may, however, be stated, in general, that in acute hydrocephalus there is seldom slow, partial, spasmodic paralysis of the extremities: the sight and the speech are much more frequently affected. It is also characterized by high fever, general convulsions, irritability of the stomach, ending in a state of collapse and coma; symptoms much more resembling those of arachnitis than of partial cerebritis. When hemiplegia or other forms of paralysis have occurred during its progress, inflammation and softening of the brain have generally been found, in addition to the ordinary morbid appearances of hydrocephalus.

It is of importance to attend to the circumstance that, in children, diseases of the brain often come on very insidiously, and may have existed for some time previous to the appearance of any very decided symptom. The case of a child affected with fever, restlessness, headach, slight convulsions, irritability of stomach and vomiting, a foul tongue and disordered bowels, is looked upon as one of gastric remittent fever, or as the effect of dentition, whilst there is inflammation going on in the brain or in its membranes, which, however, is not suspected until delirium, strabismus, or convulsions, point out an advanced stage of cerebral disease. The condition of the brain, in the febrile and inflammatory affections of children, should always therefore be attentively watched.

Some of the premonitory symptoms of cerebritis, such as pains in a limb, numbness, weakness, or stiffness, have been mistaken for rheumatism, and treated by local applications, while these symptoms were produced by disease of the brain. The absence of all local swelling, redness, or tenderness on pressure, will assist in sufficiently distinguishing the muscular pains in cerebritis. In the same manner vertigo, cephalalgia, irritability of temper, disturbed sleep, loss of appetite, and impaired digestion, indicating the approach of cerebritis, have sometimes been treated as nervous or bilious headach, connected with dyspepsia; and the true character of the complaint has been overlooked, until the brain has sustained some material injury. The importance of diligently watching all those premonitory symptoms which indicate a threatened attack of cerebral disease, cannot be too strongly enforced.

Epilepsy, chorea, nervous and hysterical convulsions, and several other nervous affections, bear some resemblance in many of their symptoms to those of cerebritis. We must refer, however, to the history of these diseases, for a more particular account of their diagnosis. We shall only observe in general, that the greatest attention is often required to discriminate cephalalgia, vertigo, confusion of sight, and other symptoms of affection of the brain, connected with vascular excitement, from purely nervous irritation. It must be remembered, in forming our diagnosis, that both causes sometimes re-act on each other.

The absence of all tendency to permanent paralytic affections in the purely nervous cases, will be a good general rule of distinction. Much useful information is moreover to be obtained by attending carefully to the predominant character of the temperament, and of the prevailing diathesis, whether sanguineous or nervous. The great irreg-

ularity and mutability of pure nervous symptoms form a striking contrast with the comparatively uniform and durable nature of those which originate in disorder of the vascular system. We must not, however, be led to imagine that pallid, thin, and apparently nervous people, are exempt from inflammatory affections of the brain, or that others of a full habit and florid complexion are not subject to purely neuralgic complaints.

There are some conditions of the system in which a distinction between the genuine and spurious symptoms of inflammation and compression of the brain is of great importance. A patient in a state of exhaustion after long illness, intense pain, copious bleeding, and other evacuations, is suddenly seized with violent headach, restlessness, hurried pulse, convulsions, coma, and apparently all the symptoms of acute cerebral inflammation. This is a common affection in children, and has often been mistaken for acute hydrocephalus. In other cases, after great anxiety and depression of spirits, a person is affected with delirium, incoherence, maniacal excitement, a hurried manner, great volubility, and hallucinations; the pulse is hurried, rising suddenly to perhaps 160: these symptoms pass rapidly into fatal collapse and coma. No morbid alteration is found in the brain in these cases, except, perhaps, slight vascular injection. This affection has been mistaken for arachnitis, mania, hysteria, and its true nature overlooked, until the patient has rapidly sunk. The use of evacuations in such cases is sure to hasten death; whilst under the timely administration of cordials, stimulants, and opiates, the symptoms are often speedily relieved. Towards the close of low fevers, when a decided amendment has taken place, a series of symptoms sometimes occur, simulating a dangerous affection of the brain. The patient becomes restless, complains of headach, and does not sleep, and at length lapses into muttering delirium. These symptoms are, however, purely nervous and relieved by mild opiates and a moderate allowance of wine.

Cerebritis may exist in combination with a variety of other diseases, such as hypertrophy of the heart, chronic inflammation of the lungs, the liver, stomach, and bowels; with continued fever, measles, scarlatina, erysipelas, mania, &c. The diagnosis in such cases is not in general attended with much difficulty, although one disease sometimes lessens the violence of the other. We have already directed attention to the important fact of severe cerebral inflammation completely concealing for a time the existence of other diseases with which it may be combined.

There are partial paralytic affections of the face, neck, and extremities, depending on inflammation and compression in the course of the nerves, or on diseases of the vessels, which may be referred by mistake to disease of the brain. We are indebted to Sir Charles Bell for a most interesting and satisfactory description of some of these affections. The absence of any cerebral symptoms capable of accounting for the paralysis will direct the attention of the practitioner to its real causes. The same may be said of the diagnosis between cerebritis and paraplegia arising

from spinal disease, and the paralysis also occasioned by mineral or other poisons.

Before concluding the subject of diagnosis, we shall briefly allude to the interesting inquiries of some French pathologists, who have endeavoured to point out the parts of the brain affected in cerebritis, by the various modifications of the paralytic symptoms. We have seen that paralysis may affect one extremity, or both; one entire side of the body, or the eyes, face, and tongue, either singly, or in a variety of combinations; that there are the same diversities in the state of the sensibility and intellectual faculties. How are these modifications to be accounted for? Several of the older writers had conjectured that, if the nervous filaments could be traced up to their remote origin in the brain, it would be found that each part of the body receives regularly its nerves from a determined part of the brain, so that any lesion of that part must necessarily affect the functions of the organ to which it sends nerves. The following are the results of numerous pathological observations made on this subject, by MM. Foville, Serres, Pinel Grandchamp, and Bouillaud. They are, of course, to be received with a good deal of reserve; but we still think them deserving of notice, if it were only to direct others in the path of inquiry.

1. The paralysis of the organs of speech depends on diseases of one or both anterior lobes of the brain. There are seventeen cases reported in the works of Lallemand, Rostan, and Bouillaud, with paralysis of the tongue, in which the anterior lobes of the brain were found affected with various degrees of inflammation and softening; on the other hand, an examination of about fifty cases, in the same authors, without loss of speech or paralysis of the tongue, does not afford a single instance of inflammation or softening in the anterior lobes. It should be noted that there may be loss of speech without paralysis of the tongue, from mere loss of memory; and M. Bouillaud's observations lead him to think that the anterior lobes of the brain preside over the memory of words, as well as over the organs of speech. The above statement, if the facts on which it is founded can be relied on, is certainly very remarkable, and deserving of further investigation.

We remember an interesting case under the care of Dr. Cuming, of Armagh, in which there was disease in the anterior part of the brain from a blow received on the forehead just above the nose: it was found necessary to remove a portion of bone with the trephine; and after a variety of remarkable and untoward symptoms, the gentleman perfectly recovered: one of the prominent symptoms was a loss of the memory of language.

2. The paralysis of the inferior extremities depends on disease of the middle lobes of the brain, and of the corpora striata. This conclusion is not supported by the same number of facts as the former.

3. The paralysis of the upper extremities depends on disease of the posterior lobes of the brain, and of the optic thalami. This is likewise stated as yet resting only on a small number of facts. The paralysis of one arm only has been observed in a good many cases, in connection

with inflammation at the junction of the posterior and middle lobes. When several parts are paralyzed at the same time, the morbid alterations of the brain are supposed to be more extensive, or seated near the medulla oblongata. Paralysis of the arm and leg on the same side, or hemiplegia, is supposed to follow the combined affection of the corpus striatum and thalamus, or else disease of the crus cerebri, from which these two bodies derive their origin.

The last speculation on this subject which we shall refer to, is one relating to the respective uses of the cortical and medullary substances of the brain. We have seen that the cortical substance has been found, in a great many lunatics, highly injected, and often inflamed, whilst the medullary substance remained healthy. M. Foville and Pinel Grandehain have conjectured from this and some other circumstances, that the cortical substance was the seat of intelligence, whilst the medullary was intended to preside over motion. The principal other grounds of this hypothesis are, the apparent decrease of the cortical substance, which has been found reduced to a very thin layer, in cases of imbecility; the small size of the convolutions and small quantity of cortical substance observed in the brains of idiots, compared with those of intelligent beings.

In the article *Encéphale*, of the volume of the *Dictionnaire de Médecine et de Chirurgie Pratique*, just published, M. Foville, whose recent discoveries on some points of the minute anatomy of the brain have deservedly attracted much attention, enters at considerable length into the examination of the preceding considerations. He has adduced a number of striking facts and arguments in their support, and lays down the following general propositions:

1. The joint lesion of the corpus striatum and thalamus of one side gives rise to the same paralytic symptoms as the lesion of the whole fibrous substance of the corresponding hemisphere, of which they are in some manner the centres or nuclei.

2. The lesion of the crus cerebri is followed by the same paralytic symptoms as that of the corpus striatum and thalamus, which are themselves in a great measure formed by the expansion of the fibres of the crus.

3. A lesion of the medulla oblongata produces all the symptoms which arise from the joint affection of the crus cerebri and cerebelli; and if we ascend still higher in the brain, from that also of the corpora striata, thalami, and hemispheres.

4. If we direct our attention to the portion of the nervous system below this great centre of the nervous action of the brain, we shall find the cerebral influence continue unimpaired in all parts superior to any lesion of the spinal marrow, whilst it is completely intercepted in parts inferior to that lesion.

Prognosis.—Cerebritis is a disease always attended with considerable danger. When once fully developed, it has hitherto been generally considered as incurable; but since we have been enabled, by a better knowledge of its true nature, to apply with promptitude more appropriate remedies, the treatment is often successful, even under the most unpromising circumstances. The ex-

tremely delicate structure, however, of the brain, its situation in a bony unyielding case, without room for expansion, or any opening for the exit of effused fluids, and the great importance of the integrity of its functions to the preservation of life, are circumstances which must always connect a considerable degree of danger with its inflammatory affections.

It may be said in general, that so long as the inflammation is only in the first stage, and the texture of the brain not broken down by the infiltration of blood, pus, or serum, resolution is still possible. The following circumstances may lead us to hope for this favourable termination: the paralysis being only partial; the muscles firm, not flaccid, and retaining some degree of motion; the sensibility being little impaired; after an attack of coma, a gradual return to consciousness, without affection of the intellect; sound sleep; the tongue cleaning, and motion progressively returning in the paralyzed parts. It must not be forgotten, however, that there are frequently exacerbations and remissions in the symptoms; intervals of apparent recovery and a great tendency to relapse. It has been already stated that a decisive amendment often attends the passage of the inflammation from the first stage into that of softening or suppuration. Such an amendment, therefore, at a late period, is more to be suspected than in any earlier stage of the disease. The continuance of headach, uneasy sleep, shiverings, and languor are unfavourable symptoms, whatever may have been the amelioration in other respects. Headach and delirium are less unfavourable than stupor and coma. When profound coma is succeeded by headach and delirium, this is rather a favourable occurrence, as it indicates a return of the previously paralysed action of the brain; when, on the contrary, they are followed by coma, it is a bad omen. The danger is of course in proportion to the extent of the paralysis, and greater in complete hemiplegia than when the paralysis is confined to one limb. When the paralysis extends to the side of the body which was at first free, the danger is imminent, since both hemispheres are then affected; and when both sides are simultaneously paralysed, a speedily fatal termination may be predicted. Embarrassed breathing is always a bad symptom.

When the inflammation has reached the second stage, and the diseased portion of brain has become softened and infiltrated with pus, the danger is great and the recovery very doubtful. Paralysis of the bladder and retention of urine are generally fatal symptoms.

The chronic form of cerebritis, accompanied by very slow and creeping palsy, is always an unpromising disease. The circumstance of the symptoms at first being slight, and confined to an apparently trifling numbness or weakness in a few muscles, must not throw the practitioner off his guard. This form of disease is almost always attended with a considerable degree of failure of the powers of the constitution; and sooner or later, in the majority of cases, comes to an unfavourable termination. The more acute cases afford a better prospect of recovery, there being sufficient strength to admit of the use of active remedies.

The coma and paralysis following a sudden attack of sanguineous apoplexy are attended with less danger than the coma and complete paralysis of the latter stage of cerebritis; for there are numerous instances of the resorption of a clot of blood, whilst those of the resorption of pus and healing of an abscess are extremely rare. The inflammation of the brain consecutive to sanguineous apoplexy is always dangerous, and greatly lessens the chances of recovery. Cerebritis following concussion is generally severe, and attended with greater danger than that consequent upon an injury of the head with opening in the skull.

The duration of cerebritis varies according to its form. Acute cerebritis generally runs a rapid course; it may prove fatal the first, second, or third day, and seldom lasts more than from ten to twelve days. Chronic cerebritis is very variable in its duration, being often attended with intermissions and relapses; the disease may thus be prolonged for several months, and some cases have been described as lasting even several years; but it is more than probable that when symptoms resembling those of cerebritis continue beyond five or six months, they do not arise from genuine cerebral inflammation, but are to be attributed either to an organic tumour, or to some neuralgic affection simulating chronic cerebritis. In a collection of thirty-four cases, nine died in the course of the first week, six in the second, six in the third, two in the fourth, and eight in the course of from two to six months.

With respect to age, it appears that old age and childhood are the two periods of life the most exposed to cerebral inflammation. The examination of a large number of cases shows that more than two-thirds were persons above forty-five, and a majority of these between forty-five and seventy. It is a disease, however, which may affect all ages. The frequency of falls and blows on the head in children, the irritation of dentition, the pressure of the head during parturition, predispose them to cerebritis, although there is perhaps a greater tendency at that period of life to membranous inflammation. Traces of cerebritis have been found in still-born children. Men are more subject to cerebritis than women, in the proportion of about two-thirds, owing probably to their being more exposed to the influence of exciting causes. The disease, also, is more common in hot than cold climates, and in summer than winter.

