestry of the Department of Agriculture which calls attention to the recent forms of legislation against forest fires and summarizes the existing acts now in force in the different states. The most complete law is said to be that of Minnesota, which is quoted entire, while the provisions of the Maine law are given with some detail.

It has been often argued that when orchards are sprayed with arsenical poisons while the trees are in blossom a great many bees are killed. The bees are not only useful as honey gatherers, but they are very helpful in fertilizing the flowers. Some experiments made last year at the Ohio Station show conclusively that bees may be killed in large numbers by spraying while the flowers are open, and since this practice is never necessary at that time for the destruction of injurious insects it should be avoided. The trees should be sprayed just before flowering and as soon as the blossoms have fallen, but never while they are in bloom.

The American Architect and Building News speaks appreciatively of the timber tests made by the Forestry Division of the Department of Agriculture, and adds very justly that when engineers, architects and builders are expending hundreds of millions of dollars every year for timber, that the collection of accurate information as to the qualities of our different woods is a matter second only in importance to the preservation of the forests. It is to be hoped that Congress will not be so short-sighted as to adjourn without making an appropriation for continuing the tests which have been going on now for several years. Of course, the value of such work depends largely on the number of experiments made. Only when tests are made in large numbers and under many conditions can we have confidence in the trustworthiness of the accumulated data in regard to the range of strength and other qualities of a given species.

The unusually hot weather during the second week in April, when the thermometer rose to ninety degrees, Fahrenheit, has hurried all spring-flowering shrubs into bloom. Before the hot weather began—that is, up to the 10th of April—no shrubs were in bloom in this vicinity, except occasionally a *Daphne Mezereum*, and Mr. Joseph Mehan wrote that *Prunus Davidiana* was flowering in company with the *Daphne* in Philadelphia. Last week, however, *Magnolia stellata* had burst into bloom, and is now much past its prime, and *M. conspicua* and *M. Soulangeana* were hardly a day behind it. The *Forsythias* and our native *Spice Wood* opened about the same time, and with them *Cornus mas* and the early bush *Honeysuckles*. Before this paper is read the *Peach-trees* will be in full bloom as the result of a week of August weather in the middle of April. It will be unusually good fortune if we are not visited by a severe freeze before another paper is published.

Mr. J. H. Hale, President of the Hale Georgia Orchard Company, says, in the current number of the *Fruit Trade Journal*, that from personal examination of the Peach orchards in that state he finds the prospects better even than last year, when Georgia had the best peach crop on record. The frosts that occurred during blooming time this year thinned out the prospective crop considerably, but it is difficult to find anywhere a single tree that is not now carrying a fair crop of fruit, while there are many trees so overloaded that if two-thirds of the fruit would drop off there would be more than enough left for a full crop. In the orchards in which Mr. Hale is directly interested, comprising 100,000 trees, Elberta is stated to be the only variety that is not greatly overloaded. The total crop of the state is estimated at fifty per cent. larger than that of last year, allowing for the first crop of several hundred thousand young trees in the Fort Valley section. The season is fully ten days in advance of last year. Mr. Hale concludes that good Georgia peaches of the Alexander type should be plentiful in northern markets by the 15th of June. New York fruit merchants are anticipating the first Florida peaches before the close of April.

Asparagus is now coming from as far north as Charleston and Norfolk, and the New Jersey crop is looked for any day. Fifty to seventy-five cents a bunch is the price at this time. Beans from Charleston cost twenty-five to thirty cents a quart, and peas from the same section seventy-five cents

a half-peck. New white turnips, from Virginia, may be had for ten cents a bunch. Well-grown white squashes from Florida cost ten to fifteen cents each, and southern tomatoes twenty-five cents a pound, the northern hot-house product bringing forty cents. Hot-house cauliflowers cost thirty-five to fifty cents each, lettuce ten to fifteen cents a head, and cucumbers twenty cents each—those from New Orleans filling out the needed supply at slightly lower prices. Mushrooms sell for ninety cents a pound.

Bulletin No. 59 of the Indiana Experiment Station treats of the bacteriosis of Carnations, an almost ever-present disease of these plants. It is easily detected, now that the cause is known and has been studied, but for years the leaves of the plants turned yellow and dried up before the cultivator's eyes, and not until half a dozen years ago was the true cause of the trouble known. Investigation has shown very plainly the presence of a true parasitic bacterium in the leaves of the *Carnation*; the germ has been separated and cultivated, and other plants have been artificially infected with it, so that there is no question as to the correctness of the diagnosis. This bulletin, which has been prepared by Professors J. C. Arthur and H. L. Bolley, gives a full history of the germ, which is called *Bacterium Dianthii*, and explains how it enters the plant and how it acts to destroy its host. It seems that no variety of *Carnation* is entirely exempt from the disease, but weakly varieties like *Buttercup*, *Sunrise* and *La Purité* are most affected. Poorly grown plants more readily succumb than those well grown, and partly starved or stunted plants are especially liable to attack. As it is necessary that there should be sufficient moisture on the leaves to enable the bacteria to move about and enter the pores, and thus gain access to the interior of the leaf, it is plain that keeping the foliage dry will prevent the disease. The trouble is that in this case the red spider might be as fatal as the bacteria. Dry foliage is in a direct line with the requirements of the plant, which is by its structure adapted to a dry atmosphere; its thick, smooth leaves and firm epidermis, and the waxy bloom of its surface, are all devices for conserving moisture. The true treatment, therefore, is to water the ground between the rows of *Carnations* with a stream of water, beneath a wire netting which is so arranged as to lift up the foliage. Spraying overhead should be practiced only occasionally, and on bright days, when the water will dry off quickly, and the water should contain a small amount of ammoniacal copper carbonate, as the germs cannot live in even a very weak solution of this compound.

The sudden change twelve days ago from persistent cold and rainy weather to midsummer temperature has affected the fruit market here in many respects. Oranges, for example, during last week declined fifty to seventy-five cents a box. Some 1,100 barrels of Jamaica oranges, variously known in the trade as *Late Bloom* and *New Crop*, are a part of the regular offerings. The quality of this crop, which appeared early this season, is unusually fine. Besides the usual receipts of Mediterranean oranges, California Navels continue plentiful. Exceptionally large specimens of the latter, sixty-four to the box, desirable mainly for decoration, sell at \$3.00 a box wholesale, while those of average size, 112 fruits to the box, and the yet more desirable size, 126 to the box, command \$3.50 to \$4.00. The hot weather caused an advance of fifty cents a box in the prices of lemons. Grape-fruit is still seen in the collections of retail dealers, but the extremely high prices of the past few months are not maintained by these belated specimens. Two cargoes of new-crop pineapples, altogether 2,500 fruits, reached this port from Cuba during last week, and somewhat larger invoices are expected during this week, the quantity in the corresponding periods of last year having been two or three times as great. The price now ranges from ten to twenty-five cents each, at wholesale, whereas a year ago the same grade brought six to eighteen cents. The first California cherries of the season reached here on April 16th from Vacaville. The variety, *Early Purple Guigne*, was of fair size, but lacked the deep rich color of fully ripe fruit. They sold at retail for \$1.25 a pound. Although strawberries continue to come from Florida, and the first shipments from North Carolina are already in our markets, prices are higher than they were several weeks ago. Last Saturday good strawberries sold for seventy cents a quart box by the crate, and some exceptionally fine fruit brought the remarkable price of ninety cents a quart at wholesale. On Monday seventy-five cents was the lowest price asked for a single box of choice fruit. The probable reason for higher prices for southern strawberries so late in the season is the increasing demand from buyers for hotels and restaurants.

Park Work near Boston.

IN 1893 the Legislature of Massachusetts passed an act which enabled the cities and towns surrounding Boston to cooperate with that city in securing open spaces for the use of the public, and the Metropolitan Park Commission was created to select and control these spaces. To the original Commission of Inquiry when it was making a preliminary study of this great park system the landscape-architect reported that long and continuous open areas, to be of the greatest benefit to the whole population of the metropolitan district, ought to be situated (1) on wooded and rocky hills; (2) along brooks and rivers, and (3) by the shores of the Bay and the sea. This thought, suggested by the geography of the district, has been steadily adhered to, and all the reservations created by the Commission belong to one of these three classes. In the report of the landscape-architects for 1895, published not long ago, it is stated that the areas now or soon to be controlled by the Commission include more numerous large pleasure-grounds than are governed by any public authority in North America, with the exception of the Governments of the United States and Canada. They comprise the Blue Hills reservation, five miles long; the Middlesex Fells reservation, two miles square; Stony Brook reservation, two miles long; Charles River reservation, including the semi-public river-banks, five miles long; the Mystic Valley parkway, two miles long, and the Revere Beach reservation, three miles long. The development of a work of such magnitude has more than a local interest, and the annual reports of the landscape-architects, as they give a record of the progress of the work and unfold the design, make a series of documents of the highest value to all who are interested in providing recreation-grounds for a large population.

To descend to the details of the work reported during the year just passed it is to be noted that the chief attention has been given to revising the boundaries of the public lands. Commissioners who purchase land for public use are not in the habit of making any serious study of boundary problems, nor are they adequately equipped, as a rule, to settle them intelligently, and therefore almost every park in this country is disfigured or, at least, fails to

produce the highest effect because details which are essential to its completeness have been omitted or some incongruous feature has been included. It is not to be expected that a park line which follows property lines between private owners will include all that is essential and exclude what is not essential to its highest value. A sad example of this is to be found in our own city, where large park areas have been purchased with their boundary lines established by chance or, at least, without any serious study of their actual significance. Considerable care was exercised in the purchase of metropolitan park lands for the greater Boston, and yet we find in the report of Messrs. Olmsted, Olmsted & Eliot that many amendments in the boundaries of all these reservations need to be made. A strip of land is added here to permit the construction of a boundary road without injuring a row of fine trees; a winding tongue of land is added there to give access to the same park from an important highway; a triangle is added here and a sliver of land is added there, an irregular and useless tract is restored to its owner in another place—in short, the whole ground has been subjected to a thorough study, so that whatever is essential to the charm of the place may be retained, and every facility for reaching it by cheap and rapid transportation provided.

Meanwhile it is to be noted that no haste is made toward building substantial stone-filled and graveled carriage-roads through the reservations. It is true there are roadways now existing and others which have been built under the authority of local superintendents, and these, to a certain extent, have opened the reservations to the driving public, but it is admitted that these roads do not exhibit the scenery of the reservations as advantageously as it ought to be exhibited and as it will be shown in the future, and they possess bad grades and bad lines. Nevertheless, before a comprehensive scheme of permanent roads can be studied it is certainly better to adopt the plan of the Commission and avoid all expensive constructions. The money available for such wheelways is well devoted to the clearing out of new walks and bridle-paths, and marking them with guide-posts, until the completion of the study may make it possible to give the permanent carriage-ways their best location.

These reports furnish salutary reading for all persons who think that the sole, or even the chief, work of a landscape-architect or a professional designer of parks is to make pretty pictures of flowers, and grass, and shrubs and trees, or to erect structures for merely ornamental purposes. Unfortunately, too many landscape-gardeners have no more elevated professional ideals than this. They do not recognize the fact that true art is not the servant of some temporary fashion, but something that is to endure, and must, therefore, have a permanent basis in the necessities and aspirations of human life. In these immense areas of rugged hills and wooded slopes, sunny glades and sparkling watercourses, the greater Boston has acquired a property in scenery which has a positive and inestimable value for the health and refreshment of the people whose lives must be passed in the noise and confusion and rectangular ugliness which seem to be the essential conditions of life in thickly crowded cities. It is evidently not the purpose of the designers to trick out the noble features of these northern landscapes with exotic vegetation or with incongruous bits of architecture, but to restore and retain, as far as possible, the original poetic charm of the place, which is its essential value. Balustrades and terraces and parterres of flowers or any other artificial ornaments are sorry substitutes for a real woodland walk or a group of noble trees like the Waverly Oaks, or a look over the restless sea. It is real nature and not affected naturalism that soothes the city-wearied spirit and has a genuine sanitary effect upon a mind harassed with business cares. Among these wild hills and shady defiles and extended views the active business man is furnished with the most certain relief from that nervous exhaustion which comes from the excitement and stress of city life, and the

poor can find that refreshment which the rich secure by expensive travel and luxurious establishments in the country. Public pleasure-grounds are possessions of rare value when treated with the full knowledge that they are to meet the elementary wants of the human soul by men who have a reverent love for nature, and whose primary aim is to develop the latent possibilities of the scenery on its poetic side and make these kindly influences accessible to all. They are more to be prized, shall we say, than great cathedrals or libraries or museums of science or art.

In the report of the landscape-architects for the Park Department of the city of Cambridge, Massachusetts, the most interesting portion is that which relates to the Cambridge Field, a rectangular playground, which is to have a central building as a meeting-place and shelter from showers, a band-stand, a check-room for deposits of clothing, skates and other articles, closets and wash-rooms, and a counter for the sale of light refreshments, etc. Inasmuch as experience has proved that whenever such a playground is treated in a makeshift way people are apt to abuse it, it is urged that the finish should be of the best, with arrangements ample and attractive, so that as soon as it is open it will become a success and will help to form good habits in the people who frequent the place. After explaining that the cost of maintaining the central building would be practically nothing, because some worthy person would take the position of caretaker without any other pay than the privilege of selling refreshments, sharpening skates, etc., the landscape-architects add:

Believing as we do in the great practical usefulness and value of the proposed building, we have, as you know, made it the central and dominating feature of our design for the whole field. In rural parks, buildings are rightly kept subordinate to the scenery; and to this end they are often given picturesque forms, such as blend easily with the foliage. In such parks buildings are best when half-concealed or even hidden. In a confined, level, formal and generally rectilinear public ground, like Cambridge Field, buildings should certainly, so it seems to us, both stand forth openly and possess a dignified architectural character. A rural cottage would be as incongruous in a formal square as a classic mansion would be in a rough New England pasture. If, therefore, the Commission cannot afford at this time to set up an appropriately substantial architectural structure, we would suggest that building be for the present postponed. The site allotted to the building on the plan may be kept open, and the two necessary but temporary small closet buildings may be conveniently placed in the spaces which are marked on the plan as intended for the children's and girls' playgrounds. We are quite sure that this course will prove wiser than would be the immediate construction of any building which would not correspond in style and appearance, as well as in use and convenience, with the general plan for the Field.

We are glad to know that a building of dignified character has been designed and that work will begin on it at once, and we agree with the landscape-architects that such a house will so enhance the value of the Field to all who may frequent it, and particularly for women and children and babies, that it will more than repay its first cost.

Some Native Ornamental Grasses.—II.

MOUNTAIN RICE, *Oryzopsis membranacea*, is a remarkably pretty grass, with large open panicles of white, silky, hairy spikelets. In the Rocky Mountain region, where it abounds, it is esteemed as one of the Bunch Grasses. One of the plants that have received the name of Hair-Grass is *Muhlenbergia capillaris*. It is impossible to exaggerate the beauty of this plant with its red-purple, hair-like panicles that bend before the lightest breeze. *Muhlenbergia Texana*, a species inhabiting the dry plains of the south-west, has a similar, but much smaller, panicle.

Tussock-Grass, *Deschampsia cæspitosa*, native of the cooler parts of both hemispheres, is a rather elegant grass. Especially so is a variety found in the mountains of Colorado and Wyoming, with tufts of short fine leaves and a

panicle tinged with bronze and purple. In the Appalachian region *D. flexuosa* is not infrequent, dwelling upon rocky ledges. The slightly bending panicle is of a chestnut-brown color, and has a certain delicate grace that makes it a very attractive plant.

The group of grasses known to botanists as the tribe Chlorideæ comprises more showy and ornamental species than almost any other. Some of the species of *Chloris*, the genus from which the tribe takes its name, are cultivated for their beauty. They are easily recognized by their flower-clusters, consisting of slender spikes digitately arranged like those of the common Crab-Grass. In Florida two species, *C. glauca* and *C. Swartziana*, are notable for their elegance. They are smooth, glaucous plants with brownish spikes. *C. elegans* in the arid region of the south-west is a showy grass with densely bearded white or pinkish spikes. The Grama or Mesquit grasses of the prairies and the still drier region to the south are all of them pretty. Among them, *Bouteloua breviflora*, a rare western Texan species with rigid stems and leaves and short spreading spikes, is particularly ornamental. Not less so is *B. prostrata*, which grows in tufts spreading out on the ground, and bears short, curiously curled spikes. Some of these small Gramas would be good plants for edgings.

The Toothache-Grass, *Ctenium*, of moist Pine-barrens in the south Atlantic and Gulf states, owes its popular name to a reputed virtue of its pungent root-stock. It is an odd grass and a handsome one. Its brown spikes are wide-spreading when young, but as they mature they curve inward, after the manner of a wounded centipede. This is one of our few fragrant grasses, the older plants having an odor like that of the Balm of old gardens.

Among the Melic-Grasses, *Melica*, there are some pretty species. The unarmed Nodding Melic, *M. nutans*, whose slender clusters of nodding whitish and purplish spikelets are to be seen in May on river bluffs in the eastern states, is worthy of mention. *M. spectabilis*, found in the Rocky Mountain region, has large showy, red-tinged spikelets and culms with a bulb-like base. One of the few of our native grasses sometimes seen in cultivation is *Uniola latifolia*, a truly beautiful plant with broad leaves of a singularly rich green and drooping panicles of flattened spikelets. It is a native of river-banks in the eastern states, especially southward. It has a preference for rich soil. Sea Oats, *Uniola paniculata*, is of quite a different aspect. Its stems and leaves are rigid and glaucous. The whitish panicles are very conspicuous, and are sometimes gathered and dried for winter bouquets. Sea Oats is found from Virginia to Texas on ocean beaches, where its strong root-stocks do good service in holding the drifting sands. The common Reed, *Phragmites communis*, is one of our largest and showiest grasses, much resembling the closely related *Arundo Donax*. It abounds in the coast marshes, where it grows with Cord-Grass, and about inland lakes and ponds. It deserves a place in every park or pleasure-ground where marsh or water plants can be grown. Another grass suitable for cultivation in aquatic gardens is the Reed Meadow-Grass, *Glyceria aquatica*, a large species often growing in shallow water. It grows wild across the continent northward. Water-fowl relish the seeds, which are produced in great quantity, and fish are said to eat them.

Squirrel tail Grass, *Hordeum jubatum*, is a handsome grass with lustrous pale green or purplish spikes. On account of the long awns or beard it is sometimes a troublesome weed. It is quite an ornamental grass, but has a great drawback in the tendency of the spikes to break up as the seed ripens. This habit, perhaps, once existed in the related Barley, but has been cured by long cultivation and selection. *Arundinaria macrosperma*, the Big Cane of the southern states, is our only woody grass. It is not a handsome plant—is decidedly unsightly, in fact. But, as it forms almost impenetrable thickets, it might be useful for hedges and wind-breaks where the climate is sufficiently mild and the soil is sufficiently moist.

Besides these indigenous grasses there are a number introduced from the Old World and naturalized in various parts of the country that might be referred to in passing. Velvet-Grass or Meadow Soft-Grass, *Holcus lanatus*, is quite conspicuous in grass-lands by reason of its whitish color and the often beautifully pink or purple tinted panicle. Hare's-tail, Quaking-Grass and Hair-Grass, *Aira caryophylla*, are pretty grasses, sometimes cultivated, chiefly in Europe, for dry bouquets. They are mostly natives of the Mediterranean region, but now grow wild in various parts of North America. *Arundo Donax*, from southern Europe, is said to be established in Virginia and along the lower Rio Grande.

Only a few of our beautiful native grasses are mentioned here. There are others quite as handsome; and from the four quarters of the earth hundreds of ornamental species could be gathered. Grasses have been too long neglected in the flower garden. Planting them in the shape of lawns to be kept closely mown is not enough, for it does not allow the often graceful and delicately colored flower-clusters to be seen. Grasses are easily cultivated and require but a minimum of care. That they are more hardy than most plants, and less easily injured by transplanting, is shown by the readiness with which the natives of one country are naturalized in another when accidentally introduced. To what extent some of them may be improved for ornamental purposes by cultivation and selection remains to be seen; but, even as they are, many of them have qualities that entitle them to the recognition of the horticulturist.

Department of Agriculture, Washington, D. C. T. H. Kearney, Jr.

Spring in the Pines.

I AM writing on the 19th of April, and vegetation is further advanced than it ordinarily is at this date and yet ten days ago, after an unusually cold March and early April, all vegetation in the Pines seemed at a standstill and the season was unprecedentedly late. But ten days of August weather, following hard after frost, has aroused the latent forces of nature to an activity which has been almost startling. We can hear and see the buds swelling and bursting, especially in the early morning and evening.

Whether we look or whether we listen,
We hear life murmur, and see it glisten;
Every clod feels a stir of life,
An instinct within it that reaches and towers,
And creeping blindly above it for light,
Climbs to a soul in grass and flowers.

No one ever saw the Bloodroot pushing up and spreading its white petals in such haste to meet the sun. Trailing *Arbutus* and *Pyxie*, due to flower long ago, were held back by the cold, but under the genial influences of an hour they were both in full bloom. The red keys are hanging on the Swamp Maples, and the White Maples have already shed their flowers. March checked the Filbert and Alder tassels, which were shedding their pollen as long ago as February, so that there were some fresh catkins still left to open with the sudden warmth. The bursting buds of the Bayberry are crowding off the old but still green and fragrant leaves from the stem, and the spicy aroma about the *Sassafras* tells us that its flowers are opening. The *Amelanchiers* have been somewhat tardy, but they are now covered with bloom like the other early-flowering trees. Some of the dwarf Willows in the Pines are exceedingly handsome now, with their flowers ranked thickly along the stem; the deep scarlet stamens, just before they shed their pollen and later as they expand into yellowish fluffy flowers, make them most desirable shrubs for a spring garden.

After all, the bursting of the leaf-buds and the sudden expansion of the leaves seem more wonderful, if possible, than the opening of the flowers. To-day a tree is enveloped in a soft haze of light yellow or a greenish mist and to-morrow it waves boughs of foliage dense enough for shade, and in the deciduous woods here the range of varied

color is beyond all description. In the garden, Cherries and Plum trees are fragrant with their white flowers, while Peach and Almonds with their rosy blossoms add to the picture. Even the Apple-trees are showing the pink tips of their flower-buds, an unusual spectacle in mid-April. The Japan Quince and *Exochordas*, the early *Spiraeas* and *For-sythias* are at their very best, and so is the *Akebia* with its chocolate blossoms.

The effect of this midsummer weather upon the birds is amusing. It is very plain that they imagine they are behindhand in their work. Three robins have constructed nests near my house, two of them building after the normal fashion, with mud foundations, but the third evidently feels called upon to do something out of the ordinary, and is trying to found her house on a few dry twigs and a quantity of chicken feathers. The nest is in a Hemlock near the ground, so that we have no difficulty in watching its progress. The bird hurries to the chicken-yard and selects long feathers, so that she can weave them in with the twigs. But it is a novel kind of architecture for her, and she is making an untidy mess of it. Her mate does not assist in the building, but perches himself on the naked branch of a Mulberry-tree near by, and when she arrives with her load of feathers he looks at her in such a comical way that one can almost hear his comments on her work. Plainly she has caught the spirit of the age, and, like the new woman, she will not be bound to the traditions of her race. A pair of golden-winged woodpeckers are making an excavation in a Maple within a few feet of the house. These large and beautiful birds are joint partners in this work as well as in other household affairs. One of the pair will work vigorously for a time, and then, promptly responding to a call, the other will come to take its place at the hole, while the first retires to a distance and keeps guard. Let me approach ever so cautiously that side of the house where the tree stands and the watching bird will sound the alarm, the tapping ceases instantly and the head of the worker is thrust out to investigate. If I approach nearer it flies away, but if I slowly move off it soon begins work. Thrushes, wrens, song sparrows and vesper sparrows are filling the air with glad music; insects are buzzing among the flowers and butterflies are flitting here and there; in fact, the whole scene is filled with action where but ten days ago every sign of life was locked up in frost.

Mary Treat.

Foreign Correspondence.

London Letter.

PARROTIA JACQUEMONTIANA.—This is now flowering for the first time in the arboretum at Kew. It differs from *Parrotia Persica* in having smaller flowers arranged in a conical head and surrounded by ovate petaloid whitish bracts nearly an inch long. The flowers are developed before the young leaves. When mature, the leaves are orbicular or obovate, distinctly toothed all around the edges, dull green, and they do not assume the bright colors in autumn so characteristic of the Persian species. The former is a native of Kashmir at an elevation of from 5,000 to 9,000 feet, where it forms a Hazel-like bush, six to twelve feet high. Dr. Aitchison found it in abundance in Afghanistan in the interior of the hills, forming much of the shrub jungle there. He says the long slender stems and pliant branches are used in wicker-work and for the handles of farm implements. As a garden plant it is not as valuable as *P. Persica*, which at Kew forms a beautiful shrub or small tree, bearing large glossy green leaves all summer, which in autumn change to the richest hues of orange, red, brown and yellow.

WIDDINGTONIA WHYTEL.—The Milanji Cypress, as this plant is popularly known, has been largely distributed from Kew by means of seeds and young plants. It bids fair to become a useful garden plant, and also, in countries favorable to its growth out-of-doors, a valuable timber tree. It was discovered in quantity a few years ago on the mountains of British Central Africa, where it forms large forests,

and the wood is so valued there that Sir H. H. Johnston, Her Majesty's Commissioner in that territory, has taken steps to protect the remnants of the forests and to plant more on an extensive scale. According to a report recently made there are about 150,000 large trees covering some thousand acres, with an average of forty cubic feet of timber in each tree, which is valued at three shillings per foot. The destruction from forest fires, etc., has recently been so great that "it is no exaggeration to say that five or six years' more delay in the assumption of control over the remaining forests would have meant the entire extinction of this unique conifer." It grows to a height of about 150 feet, the trunk being six feet in diameter at the base.

PRUNUS PSEUDO-CERASUS.—English horticulture has only recently become acquainted with the value of this beautiful spring-flowering tree, but now it is certain to be soon abundantly represented. I first saw it in the nursery of Mr. A. Waterer, at Knap Hill, where it was called *Prunus Watereri*. Messrs. Veitch & Sons exhibited it last week before the Royal Horticultural Society, and in the last issue of *The Gardeners' Chronicle* there is an excellent illustration of it. Young trees of it at Kew are at the present time literally laden with beautiful, large, rose-tinted or white flowers in crowded clusters; a yellow-flowered variety is also in bloom at Kew. The Japanese nurserymen recommend it as a street-tree, and offer about a dozen named varieties characterized by white, various shades of pink, greenish white, single and double flowers. The wood is also said to be invaluable for engraving. As a spring-flowering tree *P. pseudo-cerasus* deserves to rank with the Almond, double Red Peach, *P. triloba* and *P. Mume*. The last-named is also offered in considerable variety by Japanese nurserymen, who call it the queen of Japanese trees.

PRUNUS SPINOSA FLORIPLENO.—One of the most attractive shrubs in flower in the arboretum at Kew is a bush of a double variety of the Black Thorn, its branches being thickly clothed with clusters of pure white flowers, composed of many petals spreading outward and showing a bright green eye. The black bark of the branches heightens the effect of the pure white, and when the sunlight is upon it the bush appears to glisten like snow. This is a plant of exceptional merit, and is as hardy as the Black Thorn.

PRUNUS TRILOBA.—I omitted in my last letter to emphasize the fact that this plant should not be grafted on to another species, as is too commonly the practice among nurserymen. Grafted plants of it invariably die young. It may be increased by layering or from suckers, and when on its own roots it goes on happily for many years.

PRUNUS GRAYANA.—This is now in flower at Kew. It does not appear to differ from *Prunus Padus*, the Bird Cherry. The Kew plant was obtained from Dr. Dieck.

BERBERIS NEPALENSIS.—This noble species is hardy only in the warmer parts of England. In Cornwall it is represented by large specimens, and I have seen it about fifteen feet high in a garden near Dorset. At Kew it does not grow well, and is injured by frost in winter. The foliage of healthy plants is very ornamental, being pinnate, a foot or more long, with leaflets four or five inches long of a glossy green color. The flowers are in terminal erect heads nearly a foot long, very crowded, and colored bright yellow. According to Sir Joseph Hooker, it occurs in the temperate Himalaya at an altitude of from four to eight thousand feet, and also in the Nilghiri mountains. A form of it known in gardens as *Berberis Bealei*, a native of Japan, has even larger leaves than the type. It is grown in the temperate house at Kew, and I have seen very fine specimens grown as pot-plants for the conservatory. I saw a magnificent specimen of it in the garden of Colonel Tremayne in Cornwall, where it is grown as *B. Japonica*, var. *Bealei*.

BERBERIS BUXIFOLIA.—This Chilean species, known in gardens as *Berberis rotundifolia* and *B. fascicularis*, a variety of the common *B. Aquifolium*, are two of the most attractive shrubs in flower here now. Bushes of the former, six feet high and eight feet through, are covered with pend-

ent balls of bright golden yellow, and suggest *B. Darwini*. The other plant is remarkable for the numerous clusters and bright yellow color of its flowers, far brighter than any other form of *B. Aquifolium*.

SAXIFRAGA STRACHEYI.—Flowering examples of this species were shown a fortnight ago by Mr. G. Paul, and obtained a first-class certificate. Although introduced from the Himalaya by Sir Joseph Hooker in 1851 and cultivated out-of-doors at Kew for many years, it has not become popular, probably because it is not so hardy as its ally, *Saxifraga ligulata*, although it is handsomer than that species. At Kew it is grown on the rockery, where its thick contorted prostrate stems embrace and nestle against the gray stones in a partially shaded position. Here it has grown freely and flowered profusely every year. The leaves are deciduous and the flowers are developed in March or April before the new leaves appear. In colder localities it ought to be protected in winter or lifted and placed in a frame till danger is over. The flowers, which are borne in large cymose clusters, are an inch across, white, tinted with rose. There is a yellow-flowered variety. *S. Stracheyi* is a native of Kashmir at an elevation of 8,000 to 14,000 feet.

PINGUICULA CAUDATA.—A few pans of this pretty Butterwort help to liven up the greenhouse in the early months of the year. At Kew it is grown along with the Mexican Orchids and thrives satisfactorily. The plants go to rest in winter when they are kept moderately dry. They are again started into growth in February by repotting them into new soil and placing them on a shelf in a temperature of about sixty degrees. At present they are in full flower and are as effective as large-flowered *Masdevallias*. A stock of plants can easily be raised by breaking off the outer leaves from the plants when at rest and planting them in sand in a propagating-house. It is now fifteen years since this species was introduced from Mexico by Messrs. F. Sander and first flowered at Kew. If a number of plants are grown and started in batches a succession of flowers may be had from spring until late in the autumn. Seeds are ripened freely, and from them some variation in flower-color has resulted. Good varieties have flowers two inches across and of a brilliant crimson color.

NARCISSI.—Flowers of these plants among grass are a delightful feature if tastefully planted. I have lately seen attempts at this kind of wild or natural gardening in some of the London parks which are an utter failure, owing to the formal massing of the bulbs. Anything in the nature of a strict outline must be avoided. At Kew the bulbs are planted so as to look as natural as possible, here and there a thick colony with a few stragglers and smaller clusters, finally thinning down to nothing. They are most effective when planted on lawns where trees are numerous and especially where conifers and deciduous trees are mixed. In such situations a glade-like effect is obtained. In one part of the garden the *Incomparabilis* and *Poeticus* varieties have been planted so extensively among the grass that they present the appearance of a meadow overrun with Daffodils. The bulbs of these plants are now so abundant and cheap as to place such a display as is here described within the means of all gardeners. But the bulbs must be planted with taste.

London.

New or Little-known Plants.

Rose, Mrs. Pierpont Morgan.

THIS comparatively new Rose (see opposite page), which is much admired, and promises to be an important commercial variety, is a sport from the well-known Tea Rose, Madame Cusin. It is a strong plant of good habit, and it grows vigorously under glass, making sturdy stems with luxuriant foliage and producing a flower on every shoot. Good judges pronounce it the most prolific of all Roses for greenhouse cultivation. The flowers are larger than those of Madame Cusin, and when fully developed are as large as those of the Hybrid Perpetual class, being at

Fig. 28.—Rose, Mrs. Pierpont Morgan.—See page 174.

their best four and a half or more inches across and very full. The color is an even shade of cerise-red, with a delicate tint of lemon at the base of the petals, which makes an exceedingly brilliant combination under artificial light, while it is pleasing at all times. The petals are broad and heavy, and they last a long time on the plants, and when cut. To give an idea of their keeping qualities, Mr. John N. May, of Summit, New Jersey, with whom this plant originated, cites the fact that a dozen of these roses were cut with long stems on the 26th of December, 1894, and sent to England. They were kept until the 15th of January, when they were exhibited at the Royal Horticultural Society of England, and, although they had then been cut twenty days, the judges found them in sufficiently good order to deserve an award of merit. Cut roses of this variety have been repeatedly shipped by express from New Jersey to Omaha, Denver and other remote western cities, where they arrived in perfect condition.

Cultural Department.

Orchid Notes.

CALANTHE REGNIERI is a useful terrestrial Orchid. Just as *C. vestita* and its varieties and *C. Veitchii* are going out of bloom, the flowers on this plant begin to open and continue until near the end of April. It is a deciduous plant, losing its leaves just before the flowers open, and it is, therefore, destitute of leaves while the plants are blossoming. If the plants are arranged among the handsome-leaved *Cypripediums* the deficiency of foliage is not observed, and the racemes show to good advantage. The pseudo-bulbs are four inches long or more, flask-shaped and jointed, and the flowers are in racemes on long stems, which attain a height of two and a half to three feet. The flower-stem grows straight for about eighteen inches high and the remainder bends over gracefully. The flowers are of pleasing colors, the sepals and petals white, and the lip rosy-pink. This *Calanthe*, like all the deciduous ones, needs a thorough rest. After the plants are done blossoming they should be put in a dry warm place and water entirely withheld. As soon as they begin to grow, the plants should be turned out of the pots, all the exhausted soil removed and the old roots shortened back within about an inch of the pseudo-bulb. They should then be planted singly into four or five inch pots, according to the size and strength of the pseudo-bulb. Fibrous loam, with a small quantity of lumpy dried cow-manure, makes a good compost. After the plants are potted but little water is needed until the roots have taken hold of the fresh soil. When the pots are well filled with roots a weak solution made from fresh cow-manure should be given once or twice, as the plants may need it. Little water is needed when the pseudo-bulbs have attained their full size, and when the plants are in bloom they need just enough water to keep the flowers from drooping.

One of the handsomest *Cypripediums* in bloom now is *C. hirsutissimum*. The flowers are very pleasing, the different shades blending admirably; they measure five or six inches in diameter and are produced singly from the young growth on large scapes which measure nine to twelve inches. The dorsal sepal is large, of a reddish purple color, with a margin of clear green. The lower sepal is rather small and also of a reddish purple color. The petals are large, spatulate, twisted, hairy along the margins and narrowed down to the base. The lip is deep green, tinged with lighter green. The flowers of this plant, like many others belonging to the genus, if properly looked after, will last for many weeks. The leaves are dark green, strap-shaped and nearly a foot long. *C. hirsutissimum* likes heat and moisture and grows well here in the stove.

Another good *Cypripedium*, and one that flowers freely and is also easy to grow, is *C. Boxallii*. It is a stemless plant and has thick, dark green strap-shaped leaves, which measure nearly a foot in length. The large showy flowers on our plants are produced singly on erect scapes. The dorsal sepal is of a greenish color and the edges are white, with numerous purple spots. The petals and the lip are of a greenish yellow, tinged with purple. The flowers are distinct and have a shining appearance. It is of easy cultivation, and although often recommended for an intermediate house, it does well here in a stove temperature and produces large flowers freely. The flowers have exceptional lasting qualities, and some have been on the plants for more than two months.

A large plant of *Arpophyllum giganteum* has blossomed satisfactorily here. It is grown in a large square basket which is suspended near the roof-glass, and has produced fine, large spikes of rosy-purple flowers. It is a strong-growing plant, with drooping, strap-shaped leaves twelve to fifteen inches long; when first developed they are of a bronzy color, but later they take on a deep green. The inflorescence is a dense spike made up of numerous small rosy-purple flowers produced on stout stems. This *Arpophyllum* grows vigorously planted in a deep basket in fern-root mixed with sphagnum-moss. While growing it needs plenty of water and abundance of light. The temperature of the house where it grows ranges from fifty to fifty-five degrees, Fahrenheit. It is a native of Mexico and Guatemala, and was introduced from there to England in 1839.

Botanic Garden, Harvard University.

Robert Cameron.

The Cultivation of Nepenthes.

NEPENTHES need close attention at this time of year when they are just beginning the period of most active growth. It depends altogether on their treatment for the next month or two whether the pitchers will be abundant. These last for the better part of a year on the plants, and on some kinds even longer. Without these curious adornments the plants, like some Orchids without their flowers, are anything but attractive to the ordinary observer.

Old plants of *Nepenthes*, as a rule, do not give as abundant crops of pitchers as plants one and two years old, but they are usually larger than those on young plants.

All the sorts are interesting, but they are not all easy to grow. The cultivation of some species is but little understood, and, indeed, the conditions under which some grow naturally cannot be imitated in a greenhouse. For instance, Burbidge, in his *Gardens of the Sun*, says in Borneo some species thrive luxuriantly on the summit of a hill on which, during daytime, the heat to a European is almost unbearable, while in the early morning the temperature is so low that a heavy winter overcoat is needed by the traveler. Those forms and hybrids which have originated in gardens are much to be preferred to the species on account of the ease with which they can be grown. The hybrid called *Mastersiana* is one of the very best, as with ordinary care a good-sized and very prettily colored pitcher at the end of each leaf may be counted upon. It is also one of the easiest to root from cuttings. The pitchers average six inches in length and two and one-half inches in diameter, and the color is dark red. *Nepenthes Dominiana* is an old garden hybrid, very free-growing, and has the further merit of succeeding in a lower temperature than most of the others. The color is yellowish-green spotted with brown.

Quite a number of American hybrids have been raised in recent years, and these include some specially beautiful sorts. One, named *Nepenthes Morgania*, is almost rose color, and forms a very symmetrical plant if kept dwarf. *N. Amesiana*, *N. Siebrechtii* and *N. Dormanniana* are closely related to each other, evidently springing from the same parentage. The pitchers are very large and more nearly round in outline than the first three named. *N. Claytonii* has long, narrow, dark-colored pitchers.

A very essential point in the cultivation of *Nepenthes* is the frequent use of the knife. It is a mistake to allow young plants to grow tall. If they do not show signs of forming pitchers they should be cut back to within three or four leaves of the root, and even when they do form pitchers after a sufficient number of leaves show, the growing point should be nipped out. This will cause the pitchers which are developing to become much larger than if the shoot is allowed to grow.

The material in which to grow these plants should consist of rough fibrous peat and chopped sphagnum-moss in equal parts, and a third part made up of rough sand, charcoal and broken pots, all thoroughly mixed together. The plants thrive best in wooden baskets suspended from the roof of the greenhouse. They should be protected from strong sunshine and from currents of air. They delight in a hot moist atmosphere and need an abundance of water when in active growth, most of it to be supplied by frequent syringings. When the material in which they grow becomes decomposed it should be carefully washed from the roots and renewed, an operation to be performed only when the plants are not in active growth.

Propagation is effected most readily from cuttings of the ripe growths. If the ends of the cuttings be pushed through the holes of inverted three-inch pots and plunged in sphagnum-moss in a close frame they will send out strong roots in a few weeks. The plants should then be potted off singly in small pots, care being taken to bruise the roots as little as possible.

Botanic Garden, Washington, D. C.

Flower Garden Work.

SPRING has opened very late this season, and now, on the tenth of April, frost is still in the ground in many places. Outdoor work has been considerably retarded, but if steady warm weather sets in soon this will make a more prosperous year than early warmth followed by hard frosts.

It was feared that the losses from severe cold would be great owing to the low temperature early in the winter before much snow had fallen. This fear has proved well founded with the hardy Roses, at least, and many gaps will need filling up. This work should not be delayed longer than need be after the soil can be stirred, and dormant stock is the best to procure. We used to think that Roses on their own roots were best, but subsequent experience of the New England climate has disproved this, and there is no doubt that where a gardener is sufficiently intelligent to distinguish between the brier-shoots that will sometimes sprout from the stock, that the grafted or budded Rose is the most vigorous and the hardiest, and will produce better returns in the garden than Roses that are on their own roots. Another mistake often made is the planting of too many kinds in the hope of getting up a large collection of hardy varieties. Our experience has been that of the known kinds of reputed hardy Roses not more than one in ten is to be relied on year after year in this climate, and it is safer to use fewer kinds and plant more of them. Pruning is again reduced to a very simple operation this season. It consists in cutting out the dead portions and leaving the live ones, and this in most cases is too hard pruning to get the best returns.

The Narcissus border looks well and promises a good show of bloom soon. We feared that lack of protection had hurt these bulbs, but there is every prospect of as good a show as in former seasons of the kinds regarded as suitable for this climate. It is well to go over the beds and stir the soil up a little as soon as it is dried up sufficiently to close up the surface left open by frost. This will help to retain the moisture that is in the soil for future dry periods. If it is intended to use the blossoms for indoor decoration it is wise to put a slight mulch over the beds to prevent April showers from splashing the flowers with soil. This often happens, and a slight mulch saves the blooms from disfigurement.

Mixed herbaceous borders should be looked over now to see that none of the smaller growing plants have suffered from frost. It happens frequently that these are raised out of the ground by the action of frosts, and they will need to be replaced carefully and made firm. *Mertensia Virginica* has seeded freely here in the borders, and the young plants are often lifted out of the soil in this way. It is one of the prettiest of spring flowers of which too many cannot be had, but they need this attention at this season. *Primula Sieboldii* that are planted outside are covered in the fall as are the *Polyanthus*, and they then winter over well, but all coverings must now be removed to anticipate growth which will soon follow.

Beds of *Lily-of-the-valley* not covered with manure in the fall will be helped now by a covering of some good material, not too lumpy, so that the young shoots can come through freely. This will enable them to build up a strong growth for the next year's flowering. We always cover these plants in the fall, and the covering acts as a mulch as well as a fertilizer. It is not removed in spring, but left to enrich the plants permanently. It is surprising how the plants show their appreciation of this little attention. This is a good time to make a bed of the *Lily-of-the-valley*. The best Berlin pips or crowns should be procured and planted about eight inches apart each way in good soil in a position shady during the heat of the day, and they will be sure to give entire satisfaction in after years.

Any other planting in the mixed borders should be deferred until the plants already in place have made a little start, or some plants will be disturbed that should not be. After such herbaceous plants have made a little growth the root-action will go on with little check and will make a strong growth the coming year, provided the soil is well prepared beforehand. Plants that have been raised from seed with a view to transplanting in the garden must be well hardened off before setting out, as, though they may be perfectly hardy under normal conditions, they have been rendered as susceptible to cold as if they were of tropical origin and are as easily injured at this season. A few weeks in the cold frames, with plenty of air on warm days and nights, will make them sufficiently hardy to plant out in their permanent positions at the end of this month, or a little later in some localities. It is a part of each year's work at this time to look carefully through the borders to take out all self-sown seedlings that are not needed. These will come up in quantity all over the beds, and are usually weedy, poor variations from the type plants, so much so at times as to give rise to the suspicion that good forms of some garden

plants revert to the original types. But more often it is because the better and weaker plant has been made yet weaker by seeding freely, and its place is soon taken by a host of its progeny that in many cases are worthless. Phlox, Aquilegias and Larkspurs are plants of this description, and seedlings should be rigidly excluded from the borders other than those in semi-wild places. Here they may be allowed to care for themselves, and it does not take long for them to revert to the original types if left to their own devices. The strongest survives, and in most instances it is the weediest.

[This article was written before the untimely warm wave of mid-April, and should have appeared last week. Its suggestions, however, are still seasonable.—Ed.]

Chrysanthemums.

OUR stock plants of Chrysanthemums in cold frames will now furnish us with abundance of thrifty cuttings, and these will make much more satisfactory plants than stock secured from dealers. No grower ever thinks of getting a specimen bloom from a dealer's plant—that is, by growing it on. What he hopes for is to get his plants early enough to start them into new growth and take fresh cuttings. This he can do if he receives them in March. April is too late. Some of the stock sent out this season has been poor and late. There is no reason why dealers should not send out good strong stock. They know the importance of it as well as the grower does.

During the first week of May we shall put in our first lot of cuttings for specimen blooms. A month later will do if only medium-sized blooms are required. The cuttings will root easily without bottom-heat. A close propagating-frame is best, and the cuttings should be inserted with as little delay as possible. It will be necessary to shear off a few leaves and the tips of the upper ones. If allowed to lie on the wet sand they will be liable to decay, and damping may set in throughout the bed. Abundant watering will be required for the first week or so, and, in fact, we keep our cuttings drenched. The frame will be better for being kept closed and well shaded during the daytime and opened at night. Roots should begin to form in a week or so, and gradually the young plants should be more and more exposed to better light and air. They will be ready to pot off in three weeks. No check must be allowed from this time forward, for, whether intended for pots or benches, they must be kept in active growth.

There is no doubt the growing of large blooms has been overdone and that we shall see more medium-sized flowers. The plants would then be more diversified, and naturally make a more effective display. As cut flowers large blooms are imposing and very effective for the decoration of churches and other large buildings. They are less suitable than smaller flowers for artistic work in the parlor and for table decoration.

Our specimen plants will soon be ready for the final shift into ten and twelve inch pots, in which they will bloom. It is important that the drainage be free, and a little broken charcoal helps to keep the soil sweet. The soil recommended for previous transfers will do for this, although it may be heavier. We pot moderately firm, but never pound the soil. Watering must be done carefully until the plants are well started into growth, but on no account should they become waterlogged. Stopping must be done almost daily, and it is important that the plants be kept regular in outline.

Early Spring Flowers.

THE unexpected is due at any time in the garden, and in the short interval since my last note a few days of untempered sunlight have brought the *Lily-pads* to the surface of the water, burned up the early flowers and developed a succession of late spring flowers in abundance. It is, perhaps, not too late to offer a few hints as to the very early plants, which are practically all bulbous ones. The best early color-effects in the garden here are to be had from the blue flowers, as this color harmonizes better with the prevailing bare earth. For this color we depend on *Scillas*, *Irises*, *Muscari*, *Crocus Imperati* (reddish purple) and *Chionodoxas*. We have earlier flowers than these in the *Snowdrops*, but, however welcome and fascinating these may be, they are not very effective with us as garden plants, for at their flowering time the grass, which would prove an effective foil to their beauty, seldom shows a trace of green. There are also white forms of all the blue flowers mentioned, the white *Scilla Sibirica* and white *Chionodoxas* being especially beautiful, but they are, unfortunately,

not to be had in quantity and do not increase truly from seed. My friends who work constantly in growing seedlings of choice or abnormal varieties of such plants always have plaintive tales of reversion to the type, or failures to secure improved forms. The *Chionodoxas* seemed to me to be wonderfully varied this year, but while, perhaps, a dozen quite distinct forms could be picked out, it does not seem worth while to name them, except *C. Luciliæ*, *C. Sardensis* or *C. grandiflorum*. Of these, *C. Sardensis* varies the least, having only two forms, a dark purple with either a white or dark eye. *C. grandiflorum* would cover all the broader-petaled large-flowering kinds, mostly slaty blue, with red and white varieties. *C. Luciliæ* would well name all the others with purples and white, blue and white, pure white, and pink. *C. Tmolu* has a claim to name, appearing very distinct in masses, but it would soon disappear among *C. Luciliæ*. In fact, no collection of *Chionodoxas* could be kept distinct very long, for they come plentifully from seed, and this is mostly cross-fertilized by the insects of the season. These flowers are visited here mostly by a winter-flying insect, which is either the *Chrysanthemum-fly* or a similar insect. And as it is simply out to eat, and not to store nectar, it visits all flowers indiscriminately, or in rotation, and carries pollen not only to the various *Chionodoxas*, but the *Scillas* (of the same family) as well. The cross, *Chionoscillas*, is often noted by gardeners.

The *Narcissi* are now in full glory. They are all so satisfactory that it seems invidious to mention names, only more of them should be planted in grass. The best varieties to select for this purpose are the cheapest obtainable, being naturally the most vigorous. But even the *Daffodils* look pale in contrast with the rich yellow of *Iris orchoides*, one of the most satisfactory plants of the season, free-flowering, beautiful, distinct, perfectly hardy and rapidly increasing from year to year. It is, perhaps, the best of the bulbous *Irises*. The first of the always welcome *Tulips* have opened, and there is a promise of great bloom, though, as usual, there are too many immature or one-leaved plants, which will not flower.

Elizabeth, N. J.

J. N. Gerard.

Tulipa sylvestris.—This *Tulip* grows sparingly in deciduous woods in most countries in Europe. It is one of the most attractive of wild flowers, and it is as eagerly sought after by botanists as the rarest of *Orchids*. Its chaste yet bright color, graceful habit, in which it is superior to most cultivated *Tulips*, and its delightful fragrance make it one of the most desirable plants for naturalizing in wild parts of a park or garden. The flower, which is comparatively long, is more closed than those of the garden varieties, bright yellow within, slightly tinged with green on the outside. The leaves are linear, rather long and narrow. The species grows preferably in moist, open glades in level woodlands where the soil is deep and rich, without being wet, but also in more shady positions among trees and shrubs, where it flowers more sparingly than in the warm, bright sunshine. It forms little, scattered groups of great beauty, but is now becoming rare. The bulbs are much smaller than those of most other *Tulips*.

Correspondence.

Madison Square Again.

To the Editor of GARDEN AND FOREST:

Sir,—Your correspondent, S. A., in No. 425 of GARDEN AND FOREST, criticises the plan of Madison Square by Messrs. Bell & Langton because the centre of the park is formalized. I think the criticism just. He points out the symmetrical arrangement of paths as they exist, and says that the place is too small to contain formal as well as naturalistic effects. A seven-acre piece of ground is certainly too small for effects of wide green lawns if the centre is taken up with a rectilinear scheme covering more than an acre and a half. But seven acres are enough for naturalistic effects of respectable extent. Your correspondents (rightly, as I think) agree that formal features are desirable in a park of this kind. I do not believe, however, in the value of "symmetry" in lines of travel on a place of this size. This symmetry is not very obvious even on paper until emphasized by black lines, and it might be apparent to an observer hovering over it in a balloon. But how shall one who strolls into the square know that the path in which he walks is balanced by a similar on the other side? Artists in landscape too often forget that their paper plans are deceptive. Cannot effects of wide green lawns, abundance of shade and so forth be combined in seven acres with the popular formal effects? I think they can by relegating the formal de-

sign to a part of the ground where it will not interfere with the appearance of size. I enclose a design as a suggestion.

The points of merit in this plan I think are these:

Lines of travel sufficiently direct are provided in all directions. Little attention is paid to the symmetrical look of the paths on paper, but much to the definite and harmonious effect of their lines when laid out, a point of distinct æsthetic value. The formal design is put at the narrow end of the park, where it cannot interlere with the apparent extent of the ground. A circle is chosen (150 feet diameter) as the simplest

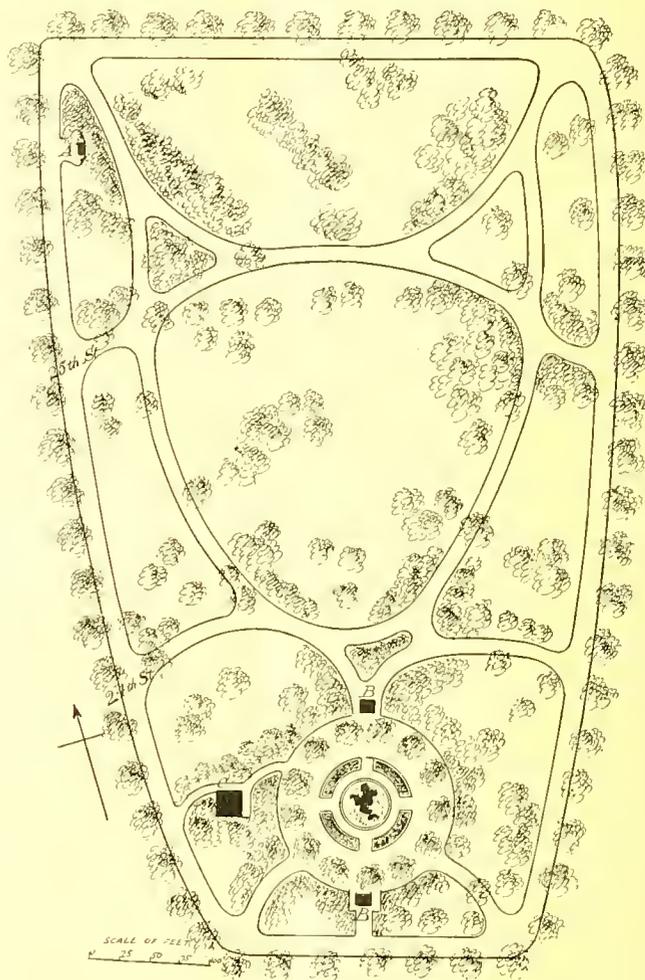

Fig. 29.—Proposed Plan of Madison Square.

and most obvious geometrical figure. It contains a row of trees along the circumference (surely an admirable place for seats in the shade), a Lily-pond and flower-beds. It is sufficiently separated from the naturalistic part of the park by trees and shrubbery.

Most of the existing trees are retained, and a good deal of shrubbery is added, to made the park interesting in detail as well as in general effect.

BB are the statues, C the kiosk, A the Farragut monument.

At the junctions of paths is plenty of room for seats.

Planting is intended to conceal the asphalt as much as possible.

Pittsburg, Pa.

H. A. Caparn.

Early Wild Flowers in Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—Spring-time comes here after the first heavy rains, which may be early or late. The rainfall during the past winter has been so limited that we have had the unusual experience at times of something like drought in the rainy season, and this has interfered greatly with the regular growth of native plants. In February, *Dodecatheon Meadia*, which the children call *Shooting Star*, was in bloom, and with it came the oddly colored rich brown flowers of *Pæonia Browni*. The scarlet-flowered *Gooseberry* was also in bloom, and a shrubby *Lupin* with long spikes of purple-blue flowers, sometimes six feet high, with a head as many feet through, was also in flower. In March the *Eschscholtzia*, or *California Poppy*, was in full

glory, covering acres near the base of the Sierra Madre Mountains, above Pasadena. In the rear of my house, in the suburbs of Los Angeles, a mountain peak rises to the height of fourteen hundred feet, and from its summit on a clear day I have seen with the naked eye the rich golden color of these Poppy fields twelve miles away. Another but much less common member of this family is *Dendromecon rigidum*, with pure golden-yellow flowers, containing not a trace of orange, but otherwise resembling those of the *Eschscholtzia*. I have lately seen specimens of it six or seven feet high and five feet in diameter and well furnished with bloom. It certainly is a plant worth introducing to our gardens, although it is transplanted with difficulty and is hard to raise from seed. It is in full flower during March and April, but continues to bear a few flowers for several months. This is the only member of the Poppy family known to me which is a true shrub, but Dr. Franceschi reports that on an island near Santa Barbara there is a less rigid species called *D. flaccidum*. The first of the *Calochorti* to appear here is *C. Catalinæ*, with large white flowers delicately shaded with purple and dark spots at the base of the petals.

Los Angeles, Calif.

E. D. Sturtevant.

Early April in Southern California.

To the Editor of GARDEN AND FOREST :

Sir,—A note of what one sees and hears during a stroll through a California garden in a morning in early April may interest eastern readers, whom we think of with some compassion as we read in telegraphic dispatches of snow-storms and freezing weather. Giant Callas lift their creamy chalices under the bay-window above the dark green of such leaves as I have never seen elsewhere, and against the side of the house tall Fuchsias are trained and thousands of their pendulous flowers are swinging in the breeze, while up the pillars and along the frieze of the portico great starry blooms of hybrid Clematis show white and shades of blue. On either side of the steps are huge bushes of Heliotrope, and a tangle of *Cobæa scandens* has climbed up an angle of the building and is covered with flowers of exquisite form and changing color.

Out in the garden are bushes of Marguerite, seven or eight feet in diameter and nearly as high, white with daisy-like flowers, but they are still more impressive when seen in the light of a full moon, when they have a fairy-like grace and an indescribable silvery glitter. The Lilacs have done blooming. The Laurestinus is almost done, but the Snowballs and Philadelphuses are in perfection. The show Pelargoniums are just opening, although the Zonal Geraniums are always in bloom. A few late Tulips linger in the bulb-beds with a few Narcissi, Ranunculi, Anemones, Ixias and Spiraxes. German Irises, with their wealth of color and Orchid-like texture, are making a noble display, and the Japanese Iris, a midsummer flower with you, will soon appear. Carnations are to be gathered every day, and the Chinese Honeysuckle which riots over a stone wall is also constantly in flower. Sweet Peas are opening on long wire trellises; Verbenas are gorgeous masses of color; Tropæolums are ablaze with spicy blossoms half-hidden in lush-green foliage, and the velvety faces of the Pansies now wear their best expression in this cool damp weather.

But the glory of the garden now is the Roses, for, although we have Roses every day, this is the time of their perfection. Tea Roses are especially handsome now, not only on account of their flowers, but on account of the young foliage in shades of olive, bronze and red, while the sprays of the Lady Banksias, sometimes twenty feet long, are covered for their entire length with tiny fragrant blossoms of white and yellow. Of course, it is impossible to describe a Rose or a Rose garden, but one who visits the southern coast of California at this season always feels that the cool beauty of the white La France, the blaze of the General Jacqueminot and the deep gold of the Maréchal Niel are never seen in such perfection elsewhere.