Causes.—The causes are predisposing and exciting. The only difference, however, between these often consists in their degree of activity; since a predisposing cause may become exciting if its activity be sufficiently increased. Every circumstance capable of causing congestion, or of disturbing the balance between the arterial and venous circulation in the brain, becomes a predisposing cause. These circumstances are a plethoric habit, particularly in individuals who have short necks and are subject to habitual constipation, the diathesis justly termed apoplectic. Persons, however, of a thin habit and slender make, with long neck and pallid countenance, and especially if such individuals are intelligent, are also under certain circumstances predisposed to cerebral affections, particularly when labouring under disease

of the heart. An hereditary tendency to fulness in the head and diseases of the brain may be reckoned among the predisposing causes. Hypertrophy of the heart, particularly of the left ventricle, is a very common predisposing and sometimes exciting cause. The celebrated Malpighi died of an inflammatory affection of the brain, attributed to hypertrophy of the heart, from which he had long suffered. Disease of the heart acts either by impeding the regular return of the blood from the head, or causing the blood to be propelled with excessive impetus towards the brain; the latter takes place more particularly when the hypertrophy is produced by obstruction in the aorta beyond the origin of the carotid arteries. Inflammation of the lungs, phthisis, and asthma act in the same manner in producing cerebritis, though these diseases are less powerful exciting causes than those of the heart. There is a great predisposition in phthisis to sudden attacks of inflammation of the brain or its membranes; the patient is all at once seized with intense headach and violent delirium, ending sometimes in confirmed mania, and it is very remarkable that the pulmonic symptoms, howsoever severe, have often in such cases suddenly disappeared, and have not returned until the attack in the head had subsided, the two affections thus alternating the one with the other. It cannot be said in every case that the cough and other pectoral symptoms are merely obscured, for we have seen cases of perfect recovery from an advanced stage of phthisis, by the supervention of an attack of mania. These are striking examples of the actual translation of disease. Dr. Abercrombie very justly observes that there may be in scrofulous constitutions a tendency to scrofulous inflammation of the brain, and that the disease of the lungs is not properly to be always considered as the cause of the head affection; that in the same manner disease in the brain may appear in connexion with the disease of any other organ, and that diseased liver has often been thus improperly stated to be the cause of hydrocephalus.

The mutual influence of the functions of the brain and digestive organs on each other is so obvious as not to require any explanation; and thus the headach, drowsiness, and other signs of cerebral congestion, which follow over-distension of the stomach, or the abuse of spirituous liquors, are easily accounted for. Habitual drunkenness is perhaps one of the most powerful causes of cerebritis or arachnitis. The striking similarity between the symptoms of the last stage of intoxication and those of apoplectic coma has been frequently noticed. The subacute inflammation of the mucous membrane of the stomach and bowels, the gastro-enterite of Broussais, is often accompanied by great cerebral irritation. This complaint, in young children from two to four years old, frequently terminates in coma. A vitiated state of the secretions of the alimentary canal is a very active and frequent cause of cerebral irritation; it accompanies that fretfulness and irritability of temper which so commonly precede attacks of inflammation in the brain. the convulsions produced by intestinal worms are also the effect of sympathetic irritation.

There is a disease of the urinary organs, known

as ischuria renalis, of rather uncommon occurrence, which predisposes sometimes to dangerous affections of the brain. Sir Henry Hallford has published an interesting paper on this subject. (Transactions of the College of Physicians, vol. vi. p. 398.) In many of the cases, after the patient has suffered for two or three days from dull pain and sense of weight in the iliac regions, these symptoms are succeeded by great anxiety, nausea, vomiting, hiccup, cramps, slow pulse, delirium; and he gradually falls into a state of lethargy and coma. The ventricles of the brain are found on dissection distended with serum.

The suppression of urine is sometimes not complete; if there be perspiration, it may have a urinous smell. Suppression of urine is sometimes not attended with any marked inconvenience. Dr. Parr, in his dictionary, mentions the case of a person who had suppression of urine for six weeks and yet recovered. Dr. Abercrombie gives a case in which the suppression was occasioned by obstruction of both ureters: the patient died on the thirteenth day, of a cerebral affection.

Ischuria renalis has in some instances been supposed to originate in a disease of the brain, causing paralysis of the kidneys. The persons most subject to this affection are fat corpulent men, between fifty and sixty years of age, of a gouty habit, and naturally predisposed to cerebral congestion, though it is sometimes also met with in children.

We have already said that inflammation of the brain may occur in the course of a variety of febrile diseases, such as continued fever, scarlatina, measles, &c. It has often been observed as one of the sequela of scarlatina; and when accompanied with anasarca, its inflammatory character has been entirely overlooked, and attributed to mere serous effusion in the brain. There is a great tendency to cerebral congestion in the continued fevers of this country; thus of eight hundred and sixty-four cases treated in a large fever hospital, six hundred and two presented head symptoms. Suppuration of the brain may sometimes occur in the course of fever, but it is not very common; of fifty cases of fever with well-marked cerebral symptoms, pus and blood occurred in only three. Subacute inflammation of the membranes is of much more frequent occurrence. The injury, however, sustained by this organ during an attack of fever with violent head symptoms, often gives a predisposition to future cerebral inflammation.

Among the predisposing causes are to be ranged suppressed evacuations. That of the catamenia, especially in young women, is often followed by dangerous affections of the brain. A similar result may attend the suppression of artificial discharges and of cutaneous eruptions, the healing of chronic ulcers, erysipelas, gouty or rheumatic affections of the joints, &c. Over-exertion of mind, depressing passions, such as grief, fear, &c. great bodily fatigue, long-continued nervous headaches, and all neuralgic affections of the brain, epilepsy, and mania, operate as predisposing and sometimes exciting causes. The brain cannot long suffer from nervous irritation without a re-action taking place in its vascular system.

External injuries are among the most direct ex-

citing causes; and this is much more frequently the case than is imagined, particularly in children. A considerable interval, sometimes two or three weeks, may intervene between the injury and the appearance of alarming symptoms; and a very trifling fall or blow, which is often the cause of serious disease, may have been altogether overlooked or forgotten.

Exposure to the intense heat of the sun is a powerful exciting cause. It may bring on either arachnitis, cerebritis, apoplexy, or mania. The same results may follow a sudden transition from heat to cold. Long exposure to intense cold acts also in a remarkable manner on the brain, bringing on inflammation, and sometimes the most violent maniacal delirium: there were many remarkable examples of this during Napoleon's campaign in Russia.

Inflammation and suppuration of the internal ear has a great tendency to extend to the brain, and it is in this manner it often proves fatal. Tedium and painful dentition is a great source of cerebral irritation; intense and long-continued pain from any cause often brings on delirium and coma. The ligature of large branches of nerves in the neighbourhood of the head has had this effect; of which the following case, related by Lallemand, is a remarkable instance. The subclavian artery was tied above the clavicle for an aneurism in the axilla on the *right* side; several branches of the brachial plexus, supplied by the third cervical, were included in the ligature; intense pain was immediately felt in the neck; this went on increasing, notwithstanding the most active treatment; coma, convulsions, and a strong retraction of the head appeared the seventh day; the patient died on the eighth. The posterior portion of the *left* hemisphere of the brain presented a large undefined abscess, containing softened diffused brain, and in the centre greenish pus; the sides of the abscess were deeply injected; the arachnoid was healthy. Such a case is interesting both to the pathologist and physiologist.

The internal use of certain narcotic and irritating poisons may become a cause of cerebral inflammation. This is the special property of nuxvomica; and we have seen its unguarded administration in hemiplegia bring on a fresh attack of inflammation of the brain. The inhalation of putrid effluvia and contagious miasmata, particularly in very hot climates, and when the system is in a state of depression, has been quickly followed by cerebral inflammation. We had experience of this ourselves some years ago, while attending a fever hospital. After inhaling a horrid fetor which emanated from a patient in an advanced stage of typhus gravior, we were instantly seized with sickness and headach, as if struck by a blow, and, in less than forty-eight hours after, a dangerous attack of typhus fever supervened, attended by strong cerebral symptoms. The action of these numerous causes is very variable; sometimes sudden and rapid, at others slow and imperceptible.

Treatment.—The inflammatory nature of the more acute forms of cerebritis and arachnitis is so obvious, that their treatment has always been conducted on correct principles. Until very lately, however, the inflammatory character of partial and chronic cerebritis was either entirely over-

looked, or so imperfectly understood, that though active treatment was sometimes adopted at the beginning of the disease, it was soon laid aside, and remedies of an opposite description substituted. These affections were in fact generally set down as nervous; mistaken for rheumatism, neuralgia, nervous dyspepsia, and debility, or nervous palsy, and treated by tonics, electricity, and stimulants; the fatal termination of the disease being thus accelerated.

Cerebritis and arachnitis are so formidable, that their prevention is of no less, if not of greater importance, than their treatment. It is extremely important to have recourse to active measures on the very first appearance of any of the premonitory symptoms, however trifling: as we may thus succeed in effectually removing that state of congestion and irritation of the brain, which is the precursor of inflammation. The means of accomplishing this are, the careful and timely removal of all the exciting causes; of every source of irritation, both bodily and mental; regulation of the diet; avoiding all excesses; relaxation from study, change of air, general and local bloodletting, counter-irritation, with occasional purgatives. Great vigilance is particularly required in the cerebral affections of infants and children, who frequently suffer without complaining. A predisposition to affection of the brain may often be suspected by some slight cast or rolling of the eyes; by dilatation of the pupils; or occasional startings, and attacks of spasmodic croupy breathing during sleep: there may be every other appearance of perfect health with these symptoms, which are often only evanescent; but they will not escape the attention of the experienced observer, and will be sufficient to put him on his guard.

When it is necessary to relieve the brain from habitual congestion by occasional topical bleeding, the method of taking blood from parts as remote from the disease as possible, seems to us preferable to that of abstracting blood from the head itself. When the vessels of a part are partially emptied of their blood, if they have been much weakened by long-continued over-distension or previous disease, so as to have lost their elasticity, there will be an immediate flow of fresh blood to the part; this will take place on mere hydrostatic principles. We have thus seen in an eye long exposed to injection and low inflammation, the redness and suffusion much greater the day after an application of leeches than it was before; and we have likewise known headach considerably increased in plethoric and bloated people, after leeches had been applied to the temples. On the other hand, no fact is better established than that the loss of an exceedingly small quantity of blood from certain parts of the body is sufficient to relieve distressing symptoms of congestion and oppression in others most remote from them; as, for instance, a very slight discharge of blood (one or two ounces) from the hemorrhoidal veins being sufficient instantly to remove vertigo, flushing, headach, or oppressed breathing: the same is the case in a still more striking manner with the catamenia, although some account must be taken of the influence of uterine irritation over the system. We prefer, therefore, in cases of habitual congestion in the brain, taking blood occasionally from

the feet or legs, by opening a vein, or applying leeches and letting them bleed in a foot-bath; or the application of leeches to the anus, whenever practicable. We have found this the surest method of affording permanent relief; and by repeating it at certain intervals, the tendency to cerebral congestion may be completely overcome. We have pursued this plan in lunatics with the very best results. It was a practice of the ancients, which has, in our opinion, been too much laid aside. When, however, there is active inflammation in a part, as it is most material to unload the vessels freely and quickly, the blood had better, in such a case, be drawn from the immediate neighbourhood of the organ affected.

The insertion of an issue is often advisable, as a preventive, in people of a plethoric habit. The head should be kept cool by the frequent use of cold ablutions; the hair cut short; the head and shoulders raised at night; tight bandages round the neck must be avoided; the daily use of the cold shower-bath is often very beneficial; but a re-action takes place in the head unless it be used with the feet immersed in hot water. The feet, legs, and lower parts of the body ought to be carefully kept warm and dry.

In the treatment of cerebritis, when fully developed, attention must be paid to its two periods of *excitement* and *collapse*. The remedies chiefly to be relied upon are, bloodletting general and topical, purgatives, cold applications to the head, and counter-irritation.

In the more acute cases the patient must be freely bled from a large orifice to the amount of from twenty to forty ounces: one copious bleeding has more effect in bringing about the speedy resolution of the inflammation than several small bleedings. If the symptoms continue unabated, the bleeding must, however, be repeated several times, at intervals of a few hours; and this practice must be carried, during the first period of the disease, to the utmost limit of the patient's strength. It often happens that very little impression is made on the disease by the first bleeding, and no amendment takes place until after the second. The symptoms often abate after bleeding; but a fresh exacerbation may take place in the course of a few hours. Topical bleeding, by cupping or leeches, is, under such circumstances, highly beneficial.

The head must be shaved, and pounded ice mixed with cold water and vinegar may be applied to the scalp. A very effectual method of applying cold is by making the patient hold his head over a basin, and pouring a stream of cold water on it from a certain height: this often removes the heat and flushing, and calms the excitement: it should be repeated as often as the heat and flushing return. The application of cold to the body is always followed by a re-action, and the temporary relief refrigerants afford will be succeeded by an increase of the inflammatory symptoms, and their use become decidedly injurious unless their depressing action be kept up by a steady and repeated application. Some practitioners have, on this account, given the preference to the use of a mixture of alcohol or ether with liquor ammonia acetatis and water, applied not quite cold, in order to produce rapid evaporation.

An excellent practice is that of keeping the patient's feet and legs immersed in hot water during the application of cold to the head.

The remedies next to bleeding and cold, and often not less efficacious, are active purgatives, which must be administered at short intervals until copious evacuations be procured. Free purging sometimes makes a greater impression on the disease than even bleeding. In some cases no marked amendment has taken place until the bowels have been freely moved: they are sometimes exceedingly torpid, for reasons which have been already assigned, and large doses of cathartics may be required. Combinations of calomel, jalap, scammony, and cathartic extract, followed by an infusion of senna with salts, are the purgatives on which the most reliance can be placed. Croton oil is also in these cases a valuable remedy, from the facility of its administration and certainty of its effects. Mercury may be given freely as a purgative, but no particular advantage has appeared to follow its use with a view to affect the constitution; it is, indeed, found very difficult in acute diseases to produce pyalism.

We have sometimes found tartar emetic of great service when there was no irritability of stomach to prevent its being tolerated; the power of tartar emetic in controlling the action of the heart, and subduing the inflammatory diathesis, is now fully established: a solution in the proportion of one grain to the ounce, and two table-spoonful given every two, three, or four hours, suspending it should vomiting occur, has often been attended with great benefit. The remedy is in general well tolerated, owing to the torpor of the stomach: violent vomiting should, however, be prevented, as it would obviously be extremely injurious.