Traité des Plantations d'Alignement et d'Ornement dans les Villes et sur les Routes Départementales. Par A. Chargueraud, Professeur d'Arboriculture de la Ville de Paris. Paris: J. Rothschild. 1896.

The unfavorable comparisons which an American visiting Europe must make between the trees in his own cities and those which he finds in the streets of Paris and other Continental cities will be explained when he remembers how carelessly and inefficiently tree-planting in American cities is performed, when it is done at all, and then learns

by reading this manual how carefully and systematically the work is done in France. Tree-planting in Paris is done by studiously considered and intelligent rule. The amount of soil and its quality for each tree is established, the particular variety of tree is selected with reference to the width of the streets and the height of buildings, and every precaution is taken to insure success by the selection of healthy, carefully pruned individuals, which are planted in the most thorough way, by protecting them from injury and by providing them, by an elaborate system of underground pipes, with a sufficient and regular supply of moisture. As a rule, in this country, any tree, however crooked, ungainly or defective, is good enough to plant in our streets and public parks, and the operation of securing shade for our city streets usually stops after the tree has been thrust into a hole, as often dug in masons' débris as in good soil, until the time comes, a few years later, when the professional tree-butcher or the lineman of some wire company comes along and disfigures it for life. In Paris, however, good trees are considered of sufficient importance to authorize the expenditure of time and money to secure them. From the official figures of the Department of Public Works of the city of Paris it appears that the cost of planting a street-tree sometimes amounts to 215 francs and 25 centimes, or, roughly, from \$40.00 to \$50.00. This includes the cost of the tree, which is put at only \$1.00, the digging of a suitable hole and filling it with good soil, the drain-pipes, tree-protectors and an open iron grille which allows air and water from the sidewalk to reach the roots. Where the soil, however, does not require renewal and the grille and drainage-pipes are omitted, the cost of the planted tree is usually not more than \$2.50.

Professor Chargueraud recommends that city trees should be planted in a continuous strip of soil not less than twelve feet wide and three feet deep, although he acknowledges that in Paris, in order to save expense, planting spaces are sometimes reduced to a width of nine feet. Where isolated trees are planted he recommends pits at least twelve feet square and four or five feet deep.

In Paris, in spite of all the care which is bestowed upon street-trees, the average period they remain in good condition does not exceed forty to forty-five years, so that of the hundred thousand trees which form the street plantations of the city two thousand are renewed annually, although Professor Chargueraud believes that if the best possible care is given them they can be made to continue in a healthy condition for a much longer period.

Minute directions are given in this manual for all the operations connected with the selection and care of city trees. It contains an account of the insects which are specially destructive to them and a descriptive list of the trees which have proved most useful in the streets of Paris, a second part of the work being devoted to discussing the problems relative to plantations along rural highways. The book is illustrated with three hundred and thirty-three engravings, which explain the text in an admirable manner. A large part of this volume ought to be translated and published in this country, with its illustrations, for the benefit of park commissioners, park superintendents, the mayors of cities, and other city and town officers whose duty it is to provide American streets with trees. They will find in it, we feel sure, much that is new to them; it will show them, too, that a good tree cannot be obtained without an expenditure of considerable money and without intelligence and technical training. As a people we spend millions on park roads, boulevards and parkways, doing this work as well as it is done anywhere, and then scrimp on the cost and care of the trees which are their chief ornament and alone make them desirable and valuable additions to urban equipment.

Notes.

The third part of Dr. Bretschneider's learned *Botanicon Sinicum*, published by Kelly & Walsh, of Shanghai, has appeared. It is devoted to botanical investigations into the materia medica of the ancient Chinese.

During the last fiscal year about \$130,000 worth of plants, trees and shrubs were exported from this country, while the plants, trees and vines imported as nursery stock amounted in value to \$632,500.

The mild winter and early spring in California have hurried the fruit-trees into blossom so that orchards and vineyards were considerably in advance of what they usually are at this season, when for three successive nights the mercury fell below the freezing point, an almost unparalleled temperature at this season. Of course, in certain sections this will injure the grape crop, the early cherries, peaches, prunes, apricots and other fruits, but it is hardly safe to trust the dispatches which state that half of the grape crop is ruined. It is interesting to know that fires and smudges which were kindled in many places proved an effectual protection against the frost. Here is a problem for experimenters. It would seem that the resources of modern science ought to be able to warn and protect the tillers of the soil against forces which, if unchecked, bring such overwhelming disaster.

On last Monday the choicest Hoffman strawberries, large and richly colored, cost forty cents a quart, and good fruit could be had for twenty-five cents, and even less. Handsome Acme pears of immense size are still offered in the high-class fruit stores and cost twenty-five cents each. The last specimens of Winter Nelis cost seventy-five cents to \$1.50 a dozen, and Easter Beurre command \$1.50 to \$2.00. P. Barry will follow these sorts and continue until summer pears are on the market. Besides the usual sales, these pears are in especial demand for baskets sent to voyagers leaving on ocean steamships. Almeria grapes cost seventy-five cents a pound, and well-ripened but small berried Black Hamburgs, from commercial graperies in Newport, Rhode Island, bring \$4.00 a pound. The latter have been offered in limited quantities for three weeks, but the season is later than usual on account of the dull weather of February and March. Navel oranges from California cost fifty cents to \$1.00 a dozen, and Rodi oranges, the celebrated Mediterranean summer fruit, are already here. Sapodillas, from Cuba and from Mexico, are in considerable demand, one down-town dealer having promptly sold 500 of these fruits at forty cents a dozen. Souari nuts, from Venezuela, are still occasionally seen, and cost thirty cents a dozen.

Instruction as to methods of propagating and cultivating the American Persimmon, with suggestions for its improvement, forms the subject of a bulletin just issued by the Indiana Experiment Station. Although there are many excellent varieties of this fruit growing wild, it has been much neglected. One reason for this neglect is that the fruit of some trees, even when thoroughly ripe, never loses the peculiar astringent property which the green fruit always contains. Another is that when cultivation has been attempted from seedlings or suckers the plants usually died or produced inferior fruit, or were infertile, and even if by chance a good variety was secured, a long time always elapsed before the trees came into bearing. But new methods of propagation have been introduced, so that trees can be brought into bearing in from three to five years from the bud or graft, and henceforward we may expect a reasonably rapid improvement in this fruit, not only by cross-fertilization, but by selection. We have often called attention to the fact that there are Persimmons in Japan with fruit as large as that of the market varieties grown in Florida and southern California, and which thrive at home in a climate as trying as that of New England. It certainly would seem worth while for our experiment stations to hybridize our native plants with some of the hardier strains of the Asiatic species.

In his address at the Arbor Day forestry meeting in Philadelphia, Mr. B. E. Fernow called the attention of the citizens of that city to the interesting fact that for seventy years they had been in possession of a forest reservation 13,000 acres in extent, which might furnish a field for study and practice for Philadelphians who are interested in forestry problems. The tract mentioned lies in Centre County and was given to the city of Philadelphia by Dr. Elias Boudinot, President of the First Continental Congress, as a trust fund, the income of which he directed to be applied to supply fuel to poor persons in the city of Philadelphia at cost prices. The property originally contained some of the best timber in the state of Pennsylvania, but being difficult of access and far from market it received little attention from the city authorities until early in the sixties, when a portion of the timber was cut under leases, but a much greater portion was stolen, destroyed by fire or lost through conflicting titles. Mr. George E. Kirkpatrick, Superin-

tendent of the Minor City Trusts of Philadelphia, in reply to an inquiry, has kindly furnished us with some of these facts, and he adds that the work of reforestation was begun in 1888 and has been continued to as great an extent as the limited means at the disposal of the commission will permit. The Chestnut and Oak which sprang up to take the place of the Pine and Hemlock have been retarded, of course, by frequent fires, but the land has been leased to a gunning and fishing club and the rental received assists in paying the expenses of protection against fire and trespass. The property is admirably situated for a game preserve, having a frontal of thirteen miles on the Susquehanna, being mainly rough hill land, far from settlements, containing within its limits many trout streams and naturally stocked with deer, bear and pheasants.

Asparagus is now coming from South Carolina, Maryland, Delaware and New Jersey in heavy long white stalks and the more slender green shoots, the best costing forty-five to fifty-five cents a bunch. New yellow crook-neck squashes, from Florida, cost ten cents each. Okra, from Cuba, small and fresh-looking, may be had for ten cents a dozen. French artichokes, from California and from New Orleans, are plentiful at fifteen cents each, the larger ones from France costing twenty-five cents. Showy white celery, from California, costs thirteen cents a stalk, that from Florida being a little lower in price, and now mainly sold for use in salads. The best table celery is that just beginning to come from Bermuda, and costs twenty cents a stalk. Bermuda onions are in abundant supply, 30,000 crates having been landed from the last steamer, together with 300 barrels of potatoes. The latter are becoming scarce, and command as much as \$8.00 to \$10.00 a barrel wholesale, seventy-five cents a half-peck being the retail price. Havana potatoes, at sixty cents a half-peck, are in favor, and many buyers prefer them for their mealy quality to those from Bermuda. New potatoes are also coming from Florida, the price for well-graded stock being \$6.00 to \$8.00 a barrel to wholesale dealers. Large plants of Romaine lettuce, from the south, cost twenty cents each, and tender field or corn salad fifteen cents a quart. Mint, tarragon, chervil, tansy, and waldmeister, the popular green used by Germans in making their May drink, are all seen in the retail markets. The dependence for cucumbers and tomatoes at present is on the northern hot-house product, the former costing twenty cents each, and the latter forty cents a pound. Firm white heads of Dutch cabbage and new southern cabbage cost ten to fifteen cents each. Other vegetables now noted in most collections are celeriac, salsify, kohlrabi, new turnips, leeks, peas, string beans and peppers.

A bulletin from the Oregon Experiment Station states that prunes are now the favorite orchard crop in Oregon, where the trees are sure to bear; no adverse climatic conditions need to be overcome, the finished product is not perishable, and the danger from insects and fungi are not so serious as with other fruits. The trees suffer from some pests, but these are nothing to compare with the codlin moth in the case of the Apple and Pear, and until the curculio and black-knot come from the east it can be said that the Prunes in Oregon are free from disease. The Italian Prune, also called the Fellenburg or German Prune, a dark purple fruit with a heavy bluish bloom, is the favorite in Oregon, and it is superior in quality and size and productiveness to any other Prune as grown there. It is larger when dried than the French prune, and its acid flavor is more agreeable to the taste of most people. The French or, as it is known in Oregon, the Petite Prune is a general favorite in the commercial world and among fruit growers where it thrives. As grown in Oregon it is medium-sized to small, violet-purple, with a bright bloom, sweet and rich, with a large proportion of solids and sugar, so that it shrinks less in drying than other varieties. The lack of acid, however, gives it an insipid flavor and renders it almost worthless when fresh. It does well only on light dry soil and in a warm dry climate, and these conditions are only found in Oregon in the Umpqua and Rogue River valleys. The Silver prune, a light yellow fruit and firm, juicy, sugary flesh when properly dried, is as good as any prune in size and flavor, but since the public demands that a white prune shall be sulphured the quality is somewhat injured by the process, and in some markets a prejudice is created against it. The Reine Claude will never be a great commercial fruit, but as a fancy product it is unsurpassed, being in quality equal to the best raisins or figs. A few other varieties are sparingly cultivated. Steam in pipes seems to furnish the most efficient and economical heat for drying the fruit, especially in large establishments, and those who contemplate building evaporators are advised to prepare for steam-heat.

The Need of an Efficient Park Service.

NO matter how carefully a park may be designed or how completely it provides for the wants of all classes of the community, it must fail, of course, to serve its highest purpose unless the details of the plan are intelligently carried out. Skill in construction and maintenance is just as essential as sound common sense, creative faculty and refinement of taste in the design. In works of any magnitude it is impossible for the designer to do more than give general directions to the men in charge of the different branches of construction, and he must trust to their knowledge to interpret sympathetically the maps and drawings and other data furnished for their guidance. This is equally true as regards maintenance after the work of original construction has been accomplished. In a large system of parks like that of Boston or New York it is not possible for the superintendent to do more than pay a hurried visit to some of them once a week. A head foreman in charge of a park of considerable size can at the best spend but a small part of any day with each of the gangs of laborers under him. It is, therefore, plain that unless every foreman, besides the ability to manage men, has a thorough knowledge of every detail of the work going on under his control, there is no assurance that the park is growing along the lines marked out by its creator. Indeed, it is certain that his plan will be marred and his purpose defeated.

Of course, there must be an organized body of skilled gardeners in every park—men who know how to plant and prune, who have a knowledge of the essential laws of plant growth, who are familiar with the ways and habits of different species of trees and shrubs and herbs, so that the place that each one is to fill is understood. In some European countries it is not difficult to secure trained gardeners, but every one who has an estate to manage here knows how difficult it is to find them. It may be doubted whether any park in a city of considerable extent in the United States is adequately equipped in this line. But, besides gardening proper, there is much park work, such as repairing walks and roads, working among trees and shrubs, grading and sodding and matters of that sort, which requires a familiarity and skill in their details, and

this skill only comes from long practice under careful supervision. Efficient park officers, from the superintendent down, and an organized corps of workmen who can be trusted always to do the right thing at just the right time are plainly essential to the proper maintenance of any park which has a design to grow up to and well-considered plans for making its charms most easily available to visitors.

Let us suppose that this truth had been realized by the commissioners who controlled and managed the New York parks thirty years ago, and had been held steadily in view by their successors. They would not only have always had a competent landscape architect and a general superintendent of executive force, adequate training and experience in his profession and a sympathetic appreciation of the artistic side of the work, but by a system of selection and promotion among the subordinates they would have had at disposal a thinking machine prepared to set itself to work at any moment and ready to meet any emergency. The history of the parks here, however, and it is paralleled, no doubt, by like experience in other cities, shows that they have been under the control of an ever-changing board of commissioners, most of whom have had little intelligent interest in parks or park management. Instead of clothing the superior officers with power and then holding them responsible for their subordinates, it has been the practice of the commissioners to look with jealousy on every exercise of independent authority by these officers as a mutiny against the supreme power of the board. Until very recent times the great bulk of the force has been selected by the political chieftains in the different wards, and too often the men, as soon as they had become sufficiently experienced to be useful, have been replaced by others who had no training whatever. All these facts are so well known that they sound like a tale of little meaning, but when we think of the square miles of park property owned by this city from Pelham Bay to the Battery and realize how its possible value can be depreciated by falling into unskilled hands, the subject of securing efficient park service is certainly worth the attention of the public-spirited people of the city.

A few days ago a visitor to one of the most beautiful and picturesque of our new and undeveloped parks noticed a gang of men turned loose by the wayside and pruning shrubbery with brush hooks. Not far from this was a blazing bonfire under a group of young Hemlocks. One slight puff of wind might have carried the flames into the dry foliage, and even if the wind did not come the heat from the fire would in a few moments have destroyed a dozen trees. Fortunately, there was authority at hand to arrest the progress of the flames at once, and on inquiry it was learned that this portion of the park was in charge of a new and highly recommended foreman who, on his own responsibility, was "clearing up things" in this wild fashion. It is stated, too, on authority that in all the force there is not a sufficient number of skilled foremen to place in independent charge of the different parks to carry on the ordinary spring work which must be done every year. One result of this lack of persistent and intelligent care is that there are parts of Central Park where the plantations already seem past their prime.

May we not hope that when the long-prayed-for millennium of municipal reform arrives every member of the force of our city parks, from the executive head down, will know just what ought to be done and how to do it, and that park commissioners will allow their employees to vote as they please, but will hold each man to rigid account for the special work he is selected to do.

AFTER the almost unparalleled destruction of property and of life by forest fires in Minnesota less than two years ago it is hardly to be wondered at that the new law against these fires in that state is the most effective of all that have been enacted in the various states of the Union. But the advocates of sound forest policy in Minnesota have

not rested here, they are making a determined move toward acquiring, in the name of the state, a large area on which it is proposed to restore and preserve the forest. We have received a circular containing a synopsis of the plan proposed by Mr. Judson N. Cross, of Minneapolis, at the meeting of the Forestry Association of Minnesota, held in January of this year, and since the plan is novel and has far-reaching possibilities, all persons to whom the circular is sent are requested to express their opinions as to the details and to send any recommendations for changes, together with reasons for the same, to the Secretary of the Association, Mr. J. O. Barrett, Brown's Valley, Minnesota.

The plan is essentially this: (1) The Legislature is to constitute state, county and town boards of forestry. For the sake of economy the town board of supervisors will act as a town forestry board, the county commissioners will constitute the county forestry boards, and the state forestry board of nine members is made up of the State Land Commissioner, the Professor of Botany in the Agricultural Department of the State University, the chief officer of the Climate and Crop Service of the United States Weather Bureau in Minnesota, and one member appointed by each of the following associations, namely, the State Forestry Association, Farmers' Institute, the Board of Regents of the University, the State Lumbermen's Association, the Board of Public Health and the Fish and Game Commissioners. These are to serve without pay, except for actual expenses, and an executive committee of three is to be selected by the entire board. (2) Owners of Pine lands which have been lumbered over and other lands, especially if they are rocky, rough or sandy, and will probably not be utilized for agricultural purposes for some years, may deed that land to the state when this course is recommended by the town and county forestry boards. This land is deeded for forestry purposes only, all rights in minerals, coal, oil, etc., being reserved. Land so deeded shall be exempt from taxes, because it is dedicated to public use. (3) This land shall be called the Reserved Forest Area, and it shall be under the charge of the State Forestry Board, who is to care for it as the Legislature may direct. (4) Of the future income to be derived from such lands, one-third shall go to the state to reimburse it and the towns and counties for care and protection and loss of taxes, one-third to the person deeding the land and his heirs for a period of, say, one hundred years, after which it is to go to some institution, the other one-third to go to some designated institution or the State University. (5) The state shall have full power to lease low meadow tracts where such are needed as protection against fire, or for pasture where this will not interfere with the growth of the forest-trees. It shall have power also to sell dead and down timber, which it is supposed when the adjoining lands are settled up will bring in a large income, and generally the state is to have full power of control, even the power of alienation of certain tracts when recommended by the State Board of Forestry in such cases, for example, as where the growth of towns, the building of railroads, water-power, etc., may necessitate such alienation.

Of course, this is the merest outline of the scheme, and we have omitted many of the details given in the circular. We call attention to it, however, as a step forward, that the great prairie states, as well as New York and those in the middle Appalachian region, are taking serious thought of securing and maintaining large areas in permanent forest. Experience in Europe and in India has demonstrated that such areas owned by the commonwealth will prove a source of revenue if properly managed. Besides, they will furnish examples which private forest-owners will be eager to follow. More than all, a community which is sufficiently far-sighted to take such action will see to it that the heights and slopes which are the sources of water-supply to the valleys below are kept covered forever as the only security against those disasters which the reckless destruction of forests on highland or lowland has invariably brought.

Clematis paniculata in a Wild Garden.

SOME time ago it was suggested in these columns that *Clematis paniculata* would be an admirable plant for use where it could clamber over wayside shrubbery, after the fashion of our native *Clematis Virginiana*, which never shows to such good advantage as it does when festooning a fence stake, or brightening with its flowers the dark foliage of the Viburnums or Dogwoods which support it. No doubt, this thought was suggested by having seen the vine making itself at home in the thickets on the borders of a pond in Westbrook, the estate of W. Bayard Cutting, Esq., on the shores of the Great South Bay, Long Island. But it was the Rhododendron season then, and one could only imagine what it would look like in September. On page 185 of this issue, however, is a picture of a portion of the border of one of the Westbrook ponds, taken when the *Clematis* was in bloom, and it shows the great abundance of its flowers and the graceful way in which it adapts itself to the spirit of the scene. A mass of Rhododendrons would become tiresome if they bloomed all summer, and the snowy glitter of these *Clematis* flowers would be oppressive if they opened in spring and continued until autumn. But, after all the shrubs have done flowering, this sudden burst of bloom in early autumn is singularly effective, and the cluster of gray feathers attached to the ripened seed later on are in perfect accord with the autumn colors of the foliage which accompany them.

These shores at Westbrook furnish many suggestions for a wild garden, by which we do not mean a garden left to run wild, but one planted and tended so as to give that appearance of untamed luxuriance, of careless and unstudied grace which suggests perfect freedom. Myricas and Dwarf Willows, Clethras and Ilexes, Beach Plums and Dogwoods and other shrubs native here unite to form that diversity and intricacy of growth, that mystery of shadow, that air of negligence or waywardness which belongs to the wildwood and gives no hint of "dressed grounds." The coarser and more aggressive species are watched and restrained, however, from oppressing and crowding out the more fragile and delicate kinds, and the picture shows that tall reeds and grasses have been introduced, and these against a background of soft masses of Pine leaves help to complete a very perfect picture. A little way back from the pond there is a secluded walk now approaching close to the shore and again receding from it and broadening out into a space for a rustic seat, where glimpses of the water can be caught through the dense leaves. Of course, the native shrubs that have been named, with many more, naturally form the great mass of the vegetation on the shore, for the world can furnish nothing more suitable and beautiful. But this Japanese *Clematis* is only one of the exotics which help to give variety to the picture. It is proved here that many of the wild single Roses of other lands, like *Rosa Wichuraiana* and *R. multiflora*, are adapted to this unconventional life as thoroughly as the Roses of our own swamps, and yellow Irises from Europe seem quite as happy amid these wild surroundings as our native Blue Flag. All this is art, but it is the art which conceals art. To create such a scene requires patience, a knowledge of plants and the prophetic eye of taste; but, after all, studies of this sort furnish one of the most satisfying diversions for the owners of country estates. There are many other places than the borders of ponds which are adapted to wild gardens of a type similar to the one figured here, but water, still or flowing, gives a distinct advantage in many ways, especially in the light and openness it secures and in the reflected pictures, broken or perfect, which it adds to the scene.

The Tannins of the Palmettos.

IN the many accounts of the uses to which the southern Palmettos are applied the reader is frequently left in ignorance as to whether the Scrub Palm, *Serenoa serrulata*,

or the Cabbage Palm, *S. Palmetto*, is intended. For information concerning the former, the papers by Dr. J. B. Read (*American Journal of Pharmacy*, 1879, page 169) and by Rusby, Bastedo and Coblentz (*Alumni Journal of the College of Pharmacy of New York*, 1895, page 169) may be consulted.

The Cabbage Palm has not been written about so much, nevertheless it is used extensively in a variety of ways; the Cabbage is a valuable article of food, and the wood is employed in constructing wharves and other works where a wood is needed to withstand the attacks of the teredo. Both Palms are used in the manufacture of brushes, brooms, etc., in which their fibre is available. One of the exhibits in the Agricultural Building of the recent Cotton States Exposition at Atlanta was composed entirely of products manufactured from the two Palmettos.

The reports which have circulated in regard to the tanning value of the Palmetto have, no doubt, always referred to the Scrub Palm, and excellent leather has been and is made from it. A recent sample yielded the following percentages on analysis :

	Moisture.	Ash in absolutely dry material.	Tannin in absolutely dry material.
Stem, above ground,	8.56	5.68	5.48
Root,	7.46	4.43	7.58

The stem examined was from above ground, and the root was a section of that part proper, and not of the underground stem.

The tannin is associated in the plant with a large proportion of red coloring matter, which has a tendency to make a dark leather. When finally separated the pure tannin gave reactions with iron salts and with bromine water, which indicated its close relationship with that from Oak bark. An ultimate analysis confirmed this by yielding the following percentages :

Carbon,	61.22
Hydrogen,	4.85
Oxygen,	33.93
	100 00

Something over a year ago a tanning extract made from the Scrub Palm appeared in the northern markets under the name of "syrup of tannin," but, as it contained a considerable quantity of the red coloring and not over seven per cent. of tannin, it did not find purchasers. Dr. Charles Mohr is authority for the statement that this extract industry has been abandoned. If a high-grade extract were offered at a reasonable price, there is no doubt but tanners could be found who would use it.

The question has often arisen about the tanning value of the Cabbage Palm, and recently, through the courtesy of Dr. J. H. Mellichamp, of Bluffton, South Carolina, two specimens have been received and examined. One was a section from a medium-sized tree five feet from the ground, and the other a section of the same tree a few inches below the sheaths of the living leaves near the top. On analysis they yielded the following percentages :

	Moisture.	Ash in absolutely dry material.	Tannin in absolutely dry material.
Section near ground,	10.04	7.80	1.79
" " top,	8.35	3.78	1.54

The section near the top, being more porous, dried out more rapidly in transit, and, therefore, yielded less moisture. The tannin percentages indicate that this species is not likely to ever have any value as a tanning agent. Some of the cortex was separated from the lower section, and it was found to contain just about the same percentage of tannin as the whole section.

The credit has frequently been given to tannin for enabling the wood of this Palm to withstand the attacks of the teredo when placed under water, but it is evident, from the foregoing figures, that this property must be attributed to something else.

Foreign Correspondence.

London Letter.

FLORA OF SOUTH AFRICA.—Botanists and horticulturists interested in south African plants will be gratified to know that the *Systematic Flora* of that region, commenced in 1860 by Harvey and Sonder, but completed only as far as the order Campanulaceæ, is being carried to a conclusion at Kew under the direction of Mr. Thiselton Dyer. Part 1 of vol. vi. has just been published. Price, seven shillings and sixpence. The volume, of which this is the first installment, will be of more than ordinary interest, as it will include the whole of the plants familiarly known as "Cape Bulbs," which have been popular in gardens for a century or more. We owe to south Africa more beautiful garden bulbous plants than to all the rest of the world put together. Thus of Irideæ alone, of which there are between 700 and 800 species, about one-half of them are natives of south Africa. These occupy over 160 pages of the publication under notice, which has been entirely elaborated by Mr. J. G. Baker, who has long been the accepted authority on this and allied orders. Among the larger genera included are *Gladiolus*, 81 species; *Moræa*, 45; *Babiana*, 26; *Tritionia*, 32; *Ixia*, 23; *Lapeyrousia*, 24; *Watsonia*, 15. The descriptions are in English. The work is published by L. Reeve & Co., under the authority of the Governments of the Cape and Natal.

THE JOURNAL OF THE ROYAL HORTICULTURAL SOCIETY for March contains several papers of exceptional interest. Mr. Francis Darwin has a paper on "Etiolation as a Phenomenon of Adaptation," in which the occurrence of white or bleached leaves or flowers in various plants is commented upon. Mr. Freeman-Mitford's valuable paper on hardy Bamboos will serve as a guide to the cultivation and an authority upon the nomenclature of these plants to those who do not possess his beautifully illustrated book upon them. Mr. A. W. Sutton contributes an account of the Potato from its introduction to its present development. His grafting experiments with the Potato and Tomato go to show that neither stock nor scion was affected by the union. Mr. Sutton is in a position to speak with authority upon the best varieties of the Potato as grown here now. Dr. Masters' paper on substitutes for Larch, which in the British islands is too often ruined by fungoid diseases, will be useful to foresters. The results of various trials at Chiswick among vegetables and flowers are given in better style in this number than before.

APPLES AND PEARS.—It is difficult for the would-be planter of only good sorts to make a selection from the hundreds that are grown and catalogued by dealers in fruit-trees. With a view to the formation of a definite list of the best varieties the Royal Horticultural Society offer this year special prizes for the best-flavored apples and pears. Six fruits of each variety must be shown, the judges to cut any three of them. The fruits must be grown out-of-doors and the place, conditions as to soil, etc., stated. If grafted the name of the stock must be given. The judges will allot points to quality, appearance and size as well as to flavor. Enormous specimens will not be preferred, as beyond a certain point size becomes a defect. A prize of ten shillings will be awarded to each apple. By this means it is hoped that an authoritative list of apples and pears of first-rate quality will be obtained. At present we are too much at the mercy of the dealer who supplies sorts which are said to be excellent, but which are too often worthless. Of course, the conditions under which the tree is grown are an important factor. I have in my garden trees that are generally admitted to be good, but which have never yet borne good fruit. [This subject was discussed on p. 161 of this volume.—ED.]

STREPTOCARPI.—The success of Messrs. Veitch & Sons in crossing and improving these plants has been marked, and this year they have some striking new seedlings. The monophyllous species, such as *Streptocarpus Dunnii* and *S.*

Wendlandii, are remarkable for their numerous flowers and bright colors, but they are unpopular with cultivators because of their ungainly leaves. The hybrids between these and the multi-leaved species, such as *S. Rexii* and *S. Galpini*, have several leaves, but they also are more or less one-sided. Three years ago Kew introduced a species with numerous large leaves and many-flowered scapes, known as *S. Fanninii*. This was crossed with other sorts, and from the hybrids thus obtained Messrs. Veitch have bred some most promising seedlings. It is impossible to say how far breeders may go with these plants. Already we have great variety of color, size and quantity of bloom, but it is evident that there are still better results within reach. The plants are very easily managed; they may be had in flower at any time of year, and their flowers are useful in various ways. Messrs. Veitch grow them by thousands planted out in frames facing south and heated to the temperature of an ordinary greenhouse. In the spring they are lifted and potted up to flower.

HIPPEASTRUMS.—These plants continue to occupy the attention of skillful cultivators and breeders, but I question if much improvement has been made in them in recent years. Certain changes in form, size or color blending have been made, but the flowers are often what may be justly termed inartistic, notwithstanding the satisfaction of the breeder when he produces a flower with broader segments or more fantastic colors. It is easy to carry these so-called improvements too far, as witness the dumpiness and total lack of elegance in the Chinese Primrose and *Cineraria* as now admired by fanciers. The *Camellia* was spoilt in the same way, so that we have gone back to the once despised singles and semidoubles. In my opinion, *Hippeastrums* may be too large in flower, and they may also be too formal in shape. I have lately seen new varieties valued at ten and even twenty guineas, which, although perhaps coming nearest the ideal of the florist, were less pleasing to the layman than varieties valued at as many shillings. Color improvement is after all the principal desideratum in the *Hippeastrum*; its original form is good enough. Several amateurs are now working with a view to better color, among them being the Right Honorable Joseph Chamberlain, M.P.

CALADIUMS.—These plants have grown in popularity in recent years. This is, no doubt, due to the improved varieties raised, chiefly, I believe, in France and Belgium, and also to their being wonderfully well grown by the two nursery firms which make a specialty of them, namely, Messrs. J. Laing & Sons, Forest Hill, and Messrs. J. Veitch & Sons, Chelsea. I saw a large houseful of them in the latter place a few days ago. The plants were in twelve-inch pots and were simply great globose masses of large, richly colored leaves of the most varied hues. Among the best of them were some new seedlings raised by the late Mr. C. F. Bause, one of the most skillful of breeders in England. These seedlings are remarkable for brilliancy of color and dwarfness of habit. They are named Her Majesty, Lady Mosley, L. Bause, Sir Henry Irving, etc. There are eleven of them altogether, and I see they are offered by Messrs. Veitch at prices varying from half a guinea to a guinea. Is it generally known that *Caladiums* are excellent plants for the tropical aquarium? Planted in a bed of mud, or in pots partially submerged in a tank of warm water they grow vigorously and color superbly.

DAFFODILS are now by far the most popular of all spring-flowering bulbous plants. Our public gardens are painted yellow with them, lawns as well as flower-beds being decorated with their flowers. New sorts are appearing almost weekly, and several specialists are devoting their gardens wholly to the cross-breeding of Daffodils. A conference and exhibition of Daffodils was held this week in the gardens of the Royal Botanic Society, Regents Park. Mr. Baker, F.R.S., presided, and addresses were given or papers read by such well-known authorities as Mr. F. W. Burbidge, M.A., Mr. W. Robinson and the Rev. S. Bourne. Magnificent collections of the flowers came from Messrs.

P. Barr & Sons, the leading growers of Daffodils among nurserymen, Mr. T. Ware, Messrs. J. Veitch & Sons, and numerous amateur growers. Cups and medals were awarded for new varieties. Mr. Baker, in opening the conference, spoke of the enormous increase in the popularity of the Daffodil within the last twenty years, due, no doubt, largely to the fact that it was a democratic flower, responding to the attention of growers of the most limited means and yielding freely its flowers, which in form and color were artistic and pleasing. The reign of the Daffodil is assured.

London.

W. Watson.

Plant Notes.

ACER CISSIFOLIUM.—This Japanese *Negundo* has been fruiting in this country for many years, and we have invited attention to it in every volume of *GARDEN AND FOREST*, and yet in half a dozen catalogues of the leading nurseries of the country, which we have just examined, we do not find it offered for sale. We may add that the same is true of other trees and shrubs whose merits have been proved long ago in the Arnold Arboretum and made known again and again in these columns. This Box Elder is beautiful at all seasons, and being somewhat formal in habit and comparatively small, it is one of the limited number of desirable trees for planting as single specimens on a lawn. It is a compact round-headed tree with a gray trunk, slender, light green leaves in summer, which turn to brilliant orange and red late in autumn. The young shoots have a habit of growing and producing new leaves all summer, or, at least, long after other trees have finished their yearly growth; and these young leaves at the extremity of the branches, showing the delicate shades of red and pink which characterize spring foliage, give a peculiar sprightliness to the general expression of the tree. It grows rapidly and is more hardy than the Japanese Maples, which are varieties of *Acer Japonicum* and *A. palmatum*.

ANDROMEDA JAPONICA.—Recent English horticultural papers speak of the beauty of this shrub as exhibited at the spring flower shows, and a correspondent of *The Garden* writes of great masses of it in flower at the Knap Hill Nurseries of Mr. Anthony Waterer and of a fine group of it by the Palm-house lake at Kew. In vol. vi. of *GARDEN AND FOREST*, page 254, Professor Sargent writes that the plant is a tree in its native home, where he had seen specimens thirty feet high with stout well-formed trunks six or eight feet in length. In our north-eastern states it grows rather more freely and has a more graceful habit than our native *Andromeda floribunda*, which is closely related to it, and when at its best, with its broad, drooping panicles of large white bell-shaped flowers, it is one of the most interesting of evergreen shrubs. It cannot be trusted to bloom, however, in our climate, although it is perfectly hardy, for the flowers open so early that they are almost certain to be killed by cold weather. Farther south, where it would flower in February, it would certainly be a most desirable shrub.

ROSA LAWRENCEANA.—The Fairy Rose, as this plant is appropriately called, is uncommon in cultivation, and Herr Leichtlin has but recently distributed it among plant fanciers. It is a double form of the white-flowered *Rosa Indica minima*, and while it may, perhaps, not prove perfectly hardy in this latitude, it is well worth cultivation by those who fancy dainty rather than big flowers. The plants make many-branched bushes, with very small leaves and dainty little pure white flowers less than an inch in diameter when expanded.

Cultural Department.

Vegetable Garden Notes.

THE month of April, 1896, must go on record as one of the most remarkable ever experienced for sudden changes of temperature. Until the 10th instant we were unable, owing to cold weather, to do any outdoor work, such as seed-sowing. A week of phenomenal heat followed, when the thermometer

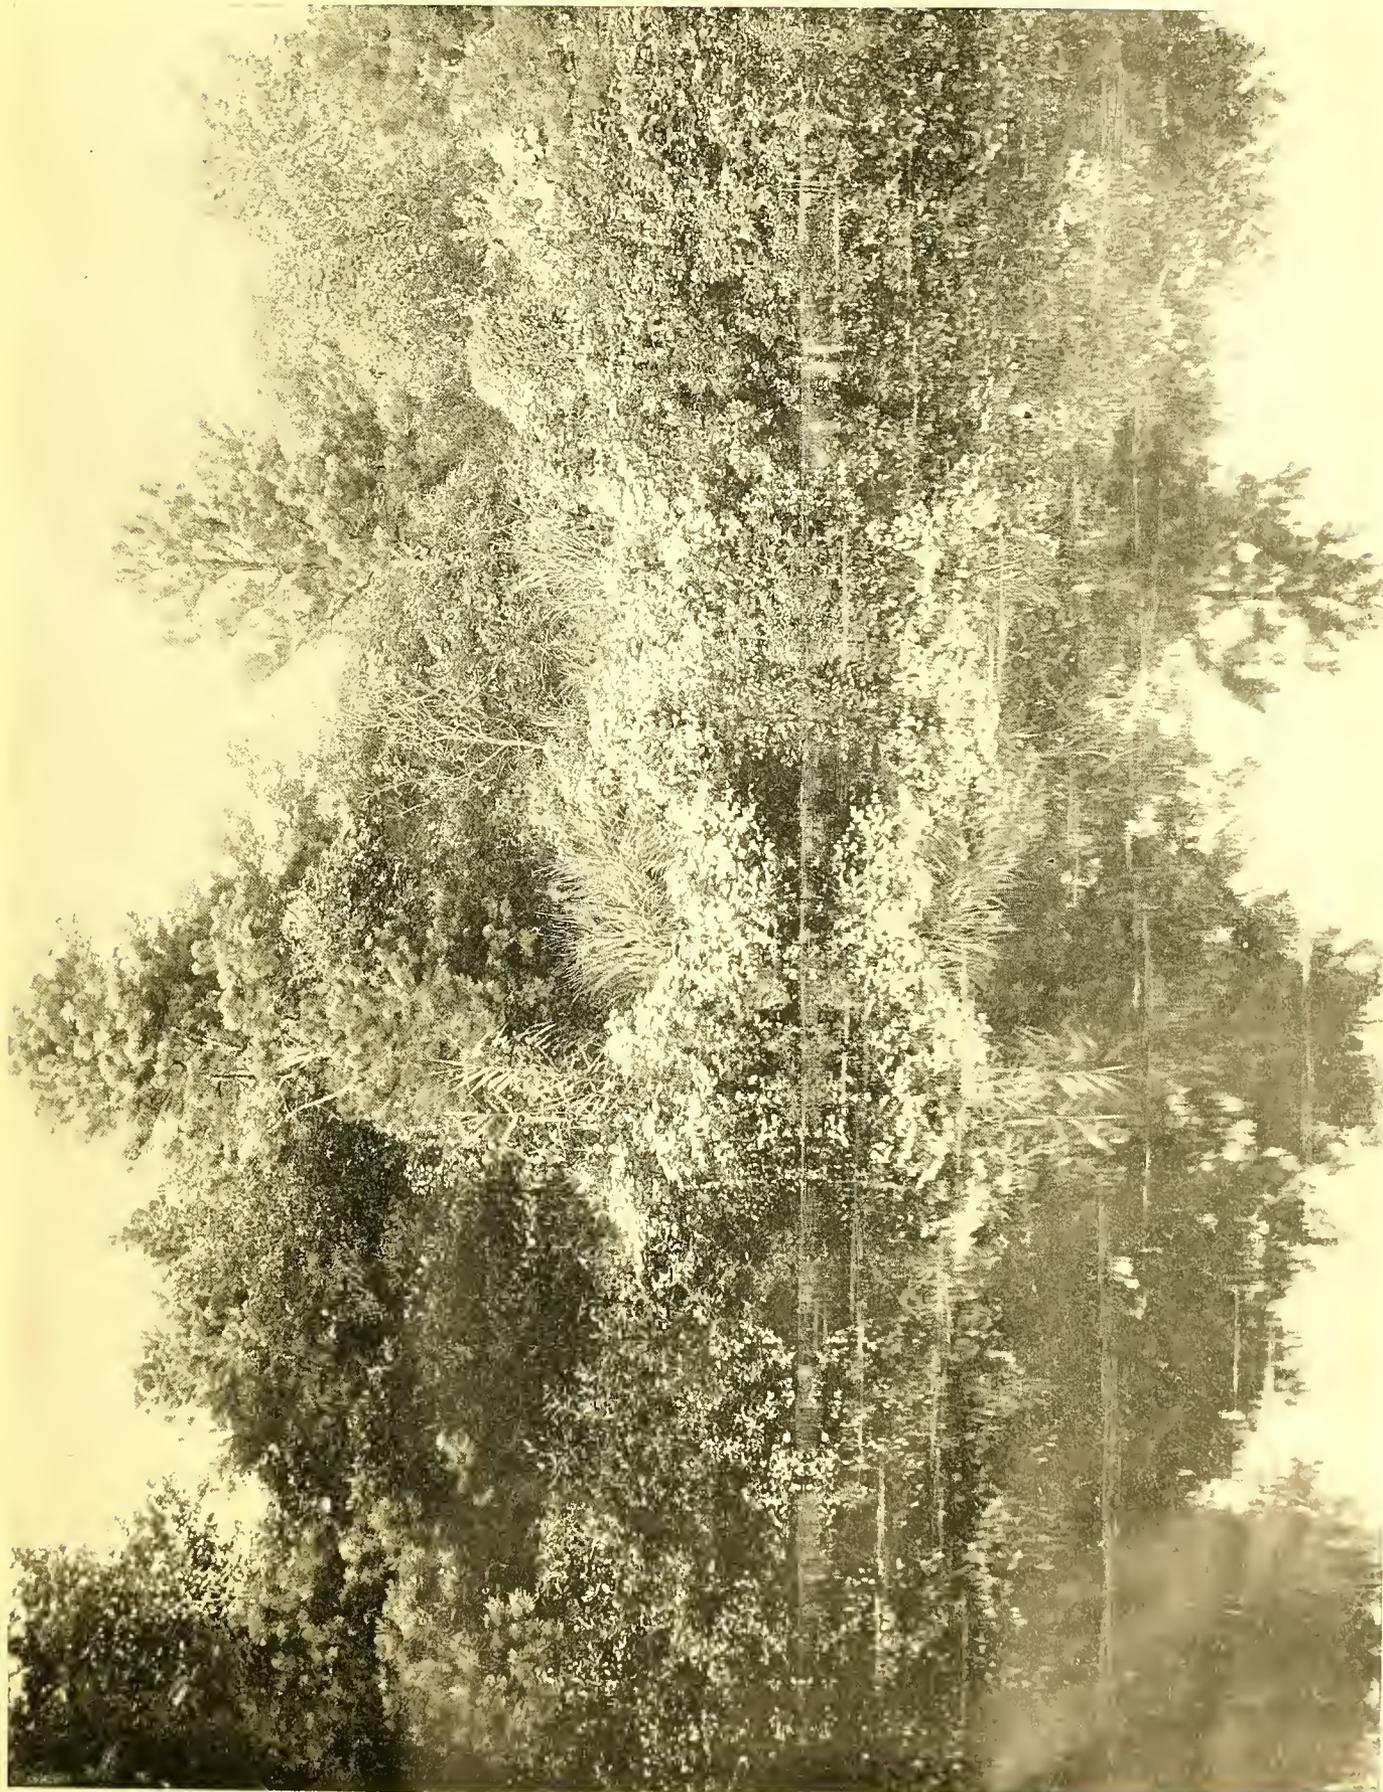

Fig. 30.—*Clematis paniculata* in a Wild Garden, at Westbrook, Long Island.—See page 182.

recorded ninety degrees in the shade on one occasion and on several days reached eighty or eighty-five degrees. Such forcing weather brought things forward with a rush, and although Peas, Onions and similar crops were sown from ten days to a fortnight later than in 1895, they are at this time more forward than they were a year ago. Now we are having a cold dry spell, with frost almost nightly, and vegetation is making slow progress. A more perfect season for seed-sowing could not be desired. There have been but two showers so far during this month. With warmer nights and more moisture crops will make rapid growth. The tropical weather in the middle of the month tempted many to plant large patches of Sweet Corn and Beans in this locality. Each year some of these crops are sown at this time, and they are always cut to the ground by frost by the middle of May. Last year there was a killing frost on May 17th, when all tender crops were destroyed. In this part of New England it is not really safe to plant out such vegetables, as Tomatoes, Peppers and Egg-plants, before May 20th. We prefer to have good stocky plants in cold frames until that date, and there we feel they are safe, whereas by planting out a week earlier there is uncertainty about their safety whenever the night turns chilly and the weather-vane points north or north-east.

Our early sowings of Peas have recently been earthed up a little and pea-brush placed among them; the ground will require frequent stirring with the hoe or cultivator to loosen the surface and keep down weeds. An iron rake drawn over the ground between rows of seeds when they first appear will stir the ground nicely and destroy multitudes of almost invisible weeds. Occasional sowings of such kinds as Stratagem, Heroine, Champion of England and Shropshire Hero have recently been made, the seed of these being covered more deeply than at our earliest sowing. Peas do much better sown while the ground is comparatively cool, as they naturally prefer a cool and moist climate. Later batches sown after hot dry weather sets in never give such good returns as those planted earlier. For sowings made after this time we choose our moistest ground, and it is helpful to mulch between the rows with grass or meadow hay. Mulching serves a twofold purpose in keeping the ground moist and cool. Where seaweed is obtainable it is one of the best things to use for this purpose, and it is also excellent for protecting Celery kept in trenches during the winter. A friend sent us on April 15th some fine heads of Boston Market Celery grown on Cape Cod and preserved in this way.

We find it risky to sow any Sweet Corn or String Beans before May 10th. Sowings made much earlier have come through all right, but the later-sown ones give better returns. Our earliest batch of String Beans in frames is now showing flower. A later sowing made in sashes from which Violets were taken are in second leaf. The sashes are thrown off these during the daytime, but it will be necessary to cover them at night for some time. Our earliest batch of forcing Erfurt Cauliflower is now giving some nice heads for cutting. These and, indeed, all vegetables in frames require plenty of water and stimulants. The ground will require occasional stirring among Lettuce, Carrot, Beet and other crops in frames, and weeds must be allowed no foothold. Artificial pollination will make early Cucumber set better and swell faster. We make our first sowing of these and of Melons in the open about May 6th, scooping out a hollow space for the seeds, which we cover with a sixteen by twenty-four sheet of glass. This is kept on until the plants are well established, ventilation and water being afforded as required. To those who do not possess hand sashes or other protecting appliances this will be found a cheap and useful method, and the plants do decidedly better than if started in pots or turf in heat and then transplanted.

Onions raised in boxes have recently been planted out in rows eighteen inches apart, allowing six to eight inches between the plants, according to the variety. Onions do so much better pricked out that we purpose relying on this method exclusively in future. Not one-fourth of the seed necessary to sow the rows is required, and, although a little time is needed to set out the plants, it is more than counterbalanced by that saved in thinning and weeding those treated in the regulation way. Some persons object to large-sized onions, and where this is the case it is best to stick to the old method. Onions like the ground pretty well primed, but on no account should it be allowed to become baked. The hoe must be kept constantly used in the cultivation of these and all other vegetable crops at this season, before weeds make any headway.

Our first batch of Celery was pricked off into boxes some time ago, and is now ready to transfer to a frame, from whence it will be planted in the open about the end of May. We have

recently made a sowing of Boston Market, Giant Pascal and Kalamazoo for a winter crop. The ground now occupied by early Peas will be utilized for this Celery later in the season. A sowing of Golden Self-blanching Celery made now will give some fine heads in the fall. This variety rusts very badly during hot weather if not kept well watered. Sown now it will give good solid heads until Christmas. This is a suitable time to make sowings of Sweet and Pot Herbs, Brussels Sprouts, Savoy and Drumhead Cabbage, Leeks and Okra. Martynia we sow about the end of May. Successional sowings of Beet, Lettuce, Radish and Turnip may be made, and if Parsley has been forgotten in the spring rush, a row of it may be sown now.

Tomatoes for the earliest outdoor crop have just been shifted into six inch pots, and fruit will be set on these before they are planted outside, insuring an early crop. The plants for the main crop are now in boxes in a frame. It is better to thin or pot off the plants if they get crowded and are in danger of becoming spindling. Short stiff plants are best. A long lanky plant which needs a stake to support it before it is many inches high cannot be expected to give satisfactory returns. Plants now fruiting indoors require at this season an abundance of water, and we give liquid stimulants three times a week, in addition to scattering a handful of sheep-manure on the top of each pot once a week. The plants require looking over at least once in ten days, when superfluous growths, decaying foliage and necessary tying can be attended to. Our latest batch indoors has recently been placed in fruiting-pots, and fruit is just commencing to set on these. These plants, with others still bearing heavy crops, will furnish us with plenty of tomatoes until the middle of July, after which an outdoor supply can be relied upon until the middle of October.

Taunton, Mass.

W. N. Craig.

Seasonable Work.

THE removal of many bedding plants to outdoor frames at this season relieves the overcrowded condition of the greenhouse, and affords the opportunity to harden off the plants before placing them in the open ground. The various cool-house plants grown for this purpose, for example, Geraniums, Verbenas, Ageratums, Alyssum, Sedums, Phlox Drummondii and many others of like hardiness, will be in better condition if placed out in a frame before this time, and from May 1st more tender plants may also be put in similar quarters. These will naturally require more care in ventilation for the first few days, so that they may not receive any check.

This partial clearance of the greenhouse will make it possible to shift on and spread various summer-blooming plants required for the conservatory next season. Among plants deserving special attention in this particular none are more prominent than the tuberous Begonias and Gloxinias, for while tuberous Begonias are valuable as bedding plants in some favored sections in this country, in the main they are more satisfactory for indoor decoration. Considerable space and light are needed for their full development, although some protection from full sunlight is also necessary when they are grown under glass. The young plants should be potted on before they become badly starved, for once stunted they seldom fully recover. The large-flowered garden varieties of the tuberous Begonias are not the only ones of value to the private grower, and well-grown specimens of *Begonia Boliviensis*, *B. Chelsonii*, *B. Weltoniensis* and *B. Froebelii* add much to the beauty and interest of a collection. The latter species is particularly striking, with its bold foliage and strong spikes of brilliant red flowers. Most of the Gloxinias should now be ready for their final shift to the pots in which they are to bloom, six-inch pots being generally large enough for this purpose. About the time these plants show bloom they will be benefited by an occasional watering with weak liquid-manure. Gesneraceous plants in general are shade lovers, and Gloxinias are no exception to the rule. In watering, the foliage should not be wet to any great extent, or the leaves become rusty.

Various relatives of the Gloxinias also demand attention at this season, among others *Achimenes* and *Tydaea*, both genera including many beautiful forms well adapted for conservatory decoration during the summer months. Large baskets filled with *Achimenes* would be a revelation of beauty to those not familiar with them, and they are not really difficult to cultivate. Thrifty young plants should be used for this purpose, and should be planted all around a wire basket of large mesh, the basket being lined with moss to retain the soil. Thorough watering is required by the *Achimenes* while in growth, and the basket should be hung in a partially shaded location and not exposed to strong draughts.

Cyclamens for next winter will also require attention now, and these plants should never be starved while young. Comparatively few growers save the old corms from one season to the next unless it be those of some particularly fine form, young plants being easier to manage and usually more satisfactory. Rather open soil and good drainage are essentials in the cultivation of Cyclamens, and perfectly clean pots should be used for them. Watering should be done carefully. Frequent light syringing is helpful during hot weather, but this should not be done late in the afternoon, as the foliage should be kept moderately dry at night. Plenty of fresh air and some shading are also necessary, and a sprinkling of chopped tobacco-stems spread among the pots will tend to discourage aphids and thrips.

Holmesburg, Pa.

Spring-flowering Plants.

THE recent exceptionally warm weather has brought into bloom most of the early spring flowers with magical rapidity, and in a week the face of nature was transformed from winter sere to the bloom and beauty of spring. Fortunately, cooler days have followed without frosts to injure this growth, and there is promise of a favorable spring season. The past winter was exceptionally fatal as to plant-life, and many of the shrubs considered hardy have been injured sadly. *Magnolia Soulangeana* has all flower-buds killed, and many other of the smaller plants of various *Magnolias* have been severely killed back. I observed to-day the first flowers open on the plant of *M. Kobus* (*Thurberii*). This plant is quite an old one, and was presented to Dr. Thurber when it was named, but it has not bloomed till now. It is not one of the showiest species, but is a vigorous grower of compact habit and of brightest green in summer. The newer *M. Watsoni* has been killed to the ground. The plants were small, but were well established last year, and, indeed, it bore flowers last spring that were much admired, and it was considered a genuine acquisition to the list of garden shrubs. It may possibly prove hardy if protected in a sheltered position, and it would be of interest to learn how it has behaved in other localities.

Pæonia corallina and *P. Wittmanniana* are two of the rarer species of *Pæony* not often seen in cultivation, and belong to the very early-flowering type of which *P. tenuifolia* is the best-known representative. Neither of the first named has flowered here before, owing, as we thought, to tenderness of the early shoots; the buds were to be seen, but they did not develop properly, but it would seem now that the failure was due to lack of flowering strength, for, now that the clumps are well established, they are both about to flower. Several species of *Pæony* are great additions to gardens when they are obtainable, but, for some reason, we do not often see them in lists, probably owing to the greater demand for the showy garden forms of *P. herbacea*, but those that flower so early in the year have a value of their own. The flower-buds of these are now showing color, while those of the garden forms are scarcely to be seen above ground.

In years past we have noted the beauty of *Puschkinia Libanotica*, and each year it is among the very first to open its blossoms in the outdoor garden, defying frost and snows, and only waiting for a few bright days to expand its pretty flowers. It is very similar to a *Scilla*, and might be easily taken for one, but the bells are of a very pale blue, almost white, with a distinct dark blue stripe down each division of the bell-shaped perianth. Here it is not only hardy, but seeds freely each year, and from a half dozen bulbs first planted we have now as many as fifty large and small. The seeds seem to grow freely where they fall, for they have never been collected or sown in the regular way, but with the non-disturbance of the soil by digging or otherwise we have quite a little colony of this pretty spring flower.

I think, also, that for the past three or four years the pretty *Fritillaria aurea* has been noted for its good ways, and the temptation is strong to speak of it again now; it is the only one of the *Fritillaries* that I know that will thrive in the outdoor garden in this latitude. *F. Meleagris* will exist for years, but not so as to give any pleasure to its possessor, and the *Crown Imperials* are very uncertain in their habits, but *F. aurea* has been perfectly happy here for the past three years. The color of the flowers is a bright yellow outside, checkered with black squares within in a very pretty fashion. It is also very easy to increase from the number of young bulbs formed round the older ones. The western *F. pudica* is also one of the prettiest of the native *Fritillaries*, but is too tender for this section to do well; it is a modest little flower with a charm all its own, but is best grown in pots indoors in winter.

There has always lingered a suspicion as to the absolute hardiness of the *Eremurus* in an open, much exposed loca-

tion, and until last fall we have always given it a protection of straw, but by accident this was omitted last November, and many were the doubts as to the result. When spring came we had deep frost without snow for protection, and many things suffered in consequence, but not so the *Eremuri*, for they are coming up stronger than ever and seem to have enjoyed the cold on the whole. The two species we have are *E. robustus* and *E. Himalayacus*, but soon we hope to try more of them, the difficulty being to get them in good strong roots of the rarer kinds, the demand being apparently greater than the supply. There need be no more doubt as to the hardiness of these fine border plants.

A plant long known in gardens as *Amaryllis Hallii* here in New England proves to be *Lycoris squamigera*, and under the latter name has been recently made plentiful by importers of bulbs from the east. As *A. Hallii* it has been cultivated in a garden at New Bedford for many years, and was possibly brought there by some of the trading ships that used to start from that port, and as a hardy bulbous plant it has great merit. It is the only really hardy member of the genus that we can cultivate here, and there was a doubt as to whether the bulbs recently obtained were identical with the older ones long known here. I am glad to see that they have come through the winter without any harm, with no protection whatever, and are growing freely, though not large enough to bloom this season; there appears to be no doubt that we can depend on the two being identical and within easy reach of cultivators.

South Lancaster, Mass.

E. O. Orpet.

[*Lycoris squamigera* was originally brought from China by Dr. George R. Hall, of Bristol, Long Island, and was distributed as *Amaryllis Hallii* by the Messrs. Hoovey, of Boston. The plant was described and figured in GARDEN AND FOREST, vol. iii., p. 176.—ED.]

Flower Garden Notes.

AZALEAS which have been forced for Easter decorations should now have all weak shoots and premature growth which usually accompanies the blooms cut out. The whole plant should be evened over, and, if trained, tied into shape. If grown continuously in pots this is a good time to repot them. Azaleas, however, are slow-growing plants; they do not need shifting often, and generally, if some of the old soil is taken away and some fresh added, the plants will continue in good condition for two or three years, and old plants often for a longer time. They must be repotted when thoroughly pot-bound; and in such cases it is advisable to chip away a quantity of the old soil, leaving a rough surface about the ball of earth so that it will easily compact with new soil. As close a shift as possible is sufficient, so long as the new soil can be worked in firmly between the pot and the ball. It is better, however, where it is possible to devote a properly prepared piece of garden soil, to plant them out for the summer. They do not need less care; they simply do better when the conditions of success are understood. A rather tenacious loam is best, in which abundance of well-decayed leaf-soil is well composted. The ball of earth should be stirred as recommended for potting, and the new soil worked in about them quite firmly, scarcely more than covering the top of the ball. A basin should be left in which water will collect.

Astilbe Japonica and the newer *Spiræa astilboides* and their varieties, now out of bloom, may be cut up and planted out. With two years' growth these will be ready to force again. If this practice is followed there should be no need of importing roots for forcing, since as good clumps can be grown here as in Europe.

The practice of growing *Deutzia gracilis* in pots is a good one. They can be grown several years by shifting on from small pots to ten-inch size. Beyond this size they become unserviceable, when they can be turned into the shrubbery. By striking a few cuttings of green shoots taken at this time it is quite easy to keep up a succession.