In the second stage of acute cerebritis, that of collapse and coma, general bloodletting is to be used more sparingly; decided advantage, however, has resulted from a moderate bleeding even at a late period. In this stage, topical bleeding is more generally indicated. There are periods of exacerbation in the symptoms which should be watched and overcome by these means; which may be persevered in as long as there is any hardness and resistance in the pulse. We have seen

patient instantly recover from a state of profound coma by the abstraction of a very small quantity of blood with the cupping-glass. When bleeding is no longer advisable, moderate purging may still be of use. In this stage, we may have recourse to counter-irritation with advantage: blisters may be applied between the shoulders, to the occiput, or to the neck or legs. There is an objection to their being applied to the whole head, that it prevents the subsequent application of cold. We have, however, in desperate cases, seen a decided amendment follow the application of a large cap blister. Particular attention should be paid to the abdominal region, and especially that of the bladder, which ought to be examined morning and evening, in order to detect retention of urine; and we must take care not to be led into error by an incontinence of urine from the over-distension of the bladder: this must be obviated by drawing off the urine with the catheter twice a day.

In the more chronic forms of cerebritis, unattended with fever or much general excitement, the

same activity of treatment is of course not admissible. We must still, however, pursue the anti-phlogistic plan, modifying it according to the urgency of the symptoms. During the period of irritation, with cephalalgia, vertigo, or rigid spasm of the extremities, moderate bleeding, general and topical, purgatives and counter-irritation, are the only remedies from which any advantage is to be expected: they must be repeated at longer or shorter intervals, according as the strength of the patient and the continuance of the symptoms may seem to indicate. A great deal is to be accomplished in all chronic inflammations by persevering in a moderate course of antiphlogistic treatment. We must watch carefully any signs of amendment, remembering that there is a great tendency to relapse, and that the natural course of the complaint is characterised by irregular remissions and exacerbations.

When the period of irritation is over, and is followed by a remission of all signs of excitement, by a complete paralysis of the muscles, and by the other evident signs belonging to the period of softening and suppuration, the strength of the patient must no longer be reduced by active treatment. In all inflammatory diseases, when the stage of excitement and disorganization is over, a process of reparation commences, which requires for its completion a certain degree of power in the constitution. If at this period we persevere in lowering the general strength, we deprive the constitution of its natural resources, and interfere with its healing operations. It becomes, therefore, an object of considerable importance to watch the moment when the tide of excitement is on the turn, and when the powers of the constitution are verging to a state of collapse, in order that we may abstain from an injurious interference, husband the patient's strength, and even support it if required. This precaution is particularly necessary in old people and young children. We think it necessary to lay some stress on this rule of practice, as there is perhaps a tendency in the present day to overlook it; and we have seen considerable harm from carrying the antiphlogistic treatment beyond its safe limitation. We have already alluded to the pseudo-symptoms of cerebral congestion and inflammation which are sometimes the consequence, especially in children, of extreme exhaustion, and require the use of cordials.

After convalescence has been established, the patient will still require to be closely watched for some time, before his recovery can be considered fully confirmed: he must be kept perfectly quiet, free from every species of excitement, and the regimen duly regulated. When the brain has once suffered from inflammation, it is slow in recovering its tone, and the most trifling cause, such as a slight mental exertion or emotion, a full meal, &c., has been, in many cases, sufficient to occasion a relapse.

When cerebritis has occurred after suppressed evacuations or the metastasis of other diseases, we should endeavour to procure their return. If menstruation be suppressed, leeches should be applied to the pubis or inguinal regions, and the frequent use of hot pediluvia with flour of mustard recommended. If cutaneous eruptions or rheumatic gouty pains in the joints previously existed,

blisters or rubefaciants are to be applied to the parts originally affected.

M. Bland has published in the *Bibliothèque Médicale*, vol. lxii. several cases in which he says that he speedily overcame the symptoms of cerebritis by the mere compression of both carotids for several seconds; stopping thus the flow of blood to the head. Laennec considered this an unsafe proceeding, and not easy to perform without the risk of suffocation. This plan has often been proposed as a means of checking inflammation, and also of preventing the accession of the paroxysm of ague. We have, however, never seen it tried, and should think its general application scarcely practicable.

The following summary gives a connected view of the various morbid conditions of the brain, which are the effects of congestion and inflammation, together with their symptoms.

1. Cerebral congestion, over-distension of vessels:—vertigo, tinnitus aurium, confusion of sight, cephalalgia; if the pressure on the vessels be carried to a sufficient extent to intercept the circulation,—*simple apoplexy*; seldom fatal; recovery rapid.

2. If the cerebral congestion be permanent, or returns frequently; drowsiness, oppressed intellect; the vessels become weakened, and on a sudden increase of congestion are ruptured; extravasation of blood,—*sanguineous apoplexy*: destruction of cerebral substance and compression; loss of consciousness, permanent or temporary; sudden and complete paralysis, without spasmodic affection of the muscles.

3. General congestion, followed by inflammation of a considerable portion of the brain; deep injection; partial sanguineous infiltration; dotted and ecchymosed striated appearance of the cerebral substance;—*general cerebritis*, (combined usually with arachnitis). Period of high excitement of all the cerebral functions, with general convulsions, followed by a period of collapse and coma.

4. Partial congestion and inflammation of the brain: *1st period*, the same deep injection and sanguineous infiltration, more circumscribed;—*partial cerebritis*. Partial symptoms of irritation in the organs of motion and sense; weakness, pain, numbness, spasmodic paralysis, confined to one side or a few regions of the body: *2d period*, infiltration of pus in the cerebral substance; softening, abscess; complete paralysis; relaxation and flaccidity of the muscles; loss of feeling; abolition of some of the external senses or intellectual faculties; death, either gradual or sudden, by the extension of the inflammation, or by pressure.

5. After sanguineous apoplexy and sudden and complete paralysis, inflammation of the cerebral substance surrounding the coagulum; *consecutive cerebritis*; the paralysed limbs affected with pains, convulsive motions, spasmodic rigidity.

6. Slow and gradual congestion, with very slight irritation; long-continued state of low inflammation, ending sometimes in *softening*, sometimes in *induration*, or else in an infiltration of serous fluids and *white softening*;—various forms of *chronic cerebritis*; sense and motion very gradually weakened and impaired, without pains or spasmodic rigidity in the muscles.

[BRIGHT, DISEASE OF. (See DROPSY.)

BRONCHIAL GLANDS, DISEASE OF THE. The bronchial glands, or ganglions, seated around the bronchia, where they dip into the tissue of the lung, are not uncommonly found larger than usual, without there being any evidence of their morbid condition during life; and hence it has been concluded that, when hypertrophied, or otherwise diseased, they seldom produce any striking symptoms. (Stokes, on *Diseases of the Chest*, Amer. edit. p. 266, Philad. 1844.) Thus, in a case recorded by M. Andral, (*Clinique Médicale*, tom i.) where an enormous mass of melanosis compressed the right bronchium, so as to diminish its diameter by one half, there was no stridulous breathing, the signs being a feeble respiration in one lung, with intense puerility in the other. He states, however, that tumours of the bronchial glands frequently cause bronchial and tracheal compression. It need scarcely be said, that if they are so large as to compress the bronchial tubes, they must interfere with breathing; still, the compression may arise so gradually as to account for the very slight effect they induced on the breathing in certain recorded cases. In children, they are frequently enlarged by the deposition of tuberculous matter, and may give occasion to dyspnoea, and to evidences of obstructed circulation. Dr. Stokes (*op. cit.*) affirms that he has never met with an instance of stridulous breathing, or even bronchial compression, produced by their diseased condition; but Dr. Golding Bird has recorded cases in which such compression was witnessed. (See the writer's *Practice of Medicine*, 2d edit. p. 383, Philad. 1844.)

Tumours of the bronchial glands would appear generally to grow forwards, and Dr. C. J. B. Williams (*Lectures on the Physiology and Diseases of the Chest*, &c. Amer. edit. p. 252, Philad. 1839) states, that he has seen them pushing out the sternum or the ribs on one side, and causing dulness of those parts, and symptoms of displacement of the lungs farther down.

When the glands are greatly augmented in children of scrofulous habits, there are no signs that can lead to more than a suspicion that the morbid state exists. The scrofulous diathesis may be accompanied with tuberculous of the lungs; and, if evidences of compression of the bronchia exist, there may be no signs that can enable us to pronounce positively, that such compression is owing to enlargement of the bronchial glands. These scrofulous enlargements sometimes soften, and are evacuated, by ulceration, into the bronchia. The bronchial glands are also, sometimes, affected by encephalosis; and it has been suspected by Dr. Williams (*op. cit.*) that encephaloid disease of the lungs generally originates in this way, and spreads afterwards along the vessels into the pulmonary tissues.

Should scrofulosis of the bronchial glands be suspected, the treatment must be such as is proper for the scrofulous cachexy in general.

ROBLEY DUNGLISON.]

BRONCHI, DILATATION OF. (See BRONCHITIS, CHRONIC.)

BRONCHITIS. This term is applied to inflammation of the mucous lining of the bronchi

or air-passages of the lungs. There are few disorders of more common occurrence; and few, perhaps none, so varied in importance. In its slighter forms it is scarcely deemed an interruption to health; but when severe, it becomes a dangerous and fatal disease. The pathology explains this diversity, and refers the danger, which attends bad cases, to interruption of the due performance of the function of respiration. It does not seem correct, therefore, to describe these different degrees under the different names, *catarrh*, *bronchitis*, *peripneumonia notha*, &c. as some authors have done. The term *catarrh* implies only the flux or secretion which accompanies the inflammation. We shall therefore include under the present head all affections of the bronchial membrane, which exhibit the characters of inflammation, and reserve the term *catarrh* for those changes in the secretion of the same membrane that do not appear to originate in inflammation.

Bronchitis presents itself under two forms, the *acute* and the *chronic*; the one differing from the other in the greater intensity of the inflammation, and in the more rapid progress of the disease. We shall therefore consider each form separately, as this method will enable us to point out the circumstances which characterize each variety.

I. ACUTE BRONCHITIS.—The commoner cases of acute bronchitis generally succeed to coryza, or inflammatory affection of the mucous membrane lining the nose and its contiguous cavities, the frontal sinuses. Sometimes the inflammation first attacks the tonsils and fauces, from thence is transferred to the lining of the larynx, and gradually extends downwards to the trachea and bronchi. In other instances the inflammation begins in the bronchi themselves; and this mostly occurs in those whose lungs are susceptible.

The first symptom which characterizes bronchitis is a feeling of roughness in the trachea, which occasions frequent attempts to clear the throat, and is much increased by exertions of the voice, or of the organs of respiration. It soon amounts to such a degree of titillation as to excite cough, which is at first hard and dry. At this time there is generally more or less hoarseness, with a tight feeling across the chest, which often amounts to pain, especially on coughing, and occasions considerable uneasiness in breathing. Some signs of fever are usually felt at this period, such as lassitude, cold shiverings, pain in the limbs, and some acceleration of the pulse. A feeling of chilliness is hardly ever entirely absent, even in the slightest cases. The cough, which at first seems to be caused by an increased sensibility of the inflamed membrane, is very soon accompanied with expectoration of a thin fluid, having a saline taste. This secretion rather increases than otherwise the frequency of the cough; and, like the fluid of coryza, when thin it seems to possess a peculiar irritating quality; for, although the fits of coughing are not so prolonged as they afterwards become, they are more frequent and more irresistible than at any stage of the disease. It is during the continuance of this form of secretion, likewise, that in the common cases of bronchitis, the dyspnoea and pain in the chest first appear; and as the expectoration becomes thicker and more abundant, these are proportionately relieved.

It is this change in the character of the cough and expectoration, that in common cases proves the signal for a general amelioration of the symptoms. The constriction of the chest is diminished or removed; the pulse loses its frequency; the skin, which was hot, becomes cooled by free perspiration; the urine, which was scanty and high-coloured, becomes more copious, and deposits an abundant sediment; and the degree and rate of the decline of all the troublesome symptoms very generally correspond with the change of the expectoration. This seems now to have lost its acrid irritating quality, and has less of the saline taste which at first characterized it. In its appearance it changes from a glairy colourless liquid to a pearly tenacious phlegm, increasing in consistence and opacity as it diminishes in quantity, until at length each fit of coughing easily brings up a pellet of opaque white, or greenish white mucus, to which the soot and smoke of the air in large towns often give a grey tinge. This change, or *ripening* of the expectoration, is first observed in the mornings only, and gradually extends, as the disease declines, throughout the day and night. Towards its termination, the cough and expectoration are chiefly observed in the morning and evening.

Such is the ordinary course of the slighter cases of acute bronchitis, for which the nature of their usual cause has obtained the name of "a common cold." But the same disease, differing from these only in the extent of membrane affected, presents a much more formidable character. In such severe cases, rigors and symptoms of general fever usually attend at the onset of the disease. The patient suffers from headach, particularly over the eyes, sickness and loss of appetite, lassitude and great prostration of strength, with occasional pains in the limbs. The tongue is foul, and the urine scanty and high-coloured. The dyspnoea is often urgent from the beginning, particularly in the night; and this symptom, as well as the tightness and pain in the chest, is much aggravated by the fits of coughing. The pain in the chest is most frequently referred to the sternum, and is more obtuse than the pain of pleurisy; it is often accompanied with a sense of weight to which the dyspnoea is ascribed. The pulse is hard and quick, but presents considerable variety as to the degree of frequency and fulness. The matter expectorated is usually scanty at first, and afterwards becomes copious; it is glairy, frothy, sometimes streaked with blood, and its evacuation affords but little relief to the cough or breathing. It has been compared to the white of egg in different degrees of dilution: it is generally most frothy when moderately viscid and in great abundance; its quantity increases, and there is a general aggravation of all the symptoms in the evening. It is at this time that the fever increases, the dyspnoea is most oppressive, and the cough most distressing.