Erica Caffra, var. *densa*, and *E. melanthera*, two easily forced Heaths, may be trimmed into shape and turned out for the summer. Heaths are usually recommended for shaded places, but we have found these do quite well in the full sun, providing they are plentifully supplied with water.

Cytisus racemosus is now extensively used for spring decorations. The long stems, clothed with graceful racemes of fragrant yellow pea-like flowers, are effective among foliage plants. The *Cytisus* is easily grown and bears hard treatment. Such as have been in bloom may be cut back and turned out, providing they have balls of earth, but young plants struck this winter are better if kept in pots. Shifted along from three

to six inch pots they grow into a convenient size for almost any kind of decorative work. To some of the plants we allow only one stem, and these make a perfect column two feet high. Others are stopped and grow mostly into pyramidal form, and some into compact bushes. Old bushes soon get leggy and out of shape. *C. elegans*, the silver-leaved kind, is by far the handsomest. It is generally found difficult to root. By stumping an old plant in and taking stem cuttings with a heel we have never had any difficulty in rooting it.

A few small plants of *Rhodotypos kerrioides* have been blooming in a cold frame since the first of April. No doubt, this handsome Japanese shrub would be well adapted for forcing in the same way as *Deutzias*, and would be a valuable addition to the limited number of shrubs available for this purpose; so also will the Crimson Rambler Rose. All who saw the specimen exhibited by Mr. Jackson Dawson, of the Arnold Arboretum, at the spring show of the Massachusetts Horticultural Society were delighted with it.

Old stools of Japanese Anemones in pots are starting in cold frames. Last spring they were repotted, and we intend to carry them through this season with a top-dressing of rich soil and liquid-manure later. We shall keep them in cold frames until all danger of frost is past, as experience has shown that they easily become blighted by even light spring frosts. Such disfigurement will last a whole season.

Violets and Carnations will be planted out as soon as the work can be reached. Such frost as there shall yet be will not injure them. Of Violets we shall grow only the Farquhar for dark blue. This Violet will entirely supersede the Marie Louise. It is superior in size of bloom and length of stem, and in color it is equal. So far as tested it has proved easy to manage.

The bulk of stock used for winter blooming in the greenhouse can be planted out for the summer. In this respect we have the advantage of the English gardener, who must grow many of these plants in pots under glass. *Mignonette*, *Sweet Alyssum* and *Shirley Poppies* will be sown, and *Stocks*, *Asters*, *Coreopsis Drummondii*, *Scabious*, *Phlox cuspidata*, *Verbenas*, *Marigolds*, *Zinnias* and other useful annuals for cutting will be planted out as soon as settled weather comes. These we keep together. Last year we found *Caryopteris mastacanthus* valuable for cutting in the autumn, as well as being a useful plot-plant. The graceful sprays of sweet-scented lavender-blue flowers are very effective.

Wellesley, Mass.

T. D. Hatfield.

***Helleborus orientalis*.**—Besides the Christmas Rose, the genus *Helleborus* contains several very showy and attractive species, known in England under the name of Lenten Roses, because they flower during the Lenten season. With us they are somewhat later unless grown in a cool frame, when they may be had in great profusion at Easter. The species most beautiful as well as most varied is the not uncommon *Helleborus orientalis*, which grows somewhat taller than the Christmas Rose, producing more slender and leafy stems, each bearing several large rose-colored flowers. As in the case of all Hellebores, the sepals form the showy part of the flower; they are from three-quarters of an inch to an inch long, rounded and spreading, of a dull rosy color, persistent, and gradually becoming green. The leaves are evergreen, smaller, and with more narrow segments than those of the Christmas Rose; pedate, with about nine oblong-lanceolate segments, which are coarsely toothed or serrated. There are some beautiful varieties, merely differing in size and color, such as *Guttatus*, with large white flowers, the sepals of which are dotted all over with small rose-purple spots; *Punctatus*, with smaller and more numerous dots; *Antiquorum*, almost pure white, slightly tinged with red and greenish gray. As all the Hellebores are woodland flowers, delighting in moist vegetable soil, in rocky woods, where the air is continually cool and moist, they should be treated accordingly. The leaves are best preserved in somewhat shady positions, but the plants flower more abundantly in moderately sunny places, if not too dry. Rocky borders of small streams, under deciduous trees, offer many opportunities for growing these charming plants successfully in ideal positions.

***Anemone ranunculoides*.**—One of the most common, as well as most attractive, spring flowers of northern Europe is the Golden Windflower, *Anemone ranunculoides*, which flowers considerably later than the common white Windflower, among which it grows. It is seldom, if ever, found in low, flat woods, preferring steep hillsides, where it grows in rich leaf-soil in comparatively deep shade. The leaves are smoother, less cut than those of *A. nemorosa*, palmately three or five parted, with deeply toothed almost trifid segments. The stem-leaves,

forming the involucre, are tripartite, petiolate, shiny green. The flowers, which, in favorable positions, measure nearly an inch across, are bright golden-yellow, from one to three on a stem. The plant grows from five to eight inches high; the creeping rhizome is rather thick and fleshy, producing several leaves. I have never seen this handsome species in American gardens, but it would, however, prove a very charming acquisition, providing its naturalization is possible.

Newark, N. J.

N. J. R.

***Pitcairnia*.**—This genus includes many handsome plants, and although they are easy to grow and have large showy flowers and bracts, specimens are rarely seen outside of a botanic garden. The genus belongs to the Pineapple family and is nearly related to the *Tillandsias*. While they come from tropical America they are grown here in a temperature ranging from fifty to fifty-five at night, along with *Billbergias*, *Echmeas* and *Tillandsias*. They do best in a position where they have plenty of light, and in bright weather require frequent syringing. The compost for potting them should consist of fibrous loam, chopped fern-root, leaf-mold and sand in equal parts. It is important to have the pots clean and well drained, as the plants need plenty of water while they are growing. For the past three or four weeks a large plant of *Pitcairnia Altensteinii* has been attractive and much admired. The plant has a very short stem, but it has graceful leaves which measure three feet and a half in length and about two and a half inches in breadth. The inflorescence is a simple subspicate raceme, and the peduncle measures two feet in length. The bright red bracts on the peduncles are about two inches in length, and long after the flowers are gone they retain their clear color. Indeed, the bracts are more showy than the flowers. The corolla is long and narrow, measuring about three inches, and of a whitish color. This showy *Pitcairnia* was introduced from western Venezuela in 1840. It is sometimes found under the generic name *Puya* and also as *Pitcairnia undulatifolia*.

Botanic Garden, Harvard University.

Correspondence.

Potato Blight.

To the Editor of GARDEN AND FOREST:

Sir,—I have just read with interest Bulletin 113 of the Cornell Experiment Station. This bulletin treats of Potato diseases, and among others describes and figures the "early blight" as it occurs at Ithaca. My interest in this topic was increased by the fact that I have now in press a bulletin on Potato blights, the publication of which has been delayed some time awaiting engravings. Among these illustrations which are to appear in our bulletin is one agreeing essentially in the diseased characters of the leaf with the beautifully colored plate which Mr. Lodeman has labeled "Early Blight." The conditions represented in our leaf (and they are unquestionably the same in the leaf figured in the Cornell bulletin) are, however, distinctly different from the "Macrosporium blight," or "early blight," as that disease has been described in various parts of America, France, New Zealand and Germany. It will only add more confusion to a subject already sadly confused if we do not sharply distinguish the two disorders. To this in my lectures before students and farmers' institutes during the past winter I have used the name "Tip-burn" of the potato, to designate this latter trouble as distinguished from the true "early blight" or *Macrosporium* "spot disease." In fact, we must distinguish at least four, and, perhaps, five, distinct forms of the so-called "blighting" of Potato leaves, which commonly occur in the north-eastern United States. So far we have names for but two. Of these the "late" or *Phytophthora* blight is now quite generally recognized and distinguished. Beyond this all is confusion, since the term "early blight," as popularly used, has been broadened to cover all forms of premature dying Potato leaves from causes other than attacks of the fungus *Phytophthora infestans*. I was thoroughly impressed with this fact during a trip made to Wisconsin last August, in which I had opportunity to examine blighting Potatoes at various points along the way. Upon my return I wrote to each of the experiment stations in north-eastern United States asking for specimens of Potato leaves showing the *Macrosporium* or "early blight" as it occurred in that locality. The material thus collected, together with a considerable amount collected in other ways during the past four years, has been carefully studied by my assistant, Mr. Tracy, and myself. The diseased conditions represented clearly fall into several classes as to cause. These are:

First: The "late blight" or mildew caused by the fungus *Phytophthora infestans*.

Second: The "early blight," *Macrosporium* disease, or "leaf spot" disease, due to the parasitic attacks of the fungus *Macrosporium Solani*, E. & M. This is characterized by the appearance of numerous sharply defined dark spots scattered irregularly over the leaf. These spots, enlarging slowly, dry, and the tissue is by this drying thrown into irregularly concentric elevated rings. The character of these rings is peculiar, and forms a valuable method for hasty identification of the disease as it usually occurs. These spots may or may not originate from flea-beetle punctures. It is agreed by all investigators that this fungus most readily attacks plants or leaves that have passed their period of greatest vigor. It is, as Dr. Sorauer says, one of the "Schwächeparasiten," but, nevertheless, a most destructive parasite when well established in a field.

Third: "Tip-burn," a disease characterized by the drying of the leaves at the tips and margins, not necessarily associated with any fungus attacks, but attributable to physiological conditions surrounding the plant, especially to dry hot weather with insufficient water-supply, and aggravated by insect attacks or any other conditions which lessen the vigor of the plants. This is clearly the trouble figured in the Cornell bulletin as "early blight." Mr. Lodeman's account of the physiological conditions leading to this disease is excellent and in accord with my own observations, but, as already indicated, we must clearly distinguish this third disease from the second, both as to cause and appearance. Of course, various fungi and bacteria capable of existing as saprophytes soon invade the tissue which has died from "tip-burn," and these soon complicate and often aggravate the disease. As shown in the material examined, the nature and extent of these secondary fungus invasions varies considerably in different localities according to conditions. These invading fungi are exceedingly interesting, and have received considerable study; a discussion of them would, however, be out of place in the present summary.

Fourth: "Arsenical poisoning" from Paris green or other arsenites applied as insecticides. In case of extremely strong application of these arsenites the leaf may be entirely killed or large areas "burned" within a short time. Usually, however, its action is slower and longer-continued. Its effects are then apparent as dead spots centering about flea-beetle punctures or other mutilations in the leaf. These spots continue slowly to enlarge for some time, and, as a result of the slow death and drying of the tissues, the surface of each is thrown up into distinctly concentric elevations or ridges forming "ringed spots" so similar to those caused by the attacks of *Macrosporium Solani* that they are extremely deceptive. There is, however, a distinctly different color to the spot, as a rule, and the rings are more regularly circular in the poisoned spots. These arsenical poisonings are of very common occurrence, and are unquestionably responsible for much of the confusion regarding "early blight."

Fifth: Dead spots sometimes occur on the margins of leaves or surrounding flea-beetle punctures or other injuries which are not invaded by fungi, and do not seem attributable to arsenical poisoning. They develop the characteristic rings, and resemble spots caused by the *Macrosporium* or the arsenical poisoning, but are often, at least, due to dry heat, as suggested by Dr. W. C. Sturgis in the Report of the Connecticut Experiment Station for 1894. In this case they should be associated as to cause with "tip-burn" rather than with "early blight."

Experiment Station, Burlington, Vt.

Nut-culture in the United States. United States Department of Agriculture. 1896.

Six years ago Professor H. E. Van Deman, who was at that time Pomologist of the Department of Agriculture, sent out circulars of inquiry to all parts of the United States where there have been any systematic efforts at planting nut-bearing trees for the production of their fruit. Wild nuts have always been so abundant in this country that there has been little need of cultivating the native sorts. Our native pecans, shellbarks, walnuts and chestnuts vary widely in size and quality, but it has been the popular belief that a long time would be required to raise the improved varieties in any quantity, since propagation is slow and grafting in many instances difficult.

Nevertheless, there have been many individual instances where success has been won with improved kinds of our native Chestnuts and the foreign sorts, with the English or Persian Walnut, with the Almond and the Pecan, and there have been hopeful experiments with the Shellbark Hickory and in the extreme south with the Cocomanut. A very good account of what has been really accomplished will be found in this book, which is a compilation of the answers to the replies made to Professor Van Deman's circular, and published by the Department of Agriculture. The text makes about one hundred quarto pages, to which are added sixteen full-page plates, some of them colored, and there is a carefully prepared index. The cultivation of the Almond is already established in southern California, and seedlings of excellent quality are constantly produced, and it seems to have become a matter of common observation that the best variety in any locality is some seedling which originated there. The cultivation of the Persian Walnut, too, has become well established in southern California and the exports are increasing annually. Perhaps the largest cultivated Walnut grove in the world is one in California, which contains seven hundred acres. The account of hybrids between different species of Walnut from eastern Asia with the California Walnut, our Black Walnut and the Persian or English Walnut suggests the possibility of producing trees of widely varying form and habit, although no distinct improvement in the fruit has yet been accomplished.

Perhaps the most interesting chapter in the book is that on the Hickory, especially the section which relates to the Pecan, a tree which equals in importance, if it does not surpass, the Persian Walnut and the Almond. This tree will thrive over a large area and the fruit varies very considerably, so that by selection it is possible to get large, thin-shelled, delicately flavored nuts. Large orchards are being planted, and in many cases trees which bear inferior nuts in the forests are cut out so as to leave room for those which bear better ones. A grove of this sort—that is, a grove made by thinning out a forest of 450 acres on the Guadalupe River, in Texas—has produced \$2,000 worth of nuts in a year. One of the plates represents a wild Pecan-tree which had been top-budded four years earlier with five choice varieties, and it already shows a vigorous head of young shoots bearing nuts. If this method is practicable with large trees it will not be difficult to utilize the abundant wild trees of the south for the production of choice nuts. A good account of the experiments with Shellbarks is also given, and the story of the improved varieties of Chestnuts, with which the readers of this journal are familiar, is told at length. It seems probable, too, that from Delaware southward the English Hazel-nut can be successfully grown, and there are some of our native Hazels in the north which bear nuts as large as imported filberts, with thin shells and altogether of superior quality. Many of the species of Pine on the Pacific slope, including Arizona, have seeds that the Indians use as food, and they are marketed in large quantities in some of the cities of California. One of the plates of this book is devoted to the seeds of these Pines, twelve different sorts being figured. Some of them are large, soft-shelled, of a delicious flavor, so that they are valued both for dessert and confectionery purposes wherever they can be had. These nuts are generally harvested by the Indians, who heat the cones until they rattle out, having been roasted in the process. Whether any of these species will reward the planter if brought into cultivation is a matter of the merest conjecture.

Little needs to be said of the miscellaneous nuts, native and imported, several of which are grown in a small way in different parts of the country. The general subject, however, is most interesting, and this bulletin is valuable for bringing together in a condensed form about all that is known of it at the present time. The truth is, that the sum total of our knowledge is now very slight indeed. Few fields offer greater attractions to the workers in our experi-

ment stations than this, and the time ought not to be far distant when nut-trees can be propagated with the same ease and rapidity as our ordinary orchard fruits.

Notes.

Egyptian onions are already seen in the wholesale markets, the first shipment of 250 crates having arrived a few days ago. The Havana product is about out of market, but nearly 30,000 crates came from Bermuda last week.

Pineapples, from Cuba, continue to come in limited quantities, about 5,000 barrels having reached this port during last week. The extremely high prices commanded by the earliest receipts of small lots of this fruit are broken in view of larger supplies. From eight to eighteen cents apiece is now the rate by the hundred. The first cargo shipments are expected by the middle of May, when the Bahamas will also contribute to the supply.

New potatoes are now coming from California, Louisiana, Florida, Cuba and Bermuda, and prices at wholesale range from \$6.00 to \$10.00 a barrel. The highest grade of sweet potatoes, from Vineland, costs \$5.00 in barrel lots. During last week 16,072 barrels of domestic potatoes were brought into this city, and since October 1st 1,091,516 barrels have been sold here, besides 5,986 sacks from Europe and 11,805 barrels from Bermuda.

The apple export season is now nearly ended, 154 barrels having been shipped from New York last week, while 267,319 barrels were forwarded to Europe from this port since September 1st. For home supply 4,622 barrels were received here during the six days ending with last Saturday, and since September 1st, 687,212 barrels. Choice Ben Davis apples now cost the retail buyer \$5.50 a barrel, Baldwins \$4.50, Roxbury Russets \$4.00, and Golden Russets \$3.50.

More than two hundred tons of cut Narcissus flowers are sent every year from the Scilly Islands to England. In addition to these, the bulbs raised here, which have excellent free-flowering qualities, constitute an important branch of trade. Mr. F. W. Burbidge states that in the crowded manufacturing centres of England these flowers and bulbs are as cheap as they are beautiful, and are largely bought by artisans, so that flower-farming in the Scilly Islands, at least, is not a business which depends for support on the luxurious rich, but one which brings freshness and beauty into the homes of the people.

The Spinach Leaf Miner is a small white maggot which tunnels through the leaves of Spinach, Beet and Pigweed, and it has been multiplying with such rapidity in the market-garden district of Long Island that the cultivation of Spinach will have to be abandoned unless it can be controlled. There seems to be no period of the year during which insecticides can be applied with success, and the only feasible plan of controlling it is to destroy all the Pigweed and plow old Spinach fields late in the fall and early in the spring. A bulletin has just been issued from the Geneva Experiment Station on the subject in which the insect is fully described and figured.

We have received a copy of the *American Florist Company's Directory*, a list of the florists, nurserymen and seedsmen in the United States and Canada, to which is added a list of the park superintendents and directors of botanical gardens and cemeteries. Besides this there is a comprehensive catalogue of the Chrysanthemums, Cannas, Roses and Carnations which have been introduced into cultivation in this country, together with the names of the introducers, the date of introduction and a brief description of each plant. A list of the officers of the most important horticultural societies in the country, with a brief history of other important associations in some way connected with the nursery, flower and seed trade, complete this compact and highly useful volume.

A bulletin of the Maine Experiment Station makes the following record of some of the comparatively new varieties of wrinkled Peas as tested last year. Station (Gregory), moderately vigorous grower, five to six peas in a pod, quality good, edible in from forty-five to fifty-five days from planting; Morning Star (Childs), growth rather less vigorous, five or six peas in a pod, quality excellent, edible in from forty-five to fifty-five days; Exonian (Thorburn & Co.), vines of medium height, but very slender, foliage noticeably light-colored, six peas to the pod, edible in from fifty to sixty days; Early Woodside (Smith), rather dwarf, six peas to the pod, quality good, edible in from sixty to seventy days; Echo (Burpee), moderately vigorous, seven peas to the pod, edible in from sixty-five to seventy-five

days; Nott's Excelsior (Maule), dwarf habit, about a foot high, five or six peas to the pod, maturing in from fifty to fifty-five days, an excellent pea.

The March issue of the *Bulletin de la Société Centrale Forestière de Belgique* contains an interesting note on a plantation of White Pine (*Pinus Strobus*) about two and a half acres in area, situated near the railway station of Gedinne, in the province of Namur. The trees, which have been planted twenty-five years, have already been thinned three times since 1888, the thinnings having been sold for six hundred francs, or in round numbers \$125. Two thousand two hundred trees are now standing, and their measurement shows that the plantation contains three hundred and fifty-four cubic metres of timber, equal to an annual growth of more than fourteen cubic metres over the whole area. It is stated that the White Pine is distinguished in Belgium by its rapid growth and hardiness, resisting the severest cold and the effects of late spring frosts, and growing, when mixed with other trees, more rapidly than any of its associates.

The eighth report of the Mississippi Experiment Station gives the results of a series of experiments with grasses and forage plants which have been conducted there now for eight years past for the purpose of ascertaining what plants will restore fertility to the soil most rapidly while giving fair returns in hay or pasture, which ones will make the best permanent meadow, which ones are most suitable for permanent pasture, especially for winter grazing, and which hay-producing plants are of the best temporary use. Five hundred and eighty-six species have been tested on different varieties of soil, the seeds having been sown under different conditions in all parts of the state. When this work was begun it is said that no hay was grown in Mississippi except that used for home consumption, and thousands of tons were brought into the state every year. The average yield per acre has since then been more than doubled, and in 1895 it was eighty-four per cent. above the average yield of the whole United States and 114 per cent. in excess of the average yield in the northern and central states of the Mississippi valley.

In the last number of *The Country Gentleman*, Mr. S. D. Willard, of Geneva, states that the extreme cold weather of January has proved very disastrous to the orchards in the great fruit region of western New York. Of Plums, the French Damson, which is grown in a limited way, is the only variety which is likely to give any crop at all. Such entire failure has never been known since the growing of plums became a recognized industry in this section, and it proves that the fruit cannot endure a temperature of twenty-two degrees below zero. The extremely dry autumn which left no moisture in the soil to supply the demands of evaporation may have aided in the injury, and yet the trees held their leaves very well and developed a good stand of fruit-buds and were in apparently good condition to withstand such winters as are usually experienced. With the exception of Hill's Chili, few varieties of Peach-trees show a single live bud. Sour Cherries will set an average crop, while of the sweet varieties Elkhorn and Windsor are in much the best condition. This last is a comparatively new variety which originated in Windsor, Ontario, and was disseminated by Ellwanger & Barry. It is of fine quality and beautiful appearance and its hardiness will give it additional value.

Andrew S. Fuller, widely known as a writer on subjects related to agriculture and horticulture, died suddenly of heart failure on Monday at his home in Ridgewood, New Jersey, in the sixty-eighth year of his age. Mr. Fuller was agricultural editor of the *New York Weekly Sun* for more than a quarter of a century, and at different times he had been connected with *The Rural New-Yorker*, *The Tribune*, *The Agriculturist* and *American Gardening*. He was the author of several popular books on arboriculture, small-fruit culture and the propagation of plants, and he had recently completed a treatise on nut-culture, which he considered his most important work. He was an authority in some branches of entomology, an enthusiastic student and experimenter in his chosen field, and was absorbed in his favorite occupations until the very hour of his death. He had gathered about him at Ridgewood a choice collection of trees, shrubs and herbaceous plants, which he grew with rare skill and distributed with unflinching liberality. His orchard of nut-bearing trees was especially interesting, and it is sad to think that the world will lose the benefit of Mr. Fuller's trained habits of observation as he watched the behavior of the numerous varieties he was testing and reported on the value of different modes of treating them.

Some Timely Lessons from the Forests of India.

INDIA has given to the world the most conspicuous example of a national forest policy adopted over a vast area. It is not, like Europe, a forest-producing country throughout, and while its tropical and subtropical climate differs widely from our own, we can pick out climatic parallels between portions of India and of the United States more readily than we can between the United States and Europe. India contains evergreen forests of great density and luxuriance, and large areas like our own great interior plain, where no natural forest growth can exist, and between these extremes we find every variety of condition in regard to water-supply, evaporation, etc., most of which can be repeated in our own country. Under the sway of the Mohammedans, which lasted 750 years, the forests of India were recklessly destroyed, chiefly by fire, to provide grazing ground for cattle, and under the British rule which followed vast areas of Government land were alienated, only a small portion of which was fit for agriculture, and as herds multiplied more forests were wiped out by fire. Meanwhile the large construction of railways and the increased demand for timber and fuel consumed the forests with incredible rapidity under the management of the lumber speculators and contractors, who had present profits in view, with no thought of the future. Americans need only look at home to see how forests can be devastated simply by clearing lands for cultivation, regardless of the future, and by unchecked logging and generally careless treatment. The analogy between the forest conditions and the forest abuses of the two countries is so clear that Mr. Berthold Ribbentrop, the present efficient Inspector-General of Forests in India, during a recent journey in the United States wrote for our instruction a brief statement of some of the salient features of the Indian forest policy. This paper is too long to publish entire in this journal, but we select a few points in the recent forest history of India which will, perhaps, be found specially instructive to American readers.

When the Indian Government began to find the timber fail for local public works it recognized at once the neces-

sity of a more conservative use of forest products, but it was years before the people of the country recognized the indirect value of forests upon agriculture and came to believe that no high degree of civilization can exist permanently without some systematic and adequate forest management. Our own country is now passing through this educational stage—that is, the people at large are only beginning to learn these truths. Just at this critical period the British Government secured the services of Mr. (now Sir Dietrich) Brandis, who recognized at once that conservative management could only be initiated by the Government, the greatest landlord of the empire, and that it was necessary to acquire and maintain possession of a large area of forest-land and secure legal and executive powers to protect it. This was an uphill struggle, largely because there were so many prescriptive rights to use the forest for various purposes. Without explaining the interesting legal complications involved, it is sufficient to say that Mr. Brandis preferred to make an early settlement with the holders of forest rights and take possession under a modified condition of possession rather than enter into long and uncertain legal controversies for a more complete ownership. Our own Government would meet with no such obstacles, for no one has rights of pasturage or rights to cut a given amount of timber on our national forest domain. What Mr. Brandis did then was simply to settle those rights—that is, to define and limit them and to prevent any increase of them in the future. Under these laws 80,000 square miles have up to date in India been formed into permanent forest reserves, in which the rights of the state and the adverse rights of the communities and private persons have been finally determined. Fifty thousand square miles more are in process of settlement, making 130,000 square miles in all.

As soon as it was resolved to protect the forest properties of the state and exploit them under direct Government supervision, a few officers were appointed with a staff of subordinates. These officers were generally selected from the military or medical staff, perhaps because they had some knowledge of botany or were considered specially fit for some other reason. A knowledge of technical forestry was not insisted upon then, and Mr. Brandis was the first to bring such knowledge to bear on the question. As soon as he was appointed Inspector-General he saw the need of technically trained assistants, and he at once took steps to organize a technical department, and brought over two trained German forest officers in 1866—Messrs. Schlich and Ribbentrop—both of whom have been his successors in office, and at the same time he made arrangements for the professional education of young Englishmen in France and Germany. Before these trained officers were available the staff was augmented by the appointment of young officers in India, who began their service in lower grades, and were promoted as they learned by experience. Later on, however, and especially since the establishment of the forest school at Cooper's Hill, every addition to the force has been a trained forester, except on one occasion, when a large number of officers were suddenly needed to take charge of new forests. The number of officers in the controlling grades now amount to two hundred, and they have the prospect of regular promotion and pension. In 1878 a forest school was also established in one of the north-western provinces at Dehra Dun, in which the education was at first superficial, but since 1887 it takes rank with the best institutions for educating a subordinate staff in any country of the world. The support of this school and the rest of the forest establishment costs four millions of rupees a year, and this expenditure must soon be largely increased, as the subordinate staff is now too small to keep pace with the ever-increasing work. On the other hand, the revenue has more than kept pace with the growth of the expenditure. The net average surplus for five successive five-year periods, beginning with 1867-8 and ending with 1891-2, is as follows: (1) 1,339,000 rupees; (2) 2,129,000 rupees; (3)

2,689,000 rupees; (4) 3,848,000 rupees; (5) 6,186,000 rupees; the cash surplus for the year 1891-2 being about seven and a half million rupees, with a tendency to grow, in the face of constantly increased expenditures for fire protection, constitution of reserves, amelioration of forest estates, surveys, working-plans, road-building and the like. In addition to this annually increasing direct income, the Government forests have yielded immense quantities of products to right-holders and other privileged persons. The annual value of this outside yield represents, at least, as much as the entire amount spent on the whole forest establishment. Besides this, the value of a well-ordered forest area to the country which lies below it can never be estimated. It is an interesting fact, however, that in one district in the Punjab, lying at the foot of a small mountain range, comprised of friable sandstone, the Government suffered an annual loss from land revenues alone amounting to 90,000 rupees a year, owing to the devastation of the fields which followed the destruction of the forests over a comparatively small mountain area. Losses like this are reduced every year since forest destruction has been arrested. Besides this, the forest improves steadily and the increase of its capital value is enormous, although it can be hardly expressed in figures. The sum of the matter is that, although in India ten million rupees are spent every year in administering the state forests, a liberal and growing surplus is realized from the annual growth of the produce, and besides this, large amounts are harvested by right-holders, the agricultural and climatic conditions of the country are substantially benefited, while the forest is not infringing upon either in area or immature stock, but is steadily growing in productive capacity.

We are certainly justified in taking heart and hope at what has been accomplished in India during thirty years, for there is no reason to doubt that the same thing can be done in America, where the Government still holds possession of large timber areas. President Gibbs, of the National Academy of Science, in his reply to the request of the Hon. Hoke Smith, Secretary of the Interior, who had asked that body to undertake an investigation of the subject of forestry in this country, has stated the points to be considered by the Commission as follows:

(1) The question of the ultimate ownership of the forests now belonging to the Government—that is, what portions of the forest on the public domain shall be allowed to pass either in part or entirely from Government control into private hands?

(2) How shall the Government forests be administered so that the inhabitants of the adjacent regions may draw their necessary forest supplies from them without affecting their permanency?

(3) What provision is possible and necessary to secure for the Government a continuous, intelligent and honest management of the forests of the public domain, including those in the reservations already made or which may be made in the future?

Most of these questions have received an actual and practical answer in the management of the Indian forests. It is admitted that the social conditions of the two countries are entirely different; but so are the climatic conditions of India and Europe, and yet Sir Dietrich Brandis and his successors have proved that the laws of forest growth are the same the world over, so that forests in India can be made to grow in productiveness and in value by adopting the same principles upon which the successful forestry of Europe has been founded. In the same way the broad principles of law upon which this forest policy has been built do not differ in different lands. Here, too, there must be a trained corps of foresters. Here, too, the Government, the only permanent possessor of the soil, must manage its own forests if there is to be any stable policy. Here, too, there must be an adjustment between local needs and the rights of the commonwealth. If once public opinion is educated up to adopting and enforcing such legislation as may be recommended by experts of recognized ability, we shall soon have legislation looking toward the selection of suitable tracts for conservative

forest treatment. If the Government will hold, protect and manage these national forests, disposing only of their annual increase, the time is not far distant when there will be a paying demand for these products, and when private forest owners will realize that it is to their interest to follow the example of the Government and place their forest property under similar control.

The Flora of the California Coast Range.—I.

THE Coast Range is the general name for the great mountain system which stretches along the coast from southern California to Puget Sound. It is not a continuous range, but a broken mass of parallel ridges from forty to seventy miles wide, with many other chains transverse to the general trend of the range, and enclosing numerous valleys, large and small, of widely different altitudes. Great streams rising in the Sierra cut through it here and there, while other streams rising in the range itself pour directly into the Pacific at various angles, and through the depressions where they flow fogs and wind pour in to modify greatly the local climates. At some points broad plains or low rolling hills lie next to the coast, and at others high mountains along the ocean shut out the wind and fog from the country behind them. San Francisco Bay exercises a marked influence on the climate of a large area, and all these factors tend to produce diversity of temperature and moisture in an apparently capricious way in places near together; in fact, no two places have the same climate and rainfall. In the Sierra Nevada the frostless belt lies at a certain altitude; in the Coast Range there is no warm belt, but isolated warm spots which depend on altitude, prevailing wind, fog and exposure. The result is that the climates here can only be ascertained by experience.

The rainfall is even more capricious than the temperature. In every rain there is a considerable difference in the precipitation between Ukiah and the Insane Asylum, three miles away across an open valley, being invariably less at the latter place. Little Lake, twenty miles from here, has a greater rainfall. Mendocino City, on the coast, has an annual rainfall of more than fifty inches, while seventy miles away, Colusa County, in the Sacramento Valley, has eight inches, and at points in Shasta County, at the head of the Sacramento Valley, the rainfall has been as great as 120 inches. The geological formation of the ranges and the character of soils constantly vary, and in the rougher sections they vary widely at very short intervals. Under such conditions the flora of the Coast Range cannot be other than interesting, and it is hardly probable that there is a more captivating field for the botanist in the world. Plants are much localized, and frequently found there out of their usual range. To the enthusiast in natural science the study of these endless variations and their causes is a source of constant pleasure.

Nowhere in the range is there greater variety than in the area comprised within Mendocino and Lake counties. Here we have a narrow table, or hill-slope, next the ocean originally covered with *Pinus muricata*, sand dunes and salt lagoons. A few miles back high table-lands lie between the deep-cut river channels, covered with a tangle of low shrubbery. Up the river cañons on the ocean side, and fringing the valleys, the great coniferous forest begins, and after a few miles the Redwood begins and stretches to the tops of the range which, at twenty miles from the sea, forms a barrier 2,000 feet high between the coast and the interior. This barrier range, diversified by masses of Douglas Spruce, Oak woods, thickets of Chemisal or mixed shrubs, open grassy slopes, tiny mountain meadows or wide enclosed valleys, and with small patches of Redwood in cañons or cool slopes on its landward side, is a most interesting field for the botanist. Midway of Mendocino County a prominent ridge crosses the mountain range, towering up from five thousand to six thousand feet above its lofty neighbors, snow-capped until summer, its lower slopes covered with forests of Yellow

Pine or Sugar Pine. This is the San Hedrin Mountain, while farther east Mount Hull, Snow Mountain and Mount St. John are higher still, each having a geology and flora peculiarly its own. Rising at the base of this range Eel River flows north-west to the ocean, while near by the Russian River flows to the south. The banks of the first are rugged and rich with conifers, while the basin of the latter is the home of a large and varied family of Oaks. East of the Russian River valley is another great barrier range, smooth and round topped, its higher slopes a vast even growth of brush, its lower slopes grassy and dotted with Oak woods, and its cañons treasure-houses to the lovers of trees and flowers. High on these shrub-covered mountains are little vales which are also mines for the flower lover.

Beyond these lies Clear Lake, thirty-five miles long, surrounded by high mountains, and although 1,300 feet above the level of the sea, it furnishes congenial homes for Orange groves. Further to the east another lofty Pine-covered range divides Clear Lake from the headwaters of the Sacramento and offers a region, half-alpine, rough and hard, yet of surpassing interest. I have been collecting in this wonderfully diversified region for sixteen years, and yet there are numberless fields that I have not explored, and every year I am reminded how little I really know of them. I shall try to convey some faint idea of the characteristic trees and flowers of some of these sections, always keeping in mind that twenty other such belts might be cut from the Coast Range, each quite as interesting to the naturalist and without any danger of monotony, while the whole series terminates at the north in that wild Olympic range between Puget Sound and the ocean, one of the most striking and least-known of our nation's possessions.

Ukiah, Calif.

Carl Purdy.

A Botanical Journey in Texas.—IV.

LEAVING Marfa very early the thirteenth day of June, we arrived in the afternoon of the same day at El Paso, one of the best-known cities of Texas, situated at the extreme western limit of the state. The city contains about twelve thousand inhabitants. It is the capital of a county of the same name, which covers eight thousand four hundred and sixty square miles. El Paso is near the one hundred and sixth meridian, near the thirty-second parallel, and the average annual rainfall for the last nine years is about ten and one-half inches.

Across the river, and nearly opposite El Paso, is the Mexican city, Ciudad Juarez, the two cities standing near the head of the "Pass," a nearly level valley extending many miles down the river, and probably an earlier lake-like expansion of it. Centuries ago the beauty of the Pass, and its adaptability to irrigated agriculture, led to the establishment of a Spanish colony and mission at Juarez, which is one of the oldest cities of America, and Baron Humboldt, who visited this locality early in our century, speaks in praise of the Pass, of the Mission, of the vineyards there and of the Mission grape.

The vicinity of El Paso is one of the principal seats in Texas of successful agriculture by irrigation. At the river rapids, about a mile above the city, low dams have been built letting the water of the river into the main ditches on each side of it for distribution to the fields of grain, vegetables and fruit. At this immediate point most of the farming is done on the Mexican side of the river. But on the American side, farther down the river, and near Ysleta, fields of Wheat, Barley, Corn and other grains are common. Alfalfa, the great forage plant of irrigated lands, is the commonest farm crop. Its growth on such fields is wonderful, three or four cuttings of it being made in a season. At Juarez are venerable Pear-trees, two or more feet in diameter, larger Apricot trees than I had seen before, vineyards, Apple orchards, and occasionally a Quince-tree, and this where cultivated trees, as well as cultivated smaller plants, live only by irrigation.

While in Mexico I visited the extensive orchards and vineyards of Dr. Alexander, a sturdy hospitable German of the old school, who bought his grange of a son of the priest who entertained Baron Humboldt in his home at the time of his visit to the Pass. The vineyards of Dr. Alexander contain about thirty thousand vines of the Mission Grape, which was probably introduced into this country by the Spaniards. Little is known of its origin or of its introduction to America. The fruit when ripe is dark purple in color, of fair size, well clustered and full of thick sweet juice, fermenting into a rich strong wine. Its leaves in general outline resemble those of the southern Muscadine, but they are larger and more deeply lobed, the larger leaves sometimes approaching in form those of our common Ampelopsis. The trunk readily takes a tree form and requires no trellis. The vine has simply adapted itself to the climatic conditions of the country to which it has been transferred, since no poles for trellising grow here. The grapes begin to ripen early in the month of August. September is the wine-making month. It is said that the wine would be better if the grapes remained on the vines until November. But for obvious reasons it is necessary to gather them much sooner.

On an average each vine yields an annual crop of ten pounds of grapes. The pure juice of fourteen pounds of grapes will afford a gallon of ripe wine. A glass of this wine kindly proffered by Dr. Alexander, although but ten years old, was well matured for its age, healthful, full of good cheer, and vivacious. Long experience has led my host to conclude that the Mission Grape is the only variety that is well adapted to the conditions of climate and soil which exist in the El Paso region, and that will afford at the least cost of production a good potable wine.

In the streets, yards and parks of El Paso I saw growing western Cottonwood, Silver Poplar, Lombardy Poplar, Willow Catalpa in handsome tree form, Barbadoes Flower Fence, or, as some people call it, Bird of Paradise Tree (*Cassipouia pulcherrima*); Jerusalem Thorn, Yellow Locust (*Robinia*), Silk Tree (*Albizia*), Mexican Elder (*Sambucus*), China Tree (*Melia*), Paradise Tree (*Ailanthus*), Wild China (*Sapindus*), Osage Orange (*Ioxylon*), English Ivy (*Hedera*), Virginia Creeper (*Ampelopsis*), Red Mulberry, *Morus*, and others. There are thousands of acres of land in this great valley now vacant, but capable, under irrigation, of becoming highly productive. Nature is doing all that is in her power to assist in redeeming and fitting the alkaline flats for agriculture. She is employing several *Hoffmannseggias*, some *Daleas*, a half-dozen species of *Atriplex*, three or four *Amaranths*, a species of *Lepidium*, *Suaedas*, *Bigelovias*, *Helianthi*, *Sesuvium*, *Trianthema*, coarse Grasses and Sedges and other plant laborers, to change and purify the soil by their living, and by their death and decay to add to its permanent fertility. The refuse-matter of the streets and stables should be utilized for the same purpose, and then the only great need would be a permanent supply of water for irrigation.

As it is now, irrigation at El Paso is far in advance of actual agriculture. Probably three times the amount of farm and garden products might be raised with little additional expense for water. But the river-bed itself is sometimes as dry and dusty as the unsprinkled streets of the city. Irrigation is yet in its infancy. A dam sufficiently strong to hold the accumulated floods of the Rio Grande and of other large rivers would involve an expense of millions of dollars and heavy damages for overflows, and could exist here only by international agreement. In time such structures might be worth far more than the cost of building them.

The general features of the flora around El Paso are somewhat peculiar. Species of the Pea family have decreased, while species of the much smaller Malva family have increased in numbers. Species of Composite, especially shrubby species, are very numerous. Crucifera hold their ground, species of *Lesquerella* being unusually abundant. Certainly two, perhaps three, species of *Agave* rep-

resent the Amaryllids. A *Dasylyrion*, several *Yuccas* and a few smaller species of other genera stand for the Lily family. Amaranths and Chenopods give character to the vegetation of the alkaline flats, while species of *Prosopis*, a *Baccharis* and "Cachamilla" Arrow-wood, *Pluchea borealis*, not a very good *Pluchea*, though as well in that genus as anywhere, attend them.

Wislizenia refracta, of the Caper family, was met here for the first time, and in the prime of its flowering. It is a plant of queer habit and of queer ways; sometimes spreading, it is usually erect and two to four feet tall. It bears its flowers in long terminal racemes. In fruiting the peduncles bend backward; hence the significance of the specific name of our plant.

Biscutella Wislizeni, a rather handsome Crucifer, grows in the damp sands of the "draws" of the mesas and in the mountain dells. This species, too, wears a peculiar habit which makes its recognition easy. It bears its rather large white flowers in pairs. They are succeeded by rounded pods, so as to appear, as its generic name signifies, like two little shields. It is the "Spectacled Plant" of Dr. Harvard's catalogue of the plants of southern and western Texas.

Martynia althæfolia is common in fertile places. This species produces rather large flowers, which are purplish on the outer and yellow-spotted on the inner side. The plant sometimes spreads over a square yard of ground. *Atriplex canescens*, which is common from the lower Rio Grande far northward, has not missed this locality. Several other species of that genus have settled here. *A. elegans* appears to be the beauty and the pet of the genus as seen around El Paso.

Helianthus ciliaris, the odd one of our species of that genus, is one of the chief groups of plant-workers that Nature is employing to remove alkali from the low bottoms of the river. It is a low-growing species, and it is kept too busily at work to enable it to take the time to make its flowers large and gaudy, nor is it able to hold its head as high or to dress in the style of its taller and more aristocratic relatives of the species of *Helianthus*.

This entire region abounds in rare and peculiar forms of plant-life. A botanist could well employ a year's time in the county of El Paso. I know of no other short ramble that a botanist or a tourist could take and see so much of living nature that should interest and instruct him as a half-day's walk from El Paso up the Santa Fé Railway by old Fort Bliss to the smelter and back along the other railway to the city, especially if the walker on his return leave the railway when about a half-mile from the city, taking the wagon-road over the hills. He could see *Acacias*, the curious Screw-bean, Arrow-wood, *Cassias*, Willow *Catalpa*, *Hymenoclea*, *Wislizenia*, *Biscutella*, *Daleas*, *Lepidium*, *Tribulus grandiflora*, *Martynia*, *Riddellia*, *Baileya*, *Janusia*, many handsome and strange Grasses, and many more extreme western Texas and Mexican species.

La Junta, Colo.

Plant Notes.

Magnolia stellata.

THE flowers of all our native *Magnolias* open after the leaves expand, and some of the Asiatic *Magnolias*, like the beautiful *M. hypoleuca*, belong to the same class. But there is another well-known group of species and hybrids which form their flower-buds completely during the summer, and these open early in the spring before the leaves appear, when their abundant large flowers always make them objects of popular interest. The best known of these is the Yulan *Magnolia*, *M. conspicua*, a large shrub, or often a symmetrical tree, twenty-five or thirty feet high, which bears large lily-like, pure white flowers. *M. Soulangeana* has the same habit as *M. conspicua*, but smaller white flowers, streaked with purple at the base, which open a few days later. This is a hybrid between *M. conspicua* and *M. obovata*, a large shrub, with flowers cream-white within and deep purple on the outside. In

its original form the latter plant is comparatively rare. *M. Lenné*, a widely spreading bush, somewhat resembles it. and it may be a hybrid between *M. obovata* and *M. conspicua*.

Magnolia stellata, which was introduced from Japan nearly thirty years ago by Dr. Hall, after whom it is often called *M. Halliana*, is now becoming quite common, and its general form is well shown in the illustration on page 195, although, for some reason, the flowers were not as abundant this year as usual. This specimen stands on the grounds of the late Mr. Francis Jenkins, of Jersey City Heights, and was planted some twenty-five years ago. It is twelve feet high and has a diameter equal to its height. The flowers usually appear a week before those of the Yulan *Magnolia*, although at the right of the illustration there can be seen a portion of a plant of *M. conspicua*, which the warm weather this year hurried into bloom with *M. stellata*. The flowers of this species are pure white, three or four inches in diameter, and they have not the somewhat disagreeable odor of the other early-flowering species, but are delicately fragrant. The petals are narrow, and they spread out into a star shape, which justifies the specific name. The plant has good foliage and is interesting at all seasons. Besides its other good qualities it is perfectly hardy; it begins to flower when it is hardly two feet high, and it will flourish in any ordinary garden soil. Like all other *Magnolias*, *M. stellata* should be transplanted in spring after the growth has started. If the fresh roots are bruised earlier than this they are liable to decay, but the wounds will heal over readily when the vital forces of the tree are active.

Cultural Department.

Culture of the Garden Bean.

IF we study the characteristics and growing habits of both the dwarf and tall growing or pole garden Beans, we shall find that while they are rapid growers and good feeders, with a root-system which can collect food from a drier and coarser soil than most garden plants will thrive in, they are not able to profit much from fresh and "unmatured" fertilizers, and will do best on soils which have been made rich by dressings applied during preceding years rather than the current one; also, that of the three elements of plant-food, nitrogen, phosphoric acid and potash, it is the last two which the Bean plant seems to find it most difficult to collect in sufficient quantities, so that application of these two elements, in such form and so mixed with the soil that the roots can readily take them in, is most likely to increase the yield and improve the quality of this crop. We shall also find that the plants are very susceptible to injury from an oversupply of water, particularly at the root, and a well-drained soil is essential to even a fair growth. Lastly, while the plants seem vigorous and are rapid growers under favorable conditions, there are few of our garden plants which are so easily discouraged and succumb so quickly to unfavorable conditions, or to any injury, particularly if it be to the root. The plant seems to lack recuperative power, and a mutilation of the root, which would be little more than a stimulant to Corn, Cabbage or Lettuce, will stunt or even kill a Bean plant.

If we keep in mind these characteristics of the plant we will be able to cultivate it more intelligently and with greater success. We should plant our Beans in the driest and warmest part of our garden. As early as possible in the spring the Bean plat should be thoroughly spaded and fined to the full depth of fertile soil; and unless it is already very rich, we should apply (after the spading) a liberal dressing of well-rotted manure, or a dressing of from four to twelve pounds of fine ground bone, and one peck to one bushel of wood ashes to the square rod. Care should be taken to spread the fertilizer evenly, and to work it well into the surface soil. A week or ten days later work the ground over again and repeat this deep and thorough cultivation every week or ten days until after the seed is planted and the first true leaves have appeared. After this the soil should be stirred or tramped on as little as possible, though any starting weeds should be destroyed by raking or shallow hoeing which merely cuts the surface. The secret of a good bean crop, either in the garden or field, as far as cultivation is concerned,

is to put the soil into the finest possible tilth before the seed is planted, thus avoiding the injury to the plant which would inevitably result from stirring the soil after it is filled with roots. The labor spent in preparing the soil for the crop is

and early sorts, like the Mohawk and Black-eyed Wax, quite early, but the bulk of the crop should not be put in until the ground is warm and settled warm and dry weather may be expected. Just after the fall of the early apple-blossoms is

Fig. 31.—*Magnolia stellata* in a New Jersey Garden.—See page 194.

not wasted, for if it is well done there will be no need of later cultivation, and surely it is easier and cheaper to do all necessary cultivation before planting than after.

In garden culture it may be well to plant a few of the hardier

usually the best time to plant Beans. As the seed is usually of good vitality and so large as to be little liable to loss we should use only a few more seeds than we expect plants. A poor yield and a poorer quality is often the outcome of overseeding

and consequent crowding. If the dwarf sorts are planted in drills a plant once in four to eight inches, or two once in about sixteen inches, are enough, and more than three to five plants should never be left in a hill. It is well to sow somewhat thicker than this and thin out as needed when the plants have formed the first true leaves.

The tall-growing varieties need some support, and we have found that they "take to" an inclined much better than to a vertical pole, hence our plan is as follows: We plant the seed in hills twenty to thirty inches apart in rows running north and south, and drive a six to eight foot pole slanting at an angle of about twenty-three degrees to the north; on the south side of each hill we saw off the tops to a line and connect them with cords. The plants will climb these poles much better than if vertical, and the pods hanging free are more easily gathered, while the vines festooned over the cords at the top are very beautiful. As soon as the plants are well up all necessary thinning, and in case of the tall varieties poling, should be done, and the ground be deeply and thoroughly cultivated; after which care should be taken not to compact it by tramping any more than absolutely necessary. In clean ground most of the weeds will have been started and killed by the early cultivation, but if any appear they should be destroyed while small by raking or hoeing.

Detroit, Mich.

Will W. Tracy.

Flowers of the Season.

IT might be added to the recent note on *Tulipa sylvestris* that this is an excellent species to naturalize in the grass or wild places, owing not only to its vigor, but also to its peculiar root-action, which conducts the young bulbs away from the flowering place of the parent. Owing to this habit this Tulip spreads satisfactorily and continues in vigorous condition since it occupies new ground. Of course, it is necessary to plant in good open soil. Good forms of *T. sylvestris* are of a rich deep yellow, very fragrant and of a charming habit, the stems being slightly pendulous at first and only carrying the flower perfectly upright as it matures. *T. sylvestris* seems to be widely distributed, and it varies very much in size, though the smaller varieties may enlarge under good treatment. The best form in my garden is an Italian one from Dammann. The flowers are not much pointed and have green markings on the outer petals; they are of large size, quite in contrast with some recently collected ones which are not much larger than a Snowdrop.

Thanks to Holland, one can buy a beautiful display of color for very little money now, and the mixed Tulips of the catalogues should satisfy any owner of a garden not given to fads. However, a nice clump of some special variety or species is always satisfactory. If only one were to be chosen I would prefer *Tulipa Greigi*, which is the most brilliant in coloring, of fine form, and has handsomely variegated leaves. These are now becoming reasonable in price. Gesner Tulips pale before these, but are very satisfactory. I planted over my Tulips last fall some young plants of *Arabis alpina*, which covered up the bare earth, and the combination of the small white flowers under the Tulips was rather effective.

The Poppies have commenced to flower this week, led by *Papaver alpinum*, which seems less generally grown than *P. nudicaule* (the Iceland Poppy), one of its near relatives. The type has finely divided glaucous leaves, but does not differ in form of flower. There are yellow, white and red varieties, and some specially dainty ones which show just a suffusion of coloring in the white. These plants are perfectly hardy if their crowns are kept above the wet ground. It is better to sow seeds each spring. Seeds sown now will produce good flowering plants in late summer, and a majority of them will winter over safely the first year, at least, and be a delight at this time. The seedlings are not at all difficult to transplant if their long roots are borne in mind.

This is also the time of the Primroses, of which one never has too many. The modern strains of hybrid Primroses, of which Dean's is the best, are perfectly hardy and endure our warm summers, yet such is the uncertainty of the climate that last winter left me scarcely a plant alive. However, this may not happen again in another decade, and a new stock is easily grown from seed. This is a good time to start them, when their beauty is most persuasive. *Primula cortusoides* has wintered perfectly, the creeping rhizomes being frost-proof and the plants deciduous. They are graceful in flowering habit, but their reddish purple color is not pleasing.

Every one knows the big Crown Imperials, but I fear few know the beauty of the dwarf Fritillaries, many of which are now in flower. There is an endless variety of these plants, but one should commence with *F. Meleagris*, or Snake's-head

Fritillary, which has large pendulous flowers, white or brown or reddish, the latter curiously checkered. The Dog-tooth Violet, too, is generally known, though its beauty is not fully appreciated. The California forms are, perhaps, not more beautiful than those of the east, but they differ in effect and are well worth attention. They do well with me in a moist border in a very stiff soil. There has been a small procession of rhizomatous Irises in flower, and their numbers are daily increasing. They seem to come in about the following order: *I. rubro-marginata*, very dwarf; *I. Chamæiris*, yellow; *I. Olbiensis*, dark purple; *I. lutescens*, light lemon; *I. Statellæ*, creamy white; *I. pumila*, purple, and variety *alba*.

These flowers are all now in bloom, and they are not rare, expensive or difficult to secure.

Elizabeth, N. J.

J. N. Gerard.

Notes from Baden-Baden.

FRITILLARIA LATIFOLIA, var. *nobilis*, is a dwarf plant only three to five inches high, but the deep vinous-red bells are as big as a small hen's egg, and these enlarge under cultivation. A very pretty species is *F. alpina*; its small widening bells are of a chocolate color, having a bright deep yellow ring, making it very handsome.

Muscari azureum Freynianum is the largest form of *azureum*. It is very early and flowers here early in March, when its turquoise-blue spikelets make it very showy. *M. elegans*, newly introduced, has comparatively narrow and rather long spikes in shades of bright blue, with a tinge of violet. *M. Szovitsianum subcaeruleum* is very striking, the pale sky-blue spikes giving it particular beauty. *M. polyanthum*, which I have introduced from Asia Minor, is somewhat late, but is, perhaps, the most showy of all. From four to six spikes come from one bulb, and these are very large, of a bright, deep and pure blue which at once attracts attention.

Iris Assyriaca is new and a showy species. It is a Juno of the Caucasus stamp, with ample foliage, and the flowers, of a milky white, or sometimes with a shade of blue, are produced in numbers all along the stem. From five to seven are open at once, and they last for three weeks.

Baden-Baden.

Max Leichtlin.

Canna Notes.

TO thoroughly prove the capabilities of a Canna the necessary conditions must be provided. These are good soil, with cow-manure added, an abundance of water and plenty of space. Two wheelbarrow-loads of cow-manure are often allowed for a single bulb. One load should be spread on the top of the bed and the soil forked out, and another dumped in the excavation. The well-mixed soil should then be thrown back and the bed neatly finished for low-growing marginal plants. A pail of water in the morning and liberal spraying with the hose at night is advisable.

The season of 1895 added two more Cannas to our tested list. Antoine Chantin (Farquhar) proved highly satisfactory. Its habit is graceful, with abundant foliage of a light but vivid shade of green, which contrasts charmingly with the flowers. I know of no other Canna which produces so many blossoms to a flower-stalk. I have counted from six to ten lateral clusters on a single stalk, seven or eight of them in bloom at one time. The color is pleasing and true to the description given—cherry-salmon.

Geoffrey St. Hilaire was less satisfactory. It is a good strong grower, but stiff in outline, and the leaves are not so purple or chocolate-colored as we are led to suppose. The flowers are said to be deep orange or capucine-red. The shade of red is far from agreeable and out of all harmony with the foliage. Dark-leaved Cannas should never be planted near a highway if the hose is to be used, as dust from every passing vehicle settles and sticks remorselessly upon the wet leaves.

Pittsford Mills, Vt.

G. A. Woolson.

The Lily Garden.

THE Lily borders on my ground are now offering the best evidence that the failures so often noted are caused by carelessness or by want of knowledge of the requirements of these plants. For many years I have advocated the practice of mulching Lilies deep enough to keep the frost entirely away from their bulbs, since careful experiments have made it evident to me that their hardiness is generally overestimated. It is frost, as I believe, which causes entire failure of many of the more beautiful sorts and seriously injures the most hardy ones.

In my experiments I have found it almost impossible to decide as to the method of planting which affords the greatest

satisfaction; whether in the mixed border, in groups, in beds with each variety kept separate, or in beds with all the species mixed without the slightest regard to class or order. For the past three years in our private garden we have adopted the latter plan, and in this way we have a Lily bed in which there are flowers from early in June until September.

Frost in winter and drought in summer are alike fatal in their results. All Lilies seem to like a loose moist soil which is well drained. Two of our native species, *Lilium Canadense* and *L. superbum*, grow freely in wet marshes or swampy grounds, their native habitat, but they both succeed better when planted in dry ground if properly mulched in summer, so that the soil is always moist and cool, and the same conditions best suit all other Lilies.

Our beds have been planted three years, the bulbs being placed singly about eighteen inches apart each way. They are a mass of strong-growing healthy plants; not a single variety has dropped out, and in many instances where but a single bulb was planted there is now a clump of six, notwithstanding that each spring all the small bulbs that form at the base of the stems the year previous have been removed. This plan should always be practiced, not only to increase stock, but to give the old bulbs all the plant-food within reach. The beds are covered about the first of December with coarse litter from the stable; we prefer that from the horse and cow stables mixed. This is put on to the depth of three inches, the paths between the beds being also covered to prevent the frost from working its way down from the outer edges to the bulbs. This has proved ample protection, and during the last six years the frost has never reached a bulb. *L. auratum*, which is generally considered a difficult subject to manage, has averaged three stems from a single bulb. Some of these are now (May 6th) two feet high and nearly three-fourths of an inch in diameter. Plants of *L. monadelphum*, which are quite as difficult to manage, are proportionately strong; *L. Hansonii*, which is provokingly slow to propagate, has this year nearly doubled in numbers, each stem being equally as strong as the single stems of last year. The delicate little *Lilium tenuifolium* and its nearly related *L. Chalcedonicum* are proportionately strong. Many of the latter will bear fifteen to twenty flowers on a single stem this year. Immense is the only word that fitly describes plants of *L. speciosum*. Last year we had forty flowers on a single stem, and this year we hope for what we have been trying for years to obtain—fifty flowers from a single spike. This is not from the *Monstrosum* section, a class we do not grow, leaving those for tastes that crave unnatural forms.

Lilium Brownii and *L. Colchesterii* produce flowers that for the brief period of their existence are equal to the best Lilies, and their near relatives, *L. longiflorum* and *L. eximium*, which are not reliably hardy, if the beds are only mulched so as to exclude all frost will thrive with as much vigor as *L. tigrinum*, which nothing can kill.

On the 10th of April we raked off the coarsest of the mulch, leaving the remainder, which is so fine as not to obstruct free growth of the more delicate kinds. As this is carried into the soil by the rains, we shall add more, using only that which is well rotted and fine. This is the only cultivation given, and all that seems required. We find the less we stir the earth the better, as the whole surface of the bed is a mass of fine roots, and anything which disturbs them injures the plants, not only for this year's production of flowers, but for the development of the bulbs, upon which future success depends.