Between the fourth and the eighth days the disease declines in favourable cases; the dyspnoea is diminished, and is confined chiefly to the evening, when there is almost always a tendency to exacerbation. The expectoration now becomes pearly and less abundant, and affords relief to the dyspnoea. The symptoms of fever subside, and

the disease either entirely disappears or passes into the chronic form. In certain cases, however, if the therapeutic means have not been seasonably resorted to, or have been insufficient to subdue the acute symptoms of the disease within a few days, a state of collapse very rapidly takes place; the pulse becomes very weak, frequent, and often irregular; the countenance pallid and expressive of great anxiety, and often covered with a cold sweat; the strength is wasted by efforts to relieve the lungs of the accumulating mucus; but the cough becomes less and less effectual to remove it, whilst the wheezing and audible rattle in the large air-tubes increase. Lividity, delirium, and other symptoms of the circulation of black blood in the system, frequently succeed, and the patient dies suffocated. A remarkable feature in the character of the worst form of bronchitis is, the rapidity with which the collapse and symptoms of extreme prostration and debility succeed to high fever and well-marked local excitement; and this circumstance indicates the serious nature of the attack on the vital functions. The whole course of these fatal cases is sometimes wonderfully rapid; death ensuing within two days from the commencement of the attack. They are commonly confounded with pneumonic inflammation, and are scarcely to be distinguished from it during life but by the physical signs. The severest form of bronchitis is, however, more formidable and rapid in its course than pneumonia itself.

In the extremes of age, and in persons of weakly and phlegmatic habit, acute bronchitis frequently presents a form so different from what has been just described, that it is necessary to advert a little to these varieties. In young children a very fatal kind of bronchitis not unfrequently comes on in a most insidious manner. It may present at first the aspect of a common catarrh with coryza, without pain, much fever, or derangement of the general health. Attentive observation, however, discovers a frequency and wheezing in the breathing, which is uncommon, particularly before and after the fits of coughing; and the pallidity of the countenance and heavy state of the child's spirits indicate something more than a common cold. The cough is not always present, so that this symptom does not indicate the extent of the disease; and as children do not expectorate, the disorder in the chest may escape remark, until the dyspnoea suddenly comes on, and renders the danger imminent. Then the pulse becomes extremely quick, and the severity of the attack is evinced by the manner in which the respiration is oppressed, and the circulation disturbed. This aggravation of symptoms often goes off for a time, leaving the child in a somnolent state without much cough or quickness of pulse; but if the breathing still continues quick, the dyspnoea returns after a while with increased severity, the frequency of the pulse is increased, stupor comes on, the lips become livid, and in this, or in some succeeding similar exacerbation, the child dies suffocated.

The disease which resembles this more than the case before described, is that form of bronchitis which attacks old people and those of lax phlegmatic habit, and which bears the name of *peripneumonia notha*, or spurious inflammation of

the lungs. Oppression of the breathing is here one of the earliest symptoms, and it is accompanied with a peculiar wheezing; but all the symptoms of inflammation are less acute than in the intense bronchitis before described; and the fever that attends is of a lower and less phlogistic type. There is perhaps a greater loss of appetite, and more disturbance of the gastric function; the tongue is loaded, and there is much thirst. The pulse is quick and wiry; the skin not much raised in temperature except in the evening. The dyspnoea is liable to temporary exacerbations, which are often so severe as to prevent the patient from lying down, and are accompanied by extinction of the voice. The expectoration is scanty at first, but afterwards becomes very copious and frothy. The terminations of this form of bronchitis, which Dr. Badham appropriately denominates *asthenic*, are much of the same kind as those of the more violent inflammation; but its duration is commonly longer, and it has a great disposition to pass into a chronic form. Persons liable to pituitous catarrh, or who have habitually a cough with copious thin expectoration, when attacked by bronchitis, generally suffer from this form.

Exciting Causes.—The usual cause of bronchitis is cold, particularly when conjoined with moisture, applied locally or generally, as for instance, by wearing damp clothing, or exposure to a cold, moist, variable atmosphere, especially after the body has been heated by exercise, crowded rooms, &c. But it appears that all sudden alterations of temperature from cold to heat, and certain epidemic states of the atmosphere also, are capable of giving rise to bronchitic affections. Irritating gases and vapours may excite inflammation of the bronchial membrane; but it is of the slighter kind, and soon passes away, unless the cause be again applied. A much more severe bronchitis accompanies some of the acute eruptive diseases, and frequently causes the chief danger that attends them. In some cases the eruption fades or is diminished, to the great increase of the bronchial affection, which is then announced by oppressive and dangerous dyspnoea. The inflammation of gout is sometimes translated in a similar manner in those predisposed to bronchial inflammation, and the suddenness of the attack renders these cases the more dangerous.

Physical Signs.—In investigating the pathology of acute bronchitis, we shall find that a much more accurate knowledge of the nature and extent of the disease may be obtained by a study of the physical signs than by any attention to the general symptoms alone.

Inflammation of the mucous membrane of the bronchi at first causes tumefaction, and consequently a diminution of the caliber of the tubes. This, occurring in individual points, so modifies the passage of the air through them, that, as in a musical instrument, a sound is produced. This sound varies according to the form of the constriction and size of the tube; but the general effect is, that on applying the ear to the chest we find the ordinary respiratory murmur accompanied by various whistling and wheezing sounds. These occasionally present a graver tone, like the prolonged note of a violoncello or the cooing of a dove, and then indicate that some of the large

bronchi are the seat of disease. To such modifications of the respiratory sound, M. Laennec gave the names of the *sibilant rhonchus* and the *sonorous rhonchus*. They are the symptoms of the earliest stage of bronchitis, and are often perceptible before the patient is aware of any suffering in the chest. They prove moreover the fact, supposed by Dr. Badham and doubted by Dr. Hastings, that the dyspnoea of the early stage of bronchitis is caused rather by the state of the mucous membrane than by the redundancy of its secretion. Both the coarctation of the tubes by which air is scantily admitted, and the general thickening of the membrane by which the oxygenation of the blood is intercepted, appear to be the physical or pathological causes of the symptom in question. Percussion on the chest does not detect any loss of resonance.

In the progress of the disease, the auscultator soon discovers the presence of a liquid secretion, by the bubbling sound occasioned by the passage of the air in the bronchi. This is the *mucous rhonchus*, and its presence announces the second, the catarrhal or secreting stage of the inflammation. By practice the ear soon becomes enabled to distinguish the several sounds that are produced in tubes of different sizes; from these a pretty accurate estimate may be made of the situation and extent of the inflammation; and these circumstances bear a relation to the severity of the case. When the inflammation occupies only the large tubes, as is the case in common colds, the bubbles of the mucous rhonchus are large and uneven, and the sound of respiration may still be heard. But if the rhonchus is fine, and accompanies the whole of the respiratory act, it may be concluded that the disease is in the smaller bronchi; and if extensive, the function must seriously suffer. In this case there is sometimes a slight diminution of the resonance on percussion of the affected part. The passage of the secretion from a thin to a consistent state, commonly called the *ripening of the cold*, has likewise its distinctive symptom. The bubbles of the mucous rhonchus first become more interrupted, and gradually give place to a clicking, or a sibilant sound, occasioned by portions of the inspissated mucus partially obstructing the bronchi. Sometimes the respiration of a portion of lung is entirely obstructed by a pellet of this mucus in its principal bronchus; and thus the dyspnoea occurring at this stage of the disease is explained. These several symptoms are liable to frequent change from the removal or altered position of the mucus consequent on coughing or expectoration; and it is useful to avail ourselves of this in our examination; for we may thus prevent the mistake of ascribing absence of respiration to peripneumony or any other cause.

The varieties that we have before described as occurring in the progress and termination of acute bronchitis, depend on the character as well as on the extent of the inflammation. In the plethoric and sanguine temperament the inflammation is intense, and remains for a while dry; and the congested and thickened state of the membrane preventing the effectual arterialization of the blood, may in this stage cause dyspnoea. The copious secretion, however, that soon succeeds,

and which appears to take place earlier in the dyspnoea of children, soon becomes an additional interruption to the function, and unless removed by expectoration or re-absorption, may soon amount to suffocation. The suddenness, as well as the abundance of its effusion, increases the danger of its effects; and this is the reason why cases of bronchitis suddenly supervening on a suppressed exanthema are amongst the most formidable. In old people, again, and those of a relaxed habit, there seems to be a serous infiltration accompanying the inflammation, which causes a greater straitening of the tubes in the first stage, than is usual in the other forms; and which is only relieved by a free secretion from their mucous coats.

Morbid Anatomy.—The anatomy of fatal cases of bronchitis, as far as it goes, is in perfect accordance with what we learn from the physical signs. The lungs do not in general collapse on opening the thorax; the escape of air being prevented by the obstructions in the bronchi. These in most instances contain a quantity of frothy liquid, of the quality of the matter expectorated before death. Not unfrequently it is mixed with bloody serum; but this, as it is not perceived in the matter expectorated, has probably exuded from the surcharged blood-vessels at the moment of and after death. Purulent matter is also sometimes observed, and mostly in very acute cases, which have proved fatal within four or five days. The mucous coat presents an appearance of red injection, diffused, or in patches, of various shades from a bright crimson to a brown red. It is sometimes thickened, but rarely softened; and never to the degree in which the gastro-intestinal mucous membrane is frequently found.

Diagnosis.—The diagnosis of acute bronchitis is to be deduced from the leading symptoms which we have given of the disease; and if we avail ourselves of the physical as well as the general signs, its character will be quite distinctively defined. It is distinguished from pneumonia by the nature of the expectoration, which, although in severe cases often viscid, is less so than in pneumonia, and wants altogether that rusty tinge so characteristic of the latter disease: it is also distinguished by the clear sound on percussion of the chest, and the absence of the crepitant rhonchus or bronchophony. (See PNEUMONIA.) From pleuritis, the clear sound on percussion is sufficient to separate it. Both these diseases may, in some cases, be confounded with bronchitis without reference to these tests, but these never fail to decide its character.

Prognosis.—The prognosis in acute bronchitis must depend on the extent of the disease. When the inflammation is partial, affecting a few bronchi only, as in common cases, and without much dyspnoea or fever, it may terminate in from six days to three or four weeks; and its disposition to pass off is always indicated by the expectoration becoming opaque and more consistent, and gradually diminishing in quantity. This change is always first observable in the mornings; the evening exacerbation restoring the thin glairy character to the sputa, even in cases tending towards convalescence. A relapse is marked by the expectorated matter becoming again transpa-

rent and glairy, and this is always accompanied by an aggravation of the cough and other symptoms.

In the more extensive attacks of inflammation, where the dyspnoea is great and unremitting, and particularly where the fever was high in the beginning, the prognosis may be very unfavourable; and if the acute symptoms have already yielded to the state of collapse, it is to be feared that the power of the system is insufficient to restore a function on which the disease has made a serious inroad. The extreme anxiety of the pallid countenance, and a slight appearance of lividity, announce the asphyxiating effects of this stage of the disease; and the universal mucous rhonchus, with little or no respiratory murmur heard on the application of the ear or stethoscope to the chest, gives direct evidence of impending dissolution.

There is sometimes accompanying continued fever a severe bronchial affection, which this examination alone can detect. There is little cough, and the general symptoms so mask the dyspnoea that it may proceed to a fatal termination without being distinguished from the symptoms of general weakness and oppression that severe cases of continued fever commonly present. (See FEVER.)

In severe bronchitis of children, likewise, the real amount of the danger can seldom be appreciated by the general symptoms in time for the effectual application of remedies; but where auscultation discovers, from a universal mucous rhonchus, that the inflammation is extensive, and occupies both lungs at once, great danger may be apprehended, whatever be the amount of dyspnoea and other symptoms at the time; for these frequently come on in paroxysms only, or are scarcely marked in the somnolent state in which the child lies during the remissions.

The danger in asthenic bronchitis, or peripneumonia notha, arises from the weakness and age of the patient; if these are great, there will be a great risk of the strength proving unequal to clear the lungs of the secretion that is so copiously poured out. The respiration of old people bears ill any sudden abridgment; for the more rigid texture of their lungs does not, as in younger subjects, admit of additional or supplementary respiration in the healthy parts. (See DYSPNOEA.) One of the most fatal forms of bronchitis is that supervening on a suppressed eruption.

Treatment of Acute Bronchitis.—1. The slighter cases of acute bronchitis are more frequently objects of domestic than of formal medical treatment. When neglected, however, a common cold may give rise to the most serious complaints; and we are far from subscribing to a prevalent opinion to which even Laennec seems to lean, that it must always run its course. By antiphlogistic diet, and a few simple means calculated to restore the secretions, and, if required, to cause revulsion from the inflamed part, a cold may often be checked in a few days, which if left to itself might run on for weeks, entailing on some subjects other and worse evils. The means which we have found most effectual are as follow:—At the first feeling of the cold, let a purgative be given, with two or three grains of ipecacuanha or James's powder. Let a hot pediluvium be used, the patient getting into a warm and well-covered

bed immediately after, and promoting any disposition to perspiration by a warm draught of thin gruel, barley-water, or any other mild diluent. If perspiration comes on and the purgative operates well, the cold is sometimes already cured; and it is only necessary to remain at home, and to abstain from animal food and wine next day, to prevent a return.

If, however, perspiration do not follow, or if the cough has already come on, the disease generally proceeds, and we must then endeavour to mitigate its severity, and bring it quickly through its course. If the patient cannot, or thinks it not worth while to remain in bed for a day or two, he should clothe more warmly than usual; for the susceptibility of the body is such as to render a very slight exposure enough to keep up the disease, and abstinence from meat and all fermented liquors or spirits is at this period equally necessary. To loosen the cough and lead the bronchial inflammation to the stage of free secretion, small doses of ipecacuanha or tartarized antimony are often most effectual; and, although called a stimulant expectorant, squills, when combined with these, have always appeared to us to exert a beneficial effect: ten minims of the tincture with thirty of the vinum ipecacuanhae, and six or eight of liquor potassae, given three or four times a day, seldom fail to facilitate expectoration and relieve the cough. Whether the alkali act by facilitating the absorption of the medicine, or by any specific action on the vessels of the bronchial membrane, we cannot determine; but its effect in increasing the action of expectorants we have proved in a variety of examples. Should nausea be produced, the dose of the medicines may be diminished; and if the cough is still troublesome at night, a little extract or incture of hyoscyamus may with advantage be added.

This treatment is generally sufficient to relieve the tightness across the chest, which yields as the cough becomes loose; but if the case is obstinate, it may be necessary to resort to a blister, or some of the means which we shall presently recommend for the more severe forms of the disease.

The inhalation of the vapour of warm water may be sometimes useful; but we have seen it in some instances increase the oppression; and from its effect of determining blood to the part, we do not deem it so universally safe a measure in recent bronchitis as it has been represented to be.

With still more force would we object to the cure by spirits or wine, as recommended by Laennec; not that we doubt its occasional efficacy, but from the experience that where it does not cure, it greatly aggravates the inflammation. Towards the termination, when the matter expectorated has become thick and loose, and all febrile symptoms are dissipated, animal food and wine may be indulged in with impunity, and even with advantage. At this period, too, if the disease shows a disposition to linger, much good may often be obtained by using some of the stimulant expectorants, as myrrh, copaiba, &c.; and if necessary, the cough may be allayed by opium. This treatment will be noticed under the head of chronic bronchitis.

There are very many remedies which are in common use for coughs, which it is impossible

here to advert to. The safest are those which are simply demulcent; many are stimulant and narcotic, and often do mischief. Ipecacuanha lozenges is a remedy worthy to be named, as the convenience of its form recommends it when more formal medicines are objected to; and although it is apt to cloy the stomach before sufficient quantity can be taken, it often proves as serviceable as the less agreeable compounds of the medicine.

2. The danger attending severe acute bronchitis renders far more energetic measures necessary; and these, although generally of the same class as those usually directed against acute inflammations, must be exercised with more than usual discretion and caution.

As long as the phlogistic state continues, with high fever, hard pulse, and great feeling of straitness and oppression in the chest, there can be no doubt of the propriety of bleeding more or less freely, according to the intensity of the symptoms, and the strength of the patient; but it is not prudent, as in pleurisy or peripneumony, to bleed to syncope, or to push the measure with an expectation of very marked relief. From sixteen to twenty-four ounces may be taken at first in severe cases: and the repetition of general bloodletting must depend on the state of the pulse rather than on other symptoms. If it is weak, or if the patient is advanced in life, we must endeavour to subdue the symptoms by less violent means, such as local bleeding and medicines, rather than run the risk of destroying strength that is absolutely required for the act of expectoration.

Cupping is generally to be preferred to leeches, as its effect is more speedy and more within control; and it is of considerable advantage to apply it to the part in which auscultation has discovered the greatest obstruction to the passage of the air.

There is an objection which obtains so against blisters, as to exclude their use in many cases of the early stage of acute bronchitis; namely, that before they rise, they always produce an irritating effect on the whole system, which is very apt to aggravate for the time the inflammation for which they are applied. This effect, however, varies much in different individuals, and in those whose skin easily vesicates under a blister, it is obviated by the serous discharge that immediately succeeds.

In other instances, it is advisable to resort to other counter-irritants, and we give the preference to the tartar emetic. To make it available in an acute disease, we have found it necessary to excite the skin previously to its application, by means of a brush or coarse flannel, by applying a warm hand wetted with ether or camphorated spirit, or by a short application of a mustard poultice. The tartar emetic should then be immediately rubbed in, either in the form of a warm saturated solution, or an ointment composed of one part tartar emetic to two of spermaceti ointment. With these precautions we have rarely failed to excite a full pustular inflammation in as short a time as that required for the rising of a blister, with far less irritation to the system, and with decided relief to the pectoral symptoms. We have reason to believe that a minute quantity of the tartar emetic is absorbed into the system, as we have sometimes observed nausea succeed its use: and this, instead of being injurious, as in the case of

cantharides, is a part of the treatment which has been found most serviceable. This brings us to the subject of internal remedies.

At the onset of the disease, the earlier the better, a brisk purgative should be given. Where the inflammation is high, calomel, with a grain or two of ipecacuanha, combined with jalap, scammony, or any of the active cathartics, is to be preferred, and followed by repeated doses of a saline aperient, containing a small quantity of tartarized antimony. This medicine proves useful not only as an evacuant, but as a sedative and diaphoretic, and the nausea, which it sometimes produces, is generally beneficial by modifying the secretion of the bronchial lining, and facilitating expectoration. For the same reason, a full emetic has been generally recommended, and is often decidedly useful; but it is better adapted to children, and to cases in which the bronchial secretion is profuse, than to the more inflammatory forms of the disease.

For the relief of the dyspnoea and cough, those medicines are to be preferred which act on the vascular system. The sensation of dyspnoea is not to be looked on as one merely of discomfort, to be relieved by means which deaden sensibility, but as an indication of the inroad made on a vital function, which, if not restrained, must terminate in its destruction. To aid, therefore, the antiphlogistic measures that we have already recommended, it is proper to administer such medicines as are likely to moderate the action of the vessels and relieve the congested lungs. Tartar emetic, digitalis, and colchicum best answer this indication, and we generally prefer the two former. The tincture of digitalis, in the dose of eight or ten minims, with thirty or forty of the liquor antimoni tartar., three or four times a day, is the form which we usually adopt. Of course it will be necessary to watch the effects of these medicines, and to diminish or discontinue the digitalis if the pulse become intermittent. It will be of considerable advantage to increase the dose of tartar emetic; and if the dyspnoea continue, and the mucous rhus in the chest is undiminished, to persist in its use even should it excite vomiting; for its beneficial effects in peripneumony, to which bronchitis, in its severe form, really approaches very nearly, are sufficient to prove its power to restrain effusion and promote absorption. Dr. Badham strongly recommends this medicine in doses frequently repeated, and increased till the maximum which the stomach can bear without vomiting is attained."

Calomel and opium combined, and given in frequently repeated doses, as in other acute inflammations, are likewise sometimes highly beneficial; and we consider that their use is especially indicated, where, as is not unfrequently the case, the bronchitis is complicated with gastro-hepatic disease. The opium should be in smaller proportion than usual, and is, perhaps, most safely given in the form of Dover's powder.

Should the collapsed stage have come on, and the symptoms of debility show that the function of respiration has been already so much injured as to reduce the excitability of the system, it is necessary to resort to expectorants of the stimulating kind. Of these the best is carbonate of

ammonia, which often enables a patient to expectorate what in his weakness might be sufficient to suffocate him. We are disposed to think that this remedy is more than an ordinary stimulant, and acts in an especial manner on the bronchial membrane.

The attenuating or solvent power of alkalies may with advantage be resorted to in the latter stage of bronchitis, when the matter of expectoration is very consistent, and, lodging in the bronchi, occasions local absence of the sound of respiration, and, if copious, dyspnoea. The liquor potassæ, in doses of ten minims, given with the vinum ipecacuanhæ, is productive of obvious benefit.

From what we know of the effects of the lobelia inflata in suffocative catarrh of the chronic kind, we should judge it to be worthy of a trial in the collapsed stage of acute bronchitis.

Besides attempts to relieve the lungs of the load which prevents the penetration of air into them, another indication presents itself in this stage, which is to obviate the bad effects of black blood in the system; for this it is, unquestionably, that gives that peculiarly depressed and adynamic type which precedes the fatal termination. Here, unfortunately, our experience fails us; and we feel the necessity of appealing to further researches of experimental physiology.

3. It remains for us to notice the modifications of treatment which the several varieties before described require.

In the bronchitis of young children emetics are peculiarly serviceable; for besides the beneficial effect they produce on the inflamed membrane itself, the muscular action of vomiting greatly assists expectoration, which can scarcely be effected at this age. Purgatives, too, are generally of more marked utility than in adults, and, if repeated, may frequently prevent the necessity for general bleeding. Dr. Hastings, however, highly recommends bleeding from the jugular vein; and in imminent cases this is probably the means most to be relied on. Dr. Badham suggests opening a vein in the foot, and immersing it for a few seconds in warm water, which causes blood to flow in sufficient abundance. In these cases, especially, we never can proceed confidently in the treatment without frequently appealing to the physical signs. The disease is so deceitful, (as Dr. Hastings remarks,) that except the universal mucous rhonchus, which nearly or entirely obliterates the respiratory murmur, no indication of the imminent danger can be discovered.

In the asthenic form of the disease in adults, bloodletting is rarely admissible, and never to a great extent. To restrain the secretion in the bronchi, and to rid them of it by means which do not greatly impair the strength, are here the obvious indications. Nauseating doses of tartar-emetic, or even larger, continued as in pneumonia until *tolerance* is established, purgatives, and derivatives, better fulfil these intentions. Blisters answer better here than in the more inflammatory disease, but to be effectual, they should be ample; and it is useful to give squill and digitalis (ten or fifteen minims of the tincture of each, three or four times a day,) during their operation; for the secretion of urine is thus kept free, and there is

less chance of irritation of the system by the cantharides. Dr. Badham recommends assafœtida in the occasional aggravations of the dyspnoea, which he supposes to arise from a temporary spasm in the bronchi. The asthenic form of bronchitis leaves a greater weakness than the more inflammatory; or rather, we should say, the weakness is the consequence of the habit of body which causes the disease to assume the asthenic form. It is therefore generally necessary to use tonics after it to restore the strength; and if an irritable cough remains, without any excitement, opium may be resorted to to allay it. Change of air may sometimes effectually answer both these purposes, and will generally be found a beneficial adjunct.

It is generally necessary to be peculiarly energetic in the treatment of bronchitis supervening on suppressed discharges and eruptions. Extensive counter-irritation, as recommended above, with tartar-emetic, would seem here to be especially indicated. In case of repulsed gout, means should be taken to bring the gouty inflammation back to the limb by mustard poultices and hot water; but these measures are not solely to be depended on.

II. CHRONIC BRONCHITIS.—Chronic bronchitis presents as great a variety of form as the acute disease; and from the complications into which it very frequently enters, it is less tractable in its nature. It is not an easy matter to define distinctly the character which entitles a case of bronchitis to the specific term *chronic*. The duration of the acute disease is very varied; and it is frequently renewed for such a length of time as might truly gain it the name of chronic. The distinction which Andral gives, although by no means perfectly exact, is perhaps the best, inasmuch as it is founded on the pathology of the mucous membrane itself. As long as the expectorated matter remains glairy and viscid, uniting in mass, and without opacity, the inflammation is acute. Towards the termination of an attack of this kind, the sputa become opaque, and are expectorated in distinct masses, which, although consistent, are not very adhesive or glutinous. Sometimes, instead of diminishing and becoming more consistent, as when the disease is about to terminate, they remain in this state, or increase and become diffuent and heterogeneous in quality, without sensible increase of fever; and they then indicate inflammation of the chronic kind.

Chronic bronchitis in its slightest form manifests itself only by habitual cough and expectoration, which are increased by certain changes of weather, and generally prevail most in winter and spring. It is most common in advanced life; and in fact very few old people are perfectly free from it. In its severer forms it is accompanied with dyspnoea, occasional pain in the chest and about the præcordia, and some febrile symptoms, especially towards evening, palpitation, and disorder of the digestive functions. The cough is sometimes very severe, especially at night, and the expectoration copious; and if these persist long, they seldom fail to waste the body and reduce the strength.

The character of the expectoration is various. Generally it consists of a greenish-white mucus, or it may assume a muco-purulent appearance,

and is often mixed with little thin pituita. Sometimes the pituita are abundant, as in pituitous catarrh, and a few masses of brownish or ash-coloured mucus float in it. Sometimes it is purulent, and streaked with blood; and in some cases it is real pus, presenting all the varieties that are seen in pus from other sources. In such instances there are generally a quick pulse and signs of hectic; and the disease tends to a fatal termination, with night-sweats, emaciation, diarrhoea, and all the common symptoms of pulmonary consumption. The worst cases are usually those which succeed to repeated or severe attacks of acute bronchitis, whether of the intense or asthenic form.

Exciting Causes.—When occurring in early life, chronic bronchitis generally follows whooping-cough, measles, small-pox, or some cutaneous eruption, and does not often succeed to an acute attack. A very distinct form of chronic bronchitis is excited by the habitual inhalation of air loaded with dust. Needle-pointers, stone-cutters, those who powder and sift the materials for making china, and leather-dressers, are particularly liable to this affection. In these cases it usually begins with dyspnoea, which may continue for a considerable time before the disease declares itself. In the course of a few months, however, the dyspnoea is increased, and accompanied by severe cough and a copious expectoration, sometimes mixed with pus and blood. Not unfrequently the cough brings on a profuse hæmoptysis. At this time the constitution generally suffers much; the pulse becomes quick; thirst and fever attend; the tongue is loaded; and the aggravations of dyspnoea occasion lividity of the countenance. Unless these symptoms are relieved by remedies, and a total abandonment of the unhealthy occupation, they become worse; the expectoration increases to a great extent, and becomes more purulent; hectic, with night-sweats, succeeds; and the patient dies with most of the symptoms of tubercular phthisis. (See ARTISANS, DISEASES OF.)

Physical Signs and Pathology.—The physical signs of chronic bronchitis do not materially differ from those of the acute disease. The resonance of the chest on percussion is scarcely if at all impaired. The respiration is varied in its distinctness, being often louder than usual, but occasionally obscure, and accompanied with mucous rhonchus. This rhonchus is not universal over the chest, and seldom accompanies the whole of the respiratory act. It very rarely happens, as in the latter stage of acute bronchitis, that the respiration is completely interrupted in a part of the lungs; and this proves that the mucus is in a more diffused state, and yields to the air passing through the bronchii. Occasional sonorous and sibilant rhonchi prove the partial obstruction of the air-passages; and this may be either by a thickening of the mucous membrane, or by portions of thick mucus; but these symptoms are not so common in chronic bronchitis as in the dry and pituitous catarrhs.

A remarkable feature in chronic bronchitis is, that dyspnoea is not unfrequently present to a considerable degree, when from the sound heard in the chest it is plain that the air enters the lungs

as well as or better than usual; the respiration being distinct or even puerile. For a complete consideration of these apparently contradictory phenomena we must refer to the article DYSPNOEA, and shall merely remark here, that the nature rather than the quantity of the bronchial mucus is probably the cause of the symptom in question.

The continuance of inflammation has the effect, ultimately, of altering the texture in the mucous membrane of the bronchi as in other parts. Its greater tenuity and simplicity of structure exempt it from a number of the changes which are incident on the gastric and intestinal mucous membranes; but it is nevertheless subject to softening, ulceration, induration, and thickening; and the effects that these produce on the caliber of the bronchi are worthy of our attention.

Morbid Anatomy.—The mucous membrane is frequently found, on dissection, of a deep red colour, the redness being diffused or in patches. It is of a more livid or violet tint than in the acute disease, where it is usually brighter and more verging on brown. Not unfrequently, however, the membrane is quite free from this; it is sometimes even whiter than usual, and this in cases where there has been copious purulent expectoration. Softening does not occur to the extent to which it goes in inflammation of the gastric mucous membrane, and the simpler nature of the membrane explains this. (See SOFTENING OF ORGANS.) Ulceration is also rare, particularly in the smaller branches of the bronchi, except in those cases which arise from the inhalation of dust, in which the mucous membrane is generally ulcerated, often to a considerable extent; and the thickening and general alteration of structure are greater than in the ordinary cases of chronic bronchitis. The ulcers are usually small, clean, and do not extend below the mucous and sub-mucous coats. Thickening of the membrane is a more common effect, and it sometimes occurs to a very notable extent, nearly obliterating the cavity of the tube. It is rarely uniform, but generally affects several points, particularly at the bifurcation of the tubes.