Floral Park, N. Y.

C. L. Allen.

Saxifraga crassifolia.—This is one of the best of earliest-flowering hardy plants. The leaves are from six to eight inches long by four wide and obovate in outline. The flower-stalks rise directly from the root-stock, and the flowers, which are of a deep pink color, are borne on a thyrsoid panicle. This plant is used largely for spring bedding in England, and when set among blue and white Dutch Hyacinths the effect is very good. The large leaves of the *Saxifraga* give furniture to the beds and help to keep the soil cool and moist, thereby prolonging the flowering season of the Hyacinths. As this *Saxifraga* is quite hardy it may be used effectively for the same purpose here. It is easily propagated by division of the root, or by seed, which should be sown in the greenhouse early in February, and the seedlings grown on all summer for planting in the beds in the fall. We have another *Saxifraga* here which I have always known as *S. cordifolia*. The leaves are somewhat larger and heart-shaped, and come into flower about ten days later than *S. crassifolia*. According to *Index Keuensis* these two species are now considered identical, though they appear to be sufficiently unlike, horticulturally at least, to be distinguished by different names. Both are natives of Siberia.

Menyanthes trifoliata.—This pretty subaquatic or bog plant is now in flower, April 29th, on the edge of an ornamental pond in this garden. The stems are prostrate and the leaves trifoliate, with sheathing petioles. The flowers are borne on erect spikes from nine to twelve inches long. The individual flowers are white, with beautifully fringed petals, and are about half an inch in diameter. It belongs to the Gentian family, and is commonly called the Buckbean.

Stylophorum diphyllum.—This plant may well be considered as a standard herbaceous plant. It is one of the earliest to flower, and continues on well into the summer. The fistulate stems rise above the foliage, and the flowers are borne in an umbel at the summit. They are bright yellow, about two inches in diameter. Most of the leaves are radical, pinnatifid, and about one foot long. The stems have two opposite leaves just below the flowers, from which the specific name is given. It is easily propagated either by seed or division of the root.

Botanic Garden, Northampton, Mass.

Edward J. Canning.

Pampas Grass.—Last spring we raised some plants of *Pampas Grass* from seed, about a dozen in all. As soon as they could be handled they were put into thumb pots and then into three-inch size, and subsequently planted out along with other grasses. In the fall they were lifted and divided up into as small pieces as possible, put in three-inch pots, kept in a cool house and potted on and divided again, until now there are about a hundred nice healthy plants in four and five inch pots. They make their thick succulent roots so rapidly that it is surprising how soon they fill the pots. In this section of the country the plants occasionally get winter-killed if left unprotected. A good way to protect old plants is to place over the crowns old cement barrels with the ends knocked out and fill them up with dry leaves. This protection will carry them safely through very severe winters.

Viola pedata.—The Birdfoot Violet is probably the showiest of our many beautiful native Violets, and the ease with which it is cultivated should make it quite a favorite among spring-flowering plants. The plants succeed well in soil just the opposite to that in which they grow in their native haunts. In this locality *Viola pedata* is found principally in sandy vegetable mold, but in a border of heavy wet loam in which I put several plants three or four years ago, it thrives and flowers well. Of the three distinct forms which I have met in a wild state the commonest is the variety *Bicolor*, with the two upper petals very dark purple, the under ones pale lavender; this variety is especially showy. The monocolored form has the petals much the same color as the under petals of *Bicolor*. The third form is by no means common; the colors are rather startling, the two upper petals being dark, as in *Bicolor*, with the lower ones pure white. This is a shy bloomer and does poorly under cultivation. In a fully exposed part of the rock-garden here several pockets are given up to their cultivation. The soil provided is the same as that in which they grow naturally. Every year young plants come up thickly from self-sown seed. These are weeded out, as the old plants remain quite vigorous year after year. On the approach of hot weather the plants are given a top-dressing of leaf-mold annually, and for two or three weeks the display of bloom is gay.

Botanic Garden, Washington, D. C.

G. W. O.

Tussilago Farfara.—This imported weed, commonly called Coltsfoot, has given me much satisfaction as an ornamental plant since it possesses much beauty and fills an important place in the flower garden. Some years ago I planted several of these plants upon an embankment of red clay, sand and muck on the north side of one of the wings of the house, where it was exposed to the direct sunshine only in the afternoon. The plants speedily clothed the embankment, densely covering it with large tropical-looking foliage all summer long, while in March or April, before a leaf appears, it sends up many scaly stems five to eight inches long, bearing handsome rich yellow heads of flowers nearly an inch across, but fully open only in the sunshine. Besides, it endures our severest droughts and looks flourishing and healthy all summer long. It should, however, receive some protection in winter, as every part of the prostrate rhizomes, or root-stems, left uncovered is sure to be killed if exposed to the freezing and thawing of our changing winter, and this will be sure to destroy many of the curious flower-buds which form in autumn. All the parts covered, however, will be sure to live. The flowers are really pretty, but its foliage is its chief beauty. The leaves rise on long (eight or ten inches), thick purple stems, and attached directly to the creeping rhizome, or root-stalk, and are at first covered by a dainty covering of wool, which soon dis-

appears, and the leaves become of a beautiful rich shining green, with purple veins, round and broad, heart-shaped, angular, their greatest breadth equaling their length—that is, from six to eleven inches where broadest. I know of no low-growing plant that produces such a rich mass of large tropical-looking foliage. I heartily recommend this plant for densely covering embankments, slopes, stream or lake borders, where the soil contains clay, sand and muck or rich loam. But it should exclusively occupy the ground where planted, as it will crowd everything else out.

Correspondence.

The California Frosts.

To the Editor of GARDEN AND FOREST :

Sir,—The mean temperature of February was five degrees above the normal, while the mean temperature of April has been five degrees below normal. We have had very severe frosts in nearly all parts of the state, and, of course, vineyards, orchards and gardens have suffered. It will be impossible to determine the exact extent of the loss for a fortnight or more, but the best authorities think that the cherry crop of the state is lessened one-half. Almonds and Apricots also have suffered severely. Contracts are being made for wine grapes, delivered in autumn, at something like three times the price offered a month ago.

I lately visited the Sacramento Valley. At Chico I found that the crop of the famous Bidwell orchards was practically destroyed, excepting peaches, half a crop, and apples. Even the vegetable gardens in this district have suffered so severely that in some cases replanting several times over became necessary. One orchard of two hundred acres of large Almond-trees will not produce enough this year to pay for picking.

The spring frosts have not yet seriously injured the Citrus fruits, so far as I can learn; it is the deciduous fruits which have suffered most. Prunes have escaped fairly well in many cases; some districts will have a very light crop, and much fruit may yet fall from the trees. There is hope, of course, that higher prices may be the result, and so the net yield of many orchards will be kept up to the average, but the fruit-growers feel discouraged over the outlook.

The truth is, that California, like all other places, has fluctuating seasons, and if we plant immense areas in fruits, often without any scientific study of the locality in question, we must, of course, learn by experience. There are all kinds of climates here, some of them adapted to a wide range of vegetation. The chief characteristics of the climate of the leading horticultural districts are dryness of atmosphere and coolness of the nights.

The southern states excel California in raising sweet potatoes, melons, cotton and many other crops which require a moist, warm atmosphere. Cassava, sugar-cane and rice do not thrive as well in any part of California, so far as tested, as in the warmer coast regions of the southern states. Occasionally enthusiastic Californians attempt to introduce Cinchona into cultivation, or Coffee, Vanilla, the Cocoa Palm or Pineapples, but without success. Even our mildest and most perfect climates are fortunately far removed from the *tierra caliente* type. Every part of California is subject to the influence of our great mountain ranges. In ten thousand valleys and sheltered nooks up and down the Coast Range, or along the giant Sierras, vineyards and orchards are and will be planted in spite of occasional trying seasons which determine unfit locations, and readjust the industry to actual climatic conditions. New orchards will be more wisely planted; unprofitable orchards will be grafted over, or will give place to other crops. Different districts will settle down to the production of whatever fruit they can best produce, and we shall no longer hear, as now, of hundred-acre orchards of Apples, Peaches, Prunes, Cherries, Almonds or Walnuts, planted where the Apple, Peach, Prune, Cherry, or whatever else it may happen to be, is foreordained to be an uncertain crop. There is enough suitable land in California for all these industries, but it necessarily takes a good many years to trace out the minor isotherms.

Niles, Calif.

Charles H. Shinn.

The Evonymus Scale in Japan.

To the Editor of GARDEN AND FOREST :

Sir,—In the Report of the Department of Agriculture for 1880, Professor Comstock described *Chionaspis evonymi*, which had destroyed nearly all the shrubs of *Evonymus latifolia* at Norfolk, Virginia. At that time it was supposed to

occur also on Orange, but this proved to be an error, the species on the Orange being distinct. More recently the *Evonymus* scale has appeared on cultivated *Evonymus* in Europe, and in Italy economic entomologists have been at some pains to devise methods for its destruction.

Mr. Craw now sends me some twigs of the Japanese *Evonymus* on which are numbers of the same scale, mixed with a few *Aspidiotus rapax*. The plants arrived from Japan, and were destroyed by Mr. Craw in his capacity of horticultural quarantine officer. The occurrence is of peculiar interest, as showing the probability that Japan is the true home of this destructive scale.

While writing I may mention that Mr. Craw also sent a leaf of *Aspidistra* on which were many *Aspidiotus ficus*. It was from Osaka, Japan; 850 plants were destroyed. This insect is well known in America also, but it is a matter of special interest to note that very many of these scales from Japan show from one to three parasite holes, indicating that *A. ficus* has an important parasite in that country which it might be well to introduce here.

Agric'l Experiment Station, New Mexico.

T. D. A. Cockerell.

Notes from West Virginia.

To the Editor of GARDEN AND FOREST :

Sir,—On the landscape-gardener devolves the delightful task of helping Nature to make beautiful pictures of our homes. Here, in amateurish fashion, we try to imitate his work and devise harmonious effects each year.

By the front piazza is a group now in luxuriant bloom, consisting of the pink and white varieties of the double-flowering Almond, with clumps of *Mertensia Virginica* from a neighboring pasture-field, hiding the stems of the shrubs which are apt to be bare and unsightly. The lovely shades of pink and clear blue are relieved by the pure white of the Snowy Almond, and there are no high colors near to mar the effect. But the salient features of the garden now, on this second day of May, are the large-flowering Dogwoods, mingled with Red-buds, against a dark background of Cedar; the groups of flowering Apples and Cherries, and the beautiful mass of *Exochordas* and *Xanthoceros* in a prominent position on a little knoll. All this conspicuous bloom, together with many handsome red and white Japan Quinces and white *Spiræas* and a few white and purple *Magnolias*, is making the grove a lovely wilderness of flowers.

The rock-garden is very fascinating and has taught me many lessons of late. I have learned that *Alyssum saxatile*, *Santolina* and some other herbaceous perennials disappear in winter in a stiff clay soil, and that *Hellebores* cannot resist our hot, dry summers without plenty of watering. I have had reluctantly to give up the whole charming *Heath* family, with its beautiful *Andromedas*, *Kalmias*, *Rhododendrons* and *Azaleas*. They refuse to be happy in our most carefully prepared beds of peat and rich mealy loam. Our dry summers wither them, our winter suns scorch them, and they pine and dwindle and disappear. Only one member of the family remains with us, and that without special care. This is the fragrant *Clethra alnifolia*. I used to think I could, by constant care, keep *Rhododendrons* in comfortable health. They did not increase much in size, but they bloomed for me as long as they lived, though that was not a long period, and constant renewals were necessary to keep their border presentable. Now the last lingerer has vanished from Rose Brake, and they are among our extinct species.

But if *Rhododendrons* despise our stiff clay soil, *Roses* revel in it, and *Pæonies* thrive amazingly on the strong food we give them, and a multitude of beautiful plants are hurrying forward to fill up the vacancies in the shrubberies. Nature will not grow everything everywhere, and that is just the reason that each locality has its own distinctive charm.

Shepherdstown, W. Va.

Danske Dandridge.

Maple Sugar in Vermont.

To the Editor of GARDEN AND FOREST :

Sir,—The maple-sugar season of 1896 in Vermont began under difficulties. In many cases the weather made pleasant promises early in the season, which it failed to keep. Nearly all sugar-makers tapped their trees during the first week in April, and some as early as March 25th. But the cold, raw winds of succeeding days greatly interfered with the sap-flow. Later, however, the weather turned warmer; and for a week or two sugar-makers had all the sap they could handle. Some who have large sugar-orchards were forced to work nights as well as days. The season, as a whole, was much shorter than

usual, the bulk of the sugar having been made up within ten days. By April 15th most makers had finished, and by the 20th all were through.

The crop is probably below the average in quantity, but is said to be considerably above the average in quality. Constant improvement in methods and facilities of manufacture of itself tends to raise the quality of the product year by year. The use of improved evaporators gives cleaner and lighter-colored sugar than could be made in the old-style kettles; and the prejudice against the lighter-colored article is rapidly disappearing. It is probable that, without reference to this year's crop, the quantity of maple sugar made in Vermont is on the increase. The increase comes both from the working of a larger number of trees and from better methods of manufacture.

The prices realized for sugar and syrup vary greatly in different parts of the state and at different seasons. Some of the first sugar put on the market brought the makers sixteen to seventeen cents a pound, while a great deal was sold in the country markets at seven to ten cents. Probably the bulk of the crop sold up to date brought the makers ten to twelve cents. Syrup sold generally at from sixty to ninety cents a gallon, though many makers put their best product up in one-gallon cans and sold on private markets at \$1.00 a gallon.

The Vermont farmer feels that his sugar orchard is one of his best pieces of property. It has been estimated that such property pays an annual dividend of ten to twelve per cent. on the investment. Whereas a few years ago there was quite a tendency to cut Maple-trees and clear away the sugar orchards, the present feeling is rather to encourage the extension of the maple-sugar industry. Vermont is proud of the high standing which her maple sugar has achieved in the market, and she gives hearty support to the laws which enable her to give constant assurance that the standard will be maintained.

Last year's run of sugar was also somewhat below the average, which is probably about 15,000,000 pounds, not counting syrup. This is greater than the output of any other state in the Union.

There are a great many Red Maples throughout the state which are sometimes tapped without distinction between them and the true Sugar Maples. Some makers are really unable to distinguish the two species. Others consider both equally available as sugar producers. Still another faction consider the sugar of the Red Maples inferior and do not tap the trees, though they may be thickly intermixed with the true Sugar Maples which are being tapped. The preponderance of opinion seems to be against admitting the Red Maple to a full equality with the Sugar Maple as a sugar producer.

Trees and Shrubs in Flower at Germantown.

To the Editor of GARDEN AND FOREST:

Sir,—I am writing on the 8th of May, and trees and shrubs are much farther advanced than usual at this date. The first Pear-blossoms rarely open before the 5th of May. Now the petals have all fallen and the fruit is quite perceptible. The various varieties of the common Lilac, *Syringa vulgaris*, are now at their best, but this is little in advance of their usual season. The plant here that most deserves special mention, however, is *Ungnadia speciosa*, the Spanish Buckeye, which is now flowering here, and perhaps it has never flowered out-of-doors before so far north as this. Our plant came from Texas some ten years ago, and it has been killed almost to the ground every year, although it started up again vigorously each spring. For some reason it went through last winter without any protection, and is now flowering finely. The rose-colored flowers are large and handsome, opening in pairs, with two or three pairs clustered together. Unlike other Buckeyes, its leaves are pinnate, and the young shoots remind one of the Walnut as they burst forth. It becomes a tree of considerable size in some parts of Texas, and, no doubt, with some protection it could be made to flower in this latitude every year. Other trees and shrubs in flower which attract attention now are the Paulownias, the beautiful *Magnolia Fraseri*, the Silver-bell Tree, some of the Thorns, our native Crab, the Flowering Dogwood and its varieties, *Viburnum Lantana*, *Xanthoceras*, the rare *Neviusia* from Alabama, *Exochorda*, sometimes called the Pearl Bush, a near relative of the *Spiræas*; *Rhodotypos*, *Kerria*, *Spiræa Thunbergii*, which is almost past its best; *S. prunifolia* and *S. Van Houttei*, which is just in flower; the Tartarian Honeysuckle and some of the early-flowering Tamarisks and the hardy Azaleas. The list, however, could be made twice as long.

Hand-list of Coniferæ grown in the Royal Gardens at Kew.

—Students and cultivators of coniferous trees will find this hand-book a helpful guide to the plants cultivated in the Royal Gardens, and a useful key to the synonymy and geographical distribution of the species of this most important order. Two hundred and twenty-seven species, with 340 varieties, belonging to thirty-seven genera, are enumerated. In the preface, which was prepared by Sir Joseph Hooker, who for more than half a century has devoted special attention to the study of these plants, we learn something of the increase of knowledge with regard to them. Of the *Abietinæ*, Linnaeus, in 1753, knew but ten species, all of which were included under his genus *Pinus*. In 1789, when the first edition of Aiton's *Hortus Kewensis* appeared, the number of known species had increased to nineteen; in 1841 the number had increased to fifty-two, and in 1866, when Parlato published his classical monograph of the *Coniferæ* in De Candolle's *Prodromus*, one hundred and sixty-two species of *Abietinæ* are described.

Among some of the interesting plants in the old Kew Pinetum is a specimen of *Ginkgo biloba*, introduced in 1754, and originally trained against a wall like a fruit-tree. The *Deodar*, *Cedrus Deodara*, was introduced in 1831. It has not proved satisfactory at Kew, and has disappointed the expectations formed of it, while the Mount Atlas Cedar, *Cedrus Atlantica*, grows with great rapidity. One of the most conspicuous trees in the garden is a specimen of *Pinus Laricio*, planted in 1825 and still in good condition.

The value and interest of the Kew collection of conifers is greatly increased by the facilities afforded by the temperate house for growing to a large size representatives of genera which are not hardy in the English climate, like the *Araucarias*, the New Zealand, Malayan and New Caledonian species of *Agathis*, a genus related to *Cunninghamia* and *Araucaria*, and the Tasmanian *Arthrotaxis*, *Tetraclinis*, *Callitris* and *Actinostrobus*, *Widringtonia Whitei*, the Milanji Cypress, from the mountains of eastern equatorial Africa, an interesting timber-tree probably of great economic value, the *Fitzroyas* of Tasmania and Patagonia, and several others.

Some idea of the richness of the Kew collection in hardy conifers will appear in the fact that twenty-six varieties of the common *Picea excelsa*, or Norway Spruce, are cultivated, while of the ordinary Yew no less than thirty-seven garden varieties are enumerated. The arrangement of the genera and the names and synonymy are those now generally adopted by Dr. Masters, the learned editor of *The Gardeners' Chronicle* and the English authority on conifers.

The value of the *Hand-list*, which is sold in the Royal Gardens for threepence, is very greatly increased by a full index of the names and synonyms of all the plants which it enumerates.

Notes.

Professor William Saunders, Director of the Experimental Farm in Ottawa, has received the degree of Doctor of Laws from Queen's University for work done in advancing agricultural science and for work of a similar character in connection with the Royal Society.

Now is the time for beginning work against the Elm beetle, and all persons who have any responsibility for trees in public grounds or private places should prepare at once for an active campaign. The Town Improvement Association of Plainfield, New Jersey, did a timely thing last week by inviting Mr. Southwick, Entomologist of the New York Park Department, to deliver a lecture, with illustrations of the most dangerous insects and the most approved machinery for holding them in check. If the people of Plainfield follow Mr. Southwick's plain directions they will not be lamenting over the defoliation of their street-trees this year.

The early-flowering bush Honeysuckles, like *Lonicera Standishii* and its near ally *L. fragrantissima*, whose odorous

flowers appear before the leaves, opened here fully a month ago, but just now *L. Morrowi* is covered thickly with its little white flowers somewhat in advance of the Tartarian Honey-suckles. This is a beautiful plant, and later on it makes a fine appearance when in fruit, although, perhaps, not quite as interesting in late June as *L. Ruprechtiana* with its dark red bloom-covered berries. These two are among the very best of garden shrubs for this latitude, being perfectly hardy and of admirable shape and easily propagated. *L. Morrowi* comes from Japan and *L. Ruprechtiana* from Manchuria.

The single-flowered form of *Pæonia tenuifolia* is rare in gardens, although, like many other single-flowered *Pæonias*, it is handsomer than the double-flowered variety. The segments of the leaves of the single-flowered *P. tenuifolia* are rather broader than those of the plant more generally grown, which is also beautiful in form and color. Both are perfectly hardy, and once planted they need only ordinary care to flower abundantly every spring. Another beautiful flower which is rather ahead of its time is the Satin Flower, *Ornithogalum nutans*, a plant of the Lily family, with a raceme of half a dozen nodding bell-shaped flowers an inch long with white perianth segments flushed with pale green without and shining like satin within. It is an old-fashioned flower and it does not deserve the neglect into which it has fallen.

Professor W. F. Massey writes to *The Southern Planter* that he begins to doubt whether the Albemarle Pippin is simply the Newtown Pippin modified by soil and climate. During last winter he has had winter apples sent from the best Pippin-growing region of Albemarle, produced by trees which had been brought from the north. They were not identical with the genuine Albemarle Pippin, but were distinctly the northern Newtown Pippin. He thinks there is danger that the growers of what is known as the Albemarle Pippin will lose their prestige if they continue to get Newtown Pippin trees from northern nurseries and plant them in the hope of getting Albemarle Pippins. The only safe course, he thinks, is to propagate from the original Ragged Mountain stock and consider the apple as a distinct variety. Whether it is so or not is a matter for pomologists to discuss. If the two varieties are not distinct he believes that it will take generations to change the northern form to a genuine Albemarle Pippin. He adds that Wine Saps and York Imperials grown in the Piedmont country are becoming the most popular apples in the northern and foreign markets, and that both in Virginia and North Carolina there are thousands of acres where these varieties can be grown, to one acre where the Albemarle Pippin will thrive.

Some time ago we published an article relating to the appreciable drying up of the small lakes of Minnesota and of South Dakota. From this it appeared that throughout the whole area of these states the larger lakes had diminished in volume, and the smaller ones have dried up. The monthly *Weather Review*, published by the Department of Agriculture and edited by Professor Cleveland Abbe, in speaking of these facts, says that the average rainfall for ten years past may have been slightly below the normal in these states, but not so much below as to justify the conclusion that this change in the lake levels is due to any great change of climate or meteorological condition. The true reason for this drying up of the lakes is said to be the cultivation of the soil and the artificial changes in drainage. Every acre of virgin prairie plowed up and cultivated begins to evaporate into the air the moisture that it formerly held, every new drain that is dug helps the water that once settled in the soil to flow off into the river. Agriculture begins with an effort to drain rich lowlands that are too wet and ends by artificially watering the dry uplands and warm lowlands—that is, we begin by evaporating and draining off the water that we eventually wish to get back again. To all this it may be said that the advocates of underdraining uplands claim that this practice by changing the texture of the soil and in other ways actually leaves more available moisture for the roots of crops than could be found in the same soil before the drains were laid. That is, it is held that underdraining is a good defense against drought.

Professor John B. Smith, of the New Jersey Experiment Station, writes to *The Rural New-Yorker* that he is about leaving for California to study the character of the ladybird beetles, which feed on scale insects in general and upon the San José scale in particular, so as to determine which of them offer the best chance of surviving in the east. When he has selected the California insects he will distribute them at different places in New Jersey and in Florida, and colonies will also be sent to Maryland and Virginia, so as to give these insects from the

Pacific coast as many chances of becoming acclimated as possible. It may be that they will survive without any trouble in Florida, and from Florida colonies can be easily sent north. If they survive in Virginia it will be easy to select specimens to send to New Jersey hereafter, and the chances are that each generation will become a little better fitted to sustain our changeable climate. The reason for all this is that the San José scale, introduced from California some years ago, is increasing rapidly in the east, and no applications have been as yet successful in arresting their progress. On the Pacific coast there are natural enemies like the ladybirds introduced from Australia, which hold the scales in check, and although there are many difficulties in the way of introducing insects from one climate to another where they differ so widely as the Pacific coast climate and our own, still there is ground for hope that some species, if properly selected, might endure our climate. At any rate, it is worth trying, and the Legislature of the State of New Jersey, at the request of the Board of Agriculture, appropriated last winter a thousand dollars for the experiment. Professor Smith's mission and its results will be watched with interest.

Bidwell peaches, from Florida, the first of this fruit seen this year, were sold here on the 7th instant, and now command \$1.00 to \$1.25 a dozen at retail. Peaches from New York state hot-houses, the white skin beautifully marked with pink, cost from \$2.00 to \$10.00 a dozen in boxes holding six neatly wrapped fruits. Cherries, from California, are coming in limited quantities, owing to injury to the crop by frost, and not in the best condition, but are of fair size and color. They cost \$1.00 a pound. The first cherries of the season from North Carolina reached New York on Monday, but were small and unattractive, and met no demand. Richly colored strawberries, from Charleston, of large size, long and green at the tip, on Saturday sold for thirty cents a quart box at retail, and the first Downings, from Maryland, more spherical and even deep red in color, brought twenty-five cents. Cups of Sharpless strawberries, from near-by hot-houses, containing a dozen immense fruits, cost fifty cents, and smaller berries twenty cents. These are decorated with their own foliage. Navel oranges, from California, may still be had for seventy-five cents, and grape-fruit, from Jamaica, for \$1.00 to \$2.00 a dozen. Limes cost from thirty to fifty cents a dozen. Shipments of Jamaica oranges continue, and one steamship last week discharged 228 barrels of this fruit at this port, besides 14,000 cocoanuts. Porto Rico pineapples of the largest size, with luxuriant tops and three to six heavy shoots at the base, command seventy-five cents each. Lychee nuts are seen in all the best fruit-stores, and, more rarely, cocoanuts in their outer shell, and Brazil nuts in round shells five inches in diameter, each enclosing from eighteen to twenty-four individual nuts closely packed together.

The windows of the uptown flower-stores still make attractive displays of choice flowers in simple and harmonious arrangements. One window of the four in one of the best establishments, on Saturday, showed half a dozen small vases containing loose, graceful masses of the yellow Sweet Sultan, *Centaurea moschata*, the clear lemon-fringed flowers standing out effectively above the Asparagus with which the floor was loosely carpeted. The only other decoration in this window was an immense bronze vase bearing a mass of the bold and striking Parrot tulips, with their confusion of rich yellow, green and crimson splashes and stripes, relieved by handsome glaucous foliage. Neat and tasteful flat bamboo baskets in their natural color, for orders for cut flowers, were displayed by another firm. Here the clean and cool-looking white tile flooring made a suitable summer relief for vases of Moss rosebuds, a bright mass of Meteor roses, sprays of flowering Almond and Dogwood, and boughs of Apple-blossoms. The most conspicuous flowers were elumps of late single crimson tulips, with purple-black markings at the base of the petals. Other showy exhibits were groups of light gladiolus, the bright red *Pæonia tenuifolia*, and William Scott, Tidal Wave and Helen Keller carnations, while among less showy offerings were the delicate white blossoms of Swainsonia, the yellow-flowered *Alyssum saxatile*, lily-of-the-valley, handsomely marked pansies, violets and sweet peas. The excessively hot days in April forced hot-house plants into early and profuse flowering, some kinds being urged six weeks ahead of the rightful season. Except in the case of carnations, which had been in scant supply, a glut naturally followed. Now that this is past there is sufficient scarcity of roses and some other cut flowers to hold up wholesale prices, and the season for flowers grown under glass will undoubtedly be shortened.

The Revised Plan for Jackson Park, Chicago.

AT the exhibition of the Architectural League, held in this city last winter, there was a plan for the improvement of Jackson Park, Chicago, prepared by Messrs. Olmsted, Olmsted & Eliot, of which we spoke at the time, and we have since then secured a reduced sketch, which we present to our readers on page 205, although, of course, many of the finer details are not evident as they were in the original. On page 204 we present for comparison the plan for the World's Fair site, which covered the same area, and if we had space it would be interesting to republish a copy of the original plan of Jackson Park, made in 1871 by Olmsted, Vaux & Co., and which contained many of the fundamental ideas which were developed in the later creations. The plan of the World's Fair grounds, on page 204, was originally published in volume v., page 291, of this journal, and the description then given would be found of interest in connection with the present design. The elements of the scenery of the park are: (1) the broad view of Lake Michigan commanded from the Shore Drive and the Concourse on Sunrise Bluff; (2) the spacious fields between the lagoons and the lake and between the lagoons and the south-west entrance, each presenting broad, quiet landscapes of the simplest pastoral sort, which are pleasingly commanded from the adjacent drives and walks; (3) the lagoons, with their intricate and bushy shore-lines, their beaches and bridges, their almost complete seclusion, with a scenery in strong contrast to that of the lake-shore and fields—scenery which can be enjoyed not only from the shore, but particularly from the boats.

The decision to retain the Art Building of the World's Fair for the Field Columbian Museum made it necessary to revise all the road-lines, together with the walks which had been designed for the original park and some of those which had been retained during the Fair, so that the surroundings of the great building should be in harmony with it. The Circuit Drive is now symmetrical to the right and left of the north and south axis of the Museum, and the straight road across the north front has been moved farther away. The pond south of the buildings is to be recon-

structed into a symmetrical basin with architectural outlines, and since the character of the planting on the margins of the lagoons will make them unsuitable for skating and will not permit the public to walk along the water margin, the Museum Basin provides for a broad walk a foot above the water-level, so that the basin can be used for sailing toy-boats and skating. In connection with these dominating architectural works provision has been made for considerable decorative planting of a formal kind. The large conservatory which it had been determined to build in Washington Park has been appropriately placed in the formal grounds about the Museum, where it will not be in view from any important part of the building and where the differences in the style of architecture of the two will not be unpleasantly obvious.

The North Haven and Wooded Island will remain substantially as they were during the Fair, although the shore of the lagoon is to be more varied with islands and bays. The west shore of the west lagoon, where the water seemed too narrow, will be carried a little farther to the west. The south end of this lagoon will be widened and extended, leaving a long and narrow island where the Electricity Building stood. The sites of the Government Building and Manufacturers' Building will be turned into slightly undulating meadow, which will be used for tennis and other lawn games. The Grand Basin in the Court of Honor will have its outline changed into irregular forms, and it will become the northern end of the South Lagoon and the Middle Bay. The view from the West Lagoon Drive is mainly to the eastward over to the lagoon, and therefore the space between the drive and the west boundary of the park would be of comparatively small landscape value, except as affording a screen of foliage against the city, and therefore two athletic grounds have been planned here, one for men and one for women, and a smaller space for small children and infants, with suitable buildings, on the general lines of similar grounds in Charlesbank, Boston, which have proved very successful.

In the south-west corner of the park will be a sixty-acre field with a slightly rolling surface, which will not only have great value as a piece of landscape, but may be used for field games of all kinds. It will be restricted, however, to the use of boys and girls of grammar-school age, not only to diminish the wear of the turf, but to lessen the danger to visitors by stray balls, which would be more dangerous if thrown or batted by men. For the first time a special provision for bicycles has been made in the shape of a path around the ball-field, with a large stand, surrounded by shade-trees, for refreshments and the social reunions that are apt to take place. This bicycle-path is not for speeding, but for such promenading as is provided for equestrians in London at Rotten Row. A bridle-path also makes a complete circuit of the path south of the Columbian Basin.

The point of land between South Haven and the lake is to be treated as a wild, wind-swept series of dunes. The ground will have the form of dunes and will be planted on the slopes toward the lake with Beach Grasses and Sedges, Beach Pea, low shrubs and other perennials. Back of the dunes Red Cedars, Prostrate Junipers, Beach Plums and other bushes appropriate to sand dunes will be grown with Beach Pine and other native Pines on the lee or western side of the highest bluff, of which advantage is to be taken to afford a commanding view for persons in carriages, as the Concourse at this point will rise to a height of twenty-five feet above the lake. The University of Chicago having developed since the original plan was made, and being situated on the north side of the Midway Plaisance, an opportunity has been provided here for boat-racing and boating carnivals, and the series of basins connected by narrow canals in the original plan has been changed to a canal uniformly a hundred feet wide and long enough for a mile race. The bridges to carry streets across the canal will have a hundred-foot span, so as to offer no obstruction to navigation. A broad walk on either side of the

canal affords facilities for thousands of people to view the races and carnivals without danger of damaging the grounds. Since the lagoons in the park are entirely unsuitable for racing or other spectacles which would cause great crowds to assemble on the shores, this will afford opportunity for wholesome sport without danger to delicate natural planting.

A mound from six to eight feet high, with a comparatively gentle slope all round the north, west and south sides of the park, is to be constructed for the purpose of concealing the city streets even in winter, and to reflect back as much as possible the noise of city traffic. These mounds are to be covered by trees, spaced sufficiently far apart to permit them to grow low branches, and dense shrubbery plantations will be grown outside of them and under them.

This is the plan in general outline, but we have omitted mention of the facilities for boating and yachting and many provisions for public accommodation apart from those which directly help to the enjoyment of the landscape. There are an unusual number of such introductions, and the skill of the architect is shown by placing these, not only so that they will do as little damage as possible to the turf and the plantations, but in such a way that they will not injure the beauty of the prospects and will interfere as little as possible with visitors who come to the park for the enjoyment of the landscape, for quiet and for secluded recreation. Besides the structures we have mentioned, like the conservatory, the museum and the like, we might name the picnic shelter at the north-east corner of the park, the Germania restaurant, the bath-house, the music court, the various field houses connected with gymnasium grounds for men and women, with the tennis lawns and ball ground, the Japanese temple, the casino, the service yards and administration buildings, the life-saving station, the Belvedere, with numerous shelters, boat-houses and landings, carriage-sheds and many other artificial works which by their nature detract from the beauty of the landscape, but which all have been concealed by grading or subdued by foliage. That is, in preparing all these attractions and conveniences the primary purpose of the park has never been lost sight of. The landscape is the essence of the park. The green pastures and still waters—pictures of peace—the outlook over the great inland sea, all the commanding charm of the place, has been preserved and heightened for the refreshment of city-wearied senses. A study of the map is like a visit to the country. One can plainly trace long lines of view which offer every advantage for enjoying the scenery. There are scores of these vistas, and they control the outline of the lagoons and islands, the grading and alignment of the roads and walks and the shape and character of the plantations. Some of them are purely natural and others are directed to bridges or buildings, which, of course, will be carefully designed. Especial attention is called to the extension of the south lagoon which lengthens the charming view through the middle of the park lengthwise of the lagoons, with the Belvedere at the southern boundary of the park as an objective point for the long vista from the north end of the east lagoon.

Shrubs, Native and Foreign.

THE uncertainties of gardening are apparent this spring in the neighborhood of Boston, where many shrubs, usually considered perfectly hardy, have suffered during the past severe winter, which has left others, that might have been expected to have suffered, untouched. All the species of Forsythia, usually remarkable for the profusion of their flowers, have practically been flowerless this spring, although their wood is uninjured. The Japanese Weeping Cherries, *Prunus pendula* and *Prunus Miqueliana*, which have usually been considered perfectly reliable, have lost all their flower-buds. Ordinary Cherry-trees have been nearly flowerless, and Pear-trees promise but a scanty crop of fruit. *Spiræa Thunbergi* has lost, as usual, the tips of its branches and most of its flower-buds, and the *Wistarias*

are without flowers. Well-established plants of *Deutzia Sieboldiana* are in many cases killed to the ground, and *Deutzia gracilis* has lost more of its wood than usual.

On the other hand, Ghent Azaleas, which frequently lose their flower-buds in severe winters, promise this season an exceptionally large crop of flowers. Rhododendrons of the Catawbiense type are uninjured in foliage and flower-buds, and conifers generally are in better condition than usual at this time of the year. Apple-trees are covered with bloom, and all the various Japanese, Chinese and Siberian Crabs are covered with flowers. The Japanese *Pyrus Toringo* and its lovely double-flowered variety, *Pyrus Parkmanni*, have never been more beautiful, and the value of these plants in decorative planting has never appeared greater than it has this spring. All the Magnolias of the Yunan section, with the exception of *Magnolia Kobus*, which still remains flowerless, have bloomed profusely, and have this season been unusually satisfactory, as the flowers have been untouched by frost or rain. All the varieties of the common Lilac are as full of flower-buds as usual, and *Syringa pubescens* is uninjured, and in a few days will cover itself with its charming fragrant flowers. The flower-buds, however, of *Syringa oblata* of northern China have been greatly injured, although the semi-double flowered hybrid of this plant, with *Syringa vulgaris*, has escaped injury. This is the earliest of all Lilacs to bloom, and for this reason, although the flower-clusters are not large, it is a desirable plant. *Cornus florida*, which in the latitude of Boston often loses its flower-buds in severe winters, is uninjured this year; and the severity of the winter has made no impression on the flower-buds of the American Judas-tree, *Cercis Canadensis*. The bush Honeysuckles are all uninjured, and native *Viburnums*, *Roses* and *Cornels* will bloom as usual.

A winter like the last one emphasizes the fact, if it needs emphasis, that our native shrubs are best suited for our climate, and that foreign plants, however hardy they are usually, are more liable to suffer than native species. Many exotic shrubs, even those which are considered the hardiest, are disfigured in spring by dead branches, and when such shrubs are used in great numbers, as they have been in the Boston parks, the labor of cutting out the dead wood is so great that it is rarely attended to, and shrubberies present a shabby appearance all summer. Our native shrubs, of course, die sometimes during severe winters or lose part of their branches, but, as a rule, they are in better condition after a hard winter than any of the exotic species, and with each succeeding season we feel more and more convinced that for planting on the large scale which must be practiced in public parks, or on large private estates, the most satisfactory material will be drawn from the native flora.

Product of White Pine per Acre.

ONE of the elements that need to be known in order to discuss the profitableness of forestry is the amount of useful wood which can be produced per acre. On this point the most erroneous and extravagant notions exist, and many calculations are made on paper which can never be realized. The rate of growth of a tree at a given age is supposed to continue indefinitely, and this rate is applied to an acre of trees, the number per acre being guessed high enough to make a good showing, and then the total amount of wood, or at least a large percentage of it, is supposed to be usable, and thus we can compute astonishing yields for the future.

The latest contribution to these rosy prospects is contained in an article by Mr. Edward Hersey, Superintendent on the Bussey Farm, near Boston, on the value of the White Pine as a timber-tree, which, besides several surprising statements regarding the felling time for Pine, contains the following:

Careful measurements and estimates of the product of many acres of Pine timber in Plymouth County, Massachusetts, have led me to the conclusion that where there is no other timber

mixed with the Pine, on a warm, loamy soil, in a growth of from thirty to thirty-five years, one hundred thousand feet of box-boards may be obtained; but on an average soil the usual thirty years' growth has been found to be about fifty thousand feet, when but little other wood is mixed with it. The expense of cutting, drawing, sawing and drying is from \$5.00 to \$6.00 per thousand feet, which, at the present price of box-boards, would leave the owner of the land about \$2.50 per thousand on the stump, or \$125.00 per acre. This sum would pay a good interest on the investment if the land had cost not more than \$15.00 per acre when the Pines first started to grow.

Supposedly, the writer, when speaking of feet, does not refer to the usual unit of board measure, but to the superficial foot with a five-eighth-inch thickness to which box-boards are usually cut. Translating his measure, therefore, to the generally accepted board measure, the 100,000 and 50,000 feet represent 62,000 and 31,000 feet, B. M., respectively. These amounts he claims can be grown in thirty to thirty-five years.

To simplify further, we may translate this measure into cubic feet of forest-grown material. It is well known that in sawing there is a necessary waste in sawdust and slab amounting, according to the diameter of the log, to from twenty to seventy-five per cent.—the smaller loss on large, the larger loss on small logs. A straight log ten inches across at the smaller end and ten feet long will waste sixty-five per cent. in common mill practice—that is to say, of the 5.4 cubic feet of wood in the log 3.5 feet are lost, and only 1.9 cubic feet reappear in the boards as they fall from the saw. In other words, to produce one thousand feet, B. M., one needs to have, not eighty-three (that is $1,000 \div 12$) cubic feet of log, but 240 cubic feet.

Since in growths of from thirty to sixty years the amount of ten-inch log material forms only a small part, the wastage on the average would be considerably greater. Yet, to throw the advantage altogether to the other side, we will not only admit no larger wastage, but in addition assume that all the wood from base to top can be utilized, although the useless tops will in reality average, according to size, from ten to fifty per cent. and more of the total growth of wood per acre. We would then require for Mr. Hersey's claim 7,400 cubic feet of wood on the acre for the smaller and twice that amount for the larger output, claimed by him as possible, at from thirty to thirty-five years of age. Although the White Pine is among our best producers, both these figures are absurdities, into which the writer has probably fallen by underestimating the age of the growths which he measured. The Division of Forestry has during the last two years made careful and accurate measurements of many acres and some five hundred sample trees of varying age from various conditions, which go to show that these estimates are from fifty to a hundred per cent. too great. Unfortunately, not a sufficient number of acre yields of the age of thirty to thirty-five years has been measured to permit their use for argument, but it will suffice to show that groves of forty and fifty years of age do not produce the amounts claimed, and that it would require a good stand of sixty to seventy years' growth and more to produce anything like the larger figure of 14,800 cubic feet.

It so happens that among the acres measured there were three from three localities in Plymouth County, Massachusetts, the very region to which Mr. Hersey refers. Their record is as follows:

No.	Age.	All the trees over 3 inches.		All the trees over 6 inches.		All the trees over 10 inches.	
		Number.	Volume.	Number.	Volume.	Number.	Volume.
1	52	328	6,559	313	6,517	182	5,064
2	50	415	5,479	346	5,279	116	2,681
3	45	475	5,831	376	5,545	136	3,111

All three stands were considered well stocked. The last one is of special interest, as it originated by sowing a piece of pasture (seventeen acres) to Pine just forty-five years before it was measured, and was considered specially well

stocked; the owner claimed to have cut fifty cords to the acre, which he calculated equal to 30,000 feet, board measure, a rather incredible result, even when the total volume of the trees over six inches is supposed to yield box-boards.

Even if we admit the entire wood production of trees over three inches in diameter on the best acre given above amounting to 6,559 cubic feet to cut box-boards, this would fall short by twelve per cent. of Mr. Hersey's figure, although the trees were twenty years older. In reality, only the trees over ten inches, or eight at best, could be cut even into box-boards. The best average production of wood per year per acre (all included) during the first fifty years appears to be round 150 cubic feet, which for the age of thirty-five years would make the yield 5,250, of which less than one-half might be fit even for box-boards, and 15,000 feet, board measure, would be quite a remarkable result. The acres of thirty to thirty-five years measured, which, however, we do not consider good, cut fifty per cent. less.

In growths forty years old, of which we have a number measured, there will be 400 to 500 trees, in the average about 425 to the acre. According to the greater or less number the diameter classes vary; no trees will have reached a diameter over eighteen inches, and only few, not more than twenty-five to thirty at best, over fourteen inches, the majority falling in the diameter class of six to ten inches, and the number between ten and fourteen inches is rarely over 150, the total volume varying between 4,000 and 6,000 feet per acre. At best 20,000 feet, board measure, may be cut, more likely much less.

There is no doubt that by judicious thinning at the right time and in the proper manner the yield could be increased, but not even with the best practice would this increase amount to more than twenty-five or thirty per cent., individual development rather than increase of total yield in the final harvest being the object of the thinnings.

Mr. J. D. Lyman, of New Hampshire, has a growth of White Pine two-thirds of an acre in extent, fifty to fifty-five years of age, which he has thinned so that in 1894 only 146 trees remained, or 223 to the acre. As a result a very considerable development of the individual trees is noticeable, but not much in the total volume per acre. Most of his trees are over ten inches in diameter, at least sixteen of them are over fourteen inches, and the best measured 22.2 inches, the height being seventy to eighty feet. The calculated volume corresponds to a production of 7,185 cubic feet of wood an acre, which under very careful practice might cut 30,000 feet, board measure. The best forest-grown tree, fifty-four years of age, which we have found standing on this ground was eighty feet high, with a diameter at base of eighteen inches, and a diameter of four inches at sixty-five feet, containing altogether seventy-two cubic feet of wood, sixty-five of which were capable of being cut into lumber. This tree at thirty years of age was only 10.8 inches in diameter; at forty years fourteen inches, and the four-inch top diameter was then at about fifty-five and sixty feet respectively. If we assumed it possible to have 300 such trees standing on an acre, which would be twelve feet each way, the total amount of wood at fifty-four years would be 21,600 cubic feet, of which 19,500 would make lumber cutting, say, round 100,000 feet, board measure. This would be an ideal stand, which general practice can hardly hope to attain.

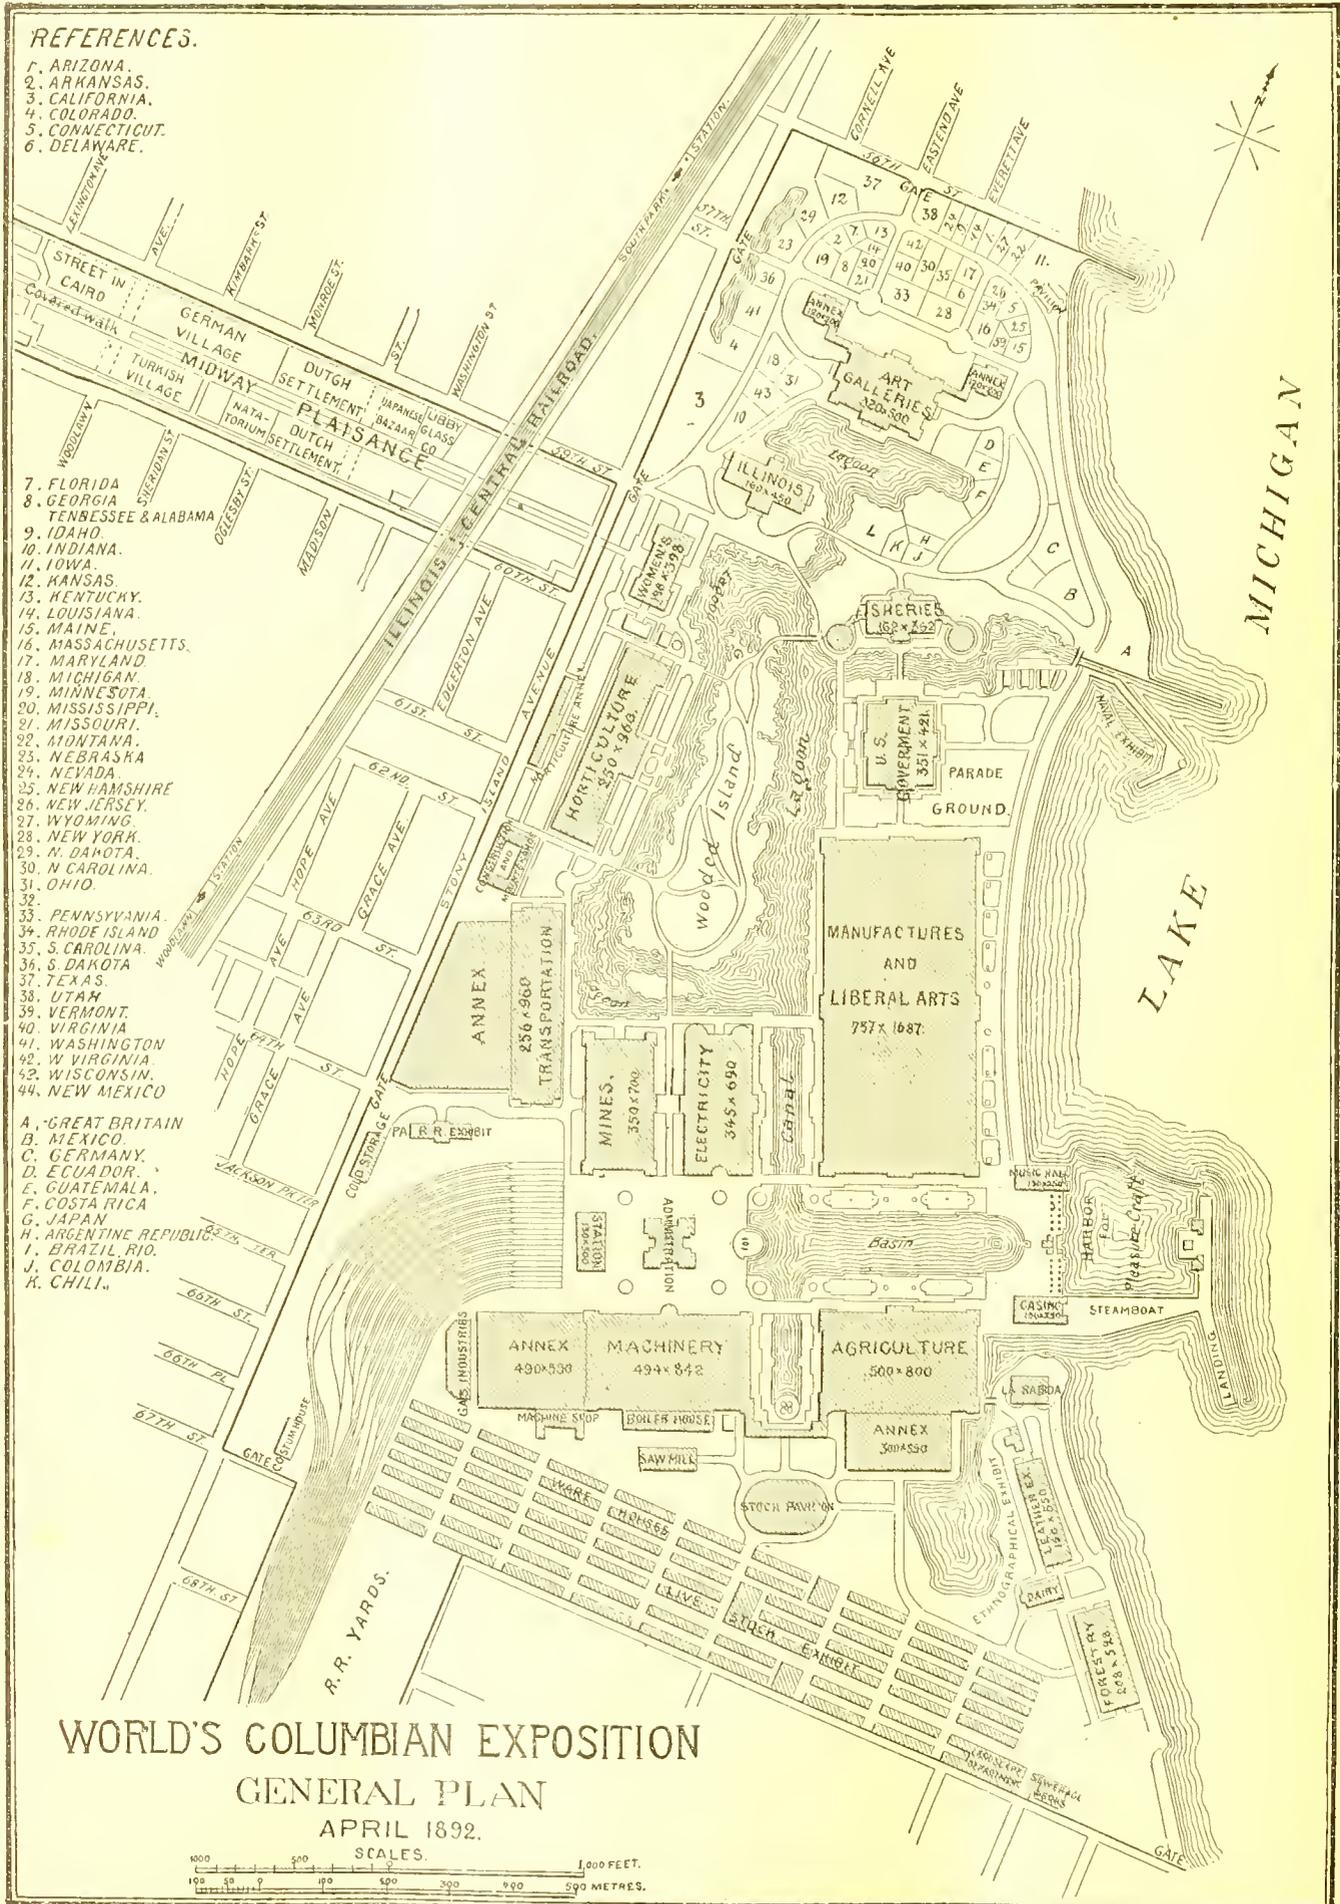

In all the above calculations it must not be overlooked that we have made reference only to box-boards—that is, the lowest quality of boards, extremely knotty. If the object were to grow saw-timber with the largest amount of clear material the results would be entirely different, since that would require the growing of a much larger number of trees per acre until the twenty-fifth or thirtieth year, when the individuals would develop in length and by the close stand clear each other of branches, but the diameter development would suffer. Then they should be thinned to develop diameter, but it would be necessary to give considerable time before good sizes are developed;

BROOKLINE, MASS

67TH ST.

before the trees are 90 or 100 years it would not pay to cut them, and then 100,000 feet, not of common box-boards but of good lumber, may well be expected.

Bamboos in English Gardens.

DURING the last six or eight years considerable attention has been given by certain English and French horticulturists to the Bamboos that are sufficiently hardy to be cultivated out-of-doors in the warmer parts of the kingdom. Previous to this period Bamboos were practically unknown as ornamental plants for the garden, the only species grown generally being the plant then known as *Bambusa Metake*, while *Arundinaria Falconeri*, often erroneously called *A. falcata*, was cultivated in a few gardens where the conditions were exceptionally favorable. In 1866, Colonel Munro prepared a monograph of *Bambusaceæ*, and in his introductory remarks he stated that "a large number of Bamboos are now in cultivation, and, perhaps, twenty species at Kew alone. I am informed there are at least fifty in Paris. Few of these, perhaps of *Arundinaria* only, are hardy in England, or even in the warmer parts of Ireland." There has been a collection of hardy Bamboos at Kew for at least twenty years, and, according to a letter from the late Canon Ellacombe to Sir Joseph Hooker in 1879, he had then in his garden at Topsham, near Exeter, "flourishing most vigorously, a collection of twenty *Bambusæ*, all named by General Munro." Nothing, however, appears to have been done to prove the value of Bamboos for the outdoor garden until Kew, Mr. Mitford and Sir E. Loder took the matter in hand. The Kew collection was formed partly by purchase from the Japanese nurserymen, from Monsieur Marliac, of Temple-sur-Lot, and from the collection formed by the late Monsieur Lavallée at Chateau du Segrez, near Paris. A garden was made specially for them in a sheltered, picturesque position, and the collection, consisting of about forty sorts, was set out in groups and masses. At the same time Mr. Mitford had decided to make a feature of hardy Bamboos in his lovely garden at Batsford, near Stratford-on-Avon. He has always taken an interest in Kew, partly from his love of plants and also from his having held for some years the position of secretary to the minister in whose department the Royal Gardens are. Probably the collections at Kew and Batsford are equally rich in number of species and varieties of Bamboo, and the success met with in their cultivation in these two gardens appears to be on fairly equal lines. Mr. Mitford has utilized the resources of Kew in naming and working out the history, cultural requirements, etc., of Bamboos in a most interesting book,* in which he states that the task of preparing it has not been an easy one, and would have been impossible but for the kindly help and encouragement which he received from Sir Joseph Hooker, Mr. Thiselton Dyer and several members of the Kew staff. The outcome of Mr. Mitford's thoroughness and perseverance in working up material for his book is a work of considerable value, both to botanists and horticulturists. It embraces all that is known of all the hardy Bamboos in cultivation in England; consequently it will be accepted as the recognized authority on all matters appertaining to these plants for some years at any rate.

The book is divided into chapters which treat upon the formation of the Bamboo garden and the positions and best time of planting for the plants; their propagation; the uses of and customs and superstitions connected with Bamboos; their classification according to easily recognized characters of habit, culm, leaf, sheath, etc.; description and history of each species; the future possibilities of these "Royal Grasses"; a plea for Bamboos ("Apologia

pro *Bambusis meis*"), and a list of the Japanese names of Bamboos, with their botanical equivalents.

Mr. Mitford is preëminently qualified to write about Japanese Bamboos from his having resided for some years in Japan. He is the author of *Tales of Old Japan*, described as "pictures of Japanese life and manners not worked out in the monotony of minute detail, but dashed in with bold, telling touches." His Bamboo book may be described as a happy combination of scientific accuracy, reliable practical directions, and a skillful, charming style. Even the descriptions of the species are drawn up in such a way as to interest even readers who know nothing of Bamboos.

Mr. Mitford, while modestly calling his book a descriptive list, claims an attraction for it "in the admirable drawings furnished by Mr. Alfred Parsons." I confess to a feeling of disappointment with regard to these drawings. They may be art, but they are of no value either to the gardener or botanist. Photographs of representative plants would have been more acceptable.

The number of species described in the book as having proved hardy at Batsford and Kew is forty-five. Of this number thirty-six are natives of China and Japan, one of the United States, five of the Himalayas, the other three being of doubtful habitat. These are all distinct and not difficult to recognize after a little practice. They present considerable variety in thickness and height of stem, size, color and form of leaf and in their manner of growth. Most of them grow with astonishing rapidity and are evergreen even through severe winters. The only drawback Bamboos have is in the somewhat shabby appearance assumed by some of the sorts in April and May, the result of the trials of winter. Against this, however, may be pitted the perfectly healthy appearance they wear throughout the autumn and winter, when most plants are looking their worst. There can be no doubt that Bamboos will add a considerable attraction to the garden, and as they are not particular as to soil, living and growing in gravel, or even sand, if only they can obtain a good supply of moisture, they are available for all gardens where the climate is not too severe for them. At the same time they well repay liberal treatment in regard to soil and manure. All the species described by Mr. Mitford "have stood through four winters and twenty-six degrees of frost, and they have resisted an even more deadly enemy than frost in the droughts of 1892, 1893 and 1895. . . . As for *Phyllostachys nigra*, *nigro-punctata*, *Boryana*, *Henonis* and *viridiglaucescens*, they simply laughed at the thermometer, and were as bright at the end of the winter as at mid-summer."

The following extract may be taken as a sample of the style of the author; it is also interesting as a description of his own garden at Batsford, one of the most charming, most informal and, at the same time, richest in grand effects to be seen in England:

As I write I look out upon a great rolling track of park-land studded with patriarchal Oaks that were saplings in Plantagenet and Tudor days, giant Ashes, Elms and Thorns planted in the reign of good Queen Anne. Far be it from me to introduce any change into such a scene. It is thoroughly English and perfect of its kind; no impious hand should dare to tamper with it. But farther up the hill there is a spot snugly screened from the cruel blasts which come from north and east, where, when the great Oaks and Elms, shorn of their summer bravery, are mere gaunt skeletons, there is still some shelter and some warmth. Here, amid the sparkling glitter of a Holly grove, are all manner of beautiful evergreens, rare Pines, steeping Fir-trees, Rhododendrons, Cypresses, Junipers. A tiny rill trickles over the green velvet of the rocks, with Ferns peeping out of crannies in which many an alpine treasure is hushed to rest, waiting the warm kiss of spring and the song of the birds, that, like Orpheus with his lute, shall raise the seeming dead from the grave. Tall Rushes and gracefully arching Bamboos, hardly stirred by the wind, nod their plumes over a little stream from which the rays of a December sun have just strength enough to charm the diamonds and rubies and sapphires; a golden pheasant, all unconscious of a human presence, is preening his radiant feathers by the water-side. It is a

* *The Bamboo Garden*, by A. B. Freeman Mitford, C.B. Macmillan & Co. Price, 10s. 6d.

retreat such as the fairies might haunt, and where in the bitter Christmastide a man may forget the outside world, and for one too brief hour revel in a midwinter day-dream of glorious summer.

There is much thoughtful writing upon gardening in general, as well as upon Bamboos in particular, in Mr. Mitford's book which is certain to rank with the very best books of horticultural literature.

London.

The Hubbard Squash and How to Grow It.

WHEN we consider the great improvement that has been made in the quality of almost all garden vegetables during the last half century, it is a remarkable fact that the Hubbard Squash, known and cultivated nearly a hundred years ago, continues to be the most popular variety. There has been improvement in uniformity of form and color, and last fall careful inspection of a forty-acre field, grown for seed, failed to discover more than twenty-five fruits which showed any signs of mixture or of being off type. But, while the stock has evidently become more fixed in external character, there are those who maintain that it has deteriorated in the quality of flesh; that the rich, dry, sweet, chestnut-like quality which made this sort so popular fifty years ago is lost. I think this apparent loss is due to other causes than the deterioration of the stock. There are no plants of our gardens in which the quality of the fruit is so dependent upon conditions of soil and climate. Gardeners know that it is quite impossible to grow a really good Melon in cold, wet soil, and that one ripened in a cold, damp atmosphere is certain to be lacking in flavor and sweetness. The same thing is true of squashes, and to develop the nut-like dryness and sweetness they must be grown in warm, dry soil and thoroughly ripened in warm dry weather. Unlike most plants of the garden they will produce more fruit and of a better quality on plants of moderate vigor of growth than on those of rapid and rank growth. Again, Squashes, like Beans, are more benefited by applications of potash and phosphoric acid, but are unlike the legumes in seeming to get much good from these elements when in a comparatively slowly soluble form.

To grow good table squashes, then, warm, dry, moderately rich soil should be selected and cultivation be begun as early in spring as possible. A liberal dressing of wood ashes is necessary, a full bushel to the square rod being as little as should be used. Just before planting, which we do about the 20th of May, the ground should be plowed and harrowed and marked out for hills about ten feet apart each way. At the intersections a handful of guano, hen-manure or superphosphate should be scattered, and also one of fine ground bone-dust or flour. Thoroughly mix this with the soil for a space two feet in diameter and plant from twelve to twenty seeds, scattering them well, as in this way one or two plants can often be saved from cutworms and striped bugs, which would have destroyed all if the plants had been close together. We do not know of any certain protection against the striped bug. Dusting with wood ashes, with lime fresh slacked, with a little sulphur, sprinkling with dilute gas-tar water, or with liquid manure made from fresh hen-droppings, are each more or less effective and will sometimes seem to keep the insects off, but at others utterly fail to do so. My advice is to use any or all of them. The lime and ashes should be diluted with bran and plaster, or, better still, with tobacco dust; if used abundantly there is danger of killing the leaves with strong alkalis. As soon as the large squash bugs appear they should be trapped under pieces of board or shingle laid near the plants and examined in the cool of the evening when the bugs will be found hiding on the under side and can be easily caught and killed. Give as little cultivation as possible, only enough to keep the ground clear of weeds, and the surface broken after heavy rains. When the plants are well started thin out, leaving two or three to each hill, and when these are three to four feet long remove the surface soil under a joint twelve to eighteen inches from the root. Press the vine down into it and fasten it, so that the stem will arch up between this point and the root and cover with earth. If the soil is at all dry water thoroughly, covering the wet surface with dry earth. The vine will make root from the buried joint, and in this way it will often escape death from the borer working at the collar.

In spite of all claims to the contrary, I am certain that the quality of squashes is often affected by the fertilization of the flowers with pollen from some inferior stock. In garden cul-

ture it is quite feasible to prevent this by going over the patch at evening and preventing the female flower, which would naturally open the next morning, from doing so by tying the tip of the blossom, and treating a few male flowers in the same way. About nine o'clock the next morning pick the male flowers; carefully tear away the corolla and fertilize the opened female flowers by dusting or rubbing some of the pollen from the male flower over the pistil, then closing and retying the female flower. While there will be failure to accomplish the purpose in some cases, enough self-fertilized fruits can easily be secured for a full crop, and any others which may appear can be cut out. As the fruits mature they should be protected from the sun unless they are well shaded by the leaves. When fully ripe, which may be known by their developing a shell so hard as not to be easily penetrated by the thumb-nail and by the part resting on the ground turning to a rich yellow, they should be gathered and stored in an open building until there is danger of freezing. In gathering, care should be taken not to break the stem of the fruit, the vine being cut instead, and also not to injure the surface.

Grown and treated in this way the Hubbard Squash will be found to have all its old-time excellence. The causes of inferior quality are that it is grown in too rich and wet soil; late sowing, so that it does not mature until cold wet weather sets in; and leaving the fruits on the vines exposed to injury from hot sun and cold nights after maturity.

Detroit, Mich.

The Rock Garden.

THE rock garden grows in interest every day as one after another the plants come into bloom. In looking it over this season we find an unusual number of self-sown seedlings. Many of these are in themselves desirable plants, but their number must be reduced or they would make a weedy effect. *Campanula Pallasii* needs thinning out. It is a handsome biennial, and effective when properly placed. Here it borders a natural shrubbery, and being aggressive takes possession of the ground beyond the limits allotted to it. When it extends into the shrubbery, along with some Sunflowers, *Helianthus laevis*, we do not object, but outside these limits it must be weeded out. *Papaver nudicaule* comes up everywhere, but it is so graceful that we let it grow quite freely. It is short-lived, and hundreds of the plants die every year. There are plants in all stages of growth—some in bloom now, and seedlings to bloom in the autumn. Some hybridization has been effected with the *P. alpinum* form, so that now we have white and several shades of orange, and some have become double. A double Iceland Poppy is not, however, to be regarded as an acquisition.

Viola cucullata is taking up too much space. In spring-time it is a hard matter to root the numerous tufts of attractive purple and white flowers. Gray's *Manual* says of this *Viola*, "flowers rarely white." All our plants were originally the variety *cucullata*, var. *striata*, and it was with pleasure some five years ago that we found a pure white-flowered variety among them. Now it has spread to all parts of the rock garden, to the exclusion of the purple form, which will need artificial propagation. *Saponaria ocymoides*, formerly of the variety *splendens*, has so far retrograded that it is now a weed. The beautiful *Heuchera sanguinea* fails to come true from seed, freely hybridizing with the commoner *H. Americana*. *Aquilegia Canadensis* seems to have improved by contact, probably with some of the early-blooming *caerulea* hybrids. We have some purple ones among them, but it is hardly probable they are hybrids with *A. glandulosa* or *A. Bertoloni*, *A. Olympica* possibly. *Alyssum Wiersbeckii* has spread itself agreeably. It is the brightest and best of all. Its long-branched spikes of bright yellow flowers are delicately fragrant and make a handsome bouquet in themselves. Tufts of *Iris graminea*, var. *haematophylla*, occur in pleasing contrast with the large Rock Cress, *Arabis albidia*. *Iris verna*, with lavender and yellow crested flowers close to the ground, is really pretty, and is at the same time one of the few fragrant kinds. We were pleased to find an uncommonly pretty and scarce British scurvy grass, *Coelocaria Anglica*, come through the winter in good condition. It was the first plant to flower, excepting the *Chionodoxas* and Squills, and was nearly a week ahead of the Rock Cress. The flowers are pure white in dense tufts, looking neat for a while, but it will evidently, like many other plants of this character, look ragged later, and end itself in going to seed. The same happens with *Iberis Tenoreana*, one of the handsomest of rock Candytufts. It is also tender, and with lessened vitality in producing seed it seldom goes through the second winter. We secure it by taking a few cut-

tings. We are on safer ground with native plants. *Mertensia Virginica* takes care of itself, and is not likely to become obtrusive. Its life above ground is short, being past, leaf-stem and all, by midsummer. Its nodding panicles of incomparable blue are always welcome.

Phloxes of the *subulata* type are the most charming spring flowers we have. Their color tones are most penetrating; a patch six by six feet, of the old variety *atropurpurea*, will catch one's eye from a hillside half a mile away, while *P. reptans*, an equally handsome kind with colored flowers, will scarcely be noticeable at that distance. *P. reptans* grows nearly one foot high with us, and the stems are long enough to pick. *P. subulata* *Sadie* is an American-raised sport from the common white Moss Pink. It is lavender-blue and unique among the true *subulata* type. It is thrifty and early, always fresh and green, whereas many of the imported varieties get winter-burned.

Rosa Wichuraiana, the so-called Memorial Rose, is badly killed, but there are plenty of live shoots left to cover the ground anew. *Megasea purpurascens* and *M. cordifolia* have also suffered severely. They are naturally evergreen, and when their winter coat of leaves is lost new ones must be made at the expense of the old root. Under such conditions the *Megaseas* will be gone in a few years. *Campanula garganica* looks fresher than ever.

We have introduced strangers to our rock garden who expected to see statuary and fountains, and others who thought we should arrange it in beds or tiers of pockets as more convenient to get at. The garden is wild and without labels, and is as natural-looking as any other bit of bank. It is hard, however, to get the names grounded into one's memory, and fresh additions every year increase the difficulty. Apart from the rock garden proper we have a piece of wild garden along a sheltered slope. It is in part shaded by sparsely planted Oaks, and grassed over to be kept green, but not to the extent of a trim lawn. Many beautiful plants can be introduced here. Native plants and such as could be mown over with a scythe without injury are desirable. There are enough to make a lovely spring picture. Blood-root, *Sanguinaria Canadensis*, *Mertensia Virginica*, all the *Subulata* Phloxes, *Violas*, *Aquilegia Canadensis*, *Silene Pennsylvanica*, *S. Virginica*, *Anemone nemerosa*, *A. deltoidea*, *A. ranunculoides*, *Erythroniums*, *Thalictrum anemonioides*, *Claytonia Virginica*, *Trilliums* of several kinds, *Mularias*, *Hypoxis*, *Bluets*, *Decentra Canadensis* and many others should be included.

Wellesley, Mass.

T. D. Hatfield.

Notes from the Arnold Arboretum.

PLANTS of *Amelanchier oligocarpa* which were obtained from the mountains of New Hampshire are the earliest of the Shad-bushes to flower here, and they are really among the most pleasing of dwarf American shrubs. In its native habitat this *Amelanchier* is rarely more than a foot high, and when grown carefully on good soil it does not exceed two feet in height. The young leaves as they open are tinted red, something like those of the large forms of *A. Canadensis*. The bark when bruised has the peculiar odor of the Wild Cherry, which I have not observed in any other species or variety of *Amelanchier*. Another fine *Amelanchier* is called, I believe, a variety of *A. Canadensis*, and known as *spicata*, and sometimes *rotundifolia*. If not a good botanical species, it is certainly a very distinct plant for garden purposes. It comes into bloom late, and is just now, May 12th, in its prime, when the others are all past their bloom. As grown here it is a low dense shrub, which produces snow-white flowers very freely.

Nurserymen who are looking for new things would do well to get a stock of these on their own roots, or if they would graft them from two to four feet high on some good Thorns they would set plants which would be genuine novelties for the shrubbery. Some of the low-growing *Prunuses*, too, ought to be looked after. *P. pumila*, which rarely in its native state exceeds a foot high, although it becomes larger under cultivation, is a beautiful plant on its own roots, and so are *P. maritima* and *P. Alleghensis*, but if they were grafted as standards on *P. Americana* or *P. Myrobalana* they would make neat, compact-headed plants, which certainly would be novel, and, no doubt, useful in shrubberies. *P. incana* is the most ungainly in habit of any plant in the whole family, and yet, if it could be in any way made into a shapely plant, its pinkish purple blossoms, which come in clusters, would be greatly admired. The first of the Apple-trees to come into bloom are the varieties of *Pyrus baccata*, with blossoms of all colors, from pure white to deep crimson. Among the newer forms of *P. spectabilis* the variety *Riversi* is strikingly beautiful this year. It is completely covered with its sweet-

scented, double, rose-pink flowers. The habit of this *spectabilis* group may also be called fastigiate, as compared with the generality of Apples, and they do not begin to flower as early in age as some of the other kinds of Apples, but they make up for this by persistent flowering afterward, for there is seldom a year when they do not bloom profusely.

Complaints are made that *Daphne cneorum* is doubtfully hardy, and it is true its foliage often burns in exposed situations in winter-time, but if the plants in autumn are furnished with a scanty covering of hay or dry leaves the foliage will keep bright all winter and they will come into blossom in early spring. The delicately scented pink flowers of this prostrate plant have been abundant here for a week or more. The Redbuds, as usual, opened with the flowering Dogwoods, and it cannot be too often said what a fine forest border or background to a shrubbery these two trees make at this season. One of our native Honeysuckles, *Lonicera cœrulea*, is just coming into flower. It is a neat and pretty shrub, not only on account of its lemon-colored flowers, but on account of its good foliage and the bright blue berries which follow. Just now the *Rhodora* is in its prime, and it is to be regretted that so good a dwarf shrub should be so neglected in landscape work. It certainly would fill an admirable place in connection with the *Andromedas* and *Leucothoës* when planted near the water. Perhaps it is youthful associations which make these plants so pleasing, but every boy brought up in the north where there was a peat meadow must know these flowers, and his memory will be stirred by sight of them.

Arnold Arboretum.

Jackson Dawson.

Flower Garden Notes.

THIS is one of the most interesting parts of the year in the garden, even with the extreme heat and dryness of this particular season. April showers have this year been very rare and are sadly needed.

The show of Apple-blossoms at this time is the feature of the country where apples are grown in quantity, and as a flowering tree alone it has few equals. The flowering Crabs are, perhaps, quite as pleasing, with more variation of coloring, and for this reason are finding favor with planters. There is a set of some ten kinds in flower here. They are beautiful planted in a large crescent-shaped bed, the ground being covered with late-flowering Tulips, the Parrot, *Gesneriana* and Darwin varieties mixed. The combination of Tulips is extremely beautiful now, when the early border kinds are all past. A little later the Oriental Poppies that are planted between will come on and give a second display, and when the Tulips are dying down Zinnias will be planted over them for a late summer effect. We thus get four distinct displays from the same bed with only the annual planting of the Zinnias. This plan is, perhaps, adapted only to beds of large size, so that there is a mass of color in its season.

Lily-of-the-valley is now in full bloom, much earlier than usual, owing to the heat, but the flowers are not so fine as in some years, because of the lack of water. If care is taken to thin them out every three years or so it is surprising how much better they will grow than those forced under glass in winter, provided the best variety of crowns are planted, such as are used for culture under glass.

Hardy Primroses are not esteemed very highly, and it is a question if there are any species that are to be regarded as proof against the severity of our winters. With a little protection some will prove very satisfactory at this season. A few hundred of the garden Polyanthus, raised from seeds a year ago and grown all last summer in shade under the Elm-trees, are a beautiful show at present. All the gradations of color in yellows and reds, mixed together with none that clash, make a very pleasing effect in a shaded position. Last fall, just before frost-time, a covering of straw about six inches thick was placed over these plants and removed early this spring. This is all the care taken, besides seeing that plenty of moisture was provided during the growing period. *Primula Sieboldii*, the Japan Primrose, is now at its best, treated in the same way. We find this useful for cutting, the erect stiff stems being better than those of the Polyanthus when grown under the same conditions. It is deserving of much wider cultivation. I do not remember to have seen it elsewhere, and it is usually regarded as a tender spring-flowering plant, but is hardy enough to stand out over winter, with covering. The typical *P. Sieboldii* is a rich, deep rosy purple color and is the best variety to grow, though there are numerous other kinds, some called white. But there is not the purity of color one would expect, and the same remark applies to the many other varieties of *P. Sieboldii* in commerce, the type being still in

advance of the "improved" varieties. There is also a set of double Primroses, common in English gardens, the colors varying from rich deep red to lavender, yellow and pure white. We have never been able to get the red-flowering sort, but we have the other colors and grow them in quantities in frames for early spring flowers, treating them the same as Violets. They have proved as hardy as the Polyanthus during the past winter and quite as satisfactory in the open border, under the same treatment. These are true Primroses, having one flower only on each stem, this being the point in which they differ from the Polyanthus or many-flowered Primrose.

All the yellow-flowered Narcissus are past, and we have only the Poet's varieties left, but these are very beautiful now, planted in the grass under Apple-trees in an orchard. This is the proper place for the stellate-flowered kinds, without doubt. Not only are the rich borders unfitted to them, but the flowers to be seen at their best need a green setting such as the grass affords, and under trees the grass is thin and is allowed to grow until hay-time, when the Narcissus have about matured their foliage, and may be cut off without injury to the bulbs. All of the Poeticus section, also Barrii, Leedsii and incomparabilis are eminently adapted to this mode of culture, and I am not sure that some of the large yellow Trumpet kinds would not do better under this system, but this is a matter for further trial. Some Narcissi dwindle away and some thrive in rich soil. Those that disappear probably have good reason for doing so, and it is fair to assume that, provided they are hardy, it must be from ungenial soil.

Mertensia Virginica has been beautiful for two weeks past, and is still as blue as the Myosotis. It is one of the best spring flowers we have, and as a companion for it may be recommended Corydalis nobilis, the noble Fumitory, a near relative to the Dicentras, with foliage similarly cut, and large clusters of flowers of bright yellow, with dark brown centres. It is a difficult plant to transplant, owing to the nature of the root-stock. Any one who has moved roots of the old Bleeding-heart will remember the half-decayed state of the thickened roots, and the same peculiarity applies to Corydalis nobilis, so much so that it takes a year or two for the plants to fully recover from a removal. But it is a valuable plant for spring blooming and a fitting companion for Dicentra eximia, the best form of this being now in full bloom. It is one of the best native plants we have for the open border, though it comes from Tennessee and Georgia.

Trollius Europæus and T. Asiaticus have proved so well adapted to this climate that a trial of the other cultivated sorts has been made, and a complete set of those grown in European gardens were obtained last year. These are now in bloom, with the exception of T. patulus and its white variety, the plants of which did not live. The double T. Japonicus is a real gain, owing to the brilliance of its orange-yellow color, and so is T. napellifolius, which is a fine large flower, but the improved garden forms sent are no better than those raised here from seed of T. Europæus and T. Asiaticus, and are not so well suited to our climate. It is desirable when a good form from seedling plants appears in the garden to save seed from it. Plants raised in this way often have exceptional value, and some of the best globe flowers we now have we secured by this means.

Pæonia Wittmanniana is now in flower. It comes in before P. tenuifolia, and has single cup-shaped creamy white flowers, with abundant yellow anthers and traces of purple at the base of the cup. It is interesting as a species, and also on account of its early flowering season. P. tenuifolia will be in bloom in a day or two, and there are few more desirable garden plants than the early-flowering Pæonies, including the tree varieties, and they come at a season when there are no rosebugs to devour them.

South Lancaster, Mass.

E. O. Orpet.

Carex Japonica variegata.—This is one of the most elegant of the dwarf Grasses and is perfectly hardy in this latitude. The narrow leaves are twelve to eighteen inches long and deeply channeled, and vary in color from nearly pure white on poor soil to those with interlinings of white and green on more generous nourishment. It flowers in April or May on triangular stems, which are long and pendulous and scatter the abundant golden pollen in every breeze. But the plant increases rapidly by underground shoots. It is especially desirable for a front row in the border, and would be very attractive in a greenhouse if grown in shallow pots for decorations.

Allium Margaritanicum.—This is a rather uncommon Onion from Asia Minor, which is a distinct and hardy species well suited to the rockery. Its rounded leaves are about six inches high and the flowers are clustered in a globe of about an inch diameter, forming a hairy-like white ball. Like all the hardy

Alliums this species seeds freely and will maintain itself under adverse conditions.

Why do Blossom-buds Winter-kill?

To the Editor of GARDEN AND FOREST:

Sir,—In your issue of May 6th, Mr. Willard is quoted in a note as saying that the failure of the plum crop proves that the fruit cannot endure a temperature of twenty-two degrees below zero. Mr. Willard has had more experience than I, but it seems to me that he is only considering one of the factors in hardiness of plants. The fact that fruit does not endure a certain degree of cold one winter is no proof that it may not endure even a lower degree under different conditions.

Here, we ordinarily think of fourteen or fifteen degrees below zero as fatal to the peach crop, and as we often have a lower temperature than that but few Peaches are planted. During the winter of 1894-5 the thermometer several times ranged below twenty, and once sank to twenty-five below zero, and yet only half the Peach-buds were killed, and the trees produced a good crop the season following. Last winter, with a minimum temperature of only five degrees below zero, fully one-third of the Peach-buds were killed. I do not know just what conditions made the buds more hardy one season than another, neither do I know why part of the buds on a tree should be more hardy than the rest. Even in the axil of the same leaf one bud may be killed and the other live.

Other organic substances show the same differences. In a half-bushel basket of potatoes exposed to the cold in a cellar, I have often found frozen tubers scattered through the basket and the rest not frozen. In the blossom-buds of the Cherry and Plum one or more may often be found killed, while the rest have escaped.

When we first began to spray our Peach-trees to prevent the fruit from rotting, the Bordeaux mixture used was not properly prepared, and as a consequence a large part of the leaves on the sprayed trees fell off prematurely. The next spring it was found that there was a larger proportion of live buds on the trees from which the leaves had fallen than on the rest of the same variety. My explanation at the time was that the buds become less hardy in proportion as they are more developed. We know this is true in the spring. The question at once arises, at what stage in the development of a bud is it the most hardy, and how can we best control that development? This seems to me a promising field for some careful study.

A Destructive Scale in the Marquesas Islands.

To the Editor of GARDEN AND FOREST:

Sir,—Mr. Craw sends me part of a Coccoanut-leaf and a leaf of some tree called "Vee," from the Marquesas Islands, thickly infested by a scale insect. He received the specimens from Mr. J. Wilkinson, of Tanata, who reported the insect as very destructive, remarking that "it breeds faster and attends to business better than anything else in our little world." The scale proves to be the Aspidiotus destructor of Signoret, described in 1869 from specimens received from the island of Bourbon, where it was very destructive to Coccoanut Palms, and also infested Guava and other plants. In 1891 Maskell recorded it on Coccoanut in the Laccadive Islands, and I have shown that it is common in the West Indies. Mr. Wilkinson thought it had reached the Marquesas from California or New Zealand, but it is not known in either of these localities. Care should be taken that it is not introduced into southern California or Florida.

Recent Publications.

The second part of the botanical series of the publications of the Columbian Museum of Chicago contains an account of the plants of West Virginia, by C. F. Millsbaugh, curator of the Department of Botany, and Lawrence W. Nuttall, prefaced by a short account of the topographical and climatic features of the state, its botanical history and an account of the special features of the flora. Two thousand five hundred and eighty-four species, varieties and forms of plants have been detected in the state, including more than a thousand species of Fungi and Lichens, and

1,309 species of flowering plants. It is claimed that West Virginia contains a greater amount of hard-wood timber in its forests than any other state, and the authors are convinced that "nearly or quite two-thirds of the state remains uncleared, and by far the greater portion of the uncleared land is still in virgin forests, where the axe of man has never found its way, and where magnificent specimens of forest growth stand thickly side by side and reach a towering height, no finer view of standing timber may be had within the confines of the Union. These splendid forests, covering over sixteen thousand square miles, yield nearly every species found in the north. Here trees grow to such size that ordinary methods will not suffice to handle them, and are frequently so densely compact that the light of day scarce penetrates their shade, and pathways must be cut before the axemen can find room to work." Among the principal timber-trees enumerated are the White Ash, the Beech, the Black and Yellow Birch, the Lindens, the Chestnut, Wild Cherry, the Hemlock, the Hickory, the Sugar Maple, the White and Chestnut Oaks, the White Pine, the Red Spruce, the Tulip-tree and the Black Walnut.

Notes.

More than ten thousand cases of apples reached the London market on a single steamer on the second of May from Tasmania. Permain and Ribston Pippins were reported of the first quality and evenly graded, and brought at wholesale from \$2.50 to \$3.25 a bushel, and a small quantity from Victoria brought \$4.50.

New potatoes are coming from as far north as Georgia and South Carolina, as are cabbage, string-beans, beets and carrots. New beets are also coming from Louisiana, and the first peppers of the season from that state arrived last Saturday. Peas from Maryland are in the markets, the bulk of supplies of this vegetable coming from Virginia. Cucumbers, from glass houses near Savannah and Charleston, are offered with field-grown stock from Florida. From near-by points, grown under glass and in the open, are new onions, lettuce, cauliflower, beets, sorrel, dandelion, kale, spinach, rhubarb and radishes.

Huckleberries of good quality, from North Carolina, may be had in this city for thirty cents a quart. The first blackberries, from the same state, were offered here two weeks ago, but these were small and not desirable. The first Peento peaches from Florida reached New York last Saturday and are now selling at retail for \$1.50 a dozen, the price asked also for Bidwell peaches. While strawberries have been plentiful enough, those of prime quality are scarce, owing to continued dry weather. This fruit is now coming from as far north as Maryland, and Delaware berries are looked for in a few days.

We learn from Thomas H. Kearney, Jr., of the Division of Agrostology, in the Department of Agriculture, Washington, that *Buckleya distichophylla* has been collected by Master Harry Allen, near Newport, Cocke County, Tennessee, about sixteen miles below Wolf Creek, so that its known habitat is greatly extended. It will be remembered that *Buckleya* is one of the rarest of North American shrubs. It was described and figured in this journal, vol. iii., page 236, and on page 168 of the present year Mr. Kearney gave an interesting account of its discovery at several points near Paint Rock, which for many years was considered the only place where it was found in a natural state.

A protracted drought so early in the year as this is phenomenal, but all the country hereabout is now suffering for lack of water. When pasture-fields in the middle of May look as brown as they do in August, and there is no grass growing in the meadows, and even the Plantain leaves are curling up on the lawn, the outlook for the farm and garden is not promising. The extreme hot weather forced flowering plants into bloom earlier than usual, but the flowers came all at once when they should have been spread over at least a fortnight. A forced growth is always feeble and the flowers lasted but a little while. The season of Tulips and Daffodils was never so short. Meanwhile, vegetable seeds lying in the ground, which is almost dust-dry, show no signs of germination. These droughts, which now seem to come every year at one season or another, are so destructive that no garden is safe without some appliance for irrigation.

A correspondent in writing of the Flower Carnival in San José, California, which was one of the earliest towns in the northern part of that state to revive the old Spanish custom, says that the town was filled from the sixth of May to the ninth with great crowds from every direction. More than one hundred acres of flowers had been planted in vacant lots about the town and cared for by the organization which prepared the pageant, and, besides these, car-loads of material were brought in from other places, and the entire Santa Clara valley was laid under contribution for flowers used to decorate the innumerable floats and vehicles which made up the grand parade or to be strewn about lavishly in this Battle of the Roses. The streets were decorated with arches and the houses with flowers and boughs of Douglas Spruce and Redwood, while the gray moss which streams from the White Oaks was largely used in mural decorations. The procession was three miles long, and some of the floats were considered wonders of art. Among the leading participants were the school children from the city and other points in the valley, each school competing for a prize for the most beautiful and original design.

A bulletin lately issued by the Agricultural Experiment Station of Pennsylvania gives an account of the phosphate deposits in Juniata County which were discovered last year. It has long been known that there was a narrow belt of unusually fertile soil along the two central ridges of this county, and it was in this belt that the discovery was made. Along the outcrop of the Oriskany sandstone, between this and the overlying Onondaga limestone, is a decomposed mass of marls and sands in which the phosphate material is found. The seams lie conformably with the stratification of the country and can be easily traced. Trenches give evidence of a persistent belt of phosphate which can be easily mined, is accessible to railroad, and encloses valuable material enough to constitute an industry. The material is not of a grade equal to that of the southern phosphate, but it will bear transportation to a moderate distance. What renders the discovery of special interest, however, is the fact that almost exactly similar geological conditions exist in many parts of the state, so that there is warrant for the belief that further explorations may develop phosphate deposits in various parts of the commonwealth, and it so this may result in an important addition to the agricultural resources of the state.

In regard to the sale of American apples in England, Messrs. J. C. Houghton & Co., of Liverpool, who deal in high-grade apples at wholesale, write that early in the season fine King apples always sell well, and last year they brought as high as \$5.62½ a barrel, although this fruit generally ranges at wholesale at from \$4.00 to \$5.00. As the season advances King apples become softer, and Baldwins, which are always appreciated in the English market, take their place, in a measure, at prices of from \$3.00 to \$4.25. Greenings are usually in good demand for culinary purposes, but not being used for dessert do not command the prices paid for more attractive-looking red apples. York Imperials last year were in high favor, and sound large fruit brought from \$4.25 to \$5.63 a barrel. Ben Davis, Winesap and Spitzenberg are all well known and appreciated, and bring about the same prices as Baldwins. Golden Russets usually sell for low prices while other apples are coming forward freely, but in the spring, when most varieties are exhausted, they frequently command full prices, and sales have been recently made at from \$4.25 to \$5.40 a barrel. Newtown and Albemarle Pippins are regarded there as the very best American apples, and during last season they brought at auction as much as \$8.37, but when arrivals were heavy, prices ruled at from \$3.75 to \$5.25. Of course, these prices apply to selected fruit, for small and inferior Albemarle and Newtown Pippins bring less than other varieties. In fact, it is hardly worth while for Americans to export small apples to compete with those from the European continent and English orchards. Where the Americans have the advantage is in the size and color of their fruit and in the convenient form in which it is packed—that is, in barrels. Only the larger and best-colored apples of any variety should be sent if good prices are to be assured.

The death is announced of the Abbé Delavay, for many years a missionary in Yun-nan, the south-western province of China, where he made large collections of plants, discovering in one small region more undescribed species than have fallen to any other one botanical collector of this generation. Among the plants discovered and introduced into Europe by him are numerous species of *Primula*, *Rhododendron* and other plants destined to keep green the memory of this brave, zealous and indefatigable priest.

Forest Fires—Another Lesson from India.

THE unusual drought which prevails throughout the eastern United States has made the forests more liable to fire than usual at this season, and as we write there are destructive conflagrations in the woods of southern New Jersey, western Pennsylvania, Long Island, the Adirondacks and all of the New England states. It is the same sickening story of standing timber, saplings and seedlings vanishing together in smoke, while the soil is burned to absolute sterility, or, at least, is left in a less productive condition for new forest growth. In many cases, too, fences, orchards, fruit gardens and farm-buildings have been swept away, so that the whole thing means dead loss for the present, and loss of hope for the future, without any palliation or compensating advantage. Next spring, if the weather is dry when farmers who live on the forest border begin to start their brush fires, the woods will burn again, and careless campers, locomotive sparks and the reckless tramp who owns a match will all aid in the work of destruction. This will be repeated the spring following, and so on, but it is evident that an end must come to this wanton destruction at some time in the future. Intelligent people in various parts of the country are coming to understand that the loss of the forests is not simply a loss to their owner, but a loss to the community. The legislatures of different states are enacting laws which, if properly enforced, would protect the woods. States like Maine and Minnesota have taken the lead in this legislation, and if the laws would enact themselves there would be few more forest fires. But, as we have repeated over and over again, what is primarily needed is an educated public opinion. As soon as it is generally understood by the people who live near the forest that it is as truly to their personal interest to stop a fire in the woods as it is to stop a fire in their own buildings there would be good laws, and these laws would be enforced.

This we have asserted often, because the statement is based on reasonable grounds, but we never realized to the full that it had been demonstrated on a large scale until we carefully read the paper by Mr. Ribbentrop, to which allusion was lately made on page 191. Under the sway of the Mohammedans in India, the wandering tribes fired

the forests year after year to provide grazing grounds for their growing herds of cattle. Under the British rule the herds multiplied and new areas were cleaned by fire. The woods were everywhere looked upon, as they were in the early history of this country, as barriers against progress, obstructions which must be swept away to make room for profitable agriculture. At last it began to be felt in India, as we are beginning to feel here, that wood is worth something. The Government began to realize that large portions of the forest area in the Indian Empire would be burned unless special measures were adopted for their protection. Fifteen thousand square miles were set apart for special patrol and protection in 1883. Twice that area is now protected, and the rest of the forest which is not under this special care has secured much greater immunity from fire. The protected areas include not only the ever-green woods, and those which in marshy regions are self-protected, but large areas of dry forests which were formerly subjected to yearly or, at least, to oft-recurring conflagrations. Besides this, fire is kept out of the comparatively unprotected woods, and this is largely due, according to Mr. Ribbentrop, to the spread of knowledge among the agricultural population. Their growing interest in the protection of the woods has led to a careful use of fire in their vicinity.

The Indian Forest Department has thus proved clearly that it is possible to protect large forest areas from fire even in the very driest climate by a well-considered system of patrol, and their experience has also proved that the example set by Government has caused the agricultural population to pay a greater respect to forest covering. Of course, in this country, where labor is comparatively scarce and dear, a system of forest guards will be more expensive, but, on the other hand, the education of the people is much higher than it is among Indian peasants, and, as Mr. Ribbentrop well says, "the feeling of the people in respect to a conservative forest policy has more to do with successful fire protection than any number of fire-breaks and watchers." No doubt, the way to begin to protect forests is to pay for their protection. No scheme for voluntary help is trustworthy. Strict laws are necessary and the enforcement of them requires men and money, but this will be the cheapest process in the long run, for the people will soon learn to be careful how to use fire in the dangerous neighborhood of forests, and they will soon be helpful in enforcing the laws rather than harmful in opposing them.

SINCE the above was written we have received a circular issued by the Forestry Division of the Department of Agriculture, which discusses the question whether protection against forest fires is practicable, and the answer is that although these fires cannot be altogether prevented by any system, there is abundant experience on this continent to prove that it is practicable and simple to protect large forest areas against fire, and that it is practicable to burn the debris of the lumbermen's chopping, and to do both cheaply. In support of the first proposition the report of the Commissioner of the Crown Lands of the Province of Ontario for 1895 is quoted. Here a system of fire-rangin is established under which a number of men are enlisted from May to September wherever there is special danger. The men who own licenses to cut the lumber, and who are, therefore, interested and who are familiar with the topography, are allowed to nominate the men employed, the Department reserving the right to reject or remove any one who neglects his duties. These rangers put up posters containing the fire act throughout the territory under their charge and hand the laws in pamphlet to settlers, so that everybody becomes familiar with their provisions. They are authorized to employ assistance when the fires break out, and when these assume dangerous proportions they are required to notify the Department and the licensee, so that both may be represented. The Department bears half of the expense, and at the end of the season, diaries, with sworn accounts and reports on the fire losses, etc., are sent

in. Last summer was an exceptionally dangerous one, being the driest for years, and yet owing to this close supervision no large destruction of timber took place, and altogether the service has proved admirably adapted to accomplish the end for which it was established.

On the second point a large firm of lumbermen in Michigan testify that they always burn the débris from their operations in the fall or spring when the ground is damp, and the wind is in the right direction, so that the fires will not spread. This has proved perfectly successful, and for years they have not suffered from any destructive forest fires. The open chopping dries out more quickly in the spring than the neighboring timbered land, consequently the fire burns in the open and stops as soon as it comes to the woods. Only common sense and ordinary judgment are required to point out the proper time to burn the choppings and thus remove a menace to uncut timber. These lumbermen consider this burning over a good insurance, and the cost is so trifling that it would be criminal carelessness on their part if they did not guard against losses to themselves and to their neighbors.

The cost of the protective service in Ontario was about three and a quarter cents a thousand feet, while the cost of burning the débris by the lumber companies was \$5.00 a square mile, or one-tenth of a cent a thousand feet of lumber cut. At this rate the cost of burning throughout the great lumbering states of Michigan, Wisconsin and Minnesota would be less than \$35,000 a year, and this would prevent losses which foot up to millions of dollars annually. If to this precaution a service similar to the one in Ontario were carried out at the same expense it would appear that for \$100,000 a year each of these states could have a well-organized service of special guards which would prevent nearly all the forest fires. To get some conception of what is really lost in these fires, and to show how insignificant in comparison to this the expenditure of any ordinary sum for protection would be, the following computation by the Forest Commissioner of Pennsylvania is quoted:

The most obvious consequences of forest fires, serious as these may be, are by no means of the greatest importance. Loss of logs, of bark, of standing timber, young and old, of fences, and occasionally of buildings, is not less than a million of dollars annually to this commonwealth (Pennsylvania). The indirect or the consequential damage to the state is many times greater. In fact, it is so great that it appears incredible until a careful study of the whole subject is made. For example, it is fairly within bounds to assert that if all the unproductive land now vacant and uncared for within the limits of the state were protected from forest fires for, say, forty years, the timber then growing would be worth not less than \$1,200,000,000. Now, it would seem that if this growth were destroyed by fire when but a year old, the direct loss to the commonwealth would be absolutely unimportant. The same might be said if we were to see it destroyed at two, three, four, or even five years of age. But when we remember that in burning these seedlings which are but a year old we destroy a crop which, in point of time, is one-fortieth of its way on to a money value of \$1,200,000,000, the damages, if expressed in figures, must equal not less than \$30,000,000 as the loss to the commonwealth.

Shrubs, Native and Foreign.

CONTINUING our remarks on the effects of the winter on trees and shrubs in eastern Massachusetts made in our last issue, it can be said generally that the flower-buds only of shrubs which bloom early in the season have suffered, and that, in spite of the severity of the winter, nearly all later-blooming plants are flowering profusely this season, with the exception, perhaps, of a few varieties of Rhododendrons of doubtful hardiness, which have lost their flower-buds, although their foliage is untouched. Even shrubs which ordinarily suffer in very cold winters are now covered with flowers, like the Halesia or Silver Bell Tree, which has never been more beautiful than it is this year. The variety of this plant raised by Mr. Meehan in his nursery at Germantown, and already figured in this journal (vol. v., p. 535), is covered with flowers and promises to

become a first-rate addition to our shrubberies. The fact that *Fothergilla Gardneri*, which was figured in this journal last year (vol. viii, p. 445), has escaped the winter untouched, and has been loaded with its lovely white flowers, is evidence of the value of this southern shrub for northern gardens. Among shrubs which flower the middle of May, none surpasses it in shapeliness of habit or in profusion of bloom. It is one of those shrubs which grow in attractiveness each year, and which, as has already been said more than once in these columns, should be seen in all collections of hardy plants.

Rhododendron Vaseyi (vol. i., p. 377) has been covered as usual with its lovely pure pink flowers, and the value of this species in northern gardens appears now to be fully established, although in England it is said to be much less satisfactory than it is here.

All the bush Honeysuckles are flowering profusely, displaying in their flowers a considerable range of colors from deep rose to white and to clear yellow. On the whole, this is one of the most satisfactory groups of shrubs. They are all perfectly hardy, of excellent habit and neat, clean foliage; they always bloom freely, and their flowers are followed by brilliant scarlet, yellow or black fruits which cover the branches in early or late summer, when few other plants bear conspicuous fruits. Through cross-breeding and selection there is now a large number of these Honeysuckles from which the planter can select, and by massing many plants with a reference to the color of their flowers or of their fruit remarkable effects can be produced.

Among Apple-trees, our native Crab, *Pyrus coronaria*, is the latest to bloom. This is a small tree of excellent habit and large fragrant pink flowers which, as they do not appear until after the leaves have partly grown, are somewhat hidden by the young foliage. They are, however, more fragrant than those of any other Apple-tree, and the bright waxy fruit, which hangs gracefully on long slender stems, is also fragrant.

All the Thorn-trees, native and foreign, are blooming abundantly this year, and no one who has not seen a well-established collection of these trees and shrubs can form an idea of their beauty at this season or of the uses to which they can be put in the decoration of parks and large gardens. The fact that they live to a great age, blooming profusely every year, adds to their value.

Among Barberries for northern gardens not one compares with the Japanese *Berberis Sieboldii* (vol. iii., p. 249). The bright yellow flowers of this shrub contrast brilliantly with the large lustrous foliage, and this late in the autumn assumes magnificent tints of scarlet and orange. For some reason this shrub has remained rare in collections, while the less desirable *Berberis Thunbergii* has become in the neighborhood of Boston one of the commonest garden plants.

The Dauphin Elm.

THE White Elm as a street-tree is conspicuously rare throughout central Pennsylvania, and at present is probably less planted than any other native tree. Fine specimens may be found in the older streets of cities and about old country seats, yet there are many otherwise intelligent people who believe that the Elm does not thrive in Pennsylvania or, indeed, south of New England.

Some two years ago Dr. Rothrock pointed out the fallacy of this idea, which, no doubt, was developed from the fact that the tall high-branching Elm, so associated in the popular mind with New England towns and scenery, is replaced almost entirely in Pennsylvania by the type described by Dr. Rothrock* as "branching symmetrically upward and outward from near the ground, forming a large, round head, while the tips of the branches droop until they almost suggest the Weeping Willow." It is to this type most of the Elms in and near the Susquehanna Valley conform,

* *Forest Leaves*, February, 1894.

and though the finest specimens are found in low ground, as "Old Elm" at Paxtang, with a diameter of almost five feet, others like the Elm at State Street entrance to the Capitol grounds, Harrisburg, live in entirely changed conditions without evidence of deterioration. The State Street Elm has a diameter of three and a half feet, and stands in what was originally swampy land. In 1785 it was already a large tree, and was one of the landmarks in laying out the town. The land has long since been drained, and the tree has endured everything that a street-tree has to suffer, yet, in spite of escaping gas, encroaching pavements, dust, blizzards and electric linemen, is still a beautiful tree and dignifies the entrance-way it adorns.

The great Elm at Dauphin, known locally as the Seven Brothers (see page 215), also belongs to the low-branching class, and with a circumference of twenty-four feet and a spread to branches of almost a hundred feet, is one of the most notable trees in the lower Susquehanna Valley, and if a single tree probably the largest. Its local name refers to the main branches of the tree, and not to the trunk, which, if compound, is formed of not more than four boles. Those who have known the Dauphin Elm longest, however, consider it one tree, and state that they have seen a distinct increase in its size during their lifetime.

The Elm stands on the river-bank, midway between the lock of the Pennsylvania Canal and the river, at this point only a hundred feet apart. The crest of the bank is about thirty feet above low-water mark, and the tree-trunk, which extends from near the crest some distance down the sloping bank, has pronounced differences in form on the upper more protected side, and the lower side, exposed to freshets. The lowest divergence of branches occurs on the side facing the lock, where the branching begins two feet above the ground; on the river-side the lowest divergence is four feet above the base of trunk. Owing to the peculiar features of the ground and encroaching foliage of trees on both sides of the canal, it is impossible to get a good view of this remarkable tree when it bears its great canopy of leaves. Through the summer its crown rises, dome-like, above the surrounding mass of foliage, and may be distinguished from points on the opposite shore of the Susquehanna River, here almost a mile in width.

The picturesque beauty of the Susquehanna at this point, with the bold cliffs of the Narrows below, and the wide bays of the river running inshore above, is too well known to call for any description, but the traveler by rail goes faster and faster through this part of the country, and the real Susquehanna is almost a sealed book, except to raftsmen and canoeemen, and will continue to be so unless, with the application of electricity, travel upon the canals following its course becomes once again a possibility.

The Dauphin Elm has been held in grateful remembrance by thousands of men and animals who in the more than sixty years of the canal's existence have enjoyed a brief rest in its shade, as they halted on their weary march from the mountains to tidewater. Besides this army of humble-folk, many well-known travelers passed beneath the Elm in the twenty years when packet travel was the ordinary means of transit through this part of the state, and Dickens in his *American Notes* has given his impressions of the journey.

The immediate surroundings of the Elm suggest a consideration of the present status of trees, especially those of commanding size. They appear to have no rights that any one is bound to respect, and yet there is nothing unreasonable in the idea that a tree of distinction should receive a certain amount of consideration. It is not an exaggeration to state that generally in the rural districts, the difficulty of seeing all of a tree is in direct proportion to its size. A tree of medium size will serve as a prop for spades and hoes and fence-rails, but with increase in size comes a greater opportunity to pile up, until in the case of a Chestnut whose crown and blossoms I saw last summer and supposed it to have a trunk somewhere, the visible connection between the spreading limbs and the

ground was formed of several agricultural implements, a broken wagon, some railroad ties and a stable door. The ordinary treatment of trees at present depends entirely on the point of view, and this in matters of greater importance than trees is largely a matter of condition and education. A man has an undoubted legal right to cover his own trees with barn doors, if he feels so disposed, but, with the growth of sentiments such as were expressed at the Forestry meeting recently held in Philadelphia, it is reasonable to hope that the time is passing quickly when a stately, beautiful tree, such as the great Elm, will suggest itself simply as a way station for tools, or as the party wall of a henhouse.

The photographs of the Elm and the Dauphin Chestnut (page 114, No 421, GARDEN AND FOREST) were taken by Mr. George Roberts, of Harrisburg, Pennsylvania.

Ann Arbor, Mich.

The Flora of the California Coast Range.—II.

THE MENDOCINO COAST BARRENS.

THE rivers of western Mendocino County run a short course to the sea, the larger ones rising in a high barrier range, which, running north and south, divides the county. Their course cuts through high mountain chains clothed densely with Redwood forest. The ranges decrease in height as they approach the ocean, and in the last few miles of their course the rivers are tidal canals hemmed in by steep slopes covered with Redwood, Fir, *Abies grandis*, and western Hemlock. Groves of Alder, which here reaches its best development, are found in the few narrow bottom-lands. The underbrush is varied and luxuriant. Ferns riot everywhere, and the common Brake, *Pteris aquilana*, attains giant proportions, sometimes forming dense masses eight feet high. From the tidal rivers the steep slopes rise for half a mile and suddenly open on small rolling table-lands, locally called barrens, or, very inappropriately, prairies. These barrens, found between all the larger streams along the coast, are sometimes four miles wide, while at some points they cover only a few acres. They are all of the same altitude and geological formation and appear to be the remains of an extensive table-land, through which the streams have furrowed out their present courses.

These barrens are an interesting field for botanists, and from an æsthetic point of view most picturesque. They are slightly uneven, breaking into swales at the sides and bordered by an irregular line of forests. On the ocean side the land drops by heavily wooded slopes and gullies until the point is reached where the ocean has gnawed it away into rocky bluffs, and the skeletons of the older lands are seen in islets, rocks and reefs far out to sea. Fogs roll inland over the barrens and the air is always fresh and moist. Everywhere are masses of trees and thickets, with occasional open groves of *Pinus muricata*, the Prickly Pine, the black trunks of the trees rising fifty feet high, with scanty leaves, uneven limbs, and shrinking inland from the prevailing ocean winds, the cones of many years still clinging to them, or, perhaps, all life gone and the skeleton only adorned by the ever-persisting open cones.

In the lower areas, which are so flat that the water stands there in pools in the winter, and where the scanty covering of peaty soil above the impervious clay would seem incapable of supporting life, there are thickets almost impenetrable of the north coast Cypress, *Cupressus Goveniana*, slender, straight, cone-covered, and mingled with them the north coast Scrub Pine, equally slender and straight. When this dense growth reaches a height of ten feet perhaps a bush fire will sweep through it, leaving a denuded space or skeleton stems, and the fire which consumes the thicket opens the cones and seeds the land abundantly for another tangle. In the hard struggle for existence these little trees fruit when a foot high. Dense tracts of them stretch monotonously away in every direction. The overflow from brackish pools and from dammed springs gathers along the sides in swales with deeper soils and in small

bogs, where *Kalmias*, *Rhododendrons* and the Deer Fern, *Lomarea Spicant*, form dense masses, with a growth of *Sphagnum* in the more springy parts. In the more generous soil clean, symmetrical, well-developed specimens of two Pines are found, the broad, conical *Pinus muricata*, its dark long foliage contrasting strongly with *P. contorta*, with its delicate cones and short light green needles. *Lilium maritimum* finds a congenial home in these low swales, rooting in the clumps of Deer Ferns or *Rhododendrons*, and throwing up slender stems from three to five feet high, with dark green leaves in ample whorls and deep red tubular flowers, harmonizing well with the surroundings. Further down these swales are bordered with Redwood and other timber trees until they join the main forest which encloses the barrens.

The higher barrens are covered largely with the tiny-leaved *Manzanita*, *Arctostaphylos nummularia*, with scattered Pines and *Rhododendrons* and a few of the larger fuzzy *Manzanitas*, *A. tomentosa*. *Ceanothus diversifolius*, a low-growing sticky-leaved plant with blue flowers, a beautiful shrub when in bloom, and *C. sorediatus*, a rigid spiny shrub, not without beauty when covered with its bright bloom, are found here. The small-leaved *Manzanita*, as I saw it last February, when it was festooned with tiny bells, was a most interesting plant. Little ones only six inches high were in flower, looking like the dwarf *Ericas*, and the larger ones were masses of bloom. The plant is five feet high at its best. In the mixed growth on the borders of the swales and in the deep wood grows *Rhododendron Californicum*, the loveliest of California shrubs. In the higher heaths it is a low, many-stemmed bush with gnarled charred stumps which have survived many fires. In the wood borders it is a tall shrub; in the deep wood it is twelve or fifteen feet high, its glossy evergreen leaves suggesting those of the evergreen *Magnolia*, and the pink blossoms in this moist air are produced for a long season. Even the rough woodsmen admire it, and it is a most impressive plant, even to an unobserving visitor.

The Huckleberry, *Vaccinium ovatum*, is everywhere. Here it takes a low compressed form, while in the wood it is tall and slender. It flourishes in the fogs, and late in autumn the bushes are black with juicy berries which only feed the birds. On the borders of the woods and throughout the cleared or burned lands the wild Blackberry, *Rubus ursinus*, more properly a Dewberry, trails over the ground and drapes every stump, fallen log and bush. It is perfectly at home here and produces in profusion fruit of the largest size. It is sought by parties of campers who leave their homes in the hot interior valleys in July for a few weeks of the cool foggy air of the Coast Range, with incidental berries. The Thimble Berry, *Rubus Nutkanus*, a shrub attractive in leaf and flower and with palatable fruit, thrives in the cool wood borders. Sallal, that is the fruit of *Gaultheria Shallon*, is another edible berry which grows on a low ericaceous shrub in dense mats on the woodsides.

In the higher portions a burn will show thousands of tall yellow flowers of *Zygadenus paniculatus*; the dwarf dark purple-flowered form of *Brodiaea laxa* is not uncommon, and a little *Gentian*, with many annuals, is also to be seen. The Cypress, which when crowded is often seen in its dwarf form here, becomes a beautiful and symmetrical tree. In the rich woodland borders its slender and beautiful trunk is forty feet high and scarcely seems to taper. Younger trees of the Western Hemlock are exquisitely lovely; the light green foliage and drooping terminal branches give it a weeping effect that I have never seen elsewhere. Groves of perfect young specimens of *Abies grandis* are found in the cleared woods.

Ukiah, Calif.

Carl Purdy.

The Pitch Pine is our most cheertful tree, especially in the early year when it is full of light, in perfect harmony with the yellow earth and the spring sun, and warms the landscape with its ingrained sunniness. Yet men cut down these trees and set imported Larches about their houses.—*Thoreau*.

Plant Notes.

RUBUS DELICIOSUS.—This Rocky Mountain Raspberry, or Bramble, as it is often called, is one of the most beautiful as well as the most hardy of shrubs which bloom in May, and yet it is comparatively little known to cultivation, although it was discovered by Dr. James, the surgeon of Long's expedition, as early as 1820. This year the flowers opened the first week in May, and although the flowers of all shrubs forced into bloom by the unseasonable weather have been unusually fugacious, the long arching branches of this *Rubus* are still well furnished with a succession of the large white blossoms. These are pure white, saucer-shaped, resembling small Cherokee Roses, and nearly two inches across. The plant, when left to itself, has a low, somewhat spreading growth, and old plants assume something of a straggling habit. This is obviated by cutting back the branches after the flowering season, and it becomes a stout, well-shaped shrub, with light brown or gray bark and leaves on long slender red petioles. The fruit, which does not form abundantly here, is by no means delicious, as its name would indicate, but consists of three or four dry and almost tasteless carpels, although some improvement might be made in it by selection. The plant is best raised from seed, as it is rather hard to propagate from cuttings. Its perfect hardiness and the beauty of its flowers make it a most desirable shrub.

IRIS LUPINA.—The Wolf's Ear Iris is found in Mesopotamia and Central Asia, and is one of the introductions of recent years. Like the other *Oncocyclus* Irises, this is a spring-flowering plant, and coming from a country of rainless summers, it naturally becomes dormant soon after flowering and wakes into life again when the fall rains begin. *I. lupina* varies materially from *I. Susiana*, the best known of this section, especially in the form of the flowers, the falls being lance-shaped and the standards being oval, not orbicular, as in *I. Susiana* and most other *Oncocyclus* Irises. Like other Irises of this section, it has scanty, narrow and dwarf foliage, and the characteristic coloration of narrow veins on a ground of contrasting color. In this case the veins are purplish brown on a yellow or greenish yellow ground, a combination familiar in some *Cypripediums*, and altogether quiet, dainty and indescribable. Of course, language always fails to give any adequate description of the colors of flowers, especially when they are unusual shades of primary colors, but it is quite as impossible to describe the infinite varieties of forms which give individuality to every Iris. Altogether, *I. lupina* is well worth growing for its distinctness and beauty of form and coloring. It has flowered nicely with Mr. Gerard, who, after many experiments, has finally adopted as closely as possible the method of culture worked out by Herr Leichtlin. The rhizomes, which are reliably hardy, should be dried off a few weeks after flowering and kept perfectly dry until late in the year. These Irises are treated in Mr. Gerard's garden as if they were hardy bulbs whose leaves are not frost-proof. After ripening them up they are stored in perfectly dry earth in a cool cellar and planted out at the end of November, at which time the ground is too cool to encourage growth. Planted out in a perfectly open border, without protection, they make no growth until after early frosts are over, and if they were properly grown the previous year their flowering is a matter of course. This season they have required artificial watering, as there has been practically no rain here since March. Every one who has bought *Oncocyclus* Iris roots, especially of the new kinds and those which have been collected, has been struck by their apparent weakness, and this suggested to Mr. Gerard that it might be well to grow them on so as to secure stronger plants. The result was strong roots, but no increase of flowers, so that with his present experience he is not prepared to say that strong roots and luxuriant foliage are conducive to successful flowering. On points like this, however, it is not well to be dogmatic.

NICOTIANA AFFINIS.—This Tobacco plant has probably in most places superseded the old scentless white-flowered

species which was formerly a favorite in many gardens. *Nicotiana affinis* is a stately plant with pure white flowers with long tubes and spreading lobes, the upper two of which slightly reflex. It is a perennial, but the roots sel-

transplanted in the fall from outdoors and grown in a cool temperature make strong blooming plants in March or April, and are not only as showy and attractive as one could desire in any greenhouse, but they furnish excellent

Fig. 32.—White Elm at Dauphin, Pennsylvania.—See page 212.

dom survive the winter here. This is of little importance as it produces seed freely, which germinates plentifully in the border, and the plant is more valuable late in the year than in early summer. It is still more valuable in a cool greenhouse during the early days of spring. Young plants

cutting material, and in vases for house decoration will remain in a good condition for a week. This is owing, perhaps, largely to the fact that they escape the insect fertilization which makes them so short-lived out-of-doors.

Cultural Department.

Carnation Notes.