Another and very remarkable state, produced by chronic bronchitis, is a *dilatation of the bronchi*. It is not of very unusual occurrence, and presents itself to the anatomist in different forms. Sometimes a single tube is dilated at one or more points into a sac of various sizes, in some examples capable of containing a walnut. In other instances the dilatation is uniform, and extends to several tubes, which enlarge, instead of diminishing, as they divide. Thus a bronchus of the size of a straw is seen to dilate to that of a goose-quill. Sometimes several branches from the same tube are affected in this manner. The mucous membrane can always be distinctly traced from the undilated portions of the tubes, and usually with some difference in its texture. It is sometimes thickened; in other instances so extremely thin as to give the dilated portions the appearance of shining vesicles amongst the pulmonary tissue. Occasionally either the mucous membrane or the circumjacent coat becomes considerably indurated, so that the dilatations are rigid, and scarcely susceptible of compression or dilatation; but the

mucous membrane is more frequently softened, so that it can be scraped off by the nail.

These dilatations, as the diseased bronchi in general, are frequently found full of pus, mucus, or whatever kind of matter has been expectorated before death.

Laennec considers these organic changes to be produced simply by the thick mucus accumulating and gradually causing a mechanical distension of the tubes. But in this case we should discover more frequently an absence of the respiratory sound in the part: such a sign, although common in the latter stage of acute bronchitis, scarcely ever occurs in the chronic disease. We are more disposed to ascribe them, with Andral, to the altered texture of the membrane; but even this is only the predisposing cause. The physical cause of dilatation of the bronchi, we apprehend, is to be found in acts of respiration and cough exerting a degree of pressure on the softened membrane, greater than its elasticity can resist. Thus the forcible inspiration which succeeds each fit of coughing acts with greater effect on these weaker parts; and again, the violent expiration of coughing brings an undue pressure on the same tubes, which, distended in one part, and partially obstructed by the thickening of their membrane in another, are perpetually exposed to a straining influence. Induration, the effect of another degree of the inflammatory process, sometimes succeeds, giving the dilated portions that rigidity that is occasionally noticed in them. The effect of these dilatations must be to obliterate the neighbouring cells, and to abridge the function of the lung. Accordingly the adjacent tissue is found, on dissection, to be dense, and deprived of its cellular structure; and when extensive, the disease thus causes habitual dyspnoea.

Diagnosis.—The characters of chronic bronchitis are such as easily to distinguish it from all diseases except pulmonary consumption. The severer forms sometimes so closely resemble this disease, that it is impossible to distinguish them by the general symptoms; and even with the aid of auscultation and percussion the distinction is often very difficult. The presence of pus in the expectoration, which was formerly considered characteristic of phthisis, is, we have already seen, very common in chronic bronchitis; and in fact, that which occurs in the course of phthisis, proceeds more from the inflamed bronchial tubes, than from the tubercular excavations themselves. So likewise, hectic, night-sweats, emaciation, and diarrhoea, frequently accompany both diseases.

When unattended with dilatation of the bronchi, an attentive examination of the physical signs will, however, enable us to form a pretty sure diagnosis. It is in the absence of the signs of phthisis that we recognise the character of chronic catarrh; and as this negative test is weaker than positive proof, so it is necessary that it should be often repeated to produce certainty. If, after having repeatedly examined the patient, at different hours, during several weeks, there are found no gurgling cavernous rhonchus, no cavernous respiration, no pectoriloquy, and no constant absence of the respiratory murmur, and of the sound on percussion, we may, with tolerable certitude, pronounce the disease to be simply pulmonary

catarrh; and a still further multiplication of examinations will remove all doubt.

But if there be considerable dilatation of the bronchi, the same signs which are produced by tuberculous excavations in phthisis may likewise occur in chronic bronchitis. If the dilatation is produced at one part of the tube, and is of a rounded shape, it may be the seat of pectoriloquy and cavernous rhonchus, in the same manner as a tuberculous cavity of the same size: but if, as is the more common case, the tubes are more uniformly and generally dilated, the vocal resonance in the tubes scarcely amounts to pectoriloquy, but is rather a loud bronchophony; and the breathing is accompanied with a *whiffling* sound, more distinct than the bronchial respiration of peripneumony. It is only by attention to the progress of such cases that they can be discovered not to be phthisical. A tuberculous excavation rarely remains stationary as these do, but enlarges and gives a pectoriloquy of a greater extent; whilst other excavations are usually formed in other parts. Dilated bronchi rarely affect the sonoreity of the chest on percussion to the degree that the engorgement and infiltration about tubercular excavations do; nor can they produce the other physical signs of large cavities. The most common situations of dilated bronchi are in the scapular, mammary, and lateral regions: the subclavian and acromian are the more usual seats of phthisical signs.

The only instance in which the sputa can assist in the diagnosis is, when they declare themselves phthisical by the presence of tubercle, or portions of the pulmonary tissue; in other respects they may be exactly the same. A remarkable fetor has been repeatedly observed in the sputa where the bronchi were dilated.

It must be confessed that cases do occur, although rarely, which leave the most experienced auscultator in uncertainty; but these are exceptions of comparatively little practical importance, and hardly detracting from the utility of auscultation. For it need scarcely be remarked that dilatation of the bronchi is quite incurable; and it is often connected with such extensive lesion of the bronchial membrane as would leave the prognosis the same as in phthisis.

Prognosis.—The prognosis in chronic bronchitis depends very much on its origin, and on its simplicity or complication with other disorders. When succeeding to an acute attack, and when unattended with much derangement of the general functions, it does not tend to a fatal termination. Even should there be some purulent expectoration and hectic, favourable circumstances will sometimes bring about a cure; and slighter forms, though obstinate and lasting for years, seem scarcely to have any effect in abridging life. But in its worst character, with constant dyspnoea, copious purulent expectoration, hectic, and emaciation, and especially if attended with symptoms of confirmed disease in the abdominal mucous membrane, or in the liver, it is nearly as fatal as phthisis itself. In these cases of complication, the bronchitis is frequently secondary; and there are abundant examples which prove that it may disappear entirely, if the abdominal disease is of a tractable nature, and yields to treatment.

In many cases the prognosis must depend on the nature of the physical signs: the disease is itself an attendant on phthisis; and if these do not establish with certainty that tubercles are not present, the case must always be considered of doubtful prospect. In the first stage of phthisis an extensive bronchial inflammation frequently attends, when the tubercles are very numerous and generally dispersed, before the stage of softening has come on. In all cases, therefore, which the history and constitution would indicate to be phthisical, the presence of a general mucous rhonchus, with partial dulness on percussion, must be considered a sign of the worst import, for a tubercular disease of this description generally runs a speedy and fatal course.

The cases of simple bronchitis that prove fatal are those in which the mucous membrane has become so altered in its structure and function, that it permanently impedes the oxygenation of the blood, and wastes the body by its secretion, and the wearing efforts to evacuate it. These generally occur in old persons, and those already reduced by fever or a severe attack of acute disease. [*Bronchitis asthenica, Bronchorrhœa.*] One effect of the constantly imperfect oxygenation of the blood which attends bronchitis, is a stagnation and congestion of blood in the lungs and heart; hence organic diseases of the heart, and effusion of blood and serum, not unfrequently supervene to its long continuance.

Treatment of Chronic Bronchitis.—In the treatment of chronic bronchitis, as of all chronic diseases, regard must be paid to the time required for the cure, and the strength economised accordingly. Unless in case of a temporary increase of pulmonary congestion, or aggravation of inflammation, bloodletting is not admissible; for besides its bad effect in adding to the weakness, which is one of the worst characters of the disease, it has but little power to control the action of vessels under the influence of chronic inflammation. Those remedies are to be preferred which act on the extreme vessels, whether directly, in the diseased part, or by establishing a new action in another part of the system.

The objection which we urged against blisters in the acute disease does not apply here; and they are often in a high degree serviceable. It is generally necessary to repeat them several times; for few cases yield to a single application. In some constitutions they produce a great prostration of strength, and in others their beneficial effects do not continue: in such cases an effective substitute will be found in tartarized antimony, as recommended in the acute disease. The suppurative inflammation that this excites is often more efficacious in removing inflammation from a deep-seated part than the irritation of a blister, the effects of which usually cease with the serous discharge. When it happens that a blister suppurates, a more permanent benefit is obtained; but keeping up the irritation by means of cantharides or savine ointment has not the same effect, and is more painful than salutary. Counter-irritation by tartar-emetic may, by attention, be regulated to any degree; and by slight re-application a constant succession of pustular eruptions may be continued for months, if required. From this

measure, conjoined with internal medicines, we have seen the happiest results in cases of the most formidable aspect; and we have scarcely ever known it fail to give some relief. It seems to moderate the irritation and secretion of the bronchial membrane, which often changes from purulent to mucous during its use; and it enables the system to bear a tonic and nutritive regimen without aggravation of the bronchial disease. It is by the success of a measure of this kind that a well-known modern empiric has gained a name famous enough to blind many to the gross ignorance with which he has applied it.

[Dr. Graves (*A System of Clinical Medicine*, Dublin, 1843,) has recommended the formula published at page 222 of this volume, as an imitation of the liniment of this empiric, (St. John Long,) which, he affirms, is an easily manageable and efficacious remedy.]

A large portion of the chest may be sponged daily with the liniment, so as to keep up an erythematous state of the surface.]

The utility of expectorants in the chronic form of bronchitis has been called in doubt by the question—on what principle can they be prescribed, when the secretion is already redundant? But let it be remembered that the power of expectorants is not confined to increasing the bronchial secretion; they tend also to modify it. Thus, in acute catarrh, under the same expectorant that at first tends to *moisten* the cough, the mucous secretion becomes consistent, diminishes, and gradually returns to its healthy state. Ipecacuanha is certainly capable of producing this effect, and is perhaps the most generally useful expectorant that we possess. In some cases it may be given with great advantage in emetic doses, repeated every two or three days. In some obstinate examples of the milder form of the disease attacking persons of robust habit, this practice has effected a cure. As an expectorant, it may be given in the dose of a grain or two of the powder, or twenty minims to ʒss of the wine, repeated several times in the day, according to its effects, and combined with squill, colchicum, digitalis, and opium, as the case may require. It is a useful adjunct to any expectorant medicine, and is only contra-indicated in case of profuse night-sweats.

Squill is of decided utility in some instances of chronic coughs, but rather in cases which are slighter and unattended with purulent expectoration. It is generally useful to combine it with an alkali; and a small quantity of opium may be added to prevent it from passing off too rapidly by the kidneys.

Wherever the circulation is much accelerated, and the dyspœa is distressing, the tincture of digitalis is very likely to afford relief; and those cases which simulate phthisis are frequently fit subjects for its use; but it is necessary to watch its operations, both on account of its effects on the circulation, and its tendency to disorder the stomach and digestive organs. The same thing may be said of colchicum, which is highly spoken of by Dr. Hastings, who recommends the tincture in the dose of twenty drops three times a day, increased or diminished according to the effects.

The *lobelia inflata* is a medicine less known

in this country than it deserves. Its action seems to be of the same class as colchicum and squill, but it is more decided in its effects, and therefore likewise requires greater care in its exhibition. It may be tried first in the dose of ten minims of the tincture three times a day; in many cases this may be increased to forty or fifty; but in others not more than five minims are borne without nausea, vertigo, and a feeling of faintness. From the manner in which it relieves the dyspnoea, it is probable that it operates as a sorbefacient as well as an expectorant. It is especially serviceable in those aggravations of chronic catarrh, which Laennec designates by the title of *suffocative*, and which do, in fact, sometimes produce suffocation.

In such cases, likewise, ammonia becomes a valuable remedy; and the one, in extreme cases, when suffocation is threatened, on which we must principally depend. From five to ten grains of the carbonate may be given in camphor mixture, and repeated, if necessary, every hour or half hour, according to its effects. In the weak and atonic cases, without profuse expectoration, it is a useful adjunct to squill, ipecacuanha, and other medicines, instead of the fixed alkalies; and, conjoined with assafoetida or musk, it is well suited to diminish the convulsive character of some habitual coughs, which are very apt to wear down the patient, and deprive him of his nightly rest.

[Tar-water was at one time greatly extolled in pulmonary affections, and, among the rest, in pulmonary catarrh, and in chronic bronchitis; and since the discovery of creasote—the main active ingredient in tar-water—fresh trials have been made with it. It is occasionally of service, where the ordinary excitant expectorants are indicated. Creasote itself has been given in the same cases; but it does not seem to possess more virtue than tar-water.]

It would be endless to go through all the remedies that have been extolled as effectual expectorants in chronic bronchitis. All the balsams and gum-resins have enjoyed this reputation, and fallen again in disrepute: some, as copaiba and myrrh, have been resumed by some practitioners, and not without reason; but their utility is limited to cases of the atonic kind. Myrrh we have found really serviceable, particularly after a course of the other expectorants, when its grateful and tonic effects on the stomach give it an additional recommendation. Copaiba frequently disagrees with the stomach; but when it is well supported, it often restrains and modifies the bronchial secretion. Neither of these medicines is eligible when fever or vascular irritability is present; and it may be considered a matter of doubt whether they do not act rather as general stimulants than peculiarly on the bronchial membrane.

[The acetate of lead has been thought worthy of great reliance in bronchitis accompanied by profuse secretion; its administration being limited to the period of the disease in which the secretion is excessive. The dose should not exceed twelve grains in the day, to the adult.]

There is a class of remedies from which, if they were better known, much good might be expected; those, namely, directly applied to the diseased membrane itself by inhalation. The

vapour of water does not seem to possess any property to recommend it in chronic bronchitis, unless it be in those rare cases of deficient or very viscid secretion, where it may be of some use in relaxing the vessels and facilitating expectoration. Whether combining it with chlorine or with the vapour of iodine, as lately practised in Paris in consumptive cases, may be of any avail in this affection, we want data to determine. It is probable that they can scarcely be exhibited for a sufficient length of time to be effectual in a very diluted form; and when stronger, they decidedly irritate and prove injurious.