OUR plants intended to bloom next winter are still in pots and boxes, and will remain there until toward the end of the month. They are standing in a cold frame, and the sashes are not placed over them unless the night is likely to be frosty or rainy. Usually our stock is planted out by the middle of May. Experience has shown us that even a light frost is a severe check to plants. In the fall of the year they will stand a temperature several degrees below freezing without injury, but at this season of the year, after being brought along with fire-heat, they are in a much more tender condition, and a freezing which would have no apparent effect on them in September or October would greatly cripple the plants now. Last year we had much trouble with cut-worms. During the latter part of May they ruined a good many plants, and would have wiped out the entire lot had they not been fought persistently. This season cut-worms appear to be more numerous than ever, and we prefer to keep our young stock in boxes until they are lessened. If any of the readers of GARDEN AND FOREST can recommend a radical cure for this pest it would be a decided service to many growers. We have tried about every remedy we have heard of, but none have been successful. Paris green mixed in fresh bran and scattered among the plants poisons some of the cut-worms, but the majority avoid the poison and keep to the Carnation foliage. Lime, tobacco-dust, hellebore, etc., whether dusted on the plants or scattered about the stems, do not in the least check their ravages. Carbolic acid, mixed with water at the rate of one pint of acid to fifty gallons of water, and sprinkled with a rose-can over the plants, did not seem to be any deterrent, nor was Paris green or sulphate of copper, used in a similar way. Hand-picking with a lantern, although a slow method, if persisted in nightly is as efficacious as any remedy I know of. This season we have trapped a large number by scattering succulent leaves of Cauliflower and Cabbage among Phlox, Strawberries and other affected plants. There ought to be some means of wiping out this pest, but growers in this locality seem to be of opinion that cut-worms and rose-bugs cannot be destroyed unless insecticides are used strong enough to injure or kill the plants.

Plants in the benches indoors require plenty of water during such hot weather as we are now having. We recently gave our benches a mulching with well-rotted cow-manure, after having previously tied up the plants and slightly loosened the surface. There is no reason why good blooms cannot be had indoors until planting-time comes around again if the necessary water, stimulants and syringing are supplied. Syringing with good force on mornings and evenings of clear days will benefit the plants and keep red spider in check. Of course, plenty of outdoor blooms may be had by the middle of July from stock specially grown for summer flowering; but those produced under glass are cleaner than those grown outside, although their stems may not be so wiry.

A good deal has recently been written in the horticultural press concerning Fowler's arsenical solution as a cure for Carnation-rust. Mr. E. G. Hill, the well-known Carnation grower, of Richmond, Indiana, who exhibited some of the finest blooms at the New York Carnation Show last February, states that a one-ounce bottle of the solution mixed with eight gallons of water and applied once a week, so as to thoroughly wet all the foliage, cleared up some of his worst cases of rust after three applications given at intervals of a week, that the diseased leaves turned black, after which they were gathered and destroyed. We have tried this arsenic cure on a few affected plants of Rose Queen and Daybreak, but cannot see that it has checked the disease, and the leaves have not become discolored. We experimented with the solution in different strengths and find that by applying it at the rate of one ounce to two gallons of water the rust is apparently killed after two applications. As a further experiment we tried the solution on a few plants at the rate of one ounce to one-half gallon of water and failed to detect any injury to the plants, although possibly repeated syringing with this strength might result in injury. There is no question but the dangers of rust have been exaggerated to some extent, but it is, nevertheless, the worst foe the Carnation grower has to fight. We have tried copper solutions with only a moderate amount of success. I believe a great deal may be done to prevent the spread of rust by cleanliness in the houses and by careful hand-picking of any affected plants when they first show the disease. But when whole houses are attacked it will not pay to use such measures, and from an experience with Fowler's solution I am satisfied that it will destroy the rust if applied somewhat stronger than Mr.

Hill recommended. It has not been claimed that it will prevent spread. A longer trial is necessary, on a more extensive scale, to thoroughly settle how far the arsenical solution is a success, but it has proved a benefit in our own case, and we feel certain, if given a fair trial, it will be of advantage to others. A good deal of labor is involved in spraying whole houses of plants so as to thoroughly wet them all, but as most private places grow only a few dozen, or at most a few hundred plants, the work can readily be accomplished.

Of last year's introductions, Alaska is likely to prove the best. It is a persistent bloomer, with a stout wiry stem, flowers of good size and form; and the plant is a vigorous grower. Eldorado, yellow, raised by Mr. Shelmire, is well liked in this locality by those who have grown it. Its flowers have brought as much as a dollar and a half a hundred at wholesale in the Boston market. It flowers more freely than Bouton d'Or, Gold-finch or Buttercup. Meteor, as a crimson, while it gave some fine flowers early in the year, cannot be classed as a prolific bloomer, and compares unfavorably with the older F. Mangold. Rose Queen and Bridesmaid were by no means successes last winter, and we purpose trying them again next year. Rose Queen burst its calyx badly, and Bridesmaid, while of a pleasing shade, did not give more than one or two flowers on each plant. Stock of these varieties was started earlier this year, and possibly by having larger plants next September the returns next winter will be more satisfactory. Nicholson has done indifferently this year, nearly every plant having died out, and this experience is common. With the introducer at Framingham it is at this time doing well, but we do not believe it will be grown much after next season in this locality. William Scott is still proving far superior to all other pink varieties and is growing and flowering better than ever before, with no sign of disease. Lizzie McGowan continues to do splendidly in this neighborhood and is grown in preference to other white sorts. A few growers near Boston still cling to Mrs. Fisher, and as a summer bloomer it is unexcelled, but it compares unfavorably with Lizzie McGowan in winter. For some reason, however, Lizzie McGowan is not well grown by some of the leading Carnation growers in this section. As a rule, their soil is light and sandy; we find it succeeds best in a heavy clayey loam.

Taunton, Mass.

W. N. Craig.

The Hardy Flower Garden.

THE month of June is the most interesting of any in the hardy flower garden, and the plants not in bloom are fresh and green. The tall Leopard's Bane, *Doronicum plantagineum*, var. *excelsum*, is just past its best. It is about two feet tall and quite showy, and, with the Dandelion, one of few composites in bloom so early in the season. The common Marsh Forget-me-not, *Myosotis palustris*, and particularly the variety *semperflorens*, does well in the borders, and lasts for years if it is well watered during the summer months. *M. alpestris* is earlier and more tufted, blooming densely during the early spring months. It is a perennial in its native country, the European Alps, while here it is little better than an annual, and to succeed with it a new stock must be raised every year. *Polemonium Richardsonii*, a medium-growing Jacob's-ladder, does better in a rather moist shady place than in the full sunlight, as we lately discovered. Some yellow-flowered kinds, which we did not think much of, might have done better had we tried them in shade. *Phlox ovatus* is the earliest of border Phloxes, and quite showy.

The Globe-flowers, *Trollius Europæus* and *T. Asiaticus*, are among the choicest of border plants. They are rather stately, though not tall, with neatly divided and attractive foliage. The flowers are yellow, and, as the name implies, quite globular, being incurved in the same way as a Chinese *Chrysanthemum*. *T. Asiaticus* is the dwarfest and earliest, and the flowers are also a slightly deeper shade of yellow. The Day Lilies are among the handsomest of border plants, and they are thoroughly hardy. They are not aggressive, but when established will thrive under adverse conditions. I know an old cottage garden, much shaded and pestered with tree-roots, where these Day Lilies grow thriftily and never fail to bloom well. *Hemerocallis graminea* is the earliest, followed by *H. flava* and *H. Middendorffiana*. *H. Thunbergii* is an autumn-blooming kind, and the finest of all. It has been offered many years by a leading firm, but is still scarce.

Lychnis Chalcedonica is never lost. It will grow wherever it has a chance. Its heads of bright scarlet flowers compose well in bouquets. If cut down when going to seed it will start afresh and bloom in the autumn. The Ragged Robin, the double *L. Flos-cuculi*, has lately been offered, I believe, as a specially new thing. It is an acquisition, new or old. The

charming paniced cymes of pink flowers are very effective when massed in the front line of the border. The true Geraniums, or Cranebills, are all attractive, bright and healthy-looking. Our spotted *Geranium maculatum* is regarded with favor, and where not native is cultivated. *G. sanguinea*, a low-growing European species, is in bloom from spring until frost. *G. pratense* is a beautiful plant, whether we look at its handsomely cut palmate leaves or branched panicles of purplish blue flowers.

Oriental Poppies are, without doubt, the showiest of all border flowers. Their blooms are short-lived, but gorgeous while they last. Among others we have *P. pilosum*, *P. rupifragum*, *P. nudicaule* and *P. alpinum*, with the annual varieties, *P. somniferum*, *P. Rhœas* and the Shirley Poppies.

Pæonia tenuifolia is past, *P. paradoxa* and *P. decora* are opening, while the *Albiflora* and *Officinalis* groups are one week later. *Pæonias* and German Iris together in bloom make a beautiful effect, as do blue German Iris and blue Columbinas in a bed of Ghent Azaleas all in bloom together. *Dicentra spectabilis*, the Bleeding-heart, is attractive on the shady side of a shrubby border. Here it is well placed, as in an exposed sunny place it starts early into growth and is scorched by spring frosts.

Perennial Larkspurs are shooting up fast. There are numerous kinds, mostly of hybrid origin, with *Delphinium elatum* as seed parent, at least in the original hybrid. *D. formosum* is among the handsomest. *D. Sinensis* is a pretty dwarf species, which we have in blue and white varieties. In intensity of blue it is unapproached. Foxgloves make a striking show. They are most effective for the interior of shrubberies, but in full sunlight they die out quickly. Sweet Williams make a distinct display, and usually border the shrubberies. Columbinas are abundant, but being biennial in character and coming and going quickly they are not obtrusive. Some garden varieties may run out, but *Aquilegia Olympica* is as good as ever, and *A. Canadensis*, we think, has improved. I recently noted purple forms, and to-day I find one with clear yellow flowers, excepting only purple spurs; in every other respect it is of the *A. Canadensis* type. In addition to German Iris, we have *I. tenax* and *I. oxyspala*, neat native species with attractive mauve-colored flowers. *I. oxyspala* is sweet-scented.

Wellesley, Mass.

T. D. Hatfield.

Tree Pæonies.—These are among the most uncertain of flowering plants in latitudes exposed to even moderately late frosts. They are perfectly hardy, and even if they sometimes unfold their leaves early these are seldom injured by ordinary spring cold, but there seems to be a critical time in the growth of the plants just after the unfolding leaves expose the flowering buds. At that time these buds seem to be very tender, and a slight frost or even a sudden check some day from a low temperature seems enough to prevent their further growth for the season. The time during which the buds are so sensitive appears to be short, and it will sometimes be found that buds which have been exposed a day or two later than others escape damage. To flower these plants with certainty it is evident that we must take care to furnish temporary protection for a few nights when the buds are in this tender condition. There is some difference in time of moving of the Moutan Pæonies, and the only flowers we have this year are on *Gloria Belgarum*, and this exception is, perhaps, due to the fact that they unfold later than the others. A well-grown Tree Pæony with fine flowers is one of the most beautiful of garden plants, but one seldom sees in cultivation varieties which are comparable in beauty to the modern herbaceous kinds. A few fine single-flowered kinds have been introduced from Japan in recent years, the best of these being the white-flowered ones, which are sometimes pure in color and sometimes tinged with pink in the centre. With their golden stamens, and often fringed petals and glaucous foliage, they are the perfection of form and coloring. But if I were to grow but one Moutan Pæony it would be *Reine Elizabeth*, a splendid flower, very double, of a very pure salmon-pink color, deepening toward the centre, and of enormous size. Fortunately, it is not a rare plant, but it requires, like all Pæonies, a generous treatment and a few years of vigorous growth to make a good specimen. *Gloria Belgarum* is much lighter in color, an enlarged form of the ordinary light pink type.

Elizabeth, N. J.

J. N. G.

Shrubs and Climbers Winter-killed.—Though the past winter was not extremely cold, its effects upon some shrubs and climbing plants in this locality have been very disastrous. We had less snow than in any winter in the recollection of the oldest inhabitant, and, no doubt, this was one reason for the unusual number of fatalities. One of the oldest of the college buildings

has been well clothed for years with *Ampelopsis Veitchii*, and last summer this was in perfect health; now not more than one-third of the plants are alive. All the plants in a large bed of *Diervillas* planted three years ago in a moist situation, and uncommonly vigorous last summer, are now killed to within a foot of the ground, while others on higher and drier ground suffered less severely. Some nice bushy plants of *Magnolia Soulangeana* are killed back almost to the ground. *Itea Virginica* shared the same fate. A fine specimen of *Chionanthus Virginica*, standing in a very exposed position, has only barely escaped; it is now just starting into growth, while others in more sheltered locations are in flower. Some old specimens of *Rhus Cotinus* have suffered severely where exposed. Many of the evergreens are also badly browned. Last summer was an exceptional season for growth. Some of the *Magnolias* made shoots over four feet in length, and other shrubs in proportion. But the new wood did not ripen and could not withstand the cold. All the shrubs named are considered perfectly hardy here.

Solanum citrullifolium.—This *Solanum*, one of the annual species, is now flowering in the greenhouses here. It grows to about one foot in height. The leaves are about three inches long by two wide, obovate and pinnatifidly lobed, with stem and midrib covered with short prickles. The flowers are bright blue, with yellow stamens, and about one and a half inches in diameter and borne on short racemes. The corolla is deeply five-cleft. I have not yet tried it in the garden, but it looks as though it might prove a good garden annual. We received the seeds from the Munich Botanic Gardens.

Botanic Garden, Northampton, Mass.

Correspondence.

The Elm-leaf Beetle.

To the Editor of GARDEN AND FOREST :

Sir,—I have some old and beautiful Elms about my house, and the Elm beetle is already beginning its work on their leaves. Please let me know the most successful way of fighting these insects, and I should be also pleased to have some suggestions as to the best way to protect trees on the public streets.

Springfield, Mass.

W. F. C.

[All the most successful methods of combating the Elm-leaf beetle have been published in this paper from time to time, but the safest way to attack the beetle itself is by spraying with some compound of arsenic. A good formula for a spraying mixture is one pound of London purple, six pounds of lime and four quarts of flour in a hundred gallons of water. The lime prevents injury to the foliage by free arsenic, the flour makes the drench somewhat pasty and adherent. Of course, the mixture must be kept stirred, and it must be applied in sufficient quantities and with enough force to touch the surface of all the leaves. On a private place any of the numerous hand-pumps will be found effective, and to reach the top of tall trees an extension pole, such as is used by Dr. E. B. Southwick in the parks of this city, will help to spray any tree that is not more than fifty feet high. The first section of this pole is sixteen feet long and three-quarters of an inch in diameter; the second one is a quarter of an inch in diameter and eighteen feet long; the third is a bamboo bound to the top of the second one, and it is also eighteen feet long. The second pole has two rings or bands at its base, so that it can run up or down, and is hoisted or lowered by a small rope and pulley. The hose is a quarter-inch orifice and made of rubber-cloth insertion, which is strong and light. For larger trees one man can climb up in the branches, and then by using the pole the entire head of the tree can easily be sprayed. Of course, there are various nozzles like the McGowan, the Cyclone, and almost any of them are effective. The spraying should begin as soon as the beetles commence to work, which is when the leaves are rather more than half-grown. It should be repeated every three weeks all summer long, and if the poison is washed off by drenching rain the spraying should be made oftener.

As soon as the larvæ begin to climb down the tree the large limbs and the trunks should be sprayed with the kerosene emulsion. This is made by boiling together six

pounds of soft soap, four quarts of kerosene, two quarts of crude carbolic acid and two gallons of water. This is then diluted in one hundred gallons of water, and it should be sprayed on the trunks and wherever the larvæ are seen, and the ground about the base of the trees, where the insects are found in the form of pupæ, should also be sprayed. This last work should be very thoroughly done, because the insects can be easily attacked and killed in this way, and their destruction at that season will prevent the ravages of the beetles next year.

Of course, in large towns, or wherever there are large estates, several owners can unite together and purchase a steam spraying outfit, by means of which much more rapid work can be done. Several men can be employed at once to manage different lines of hose, and while two or more men are directing the spray into as many trees the same number are climbing adjacent trees, so that the engine and its attendants are occupied all the time. If the nozzle is moved rapidly about, a large tree can be sprayed in three minutes. Some arrangement for climbing large trees without using telegraph-clamps, or creepers, as they are called, ought to be devised, because these sharp metal points penetrate the bark and leave the tree a prey to other insects and fungi. Spraying is not an expensive matter where there is any coöperation, and the machine can be used against other insects, like the tussock moth, which attacks trees of other species. In several places in the country enterprising men have gone into the business of spraying fruit and shade trees—that is, they have one or more complete outfits of machinery, which they send with skilled men to operate them, taking the contract for a certain number of applications during the season at the proper time. No one now attempts to grow orchard fruits on a large scale without facilities for spraying against insects and fungi. It is just as necessary to use these remedies in the case of trees planted for shade or ornament as it is for trees planted for fruit.—ED.]

Close of the California Orange Season.

To the Editor of GARDEN AND FOREST:

Sir,—The orange season is practically at an end in California. There are a few scattering car-loads of Mediterranean Sweets, St. Michaels and Valencia's still to go forward, but all of the Navels have been sent east. About 5,600 car-loads have been shipped, and the early estimates varied between 8,000 and 10,000 car-loads.

The prices realized have been the best for the past five years. A large proportion of the Navels were sold at from \$2.50 to \$2.94 a box, free on board in southern California. The average price for good Navels has been about \$2.20, which nets the grower the satisfactory sum of \$1.70 a box. Seedlings and other varieties have also sold well, but the crop of these has been smaller than in former years. A result of these conditions has been to create a great demand for Navel nursery stock, both north and south, the demand for these trees exceeding the supply. Two or three years ago there was a general disposition to test the Mediterranean Sweet and other late varieties. But the Navel has been such a favorite in the markets of the east this winter that it now holds undisputed place as the representative California orange.

That Orange groves are still considered a good investment is shown by the proposed plantings this season. There will be a considerable addition to the acreage of southern California, particularly in San Bernardino County, where the crop has been large, not appreciably damaged by frost, and sold at good prices. Investors in the northern part of the state, encouraged by the returns from the early shipments from Palermo and Oroville, will also make some extensive plantings. It is stated that one orchard to be planted near Palermo, if the trees can be obtained, will consist of fourteen hundred acres. Prime trees in the nursery three or four years ago were worth from \$1.50 to \$2.00 each. Then there was a collapse in prices, owing to overproduction, and an almost total cessation of demand, until trees sold as low as ten cents each. Hundreds of acres of nursery stock were grubbed out and burned. This year there is a demand, not only from California, but from Arizona, Mexico and Florida. Prices have risen to fifty and seventy-five cents a tree, and it is predicted that the Navels will be worth at least a dollar apiece next year. Many nurserymen

who have a stock of late varieties are budding them over to Navel buds, although it is a disputed question whether the resulting trees are strong and healthy. As it requires four years to mature a tree for transplanting from the seed there will probably be good prices for all the trees now in the nurseries.

Reports from different parts of southern California indicate that the Orange-trees are setting heavily, that the climatic conditions have been favorable so far, and that, barring hot winds in the summer and frosts next winter, the coming crop will be a large one.

About forty per cent. of this year's crop has been handled by the Southern California Fruit Exchange, and those who have adopted this method of sale are said to be very well satisfied with the returns; the Exchange has received the highest prices in its history.

Some criticism has been made about the statement which appeared in the issue of GARDEN AND FOREST for February 5th, as to the degree of cold in Riverside on December 29th and 30th, last winter. It has been argued that it was unfair to place the lowest record of the thermometer at Riverside at seventeen degrees, and in other near-by places but twenty-six degrees. Nevertheless, the mercury did fall to seventeen degrees at one point near Riverside, although this degree of cold was not reached anywhere else. But the injury resulted not so much from an extremely low temperature as from its long continuance below freezing-point. The effect of this was not only seen in ruined fruit, but also in some groves in that locality from which the leaves have fallen and new foliage is appearing. To make the best of the matter, the frost was a very serious calamity and the results show that the original statements were substantially correct. At least 1,500 car-loads of oranges were rendered unsalable by the frost at Riverside, and the 500 car-loads shipped east immediately after the frost was damaged and brought reduced prices, so that little was realized above the cost of picking, packing and forwarding. The total shipments to this time are about 1,900 car-loads, and there are said to be about 100 car-loads now remaining in Riverside. Much of the fruit sent from Riverside since the frost, exclusive of the first 500 car-loads, has been sold at good prices, some of it as high as \$2.75 a box free on board. Just what proportion was first-class fruit and what of a lower quality I do not know. Of course, it is unfair to make comparisons, and to state that any section was more seriously damaged than the facts warrant. The loss by frost this year was a loss not to any single locality, but to all of southern California, since it emphasized the disagreeable fact that the Orange groves of this section are liable to a certain degree of damage by frost.

In spite of this fact, Orange groves are held to day at very good prices. The best are not for sale at any reasonable price. Good young orchards from five to six years of age may be bought at from \$500 to \$600 an acre. Others are held higher. One that I know of, of twenty acres, the crop of which brought this year \$2,300, at six years of age, is held at \$18,000. It is expected to produce a very much larger crop next year. From \$800 to \$1,000 an acre is the ruling price for such bearing groves, in the best localities, as are for sale. An acquaintance quoted to me a return of \$325 an acre from an orchard of old seedling trees. The largest yield that I have heard of and believe to be authentic is one of \$18,000 from forty acres, an average of \$450 an acre. These oranges were Navels, and were sold at the highest price. The best five acres in the tract brought a return of \$800 an acre. I believe an average profit of \$100 an acre a year to be reasonable and not an overestimate.

Redlands, Calif.

Wm. M. Tisdale.

Notes from West Virginia.

To the Editor of GARDEN AND FOREST:

Sir,—We have been fortunate in escaping drought through local rains. Our pasture-fields were seldom greener, but farmers only six or eight miles away complain that the ground is dry as powder, so that the Corn has not begun to germinate. The Yellow Locust, which is more abundantly planted in this neighborhood than any other tree, is past flowering, and the Clammy Locust, *Robinia viscosa*, and its varieties are in full bloom.

A group of young Laburnums and White Fringe trees is now the most beautiful object in our shrubberies. These trees are most effective when planted together. Both have handsome foliage and drooping flowers which open at the same time. Some bushes of Scotch Broom, planted near them, combine to make a sunny picture of their little shrubbery. The *Chionanthus Virginica*, or White Fringe, is, perhaps, the most

beautiful small tree we have. When in flower it is adorned as for a bridal morn, with a delicate white veil of bloom which resembles nothing so much as filmy lace. In the damp, cool weather we are now having this exquisite bloom has lasted for ten days, fresh and dainty as at first. The *Chionanthus* delights in rich soil and should not be crowded in with other shrubs. Given plenty of room it develops into a symmetrical, well-rounded little tree. The *Laburnums* are here planted ten feet apart, where they receive partial shade from large *Tulip-trees*, in company with, but not crowded by, the *Fringe-trees*. The flowers of *Phlox divaricata*, now passing out of bloom, vary from a striking shade of deep purplish blue through lead-color to white. We bring it from the woods and plant it in the wild garden, among the rocks, under the shade of Oaks, in company with *Delphinium tricornis*, *Columbine*, *Wild Geranium*, early *Crowfoot*, *Stellaries*, *Rue Anemones* and *Maiden-hair Fern*. The latter we have to water constantly through the summer, and with all our care have little success with *Ferns* on our dry uplands. They do not grow naturally in our woods, but we find small ones in abundance on the cliffs of the Potomac, where they cling to the face of perpendicular rocks and peep from their crevices in company with *Columbines* and other delicate wild flowers.

Yellow Lilies—*Hemerocallis flava*—and German Irises of pure white, lemon-yellow and delicate gray-blue, form a fine group on the lawn against a green background of shrubs. Near-by, and in striking contrast, is a bold mass of double *Pæonies* in deep crimsons, carmines and flesh colors. These are really gorgeous in coloring and require hardly any care. We never disturb them; they grow so densely that no weeding is necessary, and a heavy mulching of manure in the fall, lightly worked into the soil in the spring, is all the attention they need to make them increase in size every year.

We found the first rose on the tenth of May. It was the very early Cinnamon Rose; *Rosa rugosa* and the Persian and Austrian Briers followed quickly after; and then came *R. multiflora* and such old favorites as the Hundred-leaved Rose, the *Hermosa*, *Giant of Battles* and the *Roses of Provence*. The *Crimson Rambler* is now in bud, and *Madame Georges Bruant* is just opening a few dew-filled cups. *Monsieur E. Y. Teas*, *Ulrich Brunner* and *Pierre Guillot* are the handsomest deep-red *Roses* here, and all of them show a few fresh flowers.

Danske Dandridge.

A Natural Garden.

To the Editor of GARDEN AND FOREST:

Sir,—It is easy to find in the neighboring sand region natural gardens which, in variety of plants and in beauty and distribution of colors, equal those arranged by art. One of these was observed early in May. The area comprised about one hundred and twenty by fifteen to twenty feet in width. The fresh, but thin, grass formed an even turf and furnished a lively green foil for the various plants scattered over its surface. It sloped away from a sandy knoll at one end to wet ground and pools of water at the other. Sitting on the knoll one could readily distinguish most of the plants which made up the picture and study their colors and arrangement.

The brightest and most abundant flower was the Painted Cup, represented by both yellow and scarlet varieties and many shades between. The *Wood Betony* carried spikes of flowers of a pale yellow hue, set among the prettily divided pinnatifid leaves clustered at the base. *Bluets* peeped out from the midst of blades of grass, and in the wet ground and shallow water were *Marsh Marigolds*. The *Strawberry* and large-flowered forms of the *Windflower* added a dash of white. On the knoll were bunches of *Viola pedata* with large pale blue flowers, and in the damper ground *V. sagittata* showed a deep shade of rich violet-purple. There were dainty little cups of the *Dwarf Blueberry*, white, tinged with rose, though its chief contribution to the scheme of color came from the deep red-brown of the newly expanding buds and leaves. The most stately plant was the *Swamp Saxifrage*, raising a panicle of greenish flowers on a stout hairy scape, from the midst of large lusty leaves. Here and there in dryish spots were the flat-topped clusters of whitish flowers of *Comandra umbellata*. The *Wild Lupine* was approaching flowering, and held above its symmetrical leaves clusters of blue and white buds. *Maianthemum Canadense* was plentiful, also in bud, and mainly noticeable for its broad smooth leaves of lively green. The grass-like *Luzula campestris* was in fruit, and the *Cotton-Grass* was beginning to show the long white down bursting from the rusty scales of the maturing fruit. *Ferns* were springing up, and the *Flowering Fern* vied with the *Dwarf Blueberry* in the color of its fresh foliage. The stout

hairy fronds of the *Cinnamon Fern* were beginning to uncoil, and stood in yellowish or rusty brown bunches. Stems of *Equisetum* rose beside the *Marsh Marigolds* or crowded the pools with slender columns. In the grass the beautifully compound leaves of a *Thalictrum* were making their appearance. Small shrubs of *Salix humilis* and *S. longifolia* were scattered about, displaying cinereous and silky leaves. A diminutive *Gray Pine*, barely more than a foot high, stood in the grass, its short stiff needles giving to the wild garden a touch of the adjoining woods and *Pine-clad sand hills*, and though below the *Willows* in stature, it was still a tree in form and dignity.

Recent Publications.

Circular No. 12, issued by the Division of Forestry of the United States Department of Agriculture, is devoted to the physical and mechanical properties of the southern Pines. The data contained in this circular are condensed from 20,000 tests and an equal number of measurements and weighings, and it is published now to make the information speedily available, while fuller details will be given in a special bulletin. The importance of trustworthy information regarding the Pines of the south is evident from the fact that they furnish most of the hard pine material used for constructing purposes in the country, while the annual cut is certain to increase rapidly as the soft pine supplies of the north decrease. The Pines under consideration are first the *Long-leaved Pine* (*Pinus palustris*), the *Cuban Pine* (*P. heterophylla*), the *Short-leaved Pine* (*P. echinata*) and the *Loblolly Pine* (*P. Tæda*). The names of these timbers in the market are often used interchangeably, and the materials are mixed in the yard, and trustworthy microscopic distinctions of the wood of the four species have not yet been found. There is a very interesting paragraph in which the diagnostic features of the different woods are given to assist the identification of the species. This is followed by a table giving the bending strength and compression strength of the wood of each species, together with the relation of the strength to the weight. An interesting study of the distribution of the weight and strength throughout the tree furnishes a basis for a diagram which distinctly sets forth these variations in the different species in a graphic way. There are brief chapters on the influence of locality and of moisture, on the behavior of different woods in shrinking, the effects of kiln-drying and the influence of immersion in water on the strength of the different woods. The tests have proved conclusively that timber which has been boxed or bled for turpentine is quite as strong as that which has not been so treated if it is of the same weight, that the weight and shrinkage of the wood is not affected by bleeding and that the bled trees contain practically the same amount of resin as unbled trees, the loss of resin referring only to the sap-wood. The results of tests of strength with large beams and columns are most interesting. When we consider the care with which these experiments have been made, the large number of trees and test pieces which have been used and the uniformity of the methods employed, it will be seen that this work is of serious value, and, perhaps, it is the best original work that has yet been accomplished by the Forestry Division. It ought to be added that this circular is written with a conciseness and a clearness which deserves the highest commendation.

Notes.

No. 7 of the third volume of the *Contributions to the United States National Herbarium* is devoted to a continuation of Professor Coulter's study of *Cactaceæ*, containing a preliminary revision of the North American species of *Echinocactus*, *Cereus* and *Opuntia*.

Professor N. L. Britton, of Columbia College, has been appointed Director of the new botanical garden to be established in Bronx Park, in this city. Professor Britton has been Secretary of the Board of Managers ever since the project took form,

and it is due to his untiring labors more than to any other cause that the scheme has been organized under such promising auspices.

There were abundant rainfalls in central and northern California last week, and these were followed by frosts which did serious injury to the young shoots of the vines in Napa and Sonoma valleys. So far this year has been an exceptionally trying one for the orchards and vineyards of California.

The auction sales of plants in this city have been unusually large this spring, and common garden plants of good quality have brought so far remunerative prices. The demand is so great that special sales have been held almost every week, when the prices realized were as good on the average as those on the regular days.

Last week brief mention was made of the intrepid explorer and botanist, Father Delavay, so widely known for his botanical researches in China. It is worth adding here, as indicating the scope and magnitude of his labors, that, according to the *Bulletin of the Botanical Society of France*, Father Delavay discovered in the difficult mountain regions of Yun-nan more than fifty new species of *Rhododendron*, as many species of *Pedicularis*, forty new *Gentians* and as many *Primulas*. He sent to the Herbarium of the Jardin des Plantes about four thousand species, of which one-half were new.

A bulletin just issued by the New York Experiment Station treats of the Carnation rust, which is considered, after all, one of the most serious enemies of that plant, although it is not so much dreaded as it once was. The pamphlet contains what is known at present of this disease, and will prove interesting to all students of fungi as well as all those who grow these plants to any extent. The following treatment is recommended: Grow varieties the least subject to rust. The variety William Scott, for example, is nearly rust-proof. Cuttings should never be made from diseased stock, and it should be borne in mind that plants may be diseased and not show it. If there is any danger of the presence of the disease the cuttings should be dipped in a solution of potassium sulphide of the strength of one ounce to a gallon of water, so as to kill any spores which may cling to them. Fresh sand should be used in the propagating-bench. From the time they are struck until the plants are exhausted by flowering they should be sprayed every week with potassium sulphide or copper sulphate. Before the plants are brought in in autumn the houses should be fumigated thoroughly with sulphur. There is no known method of wholly preventing infection in the field, but plants grown all summer under glass can be more easily managed.

An unusually successful meeting of the New Jersey Forestry Association was held in Plainfield on Thursday last. In the afternoon, after a business meeting, there was a lecture by Professor B. D. Halsted on Diseases of Trees, which called forth an animated discussion as to the practical methods of keeping trees in health. In the evening Mr. Fernow, Chief of the Division of Forestry, delivered a lecture from which we hope to make extracts in some future number. There was a very instructive exhibition of photographs, maps and other illustrative matter, and the arrangements for exciting the interest of school children were made a feature of the meeting. On Friday the officers of the Forestry Association and a number of the members, together with the Palisades Commissioners, were taken up the river in one of the boats of the Pennsylvania Railroad Company to see how the cliffs had been mutilated by quarrying. Messrs. J. J. R. Croes and W. D. Morse, of the Palisades Commission, explained the proposed measures for protecting this territory as a national park and forest reserve. John Gifford, the State Forester of New Jersey, who has lately traversed this district on foot, explained the character of its forests and the advantages to be derived from having a school of forestry so near to a city like New York.

California cherries, large and showy, are now coming in large lots, the first car-loads being due here this week. Among varieties now here are Rockport Bigarreau, handsome and large, pale amber, marked with red, of good quality, and highly esteemed for canning and for shipping. Governor Wood is another good light-colored cherry now in season, and the first Royal Annes arrived last Monday; these were small, however, and fair specimens will hardly be seen within ten days or a fortnight. Black Tartarians are, perhaps, more plentiful than any other variety. A fair price at retail is forty cents a pound. The first apricots of this season arrived on Saturday, and while

some are of fair size and coloring, even the best are immature, and find slow buyers in the wholesale markets. Strawberries have been in scant supply and of inferior quality for the lack of rain, but are now beginning to come in better form. The best from Maryland commanded on Monday twenty-five cents a quart. Florida peaches cost \$1.00 a dozen. Gooseberries may be had for twenty cents a quart, and huckleberries for the same price. Almeria grapes are still shown in the best retail fruit-stores and bring seventy-five cents a dozen. White Muscats and Black Hamburgs, from Newport graperies, sell for \$2.50 to \$3.00 a pound. Rodi oranges, from the Mediterranean, and California Navels both command high prices, and since the stock is not heavy, and strawberries have been in rather scant supply, there is sufficient demand to sell this fruit at \$4.50 to \$5.00 a box, wholesale. The Navel oranges now on the market are mostly from cold storage, but some seedling oranges are still coming from the Pacific coast. Lemons have been cheap, and nearly 220,000 boxes are now on the way to American ports. Pineapples are coming from Cuba and the Bahamas; 16,286 barrels were received from Havana during last week, and two schooner-loads are due this week from the latter islands.

Messrs. James Lindsay & Son, fruit salesmen, of Edinburgh, Scotland, have written us some interesting notes about American apples, some of which we present to our readers to supplement the statement of Messrs. J. C. Houghton & Co., of Liverpool, England, which was given last week. In the Edinburgh market, as in other markets of Great Britain, the best grades of well-colored apples are in the highest demand, such as Baldwins, Northern Spies, the genuine Spitzenbergs, York Imperials and Romanites, from Virginia, which last are quite different from the fruit of the same name from other parts of the United States, the latter being a pale, undecided color, instead of dark rich-looking like the Virginia fruit. Baldwins are inclined to ripen quickly, but their quality is liked and they always command a ready sale, bringing from \$4.50 to \$5.50 a barrel. The Northern Spies are favorites, especially those from Canada, which seem to be superior in keeping quality to those grown farther south. Many apples are exported as Spitzenbergs which do not have the shape of the genuine fruit and which are quite inferior in flavor and have none of that dissolving quality which distinguishes the true fruit. The King apples, especially those from Canada, take the first rank on account of their color, their flavor, their fine fibre and the rich look of their flesh, and they always bring good prices. Of course, the Newtown Pippin is the favorite among green apples, and those grown in Virginia of the finest flavor and most melting quality, in ordinary seasons range from \$5.00 to \$7.50 a barrel, but owing to their abundance this year prices ruled lower. It should be noted that there are two kinds of Newtown Pippin which reach Great Britain, one of which is gritty, hard and inclined to be dry, resembling somewhat the Swaar. They are more beautiful, however, than the Virginia Newtowns, which do not look as bright, being of a greenish yellow with a small red spot. The Rhode Island Greening is always in demand for cooking purposes, and Greenings grown in Canada have superior keeping qualities. The prices rule from \$3.50 to \$3.75 with a fair ordinary supply, but when the importations are excessive they have fallen as low as \$2.75 a barrel. There is little demand for Russets, except when other apples are scarce. During the season of abundance they are neglected and sell at low figures. The York Imperial is a comparatively new apple, but as it has arrived this season it commands good prices on account of its size and bold appearance. It has brought from \$4.00 to \$4.50 generally, but when other kinds are scarce it has sold for as much as \$5.50. Rome Beauties have not been known much until recently, but being of good keeping quality and bright color they command ready sales, although they are rather dry in quality. Ben Davis has little to commend it except fair keeping qualities, and there is no active demand for it when there is anything like a fair supply of other kinds. Winesaps from Virginia are much sought for here. They have a rich deep color and superior flavor, excellent keeping quality, and they carry well, so that they have everything to recommend them. They generally sell at from \$4.50 to \$6.00 per barrel. The so-called Winesaps from other parts of the United States are often poor and soft. This may be due to lack of care in thinning and sorting, but, as it appears in the English markets, the even-sized, beautiful fruit from Virginia is quite as distinct as if it was a different variety, as perhaps it is. In richness of flesh the true Winesap can hardly be surpassed. The Fameuse is also a great favorite on account of its flavor and the absence of any grit in the flesh, while the smooth texture of its skin is near perfection.

County Parks.

MANY of the justifying reasons for the establishment of parks in cities will not apply to the conditions of country life. There is no need in the country of spacious open areas as antitheses to closely built stone blocks; there is no need to provide spaces for the admission of air and sunshine; there is no need of providing grass and trees as a refreshment to eyes and minds wearied by the constant prospect of rigid and rectangular enclosures. Nevertheless, grounds for associated recreation are quite as desirable in the country as in the city, and since the commons of our earlier history have gradually passed under private control there is an increasing need of provision for associated recreation which can only be met by devoting certain lands to public use forever. Of course, this is not a novel idea, but it is one which is rarely presented, and we are, therefore, glad to see that in a late bulletin from the Natural History Laboratories of the State University of Iowa the subject is discussed by Professor T. H. Macbride, who sets forth certain reasons why County Parks, as he calls them, should be established, especially in the western states. By a county park he does not mean simply public land like that owned by Government, which can be claimed and plundered by the first comer, nor, indeed, land which can be made use of by the public indiscriminately and without restriction, but land devoted specifically to public enjoyment as a holiday-ground for all the people, rich and poor. In most of our older towns and villages there are to be found greens or squares; annexed to a few of them there are public groves for picnics and other open-air festivities; but what is particularly meant here is a space belonging to a larger community, like a county or several adjacent townships, which would be sufficiently attractive to invite farmers and others who live within a radius of some miles, and large enough to accommodate several parties at once with their vehicles. Of course, such a place should be well watered and there should be woods for shade, and if it contains some romantic glen or waterfall, or other picturesque feature, it would be so much the better. Professor Macbride argues that such parks are needed at once—in Iowa, at least—and that they would have a genuine educational value both on the scientific and

ethical side, and would minister directly to the health and happiness of the community.

In the first place it is urged that the usual experiences of country life are even more weary and monotonous than the conditions of city life. In the farm, and shop, and mine, day after day, season after season, year after year, there the same ceaseless round of toil is repeated, and into it no idea of recreation or refreshment ever enters. A sad picture is painted of the effort of the rural population of the west to outwear its labor-saving machinery, but every observer will testify that this remorseless grind is quite as serious an evil in the east, and that unless something is done to brighten life in the rural districts and preserve the mental and physical health of the people, the generations which follow this will see its effects in dwarfed minds and infirm bodies. The farmer and his family come in constant contact with nature, it is true, but their days are passed in painful efforts to wrest a living from the land, to struggle against untoward conditions of climate and to fight for existence with other forms of life continually. If country people could be lured into a pleasure-ground to spend a day now and then in social mood among the grass and trees and free from care, the practice would, no doubt, have an inestimable recuperative value.

It is not apparent how such county parks could be made useful to furnish lessons in forestry, as Professor Macbride suggests, but every one will agree with him that a well-kept county park would be a perpetual object-lesson in the best means of preserving and enhancing the essential landscape beauty of any given area, and that this would suggest ways of making home-grounds attractive. That little thought is given to this matter in any part of the country is a matter of common notoriety. This is so unusually true that a farmhouse well adapted to its use, built to harmonize with its surroundings, and with grounds planned and cared for so as to develop all that is naturally attractive in the home-scene is so rare as to excite comment at once.

The third reason for the establishment of county parks—in the west, at least—is most interesting. In the older eastern states it is a matter of lamentation that nothing except the bolder original features of the country remain to show what its primitive form and beauties were. The native animals are often extinct, many of the plants are on the way to extermination, the primeval woods are gone. In the more newly settled portions of the country there are places which are still occupied by the original flora, and these can now be rescued before they are laid waste. This is a matter of importance, both from the standpoint of science and of intellectual progress, for it is well said that “such is the aggressive energy of our people, such their ambition to use profitably every foot of virgin soil, that unless somewhere public reserves be constituted our so-called civilization will soon have obliterated forever our natural wealth and leave us to the investigation of introduced species only or chiefly.” No doubt, the organization of county parks would preserve many of these localities as they were, and the very names that are given to some places in Iowa for possible reservations kindle the imagination and suggest scenes of picturesque beauty of cliffs and glens, cool springs and foaming brooks, groves of Pine and wooded hills. There is little doubt that even in the so-called prairie states there are picturesque places in almost every county which would make ideal spots for public recreation-grounds.

How such parks could be cared for is the serious question. New York, following the example of Massachusetts, has a general law in which places of great natural beauty, as well as of historic interest, can be set apart for public use forever. It would not be difficult to frame laws which would enable a county or a township to hold land for public use. The life of the early settlers of the country was a long fight against inhospitable conditions, so that Americans seem to have inherited a tendency to destroy everything that is natural. But we apprehend that the employment

of a few caretakers clothed with police authority would be all the protection needed until the people began to appreciate the value of a public playground, and the strong public sentiment for protecting it would soon be established. In older countries the people have the freedom of many of the most splendid parks and woods in the world. The greens or squares in our little villages are not defaced, for everybody cares for them and public buildings suffer little wanton defacement. The same would probably be true of larger grounds, so that the necessary requirements and restrictions in their use would be obediently and gratefully complied with as soon as the people realized that these grounds were their own, and that they were dedicated forever to the enjoyment of themselves and their children.

THE remarkable increase of bicycle riding in the past year adds a new menace to suburban gardens and orchards. Bicycle riders returning to town from the country with big bunches of flowers tied to their handlebars are familiar objects in the suburbs of all our large cities. It is safe to assume that a large part of these flowers have been gathered without the consent of their owners. Pilfering of this sort is often the result of ignorance or thoughtlessness, and the press of the country can do a real service in teaching a stricter morality than now prevails in the United States upon this point. Flower-stealing, however, is not always the result of ignorance, and it is not an uncommon sight to see women driven by liveried servants with carriage-loads of stolen flowers. Such women have not the excuse of poverty to plead in explanation of their thefts, and no amount of teaching, unless it comes through the judges of police courts, will enlighten their minds on this point. People who grow flowers are always willing to share them with their less fortunate neighbors, as the success of the flower missions throughout the country abundantly proves, but no one, however public-spirited or generous, likes to be taken advantage of or to see his trees and shrubs broken to pieces, or to feel that any rare or interesting plant, whose development he is watching, may be pulled up by some vandal who is very likely to throw it away again before he has carried it a hundred yards, thus adding insult to injury. This ignorance and lawlessness, where plants and flowers are concerned, are serious drawbacks to the cultivation of gardens near our cities, and they cast well-deserved reproach on people who would not take five cents' worth of anything else which did not belong to them. This evil is increasing every year, and it is liable to increase until public sentiment against it is thoroughly aroused, and laws against depredations of this character are promptly and rigorously enforced.

Hemlock for the Tanneries.

IN north-western Pennsylvania the bark-peeling of the Hemlock-trees begins early in May and continues through the summer until the middle of August, and during that time thousands of trees are destroyed and miles of rich woodland denuded. There is no more destructive process to the wooded sections of the country than that of bark-peeling, and unless something is done soon the fine forests of Hemlock in Jefferson, Clearfield, Elk, McKean, Warren, Forest, Cameron and Potter counties will be destroyed from the face of the earth. In recent years the discovery and cultivation of Canaigre in the southwest have promised some abatement of the injury to the forests, but it will be a long time before the Hemlock will cease to be the most profitable source of tannic acid.

Several large tanneries have been erected in the northern tiers of counties, and since 1872 the industry has been a large and thriving one here. Several of them consume the hemlock bark that grows on a thousand acres of woodland every year. When the first tanneries were erected the trees were stripped of their bark while standing and left to die and decay in this condition. There may be seen

miles and miles of these skeleton trees to-day, but such a wasteful process is no longer pursued. When the Pine timber of Pennsylvania became exhausted, a new value was given to the Hemlock-trees, since the owner of the sawmill will not only sell the lumber but supply the tanneries with bark. In some cases the tanneries erect their own sawmills.

An early spring starts the sap in May and loosens the bark so that it can be peeled off easily. Then the men go into the woods by the hundred. The bark-peeling is done altogether by contract. One contractor engages his men, and makes an agreement with the tanneries to supply so many cords of bark. The contractor has to cut roads through the woods that will admit of sleighs in winter and carts in summer, and the products of his men's labor must be piled close to these roads. His contract is a cast-iron one, and he has to live up to it to the very letter. A cord, according to the tanneries, contains 2,200 pounds, and when measured in volume it must be eight feet long, four feet high and four feet wide. Sometimes the contractor agrees to cut and cure the bark by weight, and then much bark can be used that is not the regulation length of four feet.

It takes about two thousand feet of logs to peel a cord of bark, and on the average in the Hemlock forests of northern Pennsylvania it takes one acre to produce ten cords of bark and 20,000 feet of logs. The contractor makes roads through the forests about sixty feet apart, and the logs and bark are piled between them. When the forest runs up on the sides of the hills and mountains the felled trees have to be trimmed and carted down to the roads in the valley, making the work doubly difficult. The peelers go into the woods in gangs of four and cut down the trees, trim off the limbs, peel the bark off, and cut them into the proper size logs. Each gang is composed of two log-cutters, one spudder and one fitter. The fitter goes first and selects his tree and cuts a ring around it through the bark close to the roots, and then another four feet up; the bark is then split down one side from ring to ring, and the spudder comes along and inserts his spud into the slit; with a few deft strokes he peels off the whole piece of bark as clean as a boy rings a chestnut-whistle when the sap is flowing in the spring of the year.

The choppers then follow, and with their axes and saws they soon bring the tree to the ground. The tree is trimmed when it has fallen. The fitter measures off the bark on the giant tree, and the spudder peels it off the same as before, and then the logs are cut to the length desired.

In this way the gangs of men will go through the Hemlock forests, each set of four peeling off from five to eight cords of bark a day and cutting the trees up into logs. One such gang will peel 250 cords of bark in a season and cut half a million feet of logs. The sawmills are ready to work as soon as the bark-peeling begins, and one good mill will eat up the logs from 250 acres in one year. The hemlock lumber cut in northern Pennsylvania in this way amounts to over 80,000,000 feet in a season. This means that over 40,000 cords of bark are peeled and 4,000 acres of forests stripped in a year.

The fitters, spudders and wood-choppers in the Hemlock forests receive only moderate wages, although the work is probably the hardest connected with lumbering. The ruling prices paid to bark-peelers is \$1.25 per day and board, but good spudders can secure \$2.00. The jobber who takes the contract receives about \$1.35 to \$1.50 per cord for gathering the bark, and from forty to fifty cents a thousand for the cut logs. This jobber then employs his men, and expects to make his wages in getting good work out of them. The tanners own most of the woods, and these prices are merely paid to the men for gathering the bark and cutting the logs. The bark-peelers are a typical class of men, who make their wages in gathering the hemlock-bark in summer and live by gunning and doing odd jobs in winter.

The hemlock industry has indirectly helped farming in this region, for it has created a home market for many of the farmers' small products. In the bark-peeling season there are thousands who come to the woods who buy their butter, eggs, cheese, fresh fruits and vegetables direct from the surrounding farmers. Many farmers who owned Hemlock tracts sold them to the tanneries for good prices, and others merely sold the trees on the land, and had the pleasure of seeing their farms cleaned of the trees. It is true that the stumps remained, but these were burnt or rooted out by degrees. More than this, a few of the farmers, seeing the great inroads made into the forests, cultivated the young Hemlock saplings and even planted others, and in time there may be a new industry for them in forest-planting. In the winter season the hemlock-bark has to be carted to the tanneries, and the local farmers find that they can take their teams into the woods and make good wages in a season of the year when farm-work is at a standstill. Many a farmer has made enough cash in this way to pay off mortgages and buy new machinery for his work.

The tanners have naturally made the most profits out of the woods. This is no more than any one could expect, as they invested the capital and did most of the head-work. The price paid by them for the bark has run all the way from \$3.00 to \$6.00 per cord, but never more than the latter figure, and thousands of cords have been sold by them all the way from \$10.00 to \$15.00 per cord. At present, however, there is less profit in the business, and old prices may never return again.

Foreign Correspondence.

Tulips.

MR. J. G. BAKER, F.R.S., lectured at the last meeting of the Royal Horticultural Society on the genus *Tulipa*, the botany of which has been a special study with him for many years. A large collection of the flowers of Tulips, representing both species and garden varieties, was sent to the meeting from Kew, Messrs. Barr & Sons, Messrs. J. Veitch & Sons and others. The time was in every sense propitious, Tulips generally being at their very best, and the display made by them in public and other gardens this year being very much greater than anything, perhaps, ever seen before in the neighborhood of London, at any rate. The every-day, somewhat gaudy Tulips of the Dutch gardens are being gradually supplanted here by more beautiful sorts. English Tulips and their sisters, the Darwin Tulips, are finding general favor. The botanical varieties and many of the species or subspecies are also becoming favorites in horticulture. English nurserymen are now growing them largely, for the Tulip is quite at home under the conditions afforded in most parts of England. The display it makes is of fairly long duration, and the charm of the best flowers is equal to anything we get from hardy spring flowers.

Mr. Baker admits about one hundred distinct botanical species, some of these being, perhaps, only subspecies, in a broad sense. When he monographed them about twenty years ago there were only forty-eight, but since then about fifty additions have been made, chiefly by Russian collectors. This accounts for the unattractive names many of them bear, such as *Kolpokowskiana*, *Kesselringii*, *Kaufmanniana*, *Ostrowskyana*, etc. About fifty species are cultivated in the Royal Gardens, in addition to a large number of the named varieties, and for the past three weeks or so they have been a magnificent feature.

The genus is limited in its distribution to the north temperate regions of the Old World, being concentrated in central China. It is represented in North America by the nearly allied *Calochortus*; these two genera, *Calochortus* and *Tulipa*, together having the same distribution as *Lilium*.

The genus *Tulipa* is divided into two sections, namely, *Eutulipa*, the true Tulips, and *Orithyia*, the latter being characterized by a short style, the true Tulips having the

stigma sessile on the top of the ovary. The *Orithyias* are only of botanical interest, *T. sylvestris*, the little yellow-flowered native, being the only one met with in gardens. The characters relied upon to distinguish the species are in the bulbs as well as in the flowers, so that botanists are sometimes at a loss when asked to determine the species from flowers and leaves alone. Most of the big-flowered handsome garden Tulips belong to the group represented by *T. Gesneriana*, of which an enormous number of forms are known, some wild, some of garden origin. This species has been a favorite garden flower for over two hundred years, all the old Tulips, out of which what is known as the Tulip mania had its origin, being forms of *T. Gesneriana*. Mr. Baker is inclined to look upon such so-called species as *T. Ostrowskyana*, *T. Batalini* and *T. Schrankii* as wild forms of this ancient, polymorphic plant.

What are known as English or Breeder Tulips are selected forms of *T. Gesneriana*, in which the petals are unicolored, save a large eyelike blotch of yellow or white at the base of the cup. The value of the variety in the eyes of a Tulip fancier depends upon the clearness and regularity of this eye and the uniformity of the shade or color of the rest of the flower. It is remarkable that the Darwin Tulips, the beauty of which is now generally admitted, are practically sorts which were discarded by the breeder because of the intensity or heaviness of their color and the blue-black eye at the base of the cup. They are, too, stronger and taller in scape than the English Tulip. Of their beauty it is, in my opinion, impossible to speak too highly. Messrs. Barr & Sons have about ten thousand of them in flower in their Tooting nursery, the collection exhibited by them last week being greatly admired. It is due to Messrs. Krelage & Sons, the Haarlem nurserymen, that they should be credited with the discovery and distribution of this fine section of garden Tulips. Of the many sorts in flower at Kew these Darwin Tulips are the most admired. Messrs. Barr have sorted them into about twenty colors and named them, but at Kew they are all mixed indiscriminately in a large bed on a lawn, where they produce a rich kaleidoscopic effect.

Breeder tulips are peculiar in their habit of changing color, "rectifying," as the fanciers term it, after a time. There does not appear to be any cause, time or season for this change; it may happen when the bulb is six years old or not till it is sixty, practically not at all. The change is a very decided one as regards color, those flowers with yellow eyes becoming feathered all over with that color on a ground color more or less like that of the flower before the change takes place; those with white eyes being feathered with white, the former are called Bizarres, the latter Bybloemens. The value of the rectified flower depends upon the clearness of the yellow or white, upon the regularity of the feathering or flaming, the size and form of the petals and shape of the cup being also of importance. Tulip fanciers pride themselves on having the Breeder and rectified flower side by side, and at exhibitions of Tulips they are generally placed together. When once a Tulip has "rectified" it never returns to the Breeder state; this can only be obtained by means of seeds, and from these may come all sorts except the one desired.

Long cultivation, selection, cross-breeding, etc., may account for this behavior in this species of Tulip. So far as I know it does not occur in any except *Gesneriana* and its near allies. A few years ago Mr. Baker named at Kew a beautiful Tulip with enormous rose-crimson flowers and a large blue-black eye-like base, calling it *T. macrospila*. For a time it kept true, and a large stock of it was worked up entirely from offsets. Then it began to break, first producing a paler-colored form, and afterward feathered or "rectified" flowers, in which the eye was either like the type or pure white. From this it would appear that no reliance can be placed upon the colors of some of the *Gesneriana* tulips. Fortunately, "rectification" does not mean deterioration, but generally a decided improvement in color attractions.

Mr. Baker called special attention to Tulip Greigii, a native of Turkestan, introduced in 1873. It has broad green leaves, spotted with dark brown and enormous flowers of a rich scarlet color, richer than in any tulip, while in the elegance of the curves assumed by the petals it is distinguished from all other species. So far, however, cultivators have not been successful with it, and it remains still a rare plant. Mr. Baker thinks it might pay to try it under various conditions in various climates. If only such a Tulip could be produced in quantity, as the Dutch, for instance, produce the common Tulips, it would be the most popular of all. American horticulturists might act upon this hint.

The cultivation of Tulips is easy, but there are several important points to be remembered, and the first of these is that if grown in the same soil for several years in succession the bulbs are apt to fall a prey to a fungus, the soil becoming what is called Tulip-sick. To avoid this it is necessary to either change the soil every three years or so, or to transfer the Tulips to other quarters. The second point of importance is that of harvesting. If the Tulips are planted in beds that are required for other plants in summer they must be lifted carefully about the end of May and "heeled in" clean coal ashes or light soil till the leaves have faded. Then the bulbs should be cleaned and laid in baskets or trays in the sun to ripen before they are finally placed in store to await replanting in October. Choice species and varieties should be lifted and replanted in a little fresh soil even when they occupy permanent positions in the garden. Some of the species, such as *T. Hageri*, *T. linifolia* and *T. Eichleri*, do well and look well when planted among grass in the wild garden.

London.

W. Watson.

Plant Notes.

Leucothoë recurva.

THE value of the northern native plant *Leucothoë racemosa* for the decoration of the parks and gardens of the northern states has often been insisted on in the pages of this journal. It is a hardy, fast-growing shrub which sometimes attains the height of ten feet; its slender branches are covered with ample dark green leaves which late in the autumn, long after those of every other tree and shrub cultivated in gardens have fallen, assume a brilliant and beautiful scarlet color, and its handsome waxy white cup-shaped flowers are produced in long, erect or slightly curved terminal racemes from buds formed the previous autumn and covered during the winter with closely imbricated bracts. The splendor of color of the leaves of this shrub in the late autumn makes it one of the most desirable hardy plants for our northern gardens.

Although of lower stature, *Leucothoë recurva*, a native of the southern Alleghany Mountains and botanically closely allied to *Leucothoë racemosa*, is almost as desirable a garden plant. It is a shrub with slender ashy gray stems three or four feet in height, slender divaricate branches covered with bright orange-red bark, thin ovate-acute leaves and elongated spreading and recurved racemes of handsome waxy white flowers which open late in May when the leaves are about half-grown.

Leucothoë recurva inhabits shady, rather dry hillsides, and is distributed from south-western Virginia to northern Alabama, growing usually at elevations of from two to three thousand feet. Introduced into the Arnold Arboretum in 1885, whence it has been gradually distributed among the botanic gardens of Europe, it is still rare in cultivation. Mr. Faxon's drawing, reproduced in our illustration on page 225 of this issue, which is the first that has been published of this interesting shrub, is from wild specimens gathered in Virginia and North Carolina.

CERCIS CANADENSIS.—The American Red-bud, or Judas-tree, was described two hundred years ago and was grown in English gardens as early as 1730. Like many other in-

habitants of our forests, however, it has been comparatively neglected by planters in this country, although it is one of the most desirable of small trees all the season through, from the time in early spring when its deep red calyxes and rose-pink petals are clustered thickly along the branches with the opening leaves, until the autumn, when these leaves turn to a clear bright yellow. There is no more striking combination in our wood borders than these abundant flowers of the Red-bud mingled with the white ones of the Flowering Dogwood and of *Cratægus mollis*. We have often spoken of this tree, but we make no apology for again calling attention to it as an admirable garden plant, which is perfectly hardy as far north as New England, and is one of the most effective of trees to place against a background of dark conifers. It thrives in bottom-lands naturally and on swamp borders, but will grow in any good soil, and when allowed a chance to spread it becomes a rather low flat-topped tree, although under favorable conditions it reaches a height of fifty feet. It grows rapidly and begins to flower when it is quite small. The European Judas-tree, *Cercis Siliquastrum*, is not hardy in the northern states, nor is *Cercis Chinensis*, a shrub with large rich-colored flowers, which is often seen in gardens south of Philadelphia, where it is usually called *Cercis Japonica*. Like all other native plants, our Red-bud seems to harmonize with the scenery of the country in which it has developed, and it cannot be too often repeated that our native Crabs, Hawthorns and the Flowering Dogwoods and arborescent *Viburnums* cannot be excelled for massing and composing park pictures.

FOTHERGILLA GARDENI.—This is another native shrub belonging to the Witch Hazel family, which has already been described and figured in this journal (see vol. viii., p. 446). It was also introduced into English gardens nearly a century and a half ago, and yet comparatively few people in this country or in Europe have ever seen it. Nevertheless, in early spring it presents a beautiful and striking appearance with its brush-like masses of long, white, conspicuous stamens produced at the end of branches before the leaves appear. It is a comparatively rare shrub of southern range, and yet it is perfectly hardy at the north, and this spring, in spite of a singularly trying winter, it has flowered with unusual abundance. It is a shrub of good habit, attaining a height of some five feet, well clothed with rich-colored foliage, and is an admirable plant all the season through.

Cultural Department.

Notes from Harvard Botanic Garden.

THE herbaceous grounds of the Harvard Botanic Garden are very attractive at this season. A vast number of plants are raised and tested yearly, and while some are of botanical interest only, there are many beautiful plants of distinct horticultural value. A gardener will find few better places to study them.

Among many Columbines is seen the true Rocky Mountain species, *Aquilegia cœrulea*. From seed gathered in eastern gardens it becomes variable, hybridizing freely with the commoner kinds. Some of the *Cœrulea* × *Chrysantha* hybrids are handsome, and groups of all shades of red, white, yellow and blue, associated, have a striking effect. The Globe-flowers, *Trollius*, make an interesting group. Only *T. Asiaticus* and *T. Europæus* are in bloom now. Old Honesty, *Lunaria biennis*, is showy as one sees it here. But it is only a biennial, and soon becomes ragged. *Viola declinata*, var. *losispala*, is pretty and distinct. Its color is reddish violet, almost a self, excepting only a white eye. Patches of *Cerastiums*, including a giant from Japan, afforded means of comparing the value of these low-growing evergreen Mouse-ears for garden effect. A clump of *Helenium Hoopesii*, with large orange-yellow, star-shaped flowers, caught one's eye in the distance, since there are few flowers of its color at this time. Bleeding Heart, *Dicentra spectabilis*, established its value as a garden plant when properly placed. Two little pink-flowered *Erigerons*, *E. glabelliformis* and *E. Coulteri*, struck me as likely to be useful plants for naturalizing in grass. They certainly would be pretty if they would do as well as their larger congener, *E. Philadelphica*.

cus. *Verbascum Olypticum* is the grandest of all the Mulleins. Its bold-branched spikes are closely covered with irregular salver-shaped lemon-colored flowers. The prominent violet-colored filaments and anthers, so conspicuous in nearly all the *Verbascums*, are scarcely noticeable in this one. The whole plant is densely covered with a sulphury pubescence. These Mulleins are scarcely distinguishable from the

Emodi is out of bloom, and is developing its large and beautiful pod-like fruit. *P. peltatum* is now open. These are both interesting, if not exactly beautiful, plants with classical-looking leaves. *Funkias* here show their value as shade-plants, succeeding, Mr. Cameron tells me, where it is difficult to get anything else to grow. *Orobus vernus* is past bloom and now in the seed-pod. These Vetches are hard to establish, and

Fig. 33.—*Leucothoe recurva*.—See page 224.

Celsias. *Echium Caucasicum* is a fine dark blue Boragewort. A most graceful spring-blooming plant is *Amsonia Tabernemontana*. It grows about two feet high. Its terminal thyrsoid panicles of blue flowers are delicately tinted with a metallic lustre. It succeeds only on moist subsoils, rooting deeply, and is impatient of removal. *Primula Japonica* has proved quite hardy on the rock garden, and is now in bloom. *Podophyllum*

appear to enjoy shade; the only chance of success is with seedlings. *O. palustris* is later in blooming, of a delicate purple color. The vernal Snowflake in bloom was a reminder of days gone by. It succeeds only in sheltered places. In shade also are several patches of *Cypripedium pubescens*. These plants will not succeed on a dry subsoil. *Vancouveria hexandra* is a low-growing and interesting member of the Barberry

family. The only visible sign of the relationship is in the flowers, which are formed almost exactly like those of the Barberry. It is herbaceous, and the foliage in the autumn becomes bronzy and quite ornamental.

Wellesley, Mass.

T. D. Hatfield.

Flower Garden Notes.

ONE must have a firm will these pleasant spring mornings to follow up closely the necessary cultural work, each night brings forth so many distractions of flower and foliage. It is much pleasanter to linger over the newly expanded charms of color and form than to do the necessary prosaic work.

In spite of a dry season the hybrid German Irises have flowered as profusely as usual, with no shortening of stems or decrease in size of flowers, and at about the accustomed season. The fragrance prevailing now is from masses of forms of *Iris pallida*, an Elder-like scent, this *Iris* being the most fragrant of the family, and the best strains being among the handsomest of the bearded Irises, both in form and coloring.

Of other Irises lately in flower, *I. Germanica macrantha* has been glorious with immense blue purple flowers about twice as large as the ordinary variety. The reddish purple flowers of *I. Kochii* are also bold, distinct and handsome. Of the varied Irises in a collection of these flowers perhaps the forms of *I. variegata* will usually prove the most attractive. These are flowers with yellow standards and usually reddish falls, and are mostly bright and attractive, though not of the largest size. Professor Forster's hybrid *Iris Parvar* (*paradoxa* × *variegata*), which has before been described in GARDEN AND FOREST, has again proved to be as reliable as its male parent. It has had no protection or special care in the border, and has shown none of the miffiness of its *Oncocycelus* parents, though resembling it much in foliage and still more in some features of the flowers, which are a beautiful dark vinous red. Another hybrid, *Lupina* × *Ciengialti*, did not show so much influence of the *Oncocycelus* parent and formed surface-creeping rhizomes, which unfortunately succumbed to a wet winter. This was a flower of a very odd hue, a degraded heliotrope. Lately I have had the pleasure of flowering a few more of Professor Forster's seedlings, which it may be interesting to note as a suggestion to growers who may have a fancy for hybridizing uncommon things. It is not possible to give more than a hint of the curious hues thus produced. *I. Parkor* (*paradoxa* × *Korolkowi*), with narrow foliage, flowered with a curious bloom, reddish purple with darker linings and dark signals, orbicular falls and rather modified standards—that is, not excessively large as compared with the falls. *I. Korolkowi* × *vaga* resembled closely one of the forms of *I. Korolkowi*, *venosa*, I think, a flower of small size, fawn color, with dark linings and beautiful styles of a golden brown, and in one stage with a distinct olive reflection. This hybrid produced apparently fertile seed-pods. The reverse cross, *I. vaga* × *Korolkowi*, bore flowers which were dissimilar in form and coloring, the latter being a light red-purple. The standards are tall and pointed. It is several years since *I. vaga* (*Leichtlini*) flowered here, and my memory does not serve for a close comparison. These plants must be soon dried off and kept dormant until late in the year. Another hybrid, *I. Parsamb* (*paradoxa* × *sambucina*), not yet flowered, may be expected to grow without special care, *I. sambucina* being as reliable as it is homely. Irises cross so readily and seed so freely that hybrids are produced with little trouble. There are countless hybrids of the bearded species, but there is still a wide and promising field among the newer species for interesting trials.

Fall-sown annual Poppies are now flowering as the spring seedlings are germinating. One cannot always carry over these fall seedlings from seed scattered in September, but in latitudes no more rigorous than this it is always worth while to make the trial at the risk of loss. Some seasons it is necessary to thin them out, in others few survive, but the survivors are strong plants, far better than can be produced by sowings at other times. Perennial Poppies now in flower are gorgeous, and usually even arrest the attention of those indifferent to any less conspicuous color, but they are not as handsome as the annual Tulip Poppy, *P. glaucum*, whose flowers, scarcely inferior in size, are of a most effective rich and satisfying crimson.

There does not seem to be any special reason why an amateur should take any unnecessary trouble with his garden, and it has always seemed to me that under this head was included the replanting of hardy Water-lilies in the tank boxes each season, most disagreeable and chilly work. My *Nymphæas* in the tanks are in ordinary soap boxes, and have not been replanted for three years. They are running riot now, flowers

are plentiful and as large as the average, and there is more foliage than space on the water, so that it is fair to infer that these plants do not really require the manures rich in humus which are usually advised. This is not strange when one remembers that still waters, not too often changed, accumulate available plant-food from decay of insects and organic matter.

In the centre of my plant border is a Rose bush, now three or four feet high, covered with dainty pink and white single flowers not much over an inch in diameter. This Rose is remontant and bears several crops of flowers during the season. I notice that flower fanciers are quiet before this plant and are usually glad to pocket a few hips, which it bears plentifully. This Rose is the *R. polyantha* remontant introduced a few years ago, of which seeds are offered in the catalogues. It comes readily from seed, from which it flowers in three months, and the plants are perfectly hardy here. In three or four years it has had no winter-killed branches. The flowers vary in coloring and in number of petals.

Elizabeth, N. J.

J. N. Gerard.

Nymphæa gigantea.

THE blue-flowered *Nymphæa gigantea* of Australia is unfortunate in having a specific name which is also applied to a variety of *N. odorata*. I have been unable to see anything very attractive in this variety of *odorata*, especially for Lily ponds where there is a limited water-surface. The common *N. odorata* is preferable, as it flowers profusely in smaller quarters than does its variety. The Australian species is undoubtedly one of the finest of the genus. Unlike any other kind, the flowers can be used either open or closed, for when once they open they close up in the evening in such a way that the outer covering only hides part of the petals. It is, therefore, very desirable for cutting. Unfortunately, this species has the reputation of being difficult to grow, and it is said that young plants go to sleep without any apparent cause; but so will any *Nymphæa* having tuberous roots. If the plants are kept in active growth all the time there is little danger of their going to rest. When starting the tuber into growth, it often makes one or two water leaves and then remains stationary for months. This was my experience at first, and I found that the tubers were planted too shallow in the soil, and when they did sprout, as they almost always do, with stolon-like growths, the roots did not get a chance to take hold of the soil, which as a rule is loose at the surface and very much mixed up with a confervoid growth. Two inches beneath the surface is a safe distance. As soon as the tuber develops two or three fairly good-sized leaves, it is an excellent plan to sever the stolon-like growth from the tuber and pot it carefully in loam and sand and grow it on in this way. If it has no check from a sudden change in the temperature of the water, it will form a blooming plant just as quickly as any of the *Zanzibarensis* varieties. The little tuber should be put back in the soil to sprout again, which it will do several times over, without any apparent diminution in vigor. In fact, I have sprouted a tuber more than a dozen times during a summer and kept it over till the next season, evidently as sound as ever. By keeping a few plants in a small state all the time we have an unceasing supply, and if one plant fails when put out there are others ready to take its place.

Botanic Garden, Washington, D. C.

G. W. Oliver.

Rex Begonias.

THE popularity of these plants is more or less injured by the fact that quite accurate artificial imitations are so often seen. Of course, these shams can be easily detected by any close observer, but the real plants themselves have, to some eyes, a made-up artificial look, and the prevalence of counterfeits in shop windows helps to strengthen the impression that they are stiff, unnatural and undesirable. Nevertheless, many of them are really beautiful, rich in color and not devoid of grace in form and habit. The varieties of the large-leaved section of these Begonias *B. Rex* is the principal progenitor of, may be counted by the hundred, and new varieties are constantly being produced, all laying claim to some special points of superiority in coloring, form of foliage or habit of growth. Of somewhat recent introduction, and quite a departure in form of foliage, is Countess Louise Erdody, which has the two lobes at the base of the leaf wound in a spiral way suggesting the appearance of a snail's shell. The entire leaf shows a rich metallic lustre, the centre a dark silver shading to coppery rose toward the margin. The plant is a free grower and makes a striking specimen. Leaf-cutting is prob-

ably the most practicable method of increasing the newer and rarer sorts, but well-matured leaves should be selected, and after the stronger nerves on the under side of the leaf have been cut they should be laid in sharp clean sand, a few pebbles being placed on top to keep them down. The sand should be kept moist, but not sodden. Little plants soon begin to make their appearance on the surface of the leaf, but it takes some time before they attain much size. A much more speedy process for the older sorts, from which plenty of leaves can be obtained, is to cut away the principal part of the leaf, leaving only a little of the base, and about an inch of the stalk. If this is inserted in the propagating-bed like an ordinary cutting, roots will soon be emitted from the end of the leaf-stalk, while fresh growths will break away from the old base. By this method good-sized plants can be had in a much shorter time. Divisions of the plants may also be used as a means of increase where only a few are wanted.

Ordinary greenhouse treatment, with moderate shade and plenty of moisture, suits the general requirements of these plants. They like an open, well-enriched compost, with free drainage. During the early winter months they should be induced to rest by being kept moderately dry, and when the days begin to brighten and grow warmer they should be repotted and started afresh. It is not advisable to shake them out severely, but is better to remove only a little of the old soil and use a larger size pot. During the summer months they may be used for house decoration, for grouping with other plants around piazzas and other shady places, and for window boxes or vases, but they should never be exposed to the direct rays of the sun or they are apt to either burn or lose the more delicate tints of their foliage.

Tarrytown, N. Y.

William Scott.

Chrysanthemums.—Plants intended for specimens have had their final shift, and are now well rooted in the new soil. Their growth will be rapid from this time onward, and frequent topplings will be required to keep them well balanced. We shall soon select the most promising plants and spread them into shape with a few of last year's stakes. These will be removed when the final tying out is done. When these bushy plants are left unspread the central stems are weakened and the leaves turn yellow and decay. Light develops them, and the object particularly now is to produce as many growing shoots as possible as a foundation for the future plant. Only the tips of the shoots should be taken, and none must be allowed to get away. When this happens by an oversight, and it is necessary to cut out two or three inches to bring the shoot back to the level of the others, it will be noticed that such shoots rarely break well. I am frequently asked how I manage to keep my plants so even and bushy, and how often I top them. The stopping is done every day without fail. Liquid-manure must not be given until the plants are quite vigorous and becoming pot-bound. A month hence will be time enough. Cuttings intended for single blooms ought to be ready for potting or boxing off, as is most convenient. These, again, will be ready for benching by the 20th of June. First-class blooms can be grown from plantings made at this date, and medium-sized ones from plantings made a month later. This year we are growing a number of Chrysanthemums in eight-inch pots intended to carry from ten to a dozen medium-sized blooms. Large blooms are not available for all kinds of decoration, and medium-sized ones are useful for dinner-table work.

A New Hybrid Canna.

To the Editor of GARDEN AND FOREST:

Sir,—During a recent visit to Santa Rosa, California, I called upon Luther Burbank, and among other things was shown a new hybrid Canna which, when introduced, will probably create as great a sensation as Madame Crozy did. This plant is not a seedling of the well-known strains so deservedly popular, but is a hybrid between Madame Crozy, which has so long been the standard of excellence, and *Canna flaccida*.

Canna flaccida is a native of Florida, of a dwarf habit, and not a strong grower. Its exquisite light yellow flowers would, in spite of these defects, give it a high place in the garden were they not so very ephemeral. So frail and fleeting are they that an hour in the morning often measures their term of existence. I remember well that it was days before I got a sight of the flowers on a blooming plant of my own. The flower of *C. flaccida* is unique among Cannas in having

something of the grace of an Iris and a peculiar silvery sheen that is very beautiful.

For years Mr. Burbank has been trying to make a cross in which some of these fine qualities of *Canna flaccida* might be united with the vigor and lasting qualities of the Crozy strain, but while many seedlings were grown and bloomed, all, with a pertinacity which is so often the despair of the hybridizer, followed one of the parents, and that Madame Crozy.

Last summer, in the third generation of hybridized seedlings, the new seedling appeared, and any one knowing *Canna flaccida* would have instantly recognized its parentage. Only a single seedling among thousands, yet Mr. Burbank feels that it well repays the trouble.

In the new and as yet nameless *Canna* are united, happily, the Iris-like form, the satiny sheen and the large size of flower of *Canna flaccida*, while the Crozy blood, giving to the plant a vigor of growth even surpassing either parent, and a lasting quality to the flowers about the same as Crozy possesses, is only apparent in the coloring in a lemon more intense than in *flaccida*, and a few reddish spots in the throat.

A marked feature of the new race is the development of some of the minor petals which in the Crozy strain are all but rudimentary. In the new *Canna* they are broad and flat, giving a bold fullness of outline until now quite unknown in Cannas.

Considering the predominance of *Canna flaccida* in this seedling, the most critical point is its keeping qualities. In this regard it is not quite the equal of Crozy. The flower opens up a clear lemon-yellow never before known in Cannas, and is unspotted, except for a few dots well in the throat. With age it becomes lighter in color, and in ordinary weather will last about as long as Madame Crozy, and I think for exhibition it is superior to any other *Canna*.

The foliage is of a light green, the growth a little stronger than that of Madame Crozy, the flowers well carried above the leaves and somewhat larger than those of the Crozy type.

The breadth of petal in the new strain is a marked feature which we can expect future hybridizers to still further develop.

Ukiah, Calif.

Carl Purdy.

[The photograph of a flower of this new hybrid with one of Madame Crozy for comparison shows it to be almost identical with the variety Austria, which we have already described, although there seems to be more scarlet in the lower petal than is found in the flowers of Austria. It seems strange that in such widely separated countries Mr. Burbank in California and Dammann in Italy should have raised plants at about the same time which are so nearly identical, but these coincidences are common. When seen together the two plants may show differences which we cannot observe in the photograph, but their comparative value, of course, can only be determined by actual trial. Dammann's hybrids, Italia and Austria, have raised the standard of perfection in the flowers of these plants, but the question whether they will have substance enough to stand out-of-doors in this climate has not been settled, and it may be that the southern blood derived from *C. flaccida* will be seen in a lack of sturdiness. It is to be hoped that an opportunity will soon be offered to try the California hybrid by the side of the Italian one.—ED.]

The Stanford University Grounds.

To the Editor of GARDEN AND FOREST:

Sir,—The other day I visited Palo Alto, in Santa Clara County, and spent some time in the beautiful grounds which were the pride of the late Senator Stanford. Much has been written about the University, but I have seldom seen anything in print about the possibilities for future work in forestry and horticultural experiments offered by the great Palo Alto estate. The original San Francisquito Rancho of 1,400 acres was added to by Senator Stanford at various times since 1870, until the property now embraces over 8,000 acres, all of which is dedicated to the uses of the University. The University also owns the famous Vina Ranch of 55,000 acres, in Tehama County, and the Ridley Ranch of 21,000 acres, in Butte County. It is evident that when Stanford University is ready to establish courses in forestry, viticulture, pomology or any and all other departments of agricultural science, whatever lands are needed can easily be set apart, while the operations of the various farm divisions can be made to give much practical training to students. All the estates—in part valley, in part foot-hills—offer a very wide range of soils and climates. In these respects, as

in many others, Stanford University is especially fortunate. The home estate, Palo Alto, lies at the base of the Coast Range foot-hills, near the southern line of Santa Clara County. I have heard this portion of the mountains of the backgrounds called the Sierra Morena; in fact, the whole Coast Range easily divides into a multitude of smaller groups, separated by valleys and cañons.

The site of the University is in a land of Oaks, both deciduous and evergreen. One lordly group of Redwoods, thrust far out from its companions, twenty miles from the coniferous forests, lying toward the sea and ten miles from the nearest hills, has been a landmark from earliest Spanish days. Hence arose the name of the estate, Palo Alto—tall tree. Spanish priests and explorers of the closing years of the eighteenth century, riding hour after hour through the wild Mustard and chapparal of the unfenced valley between Santa Clara Mission and the drifting dunes of Mission Dolores, well knew this great evergreen spire, 200 feet high, at the crossing of the San Francisco. Once it was a group growing from a mass of roots, as is the fashion of Redwoods. We have a record of three trees standing among lesser ones, then of two, but now there is only one, the sentinel of the whole valley, the University tree, par excellence. It was long ago bulwarked with great care against winter floods, and it has passed into college literature. Thus *Sequoia sempervirens* has become the guardian tree of Stanford, even as *Quercus agrifolia* is the preëminent tree of Berkeley.

Senator Stanford was always a lover of trees. He spent much time upon his plantations, and he never allowed a healthy Oak-tree to be removed. About three hundred acres of the richest valley land at Palo Alto were long ago planted with a great variety of shrubs and trees. A large part of these shrubberies and woodlands can be made of immediate scientific value. Nearly every species which the various nurseries of California can furnish is represented here, and doubtless there is much that it would be hard to find elsewhere, for Senator Stanford was a liberal importer of rare plants. The Arizona garden, for instance, could only be duplicated at very great expense, because Senator Stanford's opportunities as a railroad man were unusual. He was able to send men out into the desert and collect the finest and largest specimens of desert plants, bringing them in wagons to the nearest point on the railroad, where they could be loaded on his freight cars.

In driving over the grounds one sees superb specimens of both the Sequoias and of nearly all the other California conifers. Among many fine Araucarias, I noted a noble *Araucaria Bidwilli*, with trunk fourteen inches in diameter and shaft rising to a height of fifty feet. Very large Hawthorns in full bloom, groups of fruit-laden Oranges and Lemons and many brilliant flowering trees give color to the May-time woodland. Nothing is as yet labeled, and the University botanists and foresters of the future will have a great deal to do in putting this raw material in shape. But it is magnificent material.

The general impression, which is all I have undertaken to give in this brief article, is that of enormous undeveloped resources for future educational work in the right hands at the right time. The estate already has greenhouses and propagating-houses, which can be enlarged when necessary. All in all, the garden, the shrubberies, the woodland, the orchards and vineyards, taken collectively, are equivalent, in some respects, to a twenty years' start. This is chiefly because the Stanford estate was laid out on a grand scale to begin with, and is nowhere cramped.

Niles, Calif.

Charles Howard Shinn.

[Some account of the original design of these grounds by Mr. Olmsted, together with a diagram, will be found in vol. i. of GARDEN AND FOREST, page 507.—ED.]

Elæagnus multiflora in Wisconsin.

To the Editor of GARDEN AND FOREST :

Sir,—In the spring of 1892, six plants of this shrub, the *Elæagnus longipes* of many gardens, were set on the grounds of the Wisconsin Agricultural Experiment Station at Madison. Two of these plants were set in the lawn, and they have been protected each winter by covering with earth or coarse manure. The other four were set in the nursery and have received no winter protection other than that afforded by snow a portion of the time. The experience gained from these two plantings enables us to judge something as to the climatic conditions that this plant is capable of enduring.

The winter of 1893-4 was considered rather a mild one for this locality. We had one cold period during which the mini-

mum thermometer registered below zero each day for six days in succession, the lowest point reached being eighteen degrees below zero. The unprotected plants in the nursery killed back a little at the tips and produced no flowers the following spring, but none of them were seriously injured. The protected plants on the lawn were alive to the terminal bud and yielded a fine crop of fruit the following summer.

The next winter, 1894-5, was more severe. During nineteen consecutive days, in January and February, the minimum thermometer registered below zero every day but one, when it registered plus two degrees. Three of these days the mercury descended to fourteen degrees below zero, one to sixteen, one to seventeen and one to twenty-one degrees below, the last being the lowest point reached during the winter. The snow in the nursery during this cold period was deep enough to cover about the lower half of the stems of the *Elæagnus* shrubs, and all of the part that reached above the snow was killed, while that below the snow-line not only survived but bloomed freely the following spring. The protected plants showed no injury whatever.

The past winter was unusually mild. The mercury was below zero on eleven different days, but did not register lower than minus thirteen degrees. The plants in the nursery killed back a very little at the tips, but the flower-buds are uninjured.

From these observations we can summarize as follows :

With a minimum of minus thirteen degrees flower-buds were uninjured and stems were very little injured. With a minimum of minus eighteen degrees, wood was not much injured, but flower-buds were killed. With a minimum of minus twenty-one degrees, accompanied by prolonged cold, exposed wood was destroyed, but wood and flower-buds covered with snow were uninjured. No injury has resulted at any time where protection of earth or coarse manure was given.

I find that seeds of *Elæagnus multiflora* buried in sand beneath the soil germinate freely the following spring, especially when washed from the pulp. The seedlings, however, appear quite delicate, and I think, with us, must be taken up in autumn and wintered in the cellar. At least a covering of earth during the past mild winter was not sufficient to save ours from destruction.

It is unfortunate that the fruit of *Elæagnus multiflora* has so much of astringency. There is no reason to doubt, however, that varieties may be obtained that are without this quality, and then we shall have a valuable addition to the list of small fruits which can be depended on in this climate.

University of Wisconsin, Madison, Wis.

E. S. Goff.

A Novel Method of Tree-planting.

To the Editor of GARDEN AND FOREST :

Sir,—The obstacles to fruit-growing on the plains have led to various methods of culture peculiar to the region, and many experiments have been and are still being tried in the hope of more fully overcoming these obstacles. One of the most noteworthy of these is that known in Nebraska as the Leonard method of tree-planting, from the name of the grower advocating it. The greater part of this region is underlaid by a subsoil that, while, perhaps, not so hard as that commonly found in the eastern states, seems to be so hard that the roots of Apple-trees do not penetrate it to any great extent, but spread out near the surface. This, taken in connection with the small rainfall and greater evaporation of the region, seems to be unfavorable to the full development, health and longevity of the tree. The new method of planting is based on the theory that if it is possible to penetrate this subsoil and reach a softer and moister layer beneath, the tree will have access to more water and be able to form a deeper root-system, thereby becoming less subject to the influences of surface and atmospheric conditions. Accordingly large holes, six or eight feet in diameter, are dug deep enough to get through the harder subsoil layers, if possible. If this cannot be done the hole is dug six or eight feet deep, then from the bottom a hole is bored with a post auger, three or four feet deeper, reaching a moister layer of soil, if possible. The whole is then filled with surface-soil, raising it ten or twelve inches above the level of the surface, to allow for settling, and the tree planted in this position. The method has not been in use long enough to determine its value, but it is being watched with a great deal of interest. Trees planted in this way have made a very promising and vigorous growth, but it should be added that Mr. Leonard gives ideal cultivation, and it is impossible to say how much of this growth would be brought about by the cultivation alone. In order to give the matter a comparative test, Apple, Plum and Cherry trees have been planted in this way at the station-farm the present spring, while alternate trees in the

same row have been planted in the ordinary way. Here the methods of culture will be the same for each, and it is to be hoped the merits of the system will be shown. It will be interesting to remove some of these trees as they grow older, in order to see what effect planting in such an immense earthen flower-pot will have upon the habit of root-growth. In this planting the holes were dug about six feet in diameter and six feet deep, with a post auger-hole three feet deep in the bottom of each.

No doubt, most orchardists will say at once that this involves altogether too much work, and it does mean a good deal of work, but it is less expensive than irrigation, which we may sometimes think would bring us almost ideal conditions. These holes can be dug and filled at a cost not exceeding a dollar a tree. Now, reflect that a good Apple-tree in full bearing is worth at least as much as a good dairy cow, and then ask how many dairymen would hesitate to pay one dollar more for a healthy, vigorous, productive cow than they would for one not quite her equal. The important question is not the expense of doing the work, but the effect which such planting will have on the subsequent life of the tree, and no one can answer that question satisfactorily ahead of time.

Agricultural College, Lincoln, Nebraska.

Fred W. Card.

Larch Sack-bearer (*Coleophora Laricella*).

To the Editor of GARDEN AND FOREST:

Sir,—In the spring of 1894 I noticed that the tips of the leaves of the trees in my Larch plantation of five acres had become yellow or brown, as if touched by frost, and later on in many cases the whole leaf dying. This continued through the growing season, many of the trees attempting to put forth a new growth. Not being able myself to discover the cause of this trouble, I sent samples of the twigs and leaves to Professor C. H. Fernald, of the State Agricultural College, who informed me that they were infested with the Larch sack-bearer, as he named it. The caterpillar was so minute and so concealed under cover of the leaf that I had not observed it. On re-examining the trees after this explanation I soon discovered the caterpillars in countless numbers; they bore into the needles, so that the upper ends shrivel up and turn yellow and brown. Professor Fernald wrote me that this insect was first reported in this country by Dr. Hagen in 1886 on European Larches in Northampton, Massachusetts. He also stated that he had observed it on some Larches in Amherst, but had never heard of it elsewhere until my trees were brought to his notice. In 1895 the insects were apparently undiminished in numbers, and this spring they have appeared again; as a consequence, the growth of the trees has been checked.

My trees, although European Larches, were not imported, but came from Douglas, Illinois. The question arises, where did these pests come from? Have they been slowly increasing in numbers from a small and unnoticeable family, or has the horde dropped down from some unknown quarter? On page 311 of vol. iv. of Schlich's *Manual of Forestry* may be found the best description of this moth that I have seen. It is common in Great Britain and Germany. As to remedial measures not much has been attempted on account of the magnitude of the task. On one section, however, the lower branches have been cut off and burnt.

Boston, Mass.

J. D. W. French.

Planting in the Boston Parks.

To the Editor of GARDEN AND FOREST:

Sir,—Two years ago I wrote to your journal about the care of the Boston parks; since that time no improvement has taken place. The most conspicuous illustration of what I mean can be seen in that section of the Back Bay Fens nearest the city. For some reason this section was planted with a general mixture of anything and everything that was at hand, and a more curious collection it would be hard to imagine. Garden shrubs are crowded in with Spruces, showy perennials appear in most unexpected and inappropriate places, and just now weeds and dead wood abound in the most prominent portions.

The use of certain garden shrubs on the edge of a marsh seems to be rather questionable, but admitting their appropriateness, surely if they are to remain some care should be taken of them. At present, crowded in among plants of coarser growth, some dead and others half-covered with deadwood, they present a truly pitiable appearance. In many cases the dangerous practice of planting strong-growing vines among shrubs has been indulged in to a great extent and the evil results are already apparent, so that it really seems as if Boston would be better off if her parks were half as large and twice as well taken care of.

Trained men are needed to take care of our parks after they are planted, a constant thinning and pruning of trees and shrubs must be kept up, and for such work men of skill and experience are needed.

In the meanwhile we keep on in the same way, every year extending our park system (already too large), planting more and more ground and leaving our old plantations to fight it out among themselves.

Wellesley, Mass.

H. S. H.

Why Rhododendrons do not Flower.

To the Editor of GARDEN AND FOREST:

Sir,—I have read your note in GARDEN AND FOREST on the influence of the past winter on the flower-buds of Rhododendrons and other shrubs. I am convinced that Rhododendron buds in this neighborhood were injured in the severe cold snap of the 10th of October, when the thermometer fell suddenly to twenty-three degrees, Fahrenheit, and the most of the mischief was done at that time. The buds on several half-hardy varieties here, which were housed in cellars on the first of November, have been more or less injured, some varieties losing all their buds and others having only a few flowers in a truss. This must have been done before the plants were moved into their winter quarters. I remember that the same thing happened ten or twelve years ago.

Wellesley, Mass.

H. H. Hunnewell.

Recent Publications.

A Traveller's Notes. By James Herbert Veitch, F.L.S., F.R.H.S. Published for private circulation by James Veitch & Sons, Royal Exotic Nursery, Chelsea.

All persons who keep themselves acquainted with current horticultural literature will remember the series of letters from the far east which appeared three or four years ago in *The Gardeners' Chronicle*. Mr. Veitch has brought these together, revised them, added certain connecting links which make the narrative continuous, so that the text and notes, with the illustrations, make altogether a quarto volume of considerably more than two hundred pages. The tour made by the author was through India, Malaysia, Japan, Corea, the Australian colonies and New Zealand, and the work is chiefly descriptive of the vegetation of those regions observed from a horticultural point of view. Mr. Veitch's object was to study the conditions under which the plants of these countries have been developed, with the view of learning something about their cultural requirements when transplanted into British gardens, and also to make a search for such new plants as might seem worthy of introduction into cultivation. On the first page of the text we read of impressive groves of Coconut Palms, and all through the book the reader is among plants, garden plants generally, with descriptions of their appearance, habits and uses. Wherever a botanic garden was found its treasures were carefully noted, and one who takes even a cursory glance through these pages will get a fair idea of what trees and plants are most used for decorative purposes in the countries through which Mr. Veitch's long journey extended. There is an interesting map and numerous photogravures and reproductions of photographs by the author, many of which are remarkable, both for the interest of the subject and skill in treatment. Of course, they are largely devoted to plant life, but incidentally we see much of the splendid architecture and scenery of the far east. The pictures are beautifully printed and the mechanical execution of the book throughout is unusually attractive.

Notes.

The *Agricultural Gazette*, of New South Wales, gives the following as an example of the durability of the Yellow Box timber, *Eucalyptus melliodora*: A tree was cut down in March, 1849, and a log fifteen feet long and fifteen inches in diameter was placed while green as the ground plate or sleeper to support the posts of a veranda. About three-fourths of it was under ground, where it has remained ever since, and it is apparently as sound as the day it was cut. Another log of the

same kind of tree, which had been used as a sleeper and has been partly imbedded in the ground for forty-three years, does not show any decay even in the sapwood.

Virgilia trees are flowering in the parks and gardens about New York this year with unusual profusion. The weight of the blossoms is so great as to give the branches a still more drooping habit even than they naturally possess, and as they wave slowly in the wind the long racemes of pure white flowers among the light green and delicate foliage make a picture which cannot be excelled for beauty and grace, especially when seen against some dark background like a mass of conifers.

Since the account of Mr. Burbank's new Canna, which appears in the correspondence columns of this issue, was in type, we have again received from Mr. Frank Pierson specimen flowers of Austria, the new Italian hybrid. The color is a luminous golden-yellow, very pure and lighter in tone than that of the Canna Italia and but faintly shaded at the base of the petals. The splendid flowers stand above the foliage on long stems; they are flat, spreading, bold in appearance and nearly six inches across.

During the five business days of last week 2,420 cases of evaporated apples were received by wholesale merchants in this city, and 2,226 packages of other dried fruits. Since September 1st 159,061 cases of evaporated apples have been handled in this market, and 678,221 packages of other sorts of dried fruits. During last week 7,096 packages of evaporated and dried fruits left this port, and since the season began, nine months ago, 323,780 packages have been exported. Besides apples, evaporated and dried raspberries, blackberries, huckleberries, cherries, plums, prunes, peaches, apricots are now being sold.

Willow Twig, Cooper's Market, Ben Davis and Roxbury Russet were comprised in 1,397 barrels of apples shipped to this city during last week. The highest grade of Willow Twig brings \$5.75 a barrel at wholesale; Ben Davis, \$5.00, and Roxbury Russet, \$3.25. Cherries from near-by points are offered at fifteen cents a pound, retail. Cultivated blackberries of good size and quality, from North Carolina, cost twenty cents, and huckleberries, from the same state, an equal price. Green gooseberries are in limited supply, and sell for fifteen cents a quart. The first watermelons of the season came from Florida early last week, and sold at from sixty to seventy-five cents, wholesale.

One of the most important vegetable productions of Persia is the crop of dates which are grown to great perfection in many parts of the country. The Date Palms begin to yield at about three years of age, reaching their prime at thirty, and a good yield for one tree is from eighty to one hundred pounds. The flowers are fertilized by hand, one male tree supplying pollen for perhaps forty pistillate trees. The dates used for export are those that grow at the summit of the trees. From the action of the sun they become hard and dry and are thus easily packed, while those on the lower branches remain soft and are kept for local consumption. The exports of dates of the country could be easily doubled by planting fresh groves of Palm.

The first sugar corn of the season, from Florida, is now offered in our markets at seventy-five cents a dozen ears. Peas are coming from New Jersey, Maryland and Virginia. All the summer vegetables, but Lima beans, may now be had well grown and ripened, excepting tomatoes, which for the past few weeks have been poorly colored. Potatoes have been plentiful and cheap, the best Bermudas costing \$4.00 a barrel at wholesale, those from Florida \$3.00, and from New Orleans \$2.50. As many as 15,000 barrels of this staple arrived from the south during last week. Owing to dry weather the bulk of the stock is small. The supply of domestic potatoes from last year is still considerable. During five days of last week 40,806 barrels of the latter were received in this city, besides 2,875 barrels from Bermuda and the West Indies. In the same time Bermuda sent 21,205 crates of onions, and 5,967 bags came from Egypt.

One of the remarkable and often observed correlations between the scent of flowers and the animals who visit them is the development of the floral odor just at the time when the insects fly. Professor Kerner cites the example of certain species of Honeysuckle, Petunia, some Orchids and other plants which smell faintly or not at all in the daytime, but give off abundant odor between sunset and midnight, just

when the insects fly which feed on them. Various Pinks and Pelargoniums, which are visited by small night moths, exhale a strong odor of Hyacinth at twilight, but give off no scent during the day. On the other hand, many flowers which are visited by bees and butterflies in the daytime become scentless at sunset, like the ornamental Clover, *Trifolium resupinatum*, which smells of honey in the sunshine and becomes scentless when the bees return to their hives in the night. The same is true of the Grass of Parnassus, and a species of *Daphne*, which grows in the Pyrenees and emits a delicate violet odor during the day, but has no smell whatever after nightfall.

If the fruit-growers of the country suffer from diseased trees and vines, which can be prevented by spraying, it will be their own fault, as the literature which gives full directions for the prevention and cure of these ordinary diseases is increasing every month. A farmers' bulletin, entitled *Spraying for Fruit Diseases*, contains the latest authoritative directions which we have seen. It is written by Professor Galloway, Chief of the Division of Vegetable Physiology and Pathology, and gives the method of preparing the various fungicides, the special qualities of each and the proper time and the best means of applying them. The various diseases of the Grape, Apple, Pear, Quince, Cherry and Plum which yield to treatment are also briefly, but accurately, described, and all this within the compass of a dozen pages. In the final paragraph fruit-growers are urged to bear constantly in mind that the treatments are not curative, but preventive, and that it is, therefore, necessary that the spraying should be made at the proper time and in a thorough manner. Of course, a saving of both time and money will follow where experienced and trustworthy labor and first-class machinery are used, and the plants will be more certainly protected. Poor help, cheap makeshift machinery and lack of personal and intelligent supervision by the fruit grower himself are the chief causes of failure.

We have been interested in a little pamphlet on *Potato Culture on the Island of Jersey*, written by the Rev. Charles B. Merrill, of Beloit, Wisconsin, and published at Medina, Ohio. It is a complete description of the methods of raising Potatoes for the great markets of London and Liverpool in the Channel Islands, and shows how what is called high-pressure gardening can be made to pay on small areas. The details of the practice in the Island of Jersey might, perhaps, not be strictly adapted to our different climates and soils, but as the principles of plant growth are the same the world over there is much in these pages to make American farmers reflective. In a soil which has been cultivated for a thousand years and which has grown richer all the time, where careful tillage makes it easy to work, and clean cultivation has practically exterminated weeds, the Jersey farmer has a great advantage to begin with, but he does not neglect his crops for this reason, but gives them all the more care. He mellowes the soil deeply, fertilizes it freely with manures which have been made as fine as possible by rotting, grinding or liquidizing, spares no expense to secure the best of seed, of which he plants thirty or forty bushels to the acre, and sets the tubers in a particular way in every hill, cultivates thoroughly, harvests with the greatest of care, markets the crop as soon as it is gathered, and then hauls it over the smoothest of roads so that not a single potato is bruised or chafed on the road. The seed is never cut, but the whole tuber is planted, and then all the vigor is thrown into two or three strong shoots, rather than into a dozen weak ones. The result of all this care is abundant and paying crops. Seven thousand and seven acres, or one-third of the crop-land of the whole island, was planted in 1894, and 60,605 tons were exported, with 15,000 tons kept at home for seed and food. The average yield of the whole per acre was 333 bushels, or more than ten tons. The average price received an acre was \$343, or an average net cash of \$260. The highest yields to the acre were 500 to 600 bushels, and the highest receipts to the acre were from \$500 to \$600. This was not an exceptional year, but for twelve years past the yields and prices have ranged about the same. In other words, during these twelve years more than twenty millions of dollars—that is, more than \$300 for each acre of the Potato area every year have been brought into this country. Potato-culture is such a settled and sure source of profit that it seems to have no element of experiment or uncertainty, so that the cash rents of land range from \$25 to \$65 an acre a year, and the lands sell for from \$600 to \$1,500 an acre, if they are offered, which is rarely done, except because of death or misfortune. Though most of the farmers till their own land, yet applications for rent are continuous, and farmers whose fields are in fine condition have been offered and have refused \$70 an acre annual rent.

Where Competitive Examination may Fail.

ABOUT a month ago the office of landscape-gardener and forester for the city of Philadelphia was to be filled, and the Board whose duty it was to name the man decided to open the place to competitive examination instead of making it a subject of personal patronage. Precisely what the duties of a city landscape-gardener and forester may be in Philadelphia we do not know. He probably has charge of the street-trees and superintends the construction and planting of the small parks, and if these are his functions the examination would give a fair idea of the knowledge of the applicant in this particular field. There were questions in surveying, in drawing as applied to landscape-gardening, and in road-building. No attempt was made to ascertain how much the applicant knew of general horticulture, but there were twelve carefully prepared questions relating to trees and the way to plant, protect and care for them, so that a comparison of the answers given by the nineteen candidates would, no doubt, enable good judges to select the man whose knowledge on this subject was the most comprehensive and thorough.

The only question relating directly to landscape-gardening was the following: "What is the chief point to be considered in laying out the grounds for a public square?" This might furnish the text for an essay which would enable the judges to learn some of the views of the writer on the general subject of designing small urban parks, but little more than this could be hoped for. Indeed, it would be a difficult task to discover by a written examination whether a man has creative artistic talent. If a city wished to make an intelligent selection of an architect to design a municipal building it would not choose the man who could answer the most questions about architecture. One who wished a landscape painted would hardly think of selecting an artist by competitive examination of this kind. But it requires just as much constructive skill to adjust a piece of ground to varied public uses as it does to make a building which in all its parts shall be adapted to a given purpose, and it requires as much taste, at least, to prepare this ground so that it will make an impressive appeal to the imagination through the eye as it does to make a beautiful

building. By an examination we can ascertain whether a man is a good critic in any branch of art, but it will give no adequate idea of his creative capacity. The proper way to judge of a landscape-architect is by his works, just as we judge of a landscape-painter, or a sculptor or a poet.

Again, if we wish to be informed as to a man's executive faculty—that is, his capacity for administration, for managing men and getting things done in the right way—we naturally study what he has done, or observe what he is doing, rather than cipher up what percentage of his answers to certain questions is correct. A competitive examination conducted by eminent experts was held in one of our large cities some years ago, and the candidate whose papers were easily first in quality was appointed chief gardener of an extensive park system. He had a thorough knowledge of the shrubs and trees and plants used in our parks, he knew how to propagate them and how to cultivate them, but after his appointment it was evident that he had no idea of proper grouping and arrangement, no refinement of feeling, no taste for simple natural beauty. Besides this, he lacked the power of organization and command, and he made a miserable failure.

All this means that while the service in public parks should certainly be kept out of politics, and no one should be admitted to subordinate positions without examination, there is no certainty of securing an efficient administrative head of any departmental work by any such competition. Wherever we need moral power, the force of will, the ability to control others, we must select a man who has displayed these faculties in other positions. And the same is true where artistic talent is in question. A man may be able to write an instructive essay on landscape art without possessing a particle of faculty for original design, just as one may be a competent critic of architecture or sculpture or painting without any talent for invention or construction in either of these arts.

Daffodils in the Grass.

THE different varieties of Narcissi are beautiful anywhere, whether grown in large masses for commerce or in beds in the flower garden, but they never are more attractive than when seen among the grass along a wood border. On the 14th of April a conference on Daffodils, with an exhibition, was held in Regents Park, London, and Messrs. Barr & Son had planted thousands of Narcissus-bulbs in groups of from 150 to 200 of each variety in the turf of the park the autumn before, so that they would be in bloom for this occasion, and the display thus made was said to have been a most interesting feature of the meeting. The cheapness of these bulbs, the ease with which they can be made to bloom, the fact that they can be grown anywhere, on lawns as well as in flower-beds, their satisfying variety in form and color, have made them the most popular outdoor flower in England, and they are rapidly increasing in public favor in this country, although comprehensive collections of all the different sections, including the expensive novelties, are not yet common here. And yet we can grow, with proper care, quite as beautiful Daffodils in this country as any which England can show. Unfortunately, however, our climate is such that not so many of the different varieties can be naturalized in the grass. The Poet's Narcissus, different varieties of the Star section, the Jonquils and some of the Trumpets can be made at home in the grass. Almost any of them will bloom for a season or two, but which particular ones will grow persistently and increase from year to year no one can tell until they have been tested in different soils. Most of the varieties like some cool moist place and in well-drained meadows which are covered with snow most of the winter, and where the soil is a trifle stiff many of them will be sure to succeed.

In the admirable paper of Mr. William Robinson, read before the conference to which we have alluded, he speaks of one menace to the best effect of Narcissi in the grass; and that is the practice of scattering them evenly over a

meadow or pasture. Such monotonous planting destroys all sense of relief and repose. Where one square rod is just like all the rest the eye soon wearies and craves something with distinct features and variety of expression. This suggestion should be heeded by all who attempt the naturalization of such plants as *Narcissus*, *Scilla campanulata* and other bulbous plants in the turf. Just as Water-lilies are much more effective when they are planted in groups with a stretch of smooth water beyond them, so these Daffodils are infinitely more beautiful when there are reaches of grass between the different masses. For this turf-planting does more than furnish individual flowers for our delight. It ought to make a charming picture in the distance. If the bulbs are planted along the border of a meadow, closely here, more openly there, resembling somewhat a picturesque shore-line with capes and bays and detached islets about which the smooth turf flows like a lake, the picture will have some artistic meaning. Mr. Robinson well says that a passing cloud will often give a good form for an isolated group and will be specially instructive since it is more compact toward the centre, as groups of *Narcissi* should be in the grass.

We should like to see more fields and wood borders in this country garnished with flowers in this way. Some of our native weeds naturally arrange themselves into pictures of this kind, but most of them are destructive of the grass crop. The leaves of Daffodils, however, ripen before the grass is fit for mowing, so that the bulbs will be ready for another year's bloom before the machine passes over them. They work trifling harm to the hay crop and yield a harvest of beauty whose value cannot be estimated.

A Botanical Journey in Texas.—V.

EARLY on the morning of the second day of July I left El Paso for a visit to Mount Franklin. This is a vast longitudinal pile of rocks upon gravel and sand, and of sand and gravel upon rocks, and of mud deposits upon both, the whole resting upon granite, which on one side of the mountain is reddish in color, while on the other side, and nearer the river, it approaches white. In some places the granite seems to have intruded into the other material. Mount Franklin itself is nearly isolated, most of the range, of which it appears to be a remnant, having gone down the river to assist in filling the Gulf of Mexico, or having been used nearer home to fill the old lake-like expansion of the river.

Measurements made by Captain Ruhlen, of the United States army, give the mountain an elevation above the level of the Court-house yard of 3,000 feet, and of 6,700 feet above the level of the sea. It is, therefore, one of the highest mountain peaks of Texas. The stories told of the ruggedness of the slope and its difficulty of ascent were fully confirmed by experience. I found no springs of water, and for ten hours wandered in thirst over the mountain. Once in western Kansas I passed thirty hours without food, though with plenty of creek-water to drink, and the recollection of this hardship consoled me, so philosophy triumphed, and my work was probably as well done and as many plants were collected as there would have been if I had been fully watered and fully fed.

Since I visited the mountain to see and to collect its flora and search for rare and unknown plants, the more difficult and unusual way of ascent was taken through a precipitous ravine half-way up the mountain, thence to a different rock formation, and along the crest of the mountain until the topmost crag was reached.

Standing on the mountain-top and looking around for a new plant, the well-known habit of the handsome evergreen Sumach, *Rhus virens*, showed itself at the base of a crag just below me. It is evidently more daring and climbs higher than any of its congeners. *R. microphylla* and *R. trifoliata* are lower down on the mountain. At my feet was the humble *Paronychia Jamesii* and *Selaginella*

rupestris in the crevices of rocks. *Lechuguilla*, *Agave heteracantha*, is by far the commonest tall plant upon the high mountain, and furnishes it with its visible green. *Candle-wood* and *Solat* are not far below it, all of them ascending to about 6,000 feet. The rather rare and extreme western *Pepper-Grass*, *Lepidium lasiocarpum*, is common on the mountain, and only there, so far as I have observed it. It is a low apetalous species with hairy fruit, as its specific name indicates.

The most interesting shrub on the mountain is a *Lippia* with rounded crenated leaves and spikes of small white flowers. It is handsomer than *L. ligustrina*, and fully equals that species in the strength and sweetness of its perfume. The general habit of the shrub is like that of *Salvia ballotaefolia*. It is also to be found lower down among the foot-hills. Malvaceous plants are common higher up as well as lower down. Some of them are very handsome. With the rest, *Abutilon parviflorum*, with small yellow flowers, is abundant, especially in the lower ravines. *Pectis angustifolia* and *P. prostrata* are common on the mountain slopes and among the foot-hills. Both species are handsome little plants and lemon-scented. The former extends northward to central Kansas, where its human neighbors call it, by way of nickname, "Camphor-plant."

More species of *Boerhaavia* grow on and around the mountain than I have seen elsewhere. They all are semi-erect spreading plants, peculiar in their habit, their manner of growth, their flowers and fruit. Each is very like the other, and to know one of the species is to know most of them. A low-growing and handsome *Asclepias* is abundant on the mountain. It is probably *A. uncialis*, as it is not more than three or four inches tall. *Torrey's Lycium*, *L. Torreyi*, a tall shrub, is very abundant around El Paso. Its purplish flowers are followed by small red berries, which are used for tarts and jellies. There is another *Lycium* here, a much smaller species, with whitish flowers.

A curious and interesting plant bearing the rather pleasant name of *Janusia gracilis* is abundant in the ravines of the mountains, ascending to an altitude of, perhaps, a mile. It is found also among the foot-hills. It is a low, slender climber with yellowish flowers, which are usually borne in pairs. They are succeeded by samara-like fruits, which readily distinguish the species. It belongs to the family of plants which keep bright the memory of the old Italian botanist, *Malpighi*, the author of the *Anatomy of Plants* and the father of microscopy. Of larger shrubs on the mountain and among the foot-hills, not already noticed, a *Cercocarpus*, *Fallugia junco*, *Crown of Thorns* (*Kœberlinia*) are present, and *Ptelea angustifolia*, as distinct from its congener as nature ever makes it, which is not saying very much for its specific rank.

In all regions where dryness of the atmosphere produces aridity of the soil the vegetation is largely limited to quickly growing, annual, deeply rooted bulbous plants and woody perennial plants. In the short rainy season the annuals quickly spring up, blossom, perfect their seeds, and die. The seeds sleep in the soil until the rain comes again, when they repeat the processes of their ancestors. The bulbs, too, sleep, but they are always ready to grow. Within three days after a rain the ground may be literally white with flowers of *Cooperia*, where not an individual was to be seen before the coming of the rain. There is always water in the soil, though it may not be measured. Deeply rooting bulbs and the roots of woody plants are able to reach that water in sufficient quantities to enable them to live and to keep a slow life. The decay of their worn-out roots adds constantly, not only to their stock of pabulum, but also to the stock of fluid to infuse it. The living everywhere are drawing their subsistence from the dead.

Texas, from near the Gulf to New Mexico, is the native place of at least five species of *Ephedra*, a remarkable genus of gnetaceous Gymnosperms. All of them are low, humble shrubs, with green and sometimes shreddy bark, and few or no leaves. We wonder that Nature should stop to make such strange freaks of vegetation. We wonder

still more that she should make them so that we literally class them with the mighty Redwood and Sequoia. People who associate strange properties with strange appearances ascribe all sorts of remedial effects to these plants. Most of those are without real foundation. The largest and most peculiar of our species, *Ephedra trifurca*, is very common round El Paso on the mountain and on the mesas. This species sometimes makes itself into a neat little miniature tree, with a clean trunk fifteen to twenty inches long, two to three inches in diameter, and with a round and symmetrical head of branches. People about El Paso and in New Mexico call this species the "Brigham Young Weed."

Larrea tridentata (L. Mexicana) is by far the commonest shrub in this locality among the hills. A bath in a warm infusion of its leaves and twigs is said to be a remedy for rheumatism. In this region plants that depend on rain for their growth have become very easy and slack in their manners and observe no set time to flower and fruit. On the thirteenth day of June the hills around El Paso were yellow with flowers of *Larrea*. Three weeks of rainless weather followed, and the thousands of individuals of that species showed hardly a flower. Other rains came, and in a few days the hills were again yellow with a new crop of flowers.

Western Texas is full of plant wonders, and no plant here is more peculiar and attractive in its own way than the Screw Bean, *Prosopis pubescens*. As a shrub this species outdoes its reputed cousin Mesquit, *P. juliflora*, but the latter far excels the former as a tree. The fruit of the Screw Bean, as its nickname indicates, is a departure in fruit forms, and readily shows the species. Its short, clustered pods are twisted into screw-like coils and again coiled. In the future some daring botanist will again separate generically *P. pubescens* from *P. juliflora*, whose pods, though clustered, are straight and sometimes eight to twelve inches long and containing from six or less to twenty-four or more beans. Uniting these species under the same genus was a complete waiver of the form of the fruit as a generic character.

Euphorbia Fendleri, *E. lata* and other rare species of that genus grow on the mountain, with several *Erigonums*, *Galiums*, a large-fruited *Yucca*, a strange shrub, and other species.

The Flora of the California Coast Range.—III.

CUPRESSUS MACNABIANA AT HOME.

SIX miles south-east of Ukiah is Red Mountain, and its bold dome, rising 2,300 feet above the sea, is visible from almost any point in the thirty miles of valley which stretches north and south from its base. It is easily distinguished from the surrounding mountains of nearly as great an altitude, by the brick-red soil on all exposed places, which shows enough even in the brushy portions to warrant the name. It is a great mass torn from some other geological formation and set down in a great chain of chemise-covered mountains. It differs from its neighbors no less in flowers and trees than in soil, and is a fine example of these isolated sections which are a feature of our state. Forty miles to the east, across two higher ranges, is a region in which the geological conditions and flora which distinguish Red Mountain are reproduced on a greater scale. The mountain is almost completely detached from the main range by a stream which, rising on the north-west face, completely encircles and drains the mountain.

The eastern side of Red Mountain is covered with the most curious forest I have ever seen. A body of *Cupressus Macnabiana*, about a half-mile square, and scarcely mixed with any other tree, covers it completely. The trees are only from twelve to twenty feet high, as a rule, but, like the miniature trees of the Japanese gardeners, they have all of the appearance of great age. Old and gnarled, tough and twisted, covered with moss, and with limbs broken, they look like the old forests of Cedar of Lebanon as they are pictured. A forest a hundred feet high, looked at

through the large end of a telescope, would give the same impression. A fire has swept through one side, and the old trunks, standing black and naked, aid the deception. Only the surrounding objects by which to aid the sight, keep one from being quite carried away by the deception. These trees, dwarfed so strangely by the arid soil and bleak climate, are very old.

The west face of the mountain is no less curious. Here the Cypress forms a dense thicket, from six or eight feet high in the open hills, to fifteen feet high in the gullies, and stretching over the whole mountain-side till it breaks into cliffs at the cañon. Where the fires have burned over, the little seedlings, are coming up, but in no such profusion as I saw in the thickets of *Cupressus* on the coast. Here, at the most, there would be one tree in three or four feet. The little seedlings having the soil to themselves, are of a fine green and quite shapely, and many grow into handsome trees. A few seeds carried down the stream to gravelly flats in the valley have formed an open grove of specimens as handsome as any in a park of perfect pyramidal form and very broad at base. Handsomer trees are seldom seen.

Many of the lesser shrubs and flowers are quite as distinctive of Red Mountain as the Cypress. One *Ceanothus* in particular I have never observed except in such soils. It is much like a Holly in leaf, and forms a low bush. The flowers are white. The stream which flows down the east side has a broad bed heavily grown with a coarse grass which retains the soil and furnishes a home for many flowering plants. For fully a half-mile *Lilium pardalinum*, in a large spotted form, grows in abundance and forms great clumps. As I have seen it in July, the stem four to seven feet high and the cañon fairly filled with a wavy mass of the grand recurved red and gold blossoms, I thought it the finest floral sight I had ever seen. Our common *Columbine*, *Aquilegia truncata*, is a fine plant and the parent of some good garden plants. It flowers in May and June. In the grass and on the wet rocks of the numerous little falls a form with viscid leaves grows in profusion, and, unlike the type, blooms constantly through the summer season. The flowers are more of an orange color than the type. A variety of *Stachys*, with tomentose leaves and a pleasant fragrance, is almost as common, and in the wettest places one can see large beds of an Orchid much like a small purple and brown Lady's slipper. This is *Epipactis gigantea*, a pretty species well worth cultivation. A large clump graces my Fern-bed, and rapidly increases, blooming freely every year.