The diffusion of the vapour in the air of the apartment, as has been done with tar, is a preferable method, as it ensures the constant application of the remedy without extra fatigue to the patient. The inhalation of tar-vapour has had repeated and extensive trials since Sir A. Crichton directed the attention of British practitioners to it; and although its utility in phthisis has not been confirmed, many have testified to its beneficial effects in certain cases of chronic bronchitis. As it is of a stimulating nature, it proves useful only in cases free from irritability or from tendency to active inflammation; and it is important to watch its effects when first employed, and to diminish or withdraw it altogether, if it decidedly aggravates the cough, and quickens the circulation.

[Iodine has been administered;—at times, alone; at others, associated with conium, as advised by Sir Charles Scudamore, in tubercular phthisis (q. v.); but whilst some extol it highly, others have not observed the least benefit from it. Conium, and other narcotics, have been used in the same manner—twelve or fifteen grains of the extract being diffused in an inhaling apparatus, and the vapour drawn into the lungs for a quarter of an hour, once or twice a day.]

Another class of remedies may in many instances of chronic catarrh be judiciously conjoined with those already noticed; those, namely, that deaden sensibility, and allay that mobility of the muscular system which greatly increases the length and frequency of the fits of coughing. The most powerful of these narcotics, of course, is opium; but on account of its tendency to check secretions and increase local congestions, it cannot with propriety be given alone, unless occasionally, for the sake of obtaining a night's rest. In this case the acetate or sulphate of morphia, or any of the acid preparations of opium, such as Battley's liquor opii sedativus, is to be preferred; and these will generally be found to be safer medicines for habitual use, in combination with squill and ipecacuanha or other expectorants, than the tincture or solid form of opium. The tinctura camphoræ composita is also a very useful narcotic in chronic coughs of the less inflammatory kind.

There are other narcotics of very high utility, and which are free from the disadvantageous properties that opium sometimes manifests. At the head of these may be placed conium, the extract of which, in the dose of four or five grains three or four times a day, very signally relieves cough and irritation of the chest. Dr. Paris, who greatly extols this remedy, recommends the dose to be

increased until it produce some giddiness, tremor, and vertigo, or a heavy sensation and tightness in the forehead; unless some of these sensations are produced, he considers that the remedy has not had a fair trial. It is always advantageous to combine it with ipecacuanha; and the extract of lyoscyamus is indicated where an additional narcotic power is desired. The extract or leaves of belladonna, in the dose of a grain or two, we have found a useful adjunct where dyspnœa is present. The tincture of digitalis may be used with the same view; and either of these medicines is to be preferred to the hydrocyanic acid, which, notwithstanding the praises lavished on it, must be considered at least a very uncertain remedy.

Besides these means, directed against the local disease, it is of the greatest importance to attend to the state of the functions in general. Whenever any fever attends, the daily exhibition of a saline purgative is advisable. In the more atonic cases, if aperient medicine be required, a compound colocynth or aloetic pill is to be preferred; and where the cough shows a convulsive character, we have seen the greatest advantage result from the daily use of the pil. aloës et assafœtidae combined with ipecacuanha.

Should there be, as there very often is, any complication with abdominal disease, it is of the first consequence that this be not neglected. Thus, when pain of the right side and shoulder, with fulness and tenderness in the right hypochondrium, stools of unnatural colour, a foul tongue and turbid urine, discover disordered function of the liver and alimentary canal, it will be proper to put the patient under such an alterative course of blue pill and the like medicines as may be best calculated to bring back the healthy action of these important viscera.

Again, where a florid tongue, tender epigastrium, frequent thirst, dry skin, and nightly accession of fever, indicate that the disease extends to the mucous membrane of the stomach and bowels, it is quite apparent that many of the remedies directed against the bronchial disease will not be borne or will prove injurious, until the gastric disease be relieved by leeches and blisters to the epigastrium, castor oil, the mildest alterative aperients, and warm baths, with the most rigid regulation of diet. For more ample directions on this head we must refer to the several articles GASTRITIS, DYSPEPSIA, &c. Whether these diseases be primary or secondary is a consideration of less consequence than that, as long as they continue, the action of all remedies on the bronchial disease must be uncertain or prejudicial. Thus it is that even digitalis and colchicum may prove stimulant until the gastric disease be subdued.

If due attention be paid to the removal of such complications, and if the disease do not present a decidedly inflammatory character, the weakness of the system may be combated by tonics, especially the sulphate of quinine. In case of profuse perspirations, these are scarcely to be dispensed with, and may properly be combined with sulphuric acid.

The diet in all cases of chronic bronchitis should be mild and simple in its nature. Farinaeous and milky food is that best adapted to the plurality of cases, particularly when accompanied

by gastric disorder; but in those cases that require nutrition in a smaller bulk, simple animal food is not to be withheld. Notwithstanding the eulogy bestowed by Laennec on the spirituous treatment of chronic mucous catarrh, we consider spirits and all fermented liquors in themselves as decidedly injurious; and they are only to be admitted in a very few cases, where their assistance in the digestive process is absolutely required.

It is scarcely necessary to insist on the importance of avoiding extremes and sudden transitions of temperature, improper clothing, and all those circumstances that are in themselves frequent exciting causes of the disease: when re-applied, they must necessarily prolong it; and not a few instances are met with where, owing to the nature of our climate, it is impossible sufficiently to avoid them. In these cases, in spite of the most careful administration of these remedies, the disease persists; but a perfect cure is effected by simple removal to a more genial climate. This is, perhaps, the most effective remedy that can be resorted to; and where the circumstances of the patient do not permit him to adopt it to its full extent, a change of air to the distance of a few miles may often be productive of good. The careful regulation of the air in his apartments must be his resource in the winter months. (See CLIMATE and RHEUMATISM.) It is of importance to attend not merely to the temperature, but also to the hygrometric state of the air; and it may be useful in some cases to follow Dr. Paris's plan of diffusing the vapour of water through the room during the prevalence of those dry easterly winds which irritate the mucous membranes, and aggravate the cough.

Of the means which may be called prophylactic against bronchitis, that of sponging the chest daily with salt water, or vinegar and water, deserves warmly to be recommended. If this, which may be practised by the most delicate, and the cold plunge or shower-bath for those stronger, were more commonly resorted to, the number of pulmonary invalids would be greatly diminished.

[But few invalids, who are subject to bronchitis, can bear with impunity the contact of very cold air with the pulmonary mucous membrane; hence they are compelled to breathe through folds of gauze, or to hold a handkerchief to the mouth, whenever they are exposed to it. An instrument has been invented by Mr. Jeffreys, called a *Respirator*, which consists of several strata of fine wire, through which the air can pass with facility; and, in its passage, have its temperature modified, so that no irritation is produced in the lungs. The invention is ingenious and useful.]

C. J. B. WILLIAMS.

[III. ACUTE EPIDEMIC BRONCHITIS. (See INFLUENZA.)

IV. SUMMER BRONCHITIS.—This singular affection has received various names. It has been called *Summer Catarrh*, *Hay Asthma*, *Hay Fever*, and *Rose Catarrh*, and is met with in the summer and autumnal seasons, both in this country and in Europe. It has received those various names as indicative of the period of the year at which it occurs, or of the causes that give rise to it.

Diagnosis.—The most common symptoms are itching of the eyelids, and, at times, of the inner canthi of the eyes, with irregular attacks of violent sneezing, sense of weight in inspiration, and, at times, considerable dyspnœa, copious discharge from the Schneiderian membrane, redness of the conjunctiva, and sense of weight in the forehead, with suspension—partial or entire—of smell and taste during the continuance of the disease. The exacerbations have been commonly observed to supervene in the morning, a short time after rising; but frequently they appear several times in the course of the day. Many letters have been published from patients descriptive of their sufferings from this strange malady. (Elliotson's *Principles and Practice of Medicine*, Rogers's edit., p. 720: Lond. 1839; and the writer's *Practice of Medicine*, 2d edit., i. 273: Philad. 1844.) The attacks appear at times with such regularity, that individuals have made it a point to transact important business prior to a certain day of the year; being aware, from their experience, that on that day they are almost certain of the presence of their annual visiter.

The functional phenomena of the disease do not place it, as one of its names would import, under nervous or spasmodic asthma. It appears to consist essentially in inflammatory irritation of the mucous membrane of the eyes, nose, and the whole respiratory apparatus,—the dyspnœa originating in this cause. It is rather a form of chronic or subacute bronchitis, and scarcely to be regarded as a combination of catarrh and asthma, as it has been by some.

Causes.—The prevalent idea is, that summer bronchitis arises from vegetable matter diffused in the atmosphere; that it is derived from the flowers of certain plants, and that, in a great number of instances, it comes from grass or hay; but it is against the notion of the effluvia from hay being a common exciting cause, that haymakers themselves are said to be entirely free from it; and that it is often met with in towns, where such effluvia, if they exist at all, cannot be in any considerable quantity.

The rarity with which the disease is seen sufficiently proves that the predisposition lies in idiosyncrasy, which would seem at times to be derived from progenitors. When such predisposition exists, the smell of hay may act as an exciting cause; but in other instances it may be an emanation of a very different kind. The odour of ipecacuanha is one of the most frequent excitants: with others, the same effect is induced by the smell of the rose, the bean-flower, the guinea-pig, &c. &c.; and the case of an English nobleman is recorded, who is affected with sneezing and asthmatic symptoms if he touches a hare, or rather the fur of a hare. Cases of periodical bronchitis, analogous in their character to hay asthma, occasionally occur in which hay can by no means be ranked as a cause. An interesting example of this kind has been given by the writer elsewhere. (*Practice of Medicine*, i. 275.)

Treatment.—It does not appear that much advantage is derived from medicine in this disease. The cold shower-bath has been regarded as the best prophylactic, especially when associated with the internal use of the sulphate of quinia and the

sulphate of iron, which, although not wholly compatible chemically, form a compound that has been productive of advantage; two or three grains of the former and one grain of the latter being given three times a day. A journey to the seacoast has likewise been advised, and, from change perhaps, the paroxysm has been prevented. When the disease is fairly formed, it runs its course greatly unmodified by remedies. It does not bear depletion well nor a sedative course; yet a drachm of the tincture of lobelia three times a day is asserted by a recent writer to generally afford relief; whilst another has found a cup of strong coffee without sugar or milk the most successful remedy.

Too rigorous a diet and too free exposure to air have been prejudicial to almost all.

Distressing as the affection is, it is consolatory to know, that during the autumn it gradually ceases and disappears,—too often to recur at the same period in subsequent years. The efforts of the practitioner can only palliate the urgent symptoms, and even in this respect his powers will be found very limited, and his attempts to afford relief too often either wholly nugatory, or productive of unexpected aggravation of the symptoms.

ROELEY DUNGLISON.

BRONCHITIS ASTHENICA. (See BRONCHITIS, CHRONIC.)

BRONCHOCELE means, literally, a swelling of the throat, from βρόγχος, *guttur*, and κήλη, *tumor*; and, in fact, every indolent tumour on the fore-part of the neck, until recent times, passed under that denomination. Modern physicians, however, have confined the term to a chronic enlargement of the thyroid gland, sometimes complicated with a morbid growth in the surrounding structure. There is no precise name for the disease in this country; but, from being more common in Derbyshire than other parts, it has sometimes been called the "Derbyshire neck." In Switzerland, where in many parts it is endemic, it is called *goître*, probably a corruption of *guttur*, and is generally an attendant on that humiliating state of body and mind known by the name of *cretinism*. There is, however, by no means an invariable fellowship between the two diseases, although Professor Fodéré has ascribed the mental imbecility to the state of the gland, (*Traité sur le Goître et le Crétinisme*, 8vo., Paris, an 8,) and Dr. Rush, of Philadelphia, has even deduced a theory respecting its uses from this supposed causation among other things, (*Medical and Physical Journal*, vol. xvi. p. 208.)

The tumour, as we have stated, is of a chronic or indolent nature, increasing gradually, and often continuing for many years, or even a whole lifetime, without affecting the general health. It usually appears in early life, and is much more common among women, especially those of a lax fibre, than among men; insomuch, that in this country it is very rarely met with in the male sex. [It would seem, however, that in Switzerland, and in some parts of India, where the disease prevails extensively, the proportion of males is greater.] In all the cases admitted at the Hampshire County Hospital during the last ten years, amounting to forty-nine, the patients have, with only one exception, been women. We are informed by Dr.

Forbes, that out of seventy patients treated at the Chicester Dispensary and Infirmary during the last nine years, only two have been males. It is also worthy of notice, that both the latter cases occurred in boys of a very feeble and feminine habit of body, and very backward for their years. The disease has, in some instances, been observed to make its first appearance during parturition, and, in other cases, to have made rapid progress during gestation or suppression of the menses, (M. Brun. *Thèse sur Bronchocele*. Paris, 1815.) The swelling generally embraces the whole gland, but is sometimes confined to the lateral lobes, or the middle lobe, separately. It is usually soft and rather flabby to the touch, though somewhat unequal in that respect, and is for the most part free from pain and of a natural colour. It varies in shape, at first presenting but little outline, and while of moderate dimensions, possessing a more rounded and compact appearance than it afterwards preserves. When of considerable size it has a pendulous form, not unlike the dewlap of a turkey-cock, the bottom being the largest part. In point of magnitude it varies still more remarkably; often remaining through life of no very conspicuous size; in other cases increasing to a degree of hideous deformity: sometimes it rises as high as the ears. Alibert mentions one instance in which it descended to the middle of the sternum; and another in which it was of a tapering cylindrical shape, and reached to the middle of the thigh, (*Nosologie Naturelle*, t. i., pp. 466-468. Paris, 1817.) In cases of great enlargement it impedes respiration, deglutition, and the return of the blood from the head, by its pressure; thus occasioning hoarseness, wheezing, flushings of the face, headach, giddiness, and, in some instances, even death. In these extreme cases there are occasional pains in the tumour, and the skin becomes of a livid appearance, with the veins on its surface much swollen. The late Dr. Parry, of Bath, often observed bronchocele to follow diseases of the heart, epilepsy, and other maladies in which the blood is propelled with excessive momentum to the head, (*Elements of Pathology*, p. 187, 8vo. Lond. 1815.) Flajani has seen it accompanied with palpitations and irregular and intermitting pulse; and he believes that fatal disease of the lungs has been induced by the consequent disorder in the pulmonary circulation, (*Collezione d'Osservazioni e Riflessioni di Chirurgia*, t. iii. p. 293, 8vo. Roma.)