Few Ferns grow here, but a *Pellaea* (*P. densa*) is abundant in the loose rock which has broken from the cliffs above, and in the rock crevices as well. It grows in large bunches, and the small dissected fronds are quite handsome when the winter rains wake them from the long summer sleep; very delicate, too, the light green new growth resembling a Maiden-hair. *Calycanthus occidentalis* is not uncommon in the Coast Range and is one of our finest waterside shrubs. It is rather prettier than the eastern *C. floridus*, and, like it, the bark, leaf and fleshy chocolate-colored flowers have a pleasant odor. It especially likes the clayey soil of this cañon, and in some localities the growth is ten to twelve feet high and completely fills the gulch. In clefts of the rock a rare *Brodiaea* grows quite out of its range, for it is common forty miles eastward. The flowers are white, and it prefers the courses of streams.

The higher slopes are also rich in rare plants. One of the most attractive is *Dendromecon rigidum*, a shrub from two to eight feet high, slender, with light lance-shaped leaves and a blossom almost exactly like a light-colored Californian Poppy, except in size. This beautiful Tree Poppy in our region is confined to high altitudes. A well-developed bush is not soon to be forgotten. Morning Glories are everywhere in our state. A very common one with good-sized white flowers grows in grain fields and is a troublesome weed, pretty as it is. Red Mountain, in

Morning Glories, as in everything else, is odd, and the creeping form which I saw in bloom one morning in May had halberd-shaped leaves densely clothed with woolly hairs and a fine white flower. The stem crept about a foot.

Ukiah, Calif.

Carl Purdy.

The Reproductive Powers of Our Forests.

AT the present time the guard ranges of the Alleghany Mountains, which extend into Monongahela County, West Virginia, are covered with a mixed deciduous forest of second-growth trees. This is one of the best examples that have come under my personal observation of the natural power of forest reconstruction. During the early half of the present century this region, embracing several thousand acres lying along the north bank of the Cheat River, was the seat of an active iron-making industry. The mountains afforded a bog ore which was accessible and of great value. The mountain slopes were then heavily wooded, and as the iron industry became established a demand for charcoal was created, and to meet this demand the woods were harvested and converted into charcoal. This industry began about 1789, and was most active from 1822 to about 1852, and continued in a small way until in 1868. The largest proportion of the timber removed for charcoal purposes was cut during the most active period of the industry and before the middle of the century.

As soon as the charcoal burning became unremunerative from the exhaustion of the timber supply and the substitution of coke for charcoal in the reduction of ore, these lands, which were too steep and rugged for profitable agriculture or grazing, were allowed again to fall into the hands of Mother Nature. It is true that fire has done much injury from time to time, but even with the adverse conditions of soil, exposure and frequent fires, there is to-day upon these mountains a forest of second-growth Chestnut, Poplar and Oak worth many times the value of the land at the time the iron furnaces closed—a convincing example that our forests will reproduce themselves. This we are told is all well enough for the moist mountain districts of the Alleghanies, but will not hold in the deforested areas of Michigan, Wisconsin and Minnesota. There is no ground for this argument, for when the forests were removed no rational system of reforestation was attempted. Even the protection of the area from fire has usually been neglected, and this alone will suffice to explain why the land stripped of its forest-cover still remains bare. Natural reproductive powers have not been allowed an opportunity to assert themselves. Trees cannot grow so long as fires are allowed to run periodically over the exploited tracts; what might take place, were they suppressed and prevented, is another question upon which some light is thrown in the following remarks by Mr. H. B. Ayers, of Carlton, Minnesota, on Forest Fires*:

Even men of intelligence and prominence in the lumber business have said, "Why prevent fire? Pine will never come in again after the marketable timber is once cut." This assertion needs the strongest possible denial; the men who make such an assertion deserve ridicule. They were looking for saw-logs, and could not have looked for much else, for loggers in cutting often leave on an acre a hundred thrifty and vigorous young Pines from four to ten inches in diameter and from twenty to a hundred feet high after the log-timber is cut, and on pine-stump land that has escaped fire three years thousands of little Pine seedlings may be seen springing up. In order to be able to refute such misstatements utterly I have here the minutes of the exact location where young Pines in excellent condition for timber-growing may be seen, and right by may be seen burnt land cut the same year that could not be put into a condition as promising for timber for less than twenty dollars an acre. In fact, so favorable a soil, mulch and shade can hardly be made at once on that burnt land at any price. Several such acres on (sections) 16, 56, 22 were staked off and the trees counted; on one from which 32,000 feet had been cut three years before were thirty-two thrifty sapling White Pines, eight to eleven inches in diameter and thirty to eighty

feet high; ten Poplar, eight to fourteen inches in diameter and sixty feet high; 1,600 Poplar sprouts, one-half to one inch in diameter and five to twelve feet high; a light underbrush of Hazel and Vine Maple; and under all this were 1,267 little White Pine seedlings two years old and four to six inches high. Another acre on the same section had 200 trees of White and Norway Pine averaging eight inches in diameter and forty-five feet high. Are not these worth saving?

This is a specific example of what may be expected from one of the families of trees which it is most difficult to perpetuate. Pines, as a rule, grow only from seeds; they cannot be managed under the coppice system, yet this single observation, carefully carried out and recorded, is sufficient to set the most skeptical to thinking.

In the deciduous forests which occupy the outlying ranges of the eastern mountain systems the problem is less difficult, as most of the desirable species readily reproduce themselves from the stump. The accompanying illustration (see page 235) shows what may be accomplished if only a little care is given, the forest represented being of Chestnuts about forty years of age. I have other photographs to represent the reproductive powers of the Ash, Magnolia and other species.

The history of this region clearly shows the influence of the rise and decline of the iron industry on the forest, the benefit of the substitution of coke for charcoal and the beneficial results in the way of reforestation when such lands are simply left to themselves and partially protected from fires.

Agric'l Experiment Station, West Virginia.

L. C. Corbett.

Plant Notes.

TOXYLON POMIFERUM.—Since the recent rains the large leaves of the Osage Orange-trees in Central Park have expanded to nearly their full size and have begun to take on the gloss which is characteristic of them, and few trees of their size have a more pleasant expression at this season. Downing says of this tree that it is rather too loose in the disposition of its branches to be called beautiful, but it often grows in a compact spreading shape, and owing to the size and the abundance of its leaves it casts a dense shade. Although it grows in parts of the Indian Territory and Texas where the temperature is comparatively high, it will flourish as far north as New England, and, in spite of the fact that it has been developed in the region of abundant rain, it also flourishes on the dry prairies of the west. Besides its hardiness, the tree grows rapidly and is subject to few diseases and insect enemies, so that it is, altogether, desirable for ornamenting parks and gardens. The pistillate trees have large orange-like fruits, which add to their beauty in the autumn, and it has a certain half-tropical or foreign air that arrests the attention. It is easily grown from seeds and cuttings, and is much used for hedges. In this latitude some of the trees reach a height of forty feet, and with almost as great a spread of branches, but in the valley of the Red River they grow sixty feet high, with a trunk two or three feet in diameter.

VIBURNUM MACROCEPHALUM.—This plant bears larger snowballs than either of the other species or garden forms which bear cymes of pure white sterile flowers. In an early volume of GARDEN AND FOREST Mr. Hemsley wrote that wild specimens of *Viburnum macrocephalum* were sent to him by different collectors in China, in which but few of the outer flowers were neuter, but the plant is only known here in its sterile form, and it has been grown in England ever since Fortune discovered it in the gardens of Shanghai. The flower-clusters are as large as those of *Hydrangea hortensis*. It differs somewhat in habit from the other Snowballs, being rather low, of rigid and widespread branches. It is hardy enough to survive the winters in New England, but it does not flourish there as it does in Philadelphia and southward, where the flower-clusters often reach six inches in diameter, making it one of the most conspicuous of flowering shrubs. The old-fashioned Snowball, or the sterile form of *V. opulus*, is rather the most graceful

* *Minnesota State Horticultural Society Report for 1895*, pages 443-9.

plant of the three, but the Cranberry Tree, its fertile form, is still more desirable, just as *V. tomentosum* is more beautiful than its sterile form *V. plicatum*. The wild form of *V. macrocephalum* has never yet been introduced to cultivation.

CAMASSIA CUSICKII.—This species was figured in the first volume of GARDEN AND FOREST (see page 174), and experi-

ment was made for this purpose. These flowers are nearly white when they are open, but they turn to a pale blue. Like most bulbs this *Camassia* delights in an open or sandy soil, and it is especially necessary that the bulbs of this species, which are sometimes as large as a hen's egg, should be planted deeply. The common *C. esculenta*, the edible Quamash of the Indians, is a smaller plant altogether, and not nearly as

Fig. 34.—Second-growth Chestnut-trees, in West Virginia.—See page 234.

ence has proved what was then predicted, that it would be an excellent garden plant. It is perfectly hardy, and after a winter which has proved so disastrous to many bulbous plants this native of the west has been flowering well on spikes two feet high, with sometimes as many as forty narrow-petaled, star-shaped flowers on a single spike. They keep well when cut, and the plant can be commended for

hardy as *C. cusickii*, although it has a variety, *Leichtlinii*, with creamy white flowers two inches across, large leaves and robust stems, which seems able to withstand our winters without protection. *Leichtlin's* *Camassia*, however, does not open its flowers until late in the afternoon and blooms in the evening. *C. Fraseri*, sometimes called the wild Hyacinth, has an almost naked stem and a short spike

of pale blue flowers at the summit. This species flowers better in full light, but the flowers fade quickly in the sunlight. *C. angusta* has also been cultivated here, and it makes a good hardy border plant. The Camassias belong to that section of the Lily family which includes the Hyacinth, the Grape Hyacinth, the Star of Bethlehem and the Scilla, to which species it is nearly allied, although it has a stouter habit and a leafy stem. Most of the species have grass-like leaves rising from the base of the stem, and, with the exception of *C. esculenta*, they are hardy plants which need no extra care or coddling.

Cultural Department.

Notes from the Herbaceous Border.

THE most showy of the early yellow-blossomed Compositae is *Helenium Hoopesii*. This compact, handsome plant is perfectly hardy without protection in the winter. Although it grows as freely and is as easily raised as *H. autumnale* and its varieties, yet it is not so common in gardens. The plants produce seeds freely, and if they are sown early in spring and the young plants are well attended to during the summer and fall they will make good large-flowering plants for the following year. This fine *Helenium* thrives here in an open position and in a rich open soil. The height of the plant is not much over two feet, but with good culture it attains a height of three feet. Its stems are well clothed with leaves; their sturdiness is very useful in plants of this height, as no staking is needed. Sometimes the flower-heads are produced singly, but oftener several on a stem. The flower-head is of a bright orange color and measures fully three inches in diameter. This is a native plant and was named in honor of Thomas Hoopes, who first collected it.

The Columbines make a fine display now. The genus *Aquilegia* has many species, and every one, with all varieties, is worthy of a place in any garden. Perhaps the different species belonging to this genus are more easily cross-fertilized than any other in the garden; hence the great difficulty in getting plants true that are raised from seed where a collection is grown. To get the seed true the plants ought to be grown in isolated places, and even then there is no certainty that insects have not been at the work of crossing. In our wild garden, although it is quite a distance away from our general collection of *Aquilegias*, I see this year that *A. Canadensis*, the only species grown there, has been cross-fertilized with some other species, probably with *A. vulgaris*, from the appearance of the flowers and foliage of some of the seedlings in bloom now. The *Aquilegias* grow freely here, with the exception of *A. glandulosa*, and this plant never looks happy here. I have raised it several times from seed; the plants grow and blossom once and then dwindle away and die.

The Rocky Mountain Columbine, *Aquilegia cœrulea*, is, in my estimation, the most delicate and most beautiful species in this lovely genus. It grows here from one to two feet high, the height of the plants varying in different parts of the garden. They are neat and compact, and when two or three are planted in a clump they are very pleasing when in bloom, and before they blossom and afterward the much-divided foliage is distinct and graceful. The flowers are produced plentifully for four or five weeks, and are of a sky-blue color. The sepals are sky-blue, ovate in shape, spreading, and measure fully one inch and a half in length. The blades of the petals are white and about half the length of the sepals, but they are elongated into a long, narrow straight spur which measures nearly two inches in length and is also of a blue color. Most of the plants that are in bloom now of this Columbine were raised from seed which was collected in the Rocky Mountains. It makes a choice border plant, and is also very suitable as a rock-garden plant. *A. Canadensis* is the most floriferous of all the Columbines. It produces young plants very plentifully in our rockeries from self-sown seed. *A. viridiflora*, a Siberian species, is not a showy plant, but its flowers are greenish, and therefore of an uncommon color, and it is worthy of a place in the rock-garden. *A. vulgaris* and all its varieties grow well here. At this time a small bed of plants that were raised from seed last year is making a very pleasing display. This showy plant is as much at home here as it is in Europe. It grows just as well under the shade of trees as it does where it gets plenty of sunshine. There are many varieties of this Columbine, and most of them have pleasing colors. Some of the double-flowered varieties are very showy. *A. atropurpurea* makes a bold plant, growing to the height of

two feet or more, and it has dark purple flowers measuring about one and a half inches in diameter when fully expanded. It makes a good border plant, growing freely in a light, rich soil. The double-flowered *A. Sibirica* is useful when planted in the second row from the front of the herbaceous border. Our plants are about eighteen inches high, and the erect, dark purple double flowers are very distinct from all the other Columbines. There are many others in bloom, such as *A. cœrulea lutea*, *A. attrata*, *A. Caucasica* and *A. oxyacantha*.

In a slightly shaded place the Globe-flowers have been blossoming for two or three weeks. They grow best here in a deep, rich, damp soil. *Trollius Asiaticus* has a compact habit and a height of twelve to fifteen inches, and it bears its golden-yellow flowers in great abundance. This plant does not produce seed readily, but it is easily increased by division of the roots. It comes from Siberia and is quite hardy here. The European Globe-flower, *T. Europæus*, blossoms also at this time. Before its flowers appear the plant looks like a *Ranunculus*, but when in bloom it is easily distinguished by its pale yellow globular flowers.

The Snowdrop Anemone, *A. sylvestris*, is a compact, perfectly hardy and very reliable perennial. Its large pure white flowers are produced singly above the foliage. *A. Pennsylvanica* is not very satisfactory as a border plant, but in the wild garden it makes a splendid mass of white. It ought to be given plenty of room, as it spreads rapidly after it gets established. The Japan Anemones have proved very unsatisfactory here for the past two years. Many of our plants have been winter-killed.

The beautiful Iceland Poppies are very floriferous. They do not thrive as well here in the border as they do in the rock garden. To have them at their best in the border the ground must be well drained, so that water will not remain about the roots in winter. They multiply rapidly here from self-sown seed.

For an early summer-flowering plant nothing in the border has the grace and beauty of well-grown specimens of *Dicentra spectabilis*. Not only has this plant beautiful flowers, but it has handsome Fern-like foliage. Like many other perennials, it does not show its beauty and habit well until it gets large and well established. Some of our plants measure four feet in diameter, and they are exceedingly handsome when in flower. It is so common that many persons affect to despise it, but there is no other plant which can fill its place at this season.

In an open position in the rock garden a large patch of the hardy and free-growing *Erysimum pulchellum* is completely covered with sulphur-yellow flowers, which give a welcome distinctness of color along the front row of the herbaceous border. When it is in blossom the plant measures about a foot in height and is very compact in habit.

Lunaria biennis, hardy biennial, as its name implies, and better known by its common name of Honesty, is well worth growing for its large terminal racemes of violet-lilac flowers. After these are gone the silvery flat seed-pods are ornamental. The color of the flowers is uncommon among hardy plants at this time, and they are a very welcome addition. Plants raised from seed in spring if planted out in the garden in light warm soil bloom the succeeding summer.

The Horned Pansy, *Viola cornuta*, and its varieties are blossoming now, and will produce more or less flowers all summer. *V. lutea* is another hardy Violet that grows well here and blooms all summer. *V. Munbyana* was raised from seed last year and planted out in the border. It lived through the winter unprotected, and has been in flower for the past month. It is a strong-growing plant and has violet-colored flowers as large as those of *V. cornuta*. It is an Algerian plant. Another beautiful little Violet now in flower is *V. declinata*, var. *losisepala*. The seed of this plant came from Sweden last year. It has proved quite hardy here, and in a slightly shaded spot it is blossoming freely. It is a low plant, about six inches high, and has small Pansy-like flowers. The color of the flowers is very uncommon, it being of a dark pink.

Along the front row of the border there are some compact dwarf plants of *Gypsophila repens*, producing immense numbers of small white airy flowers. This is also an important plant for the rock garden. The rosy pink flowers of large masses of *Saponaria ocyroides* contrast well with the white ones of this *Gypsophila*. *Cerastium arvense* makes a fine mat of white close to the ground, but if used in the border it must be kept within bounds. A near relative of the *Cerastium* is *Stellaria Holostea*, which makes a much better plant for the front row of the border. In fact, it is the best dwarf white-flowered plant we have in the border since *Arabis alba* ceased blossoming.

Although *Linum perenne* is not a very robust plant here, when it once gets established it makes nice shapely plants,

which are crowned with fair-sized flowers of a pale blue color. A white-flowered variety in bloom seems to be more robust than the typical plant, and is very attractive.

Thermopsis mollis is not often seen in gardens. Although it comes from the mountains of south Virginia and North Carolina, it is quite hardy here, and gives perfect satisfaction. Its habit is almost perfect. When well established it makes compact bushy specimens a yard high. The flowers are yellow and produced in long, nearly erect racemes, and they last in good condition for two or three weeks. In a slightly damp soil and away from the shade of trees it grows freely if not too often disturbed.

The best early *Salvia* is *S. pratense*, a handsome European plant, which grows as freely as our commonest weeds. It is about two and a half feet high, and the flowers are produced in whorls of four to six flowers in spikes from twelve to eighteen inches long. The corolla is bright blue and measures one inch in length, the upper lip being much arched and the lower one broad. There is also a white form of this plant in bloom which is showy, making a good companion for the blue one. This, too, is a thrifty plant, growing well in any common garden soil.

The Japanese *Primula Sieboldii* is one of the most satisfactory and one of the most decorative of Primroses. It grows best in a warm sheltered position, where it is covered with leaves in the winter. The flowers last much longer in a place where the sun does not strike them during the hottest part of the day. There are some large clumps of this Primrose now at their best, and much admired by visitors. Since it was introduced from Japan in 1865 many varieties have been raised. The flowers measure more than an inch across and are produced in umbels on stout stems from nine to twelve inches high. Each variety has a different shade of color, and those grown here are of different shades of rose. The roots creep just below the surface of the soil, and they form buds, thus giving an easy means of increasing the plants, and if it is provided with a good situation and proper soil this Primrose grows rapidly.

Botanic Garden, Harvard University.

Robert Cameron.

Flower Garden Notes.

THE recent showers have made a great improvement in the borders and made it possible to plant out annuals to be added at this time for effects later in summer, when most of the perennials are past. This arrangement has, in past seasons, proved desirable for the best results during the entire season. Mixed borders are superseding herbaceous borders and include bulbs for the early spring. A border made up in this way will be interesting from April until November frosts.

The best feature of the garden now is the set of the more recent Japan Tree Pæonies. We have added twenty of these, and they are a great advance over the older ones, which are mostly shades of pink, and I suspect are in many instances nothing more than the stock used by the Japanese for grafting. The newer varieties are of all colors, from pure white to deep rose, and some are single, beautiful, large cup-shaped blossoms of purest coloring. They are a decided acquisition in the garden at this time, and, no doubt, will prove as hardy as the older varieties. It will, however, be safer to draw the earth about the stems in the fall for the first year or two, to avoid loss, before they are well established. I find that all of these plants are grafted, cleverly as usual by the Japanese gardeners, but they do not seem to have been wise in the selection of the stock; it shows decided tendencies to sprout from the roots. These sprouts would soon choke out the better scion if allowed to grow, and planters must use care that this does not occur. This is the only thing that can be said against these plants, and it may be remedied in later importations by the use of some stock that is not so apt to send forth shoots from adventitious root-buds.

The hardy native Orchids are mostly intractable under cultivation, beautiful as they are when growing wild. They all need special care in the selection of positions in the garden if any success is to be had. Two of the *Cypripediums* are quite reliable, or at least we have found them so for the past five years, planted on the shady side of the *Rhododendron* beds. *C. pubescens* is now beautiful, and *C. spectabile* will follow later. The latter is the most lovely native Orchid, and few exotics of this genus can compare with it. It is all the more satisfactory to know that it can be cultivated in gardens in moist black soil, such as *Rhododendrons* delight in.

Baptisia exaltata is now fine. It is not a common plant, though *B. australis* is often seen in gardens. *B. exaltata* is much taller, with larger flower-spikes, and is altogether the

better plant. It is a good companion to the *Lupins* that are now at their best. *Lupinus polyphyllus* gives a great variety in itself, the white form being in pleasing contrast with the various shades of blue and purple. I find it is necessary to save seeds of the best varieties and sow them. The parent plants seed freely, and these seeds germinate in the borders, but the self-sown plants deteriorate and the better varieties are soon lost in this way.

Many of the earlier-flowering plants are dying down now, and it is a good opportunity to plant near these such annuals as are desired to cover the space for the balance of the summer. The frequent showers will enable them soon to take root, and little care will then be needed in the borders, except to keep down weeds.

South Lancaster, Mass.

Herb Robert.

COMPARATIVELY few flowering plants mingle well with Ferns on rock-work or in the wild garden. Of these our native Herb Robert has no superior. Its dainty pink blossoms peeping out here and there among cool green fronds add just the warmth of color needed. The chief beauty of the plant is in the delicate design and varying color of its much-divided leaves, which are pale green in early summer, deepening into richer tones as the season advances, but always fresh-looking. Leaves with rich autumn colors are to be found at all seasons, and they often tempt the botanist to a hard climb for an unknown blaze of color just out of reach. For indoor culture the plant has considerable merit. In December a few young plants which had been frozen stiff were taken indoors; none of them wilted and nearly all proceeded to grow with more or less enthusiasm. One of them on a platter with Mosses and Ferns, and left pretty much to itself, was a great success, and its branching stems attained a spread of forty inches with no care save an occasional sprinkling and clipping of seed-pods before they matured. Herb Robert attracts us to-day by its delicate beauty, but the old naturalist valued it chiefly because of its supposed medicinal "vertu" in the disease known as "Sir Robert's Plague," from which it is said to have derived its name, *Geranium Robertianum*. The significance of *Cranesbill* is obvious. The Scotch Highlanders are responsible for the uncouth title of "Red Shanks," given in reference to the lovely red stems which support the leaves. Another name of grave significance for this shy wildling is *Death-come-quickly*, and in Northumberland lore to uproot or find a plant uprooted is considered a forerunner of fate.

Correspondence.

Notes from West Virginia.

To the Editor of GARDEN AND FOREST:

Sir,—Our Japanese Weeping Cherry has been flowering ever since its proper blooming time in April, and is in blossom in June, when our sweet cherries are ripe. In April the lower limbs hung out a few half-blighted blossoms, while the upper part of the tree showed no signs of life. It was badly injured by the cold of last winter, but has been gradually recovering and opening its flower-buds from the lower limbs upward, until now only the top of the tree is bare. The blossoms are a sickly pinkish white, and open a few at a time as the tree recovers strength. Thunberg's *Spiræa* failed to bloom from the same cause, but the Double-flowering Peaches were very fine. Hard-shelled Almonds bloomed, and so did Nectarines, while Apricots of the same age, and in the same enclosure, did not have a flower. *Magnolia Kobus* and *M. Soulangeana* were full of bloom at the usual time, showing their great power of enduring cold. *Paulownias* seldom flower with us, and only after an unusually mild winter. This year only a few of the flower-buds matured, a cluster of buds displaying but one perfect flower, the rest shriveling up without opening.

In spite of the vagaries of the weather, it has been a good season for gardening purposes, and the *Roses* are unusually beautiful and profuse. A group of *Penzance Sweetbriers* planted this spring and last year is making rapid growth. These hybrid Sweetbriers are not as fragrant as the type, and the flowers must be beautiful, indeed, if they are really an improvement on the *Eglantine*. The latter is now sprinkled with its dainty pink cups, to be succeeded later by showy pips, which give it a new beauty even when winter shall have robbed it of its last fragrant leaf.

Sweet Williams are making the flower borders bright and gay. There are almost too many magentas and dull crimson among them, but the light and the bright pinks and the deep

red kinds, mixed with the white and Auricula-eyed varieties, make a very cheerful group. The Sweet William is one of the flowers that one associates with cottage gardens and with thrifty and happy homes. It appeals to old association, to memories of our youth, and flourished along with hardy Pinks, Columbines, Everlasting Peas, Lilies-of-the-valley and Wallflowers in the gardens of our childhood. No rare novelties will ever quite take the place of these old favorites.

The early Mock Oranges are out of bloom, but a very beautiful specimen, which was labeled *Philadelphus Yokohama* when it came from the nurseries, is now flowering profusely. Its bloom is delicately fragrant, and the flowers are larger and of a purer white than the commoner kinds. The expanded flower measures an inch and a half across. This *Philadelphus* is one of the most beautiful shrubs at Rose Brake.

In the wild and rock gardens the Yellow Lilies are still very showy, and the Orange Lily is very effective in a bold group against a background of shrubbery. The cold, damp weather of last May lengthened the blooming period of this Lily, which has been flowering for three weeks, but is now nearly over. More delicate beauties are the little groups of *Tunica Saxifraga* and the pretty pink *Lychnis Flos-cuculi*, which also remains in bloom a long time.

Honeysuckles and Roses are making the air fragrant, and one opulent *Magnolia*, *M. glauca*, with its rich odor and creamy cups of bloom, claims our admiring homage as queen of the week.

Shepherdstown, W. Va.

Danske Dandridge.

Some Rare Erythroniums.

To the Editor of GARDEN AND FOREST :

Sir,—In 1891 the late Sereno Watson published his revision of the American Erythroniums. Mr. Watson gave a very careful study to the subject, and his work gives the student a safe guide, although in one or two instances his species seem so close together that only the skilled observer can distinguish them. No really new species have been added since Watson's revision, but several good color forms have been brought to light, of which *Erythronium Johnsonii* is the most notable addition to the flower garden. It is to be expected that a thorough exploration of the forests of the Pacific slope will bring to light many color forms, if not new species. Few know what vast tracts of the north-west have never been explored at all by trained botanists. Nothing emphasizes this so much as the fact that many species collected by the early explorers have been lost sight of and have come to be considered as mythical. I have found several species of great beauty which were not in any of the great herbariums and were thought to be errors of the authors. Even in localities near the homes of skilled observers, species are sometimes so local as to be easily overlooked.

Perhaps the most striking of the Pacific coast Erythroniums is the group related to *E. revolutum*. Only one of this group is much known in our gardens. *E. revolutum*, var. *Bolanderi*, better known as *E. Smithii*, has long been in cultivation. Of the others, a few of *E. Johnsonii* were sent out last year, and the rest are unknown in the garden.

To be appreciated properly the Erythroniums should be seen in their own homes; in the shaded cañons among the wood plants, with their mottled leaves of immense size, almost as beautiful as the flowers, and their tall graceful scapes and lovely lily-like flowers, I can imagine no more beautiful mass than a large bed of these Dog-tooth Violets.

In all of the *Revolutum* group the leaves are mottled; in the type and *Erythronium Johnsonii* the mottling is in rich brown or mahogany; in the others in green and white. As compared to the *E. giganteum* group, the scapes are stout, the flowers have more substance, and the petals, while recurved, yet more widely spreading; the stamens have broad awl-shaped filaments, and the auricles at the base of the inner petals are very prominent in all of the group and pressed closely to the filaments. *E. revolutum* and its varieties are hardly as graceful as the exquisitely formed *E. giganteum* (*E. grandiflorum* of our gardens), but excel it in the substance and coloring of the flowers.

Erythronium revolutum (type) is a plant of medium size, leaves mottled in mahogany, scape one to three flowered. In color it varies from almost a pure white, with a most delicate greenish tinge and brown and purple markings at base of petals, to a rich yellow similarly marked.

Erythronium Johnsonii is in leaf and habit the same, except that in my own garden it is one-flowered. In coloring the flowers are a bright clear red, shading to dark red toward the middle, and the centre a fine orange.

Erythronium revolutum, var. *Bolanderi* (*E. Smithii*), is a native of the Redwood forests of the northern part of Mendocino County, California. Its northward range has not been determined, as from its own habitat an almost unknown (botanically) region stretches to the north. This species is of low habit, the leaves mostly mottled in white, seldom more than one-flowered, and the widely spread blossoms opening a pure white and at last becoming purple.

I had the pleasure this spring of discovering a new variety of *Erythronium revolutum*, or, perhaps, only rediscovering this beautiful plant. Its leaves are mottled in white and green. The scapes, as I saw them in large beds, were tall, ranging from ten inches to nineteen inches high. The petals are narrower than in the other forms of *E. revolutum*. Of those seen a very few were white, deeply suffused with pink, on opening, and soon changing to a deep wine-purple. In by far the greater number of instances they opened up a delicate pink, and turned while still fresh to wine-purple. This is the largest of the group.

Its home is in the Redwood region of Mendocino County. In a note in his revision Watson says about *Erythronium revolutum*: "Described by Smith as having purple flowers, and an original specimen in Herbarium, Kew, bears the note by Sir W. J. Hooker, fl. rubr. purp., but it is rarely that the petals assume the purple tinge in drying, and the ground for the statement is unknown. No purple-flowered species is now found on Vancouver Island where Menzie's specimens were collected."

My new form corresponds very closely to Smith's description, and I have no doubt is identical. It is certainly strange if the counterpart of a species collected over a hundred years ago, and not since seen, should be found so far away.

Ukiah, Calif.

Carl Purdy.

The Increase of Redwood Forests.

To the Editor of GARDEN AND FOREST :

Sir,—In an article in your paper a few years since I called attention to the rapidity with which the woodlands in the Coast Range of northern California are encroaching on the grassy and brushy portions. Close observations since and conversations with many observing people confirm my statements. A point upon which I did not then touch was recently brought to my notice in a conversation with an intelligent pioneer. The Redwood forest of to-day is a tangle underfoot and a mass of broken limbs and fallen trees, all overgrown with Huckleberries and various *Ceanothus* and other undergrowths, which make travel, except by roads or trails, almost impossible across country. The pioneer referred to tells me that in the earlier days a man could go by horseback from the valleys in the interior to the coast in almost any direction, as the woods were almost free of undergrowth. He was told by the Indians then that they made a yearly practice of firing the grass—I presume, both to drive out the game and to clear the way. Now roads in every direction cross the forest belt, and the interests of the settlers are against sweeping fires, so that they are becoming less frequent with each year.

Here in the valleys the interest of every sheep rancher is against fires, and they do not sweep through close-cropped ranges as they did when the grass grew waist-high.

Ukiah, Calif.

Carl Purdy.

The Wild Garden.

To the Editor of GARDEN AND FOREST :

Sir,—No spot in the flower garden yields me as much pleasure as that which is devoted to the native plants which I gather from the woods and fields. While the *Crocuses* were yet in bloom, the snow-white blossoms of the *Bloodroot* appeared, quickly followed by the *Dog-tooth Violet* and the beautiful little *Dicentra cucullaria*, or *Dutchman's Breeches*. Soon after these followed two species of *Trillium*, and then the sky-blue *Lungwort*, *Mertensia Virginica*, with *Phlox polemonium* and different *Violets*. By the middle of May the feathery spikes of *Tiarella* were giving place to the graceful native *Columbine* and *Sweet Cicely*. Aside from the beauty that this plot furnishes, here is an opportunity for studying the habits of various plants which one does not enjoy unless they are constantly under the eye. The most interesting problem is the constant struggle for existence or for mastery among them. If let alone, the wild *Columbine*, *Viola cucullata*, *Thalictrum cornuti*, *Geranium maculatum*, *Lysimachia quadrifolia* and *Onoclea sensibilis* will soon smother out their neighbors. *Lungwort*, *Bloodroot*, *Moon Seed*, some of the *Vetches*, *Spring Beauty*, *Dog-tooth Violets*, some of the *Ferns* like *Osmundas* and

Aspidiums, will increase rapidly, and yet they are not objectionably aggressive. Trilliums, the low Phloxes, *Cypripedium pubescens*, *Lilium Canadense*, *Dicentras* and the delicate Maiden-hair Fern will increase more slowly, and yet at a sufficient rate to show that they are permanently established. Of course, to keep up the variety one must be constantly thinning out the more aggressive varieties and give aid to the more modest ones.

Recent Publications.

The Bamboo Garden. By A. B. Freeman-Mitford, C. B. Illustrated by Alfred Parsons. Macmillan & Co.: London and New York.

In the great family of Grasses there is no more interesting group than the Bamboos, some of them giants a hundred feet or more high and others pigmies of the humblest proportions, but all distinguished by a characteristic grace which makes them as beautiful as they are generally useful in the regions where they thrive and where the whole social and industrial economy of the people are associated with and dependent upon them. Where they abound they largely help to give character to the scenery, but here in the north there are hardly more than half a dozen which are reliably hardy. In the soft and moist airs of England a greater number of species will thrive, and all who are familiar with current garden literature have read the instructive writings of Mr. Mitford in the London *Garden* and elsewhere. He has been an enthusiastic student and cultivator of all these plants that can be made at home in England, and this beautiful book is the result of his many years of labor. It has been illustrated by Mr. Alfred Parsons, whose drawings give a fair idea of the decorative quality of the different species. We cannot help but think, however, that it would have been better to have something more accurate, even if less artistic, figures that would, at least, enable one to identify the various species. Even the reproduction of photographs would have been more useful in a treatise of this sort, although these always lack something of æsthetic value. Chapter I. gives an interesting account of the plants in general and of their characteristics, especially as they appear in cultivation; and this is followed by minute directions on the methods of propagation both by seed, by division, by cuttings from the base of the culm, and by pieces of the rhizome. In writing of the choice of position, Mr. Mitford not only explains the quality of the soil, exposure and cultivation which the plants need, but he explains how to plant them for producing the best effect. On this point he says: "A good background is of the first importance to show off the beauty of the Bamboo. A bay in a clump of Hollies or conifers will afford a most appropriate setting. The tall columns waving their dainty green foliage against such a backing under a gentle summer breeze are the embodiments of all that is graceful, while the tender leaves look like a flight of delicate green butterflies hovering in the air. A group planted on a lawn may be effective, but Bamboos are seen at their best when their bending columns are shown in contrast against softer and darker foliage." It may be added that suggestions of this sort as to methods of planting in an effective manner are scattered all through the book, so that there is much useful instruction on the general arrangement of gardens and the views are almost invariably sound. The greater portion of the book is taken up with a description of species, beginning with those which are natives of China and Japan. These are by no means dry botanical details, but an effort to give descriptions of these plants that will indicate their value for ornamental coloring, although every paragraph shows careful study of their habits and observations which are of genuine scientific value.

Mr. Mitford thinks that these plants are destined to become much more largely used in extra-tropical gardens than they have ever been. He calls attention to the fact that the famous gardeners laughed at him when he began to plant his newly imported and starveling canes, but unexpected success has attended his efforts at acclimatization,

and he thinks that there are many other species than those we now grow which can be made to beautify our gardens. There are Bamboos growing high up on the Himalayas which are only known by herbarium specimens, and one species, at least, in the Andes grows at an altitude equal to that of the summit of Mont Blanc, and he thinks there are many others waiting to be discovered on mountain heights where ice and snow are at home. He notes the fact that all the Bamboos that have proved hardy in England have the veins of their leaves checkered or fessellated, and by something of a coincidence the hardiest of the Palms also have tessellated leaf-veins. He thinks, therefore, that whenever a Bamboo is found at a great altitude, at least high enough to be surrounded by non-tropical vegetation, a leaf structure of this kind will be almost a guarantee of its hardiness.

A delightful chapter is one entitled *Apologia pro Bambusis meis*, which is a justification for his passion and a plea for his reeds. He objects to that affectation of severe taste which would banish everything from English pleasure-grounds but English shrubs and herbs, and yet he plainly belongs to those who see in the teachings of the architectural school of gardening a menace to what he considers the more beautiful and effective way of planting. Many readers will sympathize with his criticism of the "acres of paving-stones surrounded by balustrades, and bespattered by jets of greater or less size, which were dear to the French architects." Perhaps we cannot better conclude this review than by adding some other quotations.

In these heavy masses of masonry there is only dignity for those who admire that which is costly. The poetry of gardening lies in another direction. Who can conceive a Dryad making her home in an Orange-tree incased in a green wooden tub? What nymph who respects herself would bathe her dainty limbs among the glorified squirts of Sydenham? Another test: Could a painter paint these formal gardens of ashlar? Could a poet find inspiration in them? Would Saint Bernard say of them what he said of the woodland: "*Aliquid amplius invenias in sylvis quam in libris*"?

He who would lay out for himself a paradise—I use the word in old Parkinson's sense—cannot do better than to set out to drink in wisdom in Japan. Not in the Japanese gardens, for nowhere is the gardener's work more out of tune with Nature than in that country of paradoxes; but on the mountain-side, in the dim recesses of the forest, by the banks of many a torrent, there the great silent Teacher has mapped out for our instruction plans and devices which are the living refutation of the heresies of stonemasonry. There are spots among the Hakoné Mountains of which the study of a lifetime could hardly exhaust the lessons. The sombre gloom of the *Cryptomerias*, the stiff and stately Firs, Pine-trees twisted and gnarled into every conceivable shape, flowering trees and shrubs in countless varieties, combined with the feathering grace of the Bamboo, and all arranged as if the function of each plant were not only itself to look its very best, but also to enhance and set off the beauty of its neighbors, present a series of pictures difficult to realize.

The Japanese are true lovers of scenery; no people have a keener feeling for a beautiful landscape; to them a moon rising over Mount Fuji is a poem, and their pilgrimages to see the Almonds in blossoms, or the glories of the autumn tints, are almost proverbial, and yet, strange to say, in their gardens they seem to take a delight in setting at defiance every one of those canons which Nature has laid down so unmistakably for those who will be at the pains to read them. The Japanese garden is a mere toy that might be the appanage of a doll's house. Attached to some of what were the Daimios' palaces in the old days there were some fine pleasure-grounds, well laid out, rich in trees and daintily kept. The gardens of the Mikado, by the shore of the bay of Yedo, are beautiful. But the average Japanese garden is such as I have described it—a mere whimsical toy, the relic of an art imported from China, and stereotyped on the willow-pattern plate. . . .

The truth is that in every good garden there is a poetical or spiritual beauty with which these crude and flaunting artifices (topiary work, grottoes, carpet-bedding and the like) are out of tune; the air which breathed o'er Eden still in some mystic sense pervades our groves. "God planted the first garden"; and if man was formed in His image, may we not believe that certain more favored spots still reflect the idea of that first Divine Garden? To catch the spirit of these is the supreme

art of the gardener, and leads him to the realization of the next proposition of the text, "the purest of human pleasures."

I look upon gardening as one of the fine arts, and, rightly understood, not one of the least difficult. The painter or the sculptor makes his effects at once, and obliterates, or models and remodels, until he has attained that at which he is aiming. But the gardener has to consider, not what his work is now, but what it will grow into ten, twenty, fifty years hence. He has to take into account, not the present aspect of his materials, but what are their capabilities in the future and their relative powers of development. If he has a background ready made to his hand he is lucky, but if he has to make it he has to do so with trees which are mostly far slower of growth than the more immediately effective plants which it is their office to set off. He has to balance questions of soil, light, moisture. All this involves not only the poetic sense, but also great and patiently acquired knowledge. He has no Alladin's lamp wherewith to bid trees spring from the earth and form a sheltering background, yet background is the soul of all gardening, rarely, alas! seen at its best by him who has devised it. If the background be unfitting all the work is thrown away. Color, form, light and shade, grouping, all have to be studied in the composition of one of those living pictures which the gardener paints with living materials.

Notes.

An examination of trained and experienced gardeners for positions in the New York Park Department will be held on Friday, June 12th, by the New York City Civil Service Boards. Application blanks may be had at the office of the Board in the new Criminal Court Building.

The people of New York city have again shown their appreciation of open spaces in the general protest against the plan to build a public bath-house in Tompkins Square, and a detached section of the recently condemned blocks at Division, Suffolk and Hester Streets has been set aside for the building which would have destroyed the park-like character of Tompkins Square.

From September 1st, 1894, to August 31st, 1895, Sicily sent to the various ports of the United States 2,047,000 boxes of lemons. From September 1st, 1895, to May 31st, 1896, the receipts were 2,057,000 boxes, or 10,000 boxes more for nine months than for the entire previous year. During the same nine months 678,000 boxes and 156,000 cases of Mediterranean oranges were imported, probably 200,000 boxes less for this year than for the twelve months ending August 31st, 1895.

The New York Florists' Club and New York Gardeners' Society announce a flower show, to be held at the Newsboys' Home, on Duane Street, this city, June 20th. The exhibits will practically be contributions, since they will be distributed among some 20,000 children after the show. Many commercial growers have arranged to exhibit bedding plants, bulbs and seeds, and persons who do not care to enter into competition are invited to send plants and cut flowers for distribution. Schedules of classes of exhibits and other information may be obtained from James I. Donlan, Secretary Exhibition Committee, 51 West Twenty-eighth Street, New York city. The express companies have generously agreed to carry the exhibits and contributions free of charge.

At the recent meeting of the New Jersey Forestry Association, Mr. Fernow called attention to the fact that this state was once well wooded everywhere. If at that time the virgin timber on such soils as were not fit to be made into farming-land had been cut with care and systematically, and the fires kept out, it would produce now and continue to produce forever an income of not less than \$5,000,000 to \$10,000,000 annually, giving employment to a large number of people. Now, through the mismanagement of former years, the 2,500,000 acres of land unfit for anything but wood crops do not yield \$1,000,000 of values, or less than one-tenth of what they would yield under management. Few persons realize what the wood crops mean in the economy of a nation.

Hemerocallis flava, or, as sometimes called, the yellow Day Lily, is still opening its pure colored flowers, and when seen near a group of white Pæonies, or among the gray-blue and purple varieties of the German Irises, no combination can be more beautiful. This is an old plant, but one of the most useful in the herbaceous border. All it wants is room, food and sunshine to make a magnificent display. The individual lily-like flowers last but a single day, but the buds will open in water, so that a single stalk will last a long time. A large vase filled with a mass of these long-stemmed flowers makes a really

imposing display. Almost as good in color and form, and flowering a month or so later, is *H. Thunbergii*, which is less common, but quite as desirable. There are several other species in cultivation of varying merit, but all are good.

From fifty to a hundred car-loads of strawberries are shipped every day from Hamonton, New Jersey, and as raspberries and blackberries come into market the output will be still greater. It was formerly the practice of the berry-farmers in southern New Jersey to send their fruit to commission men individually, but under that system berries often came into Philadelphia, the nearest market, when it was practically full, so that whole car-loads were often dumped into the Delaware River because there was no demand for them. In later years, however, a coöperative union has been formed here as well as in many of the other districts where small fruits and orchard fruits are grown, and all the product goes through this organization. These unions keep in communication with all the markets of the country, and they are prepared to ship the fruit where it is in most demand, so that hundreds of crates are sent from New Jersey as far west as Chicago, and, indeed, the largest profits are often realized from these long shipments. Philadelphia is so largely supplied by berry-fields close at hand that shipments to New York, and even to Boston, from Hamonton are large in comparison with those to the nearest important city.

Peas from Long Island sell for thirty-five cents a half-peck. Asparagus, from New Jersey and other near-by points, costs twenty to thirty cents a bunch, and cauliflower from the same sections fifteen to twenty-five cents a head. New beets, carrots and turnips from this state may be had for five cents a bunch. Squashes from South Carolina cost ten cents each, and cucumbers from the same state are plentiful and command but thirty-five cents a dozen. String beans from Virginia sell for thirty-five cents a half-peck, and sweet potatoes or yams, from Florida, at the same rate, the Vineland supply being, of course, exhausted. Celery, from Florida, is succeeding the northern and western crops, and costs twenty cents a single stalk. Okra at ten cents a dozen, and eggplants at twenty-five cents each, come from Louisiana, and tomatoes from Florida and Mississippi. The latter cost fifteen cents a pound, the hot-house product selling for double that price. The best Bermuda potatoes bring thirty-five cents a half-peck, and onions from the same islands cost ten cents a quart. The largest cargo of Bermuda onions received this season arrived last week, when the steamer Trinidad discharged 40,000 crates, and 32,000 crates were due by the steamer Muriel on Monday of this week.

Nine car-loads of California fruits were sold in this city last week, mostly cherries. The variety Royal Ann, known also as Napoleon Bigarreau, brought the highest prices, and other well-known sorts were the white-fleshed Cleveland Bigarreau, sweet and of rich flavor; the handsome amber-colored Rockport Bigarreau, with red markings; Centennial, beautifully marbled and splashed with crimson on a pale yellow ground; the favorite dark cherry, Black Tartarian; the somewhat later Black Republican, the excellent English variety, Black Eagle, and May Duke, Queen Victoria, Purity and Governor Wood. Apricots of good size and coloring now in our markets are the French variety Royal, perhaps the most popular apricot in California. The large, slightly oval fruit has a dull yellow skin and orange cheek tinged with red. The stone is free, and the firm juicy flesh has a vinous flavor. The Newcastle, more brilliant in color, is also seen, and the small Pringle, valuable mainly for its extreme earliness. Alexander peaches are coming from California, large and attractive, and Clyman plums, mottled reddish purple, with beautiful blue bloom. During last week 119,700 bunches of bananas were sold at the wholesale auctions in this city. Blackberries, huckleberries, cherries, peaches, plums, apricots, muskmelons and watermelons make an attractive display on the fruit-stands. The showiest strawberries seen here in several years are immense specimens of the variety Mary, from Essex County, New Jersey, and a new seedling from Virginia. The former is of a deep rich color, fairly regular in size, the largest measuring six inches around at the stem-end. Twenty of the fruits fill a quart box, and these sold on Monday at thirty cents. The seedling from Virginia was equally large, perhaps less even in form, lighter and more brilliant in color and less firm. Great American is another beautiful berry now in season, large, remarkably even and regular in form and a rich color. These berries sold for twenty cents a quart. Peaches are now coming from Georgia and Florida, the latter state sending the best which have ever come from that region. These sell at \$1.00 for a box containing twenty-five fruits.

An Architectural Garden.

THE location of the house of Mr. E. C. Benedict, on the Indian Harbor property, is certainly one of the finest on Long Island Sound. The old Indian Harbor Hotel (once known as the Americus Club, of Tammany fame) was built on this point some years ago, and was still standing when the present work was begun. This beautiful point of land, almost entirely surrounded by water (on the west side by a landlocked harbor), and rising as it projects toward the water, so that the point on which the house is situated is the highest point of the site, is exceptional. It is covered with beautiful wild woods in a good state of preservation (see plan on page 243).

The site of the old hotel was adopted for the present house because of its height and proximity to the water, its beautiful outlook, and also because this portion of the land, being very rocky, is less wooded and needed architectural treatment. The materials used in the main construction of the building are either stone or brick, covered with a stucco composed of cement and marble dust. The roofs, where apparent, are covered with red Italian tiles, while the architecture and landscape work are somewhat Italian in character.

At the entrance, a stone lodge, somewhat picturesque in its treatment, and stone walls across the point, with wrought-iron gates, are built among the Oak-trees in such a way as to harmonize with the natural beauty of the spot. After passing the lodge, a drive of about an eighth of a mile through absolutely wild woods leads gradually to the architectural features of the house and its surroundings, a few flowering bushes in groups being the first indication of cultivation. At the point where the different roads to the stable, service house, docks, etc., meet, a semicircular stone bench and wall are built, beyond which avenues of symmetrically planted trees lead through the natural woods to a formal entrance with stone walls and grilles. Beyond the grille, a broad and formal avenue, with six rows of trees symmetrically planted, leads through a formal landscape to the inclined drive or ramp, and to the flight of stone steps, both of which lead directly to the porte cochère. The house is at the apex of the property and also of the general composition.

The formal landscape is thus treated as a gradual transition or introduction between the perfectly natural woods and the absolutely formal portion of the composition—the house and terraces immediately surrounding it, with ramps and staircases, etc. This principle of general treatment in landscape prevails in all the fine works of Europe and other parts of the world. In Versailles, for instance the Château on the town side is treated with an entirely formal paved court, a theatre forming one wing of the court, a chapel the other, an elaborate entrance, grilles and walls enclosing it on the fourth side. The other façade of the Château faces beautiful parks, terraces and fountains, the axis of the Château being an extended vista, so that the eye glances first over entirely formal surroundings, and gradually, through a less formal garden, until it reaches the natural landscape beyond.

This effect has been sought on the land side of Mr. Benedict's house, though, of course, in a very much less ambitious and extensive way, owing to the limitations of the site. On the water side, the terraces, with overhanging balconies and balustrades and stone walls, have been treated so as to follow the outlines of the rocks and to lead gradually from the architectural to the natural, the immediate surroundings of the house being formal terraces and terrace gardens. When approaching the house, whether from the land side or from the water side, the transition from the natural to the artificial is gradual, and in itself natural, the whole landscape forming a beautiful foreground or frame for the crowning feature—the architecture. When looked at from the house the treatment forms a foreground, leading gradually to the natural, and at the same time framing the landscape.

The treatment, in detail, comprises the main house, which is L-shaped, the hollow of the L being south and east, which gives not only the most beautiful outlook, but also the best exposure for sunlight and cool breezes. The treatment of the gardens within the terraces is formal, with hedges, flowering plants, gravel paths, balustrades, steps and vases with Palms and Bay-trees. The trellis-work, or pergola, is somewhat similar to the celebrated one at Amalfi, an illustration of which is given on p. 245. It is to be covered with large-leaved vines, and to lead from the main house to the smaller house, which is built for the use of members of the family.

From the main house a flight of steps leads to the dock, which is placed at an angle to suit the channel, permitting the landing of passengers from a large yacht directly at the dock. On the upper landing a semicircular seat, surrounded by columns and covered with a trellis of vines, forms a half-way resting-place. A pavilion which overhangs the rocks overlooks the tennis-court on the land side.

The boat-house, in the hollow, is the dining-room of the old hotel, moved down and altered for the purpose. The terraces and walls along the trellis and the east and south sides of the house are the old foundation walls of the Indian Harbor Hotel, restored and altered as to details and crowned with balustrades and other features. A picturesque path leads from the stone seat at the entrance, along the water edge and along the trellis-work, down over the rocks, all around the property, following the water's edge. Between the stable and the mainland about five acres of land have been made by building bulkheads and dredging the landlocked harbor, so as to permit of its use for the anchoring of yachts. These five acres of made land will eventually be used, in part for vegetable and flower gardens, and in part for grazing lands; a small farm is located in the woods north of the made land. East of the stable, on the bulkhead that has been constructed to reclaim the land, a large coal and ice house, engine house and repair shops have been provided, as well as a dock which will permit a large yacht to be laid alongside it during the winter in a perfectly landlocked harbor.

In carrying out the details of the scheme much blasting for cellars and other features was required, furnishing practically all of the stone needed, not only for the foundation

of the buildings, but for sea walls, roads and much of the filling, so that in altering the profiles of the land little or no extra material was required beyond soil and dirt filling for the top surface. Where masses of large trees were needed holes were blasted in the rock, which is naturally full of fissures, and were filled with soil, in which the trees have been planted.

In this design it has been the endeavor of the architects to make an interesting ensemble of buildings and grounds in a ground plan studied from the artistic point of view. The forms are irregular, and as unbalanced as the letter L, yet with symmetry and circulation such as they hope will give interesting vistas in every direction. A good plan of house and grounds, as seen on paper, aside from the questions of arrangement, has proportion, form, scale, color, values and character. The drawing of such a plan will awaken as much enthusiasm in the educated architect as does the picture in the painter or the statue in the sculptor. This plan should be thoroughly studied and practically finished before the architect has more than a vague idea of the design of the exterior of the building. The plan involves and determines the entire composition; the silhouette or outline of the whole is really projected on the plane of this drawing. If the relations to each other of roads, paths, buildings and other features are well studied and look well on paper, they are almost sure to prove successful when seen in perspective after the work is completed. Such a comprehensive plan does away with the necessity of perspective drawing as a help to architectural as well as landscape study, and leaves it no place except to explain a building to a layman. The many elevations of the several buildings on Mr. Benedict's place have been evolved from the general scheme, and are the natural expression of the whole plan. No one elevation of the houses would give any idea of the entire scheme, as the greatest interest centres in the general composition of the grounds and relations of the buildings to each other, or what the French call "the plan général." They have a very characteristic name for this portion of the composition, which is the "sauce of the architecture." It is this portion of the design which unites or marries the building with its natural surroundings. Most of the same principles of composition obtain in the planning of this portion of the work, as in the planning of the buildings themselves. The silhouette must make first of all an agreeable ensemble with the silhouette of the buildings.

While the landscape or surroundings should govern the general composition of the building in the beginning, the building should in turn, when completed, influence and govern the arrangement and composition of that portion of the landscape work which comes in immediate contact with it. This landscape work is to surround and support the building, serving both as frame and as pedestal. The accessories of the architecture, such as the terraces, balustrades, paths, fountains, open spaces and vistas which come nearest to the building, and other architectural features, are really a part of the building. While the plan of the surroundings does not need to repeat the form of the building itself, it should everywhere recall its principal axis and lines, and it should accentuate its general silhouette, just as where there is a pavilion or important feature in the building there should be a circulation in the surroundings leading up to it. Fountains, balustrades, statues, and rows of trees, when desired, should be clearly indicated in plan. All these things, with the plan of the building itself, should hold together in one ensemble, while there may be interesting details in the form of niches in the verdure for statues, or recesses for seats, or vases, and small round or square breaks taken off the angles where two paths meet. All these forms should be studied almost exactly in the same way as if they were in the plan of the building itself.

The day is coming when the public and honest critics will demand of design in architecture and landscape something more than mere taste and refinement of details—

something more than a house planted in the landscape without design, or roads winding in meaningless curves through scattered trees, without unity—and this can be only when the plan is looked upon as something more than merely a question of convenient arrangement, and the picturesque as something more than an eccentric accumulation of accidentals and good details.

New York,

Thomas Hastings.

Pinus muricata.

THE characteristic Pine of the Mendocino coast region is *Pinus muricata*, which here fills the place which farther south is occupied by the kindred Monterey Pine, *P. insignis*. A hardy adaptable tree it is, making the best of all conditions, and only asking to be near its beloved sea. Hanging to the sides of the steep ocean bluffs, where the spray dashes, its growth is all on one side and horizontal. Standing on the bold headlands in groves, the wind-scarred veterans on the outside bend from the wind and protect the inner ranks, while within the sheltered park-like areas the favored trees develop into symmetrical and beautiful dark-leaved specimens. Standing alone on some wind-swept point, tall, gnarled and picturesque, the growth one-sided, with only a single living limb perhaps, and this one reaching out horizontally for a long distance and terminating with a dense tuft of green leaves, while the dead limbs are decorated with the cones of years, the tree is always in keeping with its rugged surroundings.

At Fort Bragg, *Pinus muricata* covers the sandy plains with a dense wood of straight slender trunks, the weaker dying out and leaving finally open deeply shaded groves carpeted with leaves, and the trees fifty or sixty feet high. All the oceanward slopes of this high rocky coast were once, with few exceptions, covered with forests of this Pine, but it has had to give way to green fields and gardens. It makes good lumber, but the supply far exceeds the demand, and each year sees large areas of pine woods chopped down, and in the fall fire sweeps through the tangled mass of limbs, vines and underbrush, and makes way for the plow.

Back from the coast a mile or two, where once the Redwood held sway, this Pine appears as a hardy colonist; rising from a heavy thicket of bushes of half a dozen sorts, and a network of logs and fallen trees, it disputes the mastery of the upper air with lusty sprouts of Redwood, vigorous descendants of the original occupants, with Fir and Hemlock. In the rich soil of these woods it reaches its best estate, and trees of fine proportions and seventy feet high are not uncommon.

Still farther from the coast in the barrens a hard battle has been waged for ages without material gains to either side. The struggle is for the possession of a poor thin soil, and colony after colony of *Pinus muricata*, *P. contorta* and *Cupressus Goveniana* have occupied the disputed territory for eight or ten years, only to be swept away by the resistless fires. A few groves where underbrush is thinner have managed to hold their own for ages; a few live to form groves of handsome trees perhaps twenty years of age, but more only reach the height of six or eight feet. A little farther back, where the barrens cease and the Redwood forest begins, the last Pine is seen at a distance of less than five miles from the ocean.

The cones of *Pinus muricata* are very persistent and the seeds are retained in them for many years. The coast is a region of summer fogs, and the sun is seldom hot enough to open the cones, and it oftener happens that they are never opened until a fire furnishes the needed heat, and in sweeping away one wood seeds the soil for another.