On dissecting the tumour, Hunter and Baillie found it to contain cells with a fluid more or less viscid; and Mr. Benjamin Bell states this to be frequently the nature of the disease. "These cells," says Baillie, "vary in their size in different parts of the same gland, and in different swellings of the same kind in different individuals. Some of them are so large as to be able to contain a small pea, but most of them are of a smaller size. The viscid fluid, when the gland has been preserved some time in spirits, is changed into a transparent jelly. From this account of the morbid change of structure which takes place in bronchocele, it seems not unreasonable to suppose that the swelling depends upon a vitiated and increased secretion in the gland. The secretion, being in large quantity, gradually distends

the cells, increasing thereby their capacity, and this enlargement of the cells forms the general swelling of the gland, (*Morbid Anatomy*, 8vo., pp. 87, 88.) The tumour is sometimes steatomatous. It is rarely found to contain purulent matter. Occasionally it has been in part converted into cartilage or bone. Dr. Hedenus, of Dresden, states that he has almost uniformly found this to be the case, (*Graefe's Journ. der Chir.* b. ii. Berlin.) Sometimes the enlargement of the gland is a true sarcoma. Dr. Mason Good names it *sarcoma cellulostum*, or cystose tumour, and states that it generally consists of "oval cells, currant-sized or grape-sized, containing a serous fluid, sometimes caseous," (*Study of Medicine*, vol. v.) Celsus has briefly and accurately described the appearances on dissection in these words: "Modo caro hebes, modo humor aliquis, melli aquæve similis, includitur; interdum etiam minutis ossibus pili immisti," (*Lib.* vii., cap. 13.)

[Occasionally, the whole organ is transformed into an osseous capsule, filled with various kinds of matter, especially the jelly-like, the suety, and the meliceric. Dr. Gross (*Elements of Pathological Anatomy*, p. 16: Boston, 1839,) states, that he has a specimen of the kind in his cabinet: one of the lobes has almost disappeared; the other is converted into a firm, solid capsule, as hard as bone, though scarcely a line in thickness. On sawing through this osseous tumour, which does not exceed the volume of a hen's egg, he found it filled with a white, lardy, friable substance, not unlike semi-concrete cheese.]

There have been instances in which the tumour has exhibited a complication of almost every diversity of structure. De Haen relates a striking example of this, in a person who died of dropsy from visceral tumours. "In cadavere horrendam mole thyroidæam glandulam nactus, publice dissecui. Mecum auditores mirabantur nullum ferè genus tumorum dari, quin in hac sola thyroidæa inveniretur. Hic enim steatoma, ibi atheroma, alio in loco purulentus tumor, in alio hydratrius, in alio erat coagulatus sanguis, fluidus fere in alio, imo hinc glutine locus plenus erat, alibi calce cum sebo mista," &c., (*Rat. Medendi*, pars vii. p. 285.) These circumstances countenance the opinion that the same causes may produce most of the different kinds of tumour, the modifications depending upon the difference of site, habit of body, idiosyncrasy, &c.

There are some other diseases with which bronchocele might be confounded, and which have indeed at times been included under the same name. Thus, the thyroid gland is occasionally attacked with acute inflammation, though, perhaps, less liable to it than most other glands of the body. In such cases, however, the swelling is more rapid in its progress than in bronchocele, but does not attain so large a size: it is firmer to the touch, painful on pressure, and the disease is much more liable to terminate in suppuration. Again, schirrus of the gland may be distinguished from goitre by its great hardness, by occasional darting pains in the part, and by its generally occurring in advanced age, and seldom attaining to any great size. Alibert, however, states that he has seen an instance of true goitre terminating in cancer. (*Nosologie Naturelle*) Aneurisms,

though they do not frequently occur in that situation, might possibly be mistaken for bronchocele; but they may be distinguished by their sudden appearance after violent exertion, particularly in coughing or laughing, by their being soft and compressible, by their situation directly in the course of the carotid arteries, and by their strong pulsation. The lymphatic glands are sometimes so enlarged, in scrofulous cases, as to form tumours of considerable size in the course of the trachea; they may, however, be distinguished from this disease by their greater tenderness on pressure, sometimes by an evident sense of fluctuation, by their being accompanied with swellings in other parts, and by the state of the general health. In some instances, indeed, the thyroid gland has, on dissection, been found in a natural state, the whole of the tumour consisting of a diseased state of the lymphatic glands and cellular membrane surrounding it. Instances have occurred of tumours arising in consequence of the lining membrane of the trachea being forced out between the cartilages in violent fits of coughing, sneezing, laughing, or other exertions of the lungs. Cases of this kind are styled the *real bronchocele* by M. Larrey. They might, perhaps, with more propriety, be called *hernia gutturis* or *hernia bronchialis*, names which have been sometimes given to the common bronchocele. Certainly, however, this is not the disease which has been usually known by the name of bronchocele, and to which the term is now almost universally confined; and as we are not at present considering the nosological propriety of the designation, we would include such cases among the spurious goitres. Their most characteristic symptom is the complete disappearance of the tumour when compressed. The voice, too, is almost entirely lost, and the respiration performed with the mouth wide open. Larrey observed it most frequently among the blind people who are employed by the priests to chaunt at the tops of the minarets in Egypt; and he met with two cases of it in subaltern officers, who had for a considerable time been employed as military instructors. (*Medical Gazette*, vol. vii. p. 88.) Dr. Barton, in his memoir on goitre as it prevails in America, states, on the authority of Foderé, that air has sometimes been forced, in like manner, into the substance of the thyroid gland and the surrounding cellular membrane. (*Medico-Chirurg. Trans.* vol. xi. p. 242.) Whether this be so or not, it appears certain, from the statement of various authors, that the tumour is often increased on exertion of the lungs. Goitre may also be confounded with encysted tumours situated in the course of the trachea. The latter, however, are generally rounder, more moveable, more elastic, and more equal to the touch: they are sometimes diaphanous, and fluctuation may often be perceived on pressure. The period of life, too, may at times assist in the diagnosis. In addition to these spurious or complicated cases of bronchocele, there are other instances in which the gland itself is healthy, and the tumour consists of condensed cellular membrane, sometimes interspersed with cysts. Sometimes a cyst, filled with matter of a pulaceous or purulent nature, has been formed around the gland; and there have

been cases in which the enlarged gland was surrounded by a yellow fatty mass.

We are so completely unacquainted with the uses of the thyroid gland, and consequently with the peculiar causes of disease in it, that it is not wonderful, perhaps, that there should have been so much conjecture and discordance of opinion with respect to the origin of bronchocele. Whatever may be the primary source of the disease, there is much reason for supposing that, once established, it is often continued in families by inheritance;* or, at least, that a strong predisposition to it is in this manner acquired. Thus we have known a woman with goitre, whose grandmother, father, paternal aunt, and cousins, also had it; although they did not all live in the same place, and no other person in their neighbourhood was affected with the disease. Similar instances have presented themselves to others; (*Thomas's Practice of Physic*, p. 573, 2d ed.,) and it is well known that where cretinism prevails, infants are often born with goitre. In such places, therefore, the effect of intermarriage among the inhabitants is not to be overlooked, as tending to spread and perpetuate it. The disease has sometimes been attributed to a scrofulous taint in the constitution; but as it is only met with in particular districts, as it is not always accompanied with swelled lymphatic glands or disordered general health, and as the tumour in bronchocele is scarcely known to suppurate spontaneously, while, on dissection, it has mostly been found of a totally different nature from strumous swellings, the conjecture must be abandoned. It has been held by some that bronchocele arises from a deficiency of nutritive food; and Dr. Mason Good countenances this opinion. He states, that on a visit to Derbyshire "he found a much larger number of the poor affected with this disease than he had ever seen before, while the rich escaped; and he found, also, that by far the greater part of those who were labouring under it were not only exposed to all the ordinary evils of poverty, but derived their chief diet from that indigestible and innutritive substance the Derbyshire *oaten cake*, which," he adds, "is probably the chief cause of all the glandular and parasympic enlargements which are so common in that quarter." (*Study of Medicine*, vol. v. p. 416.) That insufficient nutriment may concur with other causes in producing the disease, is probable enough; but that this is its principal origin is an untenable idea; since, in countries where the malady prevails endemically, the rich are by no means exempt from it. There are other circumstances besides diet, too, capable, it may be, of producing it, and to which the poor are more exposed than the rich, as we shall presently show. And lastly, the oaten diet, to which Dr. Good attributes the disease in Derbyshire, is still more exclusively used in Scotland, where the disease is of rare occurrence.

It was long supposed, from goitre prevailing so generally in mountainous countries, that it arose from the habitual drinking of snow-water. This notion seems to have been derived from Pliny,

* Dr. [Sir] James Clark. Notes on Climate, Diseases, &c. in France, Italy, and Switzerland, p. 709, London, 1830.

(Lib. ii. cap. 37.) and copied by succeeding writers, because it tallied with their doctrines of cold and crude matters. When it is considered, however, that no such cause exists where the disease prevails in this country; that it is rare in Scotland, though common in many parts of the south of England; that the Swiss, who live contiguous to the glaciers, and drink no other water but what flows from the melting of ice and snow, are free from the disorder; and that it is never met with in Greenland, where snow-water is the common drink; while in Sumatra, where snow is never seen, it is of frequent occurrence; it is evident that we must look for some other cause. Dr. Richardson, indeed, in his journey with Capt. Franklin to the shores of the Polar Sea, ascertained that at Edmonstone, where, it seems, a residence of a single year is sufficient to render a family bronchoceleous, the disease is seldom met with in those who drink melted snow, but is almost exclusively confined to those who use the river water. (Franklin's Narrative, &c. pp. 118, 119.) This circumstance, on the other hand, countenances the opinion that goitre arises from certain calcareous or other impregnations of the water in common drink. The same view is strongly favoured by Dr. Bally, a native of a goitrous district in Switzerland. He says, "Bronchocele appears to me to be produced by certain waters which issue from the hollows of rocks, trickle along the cliffs of mountains, or spring from the bowels of the earth. That this is the case I may instance some fountains in my own country, (Département du Lemane au Hameau de Thuët,) the use of whose waters will, in eight or ten days, produce or augment goitrous swellings. Such of the inhabitants of the above village as avoid these waters are free from goitre and cretinism." (Dict. des Sciences Médicales, t. viii.)

Dr. Coindet states that the use of hard water, or the pump-water of the lower streets of Geneva, brings on the goitre very speedily, (Observations on the remarkable effects of iodine, &c. p. 7;) and Dr. Manson attributes the prevalence of the disease in Nottingham to the same cause. (Medical Researches on the effects of iodine, pp. 4, 5, 8vo. London, 1825.) The frequency, also, of its occurrence in the valleys of the chalky districts in Hants and Sussex is certainly in favour of these views. In the central parts of Hampshire, however, we have almost uniformly met with it in the valleys only; and even there its frequency is by no means so great as, in our opinion, to justify the conclusion that it arises solely from the nature of the waters. That it should prevail to a far greater extent in these vales than in many much more confined valleys in the more northern parts of the island, may possibly arise from the greater moisture of the soil where the substratum is chalk: and partly, perhaps, from the greater degree of miasmatic evaporation occurring under a more southern sun.

[A modern writer on bronchocele, Dr. Inglis, *Treatise on English Bronchocele*, London, 1838.] affirms, that the presence of magnesian limestone always implies the co-existence of the disease; and Mr. McClelland, who had numerous opportunities for observation in India, (*Some Inquiries in the Province of Kemaon relative to Geology,*

&c., Calcutta, 1835; cited in *British and Foreign Medical Review*, for July 1839, p. 103,) states, that in the course of his professional inquiries, which extended over 1000 square miles, and were prosecuted without any regard to theory, no instance occurred, in which goitre prevailed to any extent, where the villages were not situate on or close to limestone rocks. Still, there are many places, as the Vallais, in which there are no limestone formations; and in other places, where the disease prevails, the water contains no calcareous salts.]

Whether or not the disease be necessarily connected with the impregnations of the water in those places where it prevails, every circumstance in its history tends to prove almost beyond a doubt, that it is induced by the agency of some one or more physical causes upon the constitution. Larrey observed that almost all the inhabitants in the valley of Maurienne were affected with goitres, (Mém. de Chir. Mil. t. i. p. 123;) and Postiglione remarks that, in Savoy, Switzerland, the Tyrol, and Carinthia, there are villages in which all the inhabitants, without exception, have these swellings; the form and position of which are considered as indications of beauty. (Memoria sulla natura del gozzo, p. 22.) Professor Foderé, in his journey to the maritime Alps, made numerous observations in proof of its being a disease of low and moist regions. In the chief village of the valley La Roja, which is situated on high ground, there is not a goitre to be seen, though it is very prevalent in the immediate neighbourhood, which is comparatively low. He found, indeed, that all elevated regions, and all dry situations, whether warm or cold, were exempt from the disease; and he conceives that, throughout all climates, it takes its rise from the same cause—the humidity of the valleys. Dr. [Sir James] Clark, in his "Notes on Climate, Diseases, &c. in France, Italy, and Switzerland," states that he agrees in most respects with Foderé as to the origin of goitre, and expresses his opinion, that it is probable, if the villages situate in the low, close, marshy situations of the Vallais, were destroyed, and the inhabitants removed to elevated, dry situations, cretinism and goitre, which he believes to arise from different degrees of the same cause, would disappear. Dr. Gibson, also, in the first number of the Philadelphia Journal for the Medical and Physical Sciences, has collected a great number of facts leading to the same conclusion.

It appears from his statement, that bronchocele may be found as an endemic disease in all mountainous and marshy districts of the United States; that it generally prevails in valleys at the bottom of the highest mountains, in the neighbourhood of rivers, falls, lakes, or of the sea, and where the soil is rich and sheltered. Dr. James Johnson, in his Excursion through France, Switzerland, and Italy, recently published, has some excellent remarks on the physical causes of bronchocele and cretinism in the valley of the Rhone, drawn from his own personal observation. "Were this valley beneath a tropical sun," says he, "it would be the seat of pestilence and death. As it is, the air must necessarily be bad; for the high ridges of mountains, which rise like walls on the north and south sides, prevent a free ventilation; while in

summer a powerful sun beats down into the valley, rendering it a complete focus of heat, and extricating from vegetation and humidity a prodigious quantity of malaria. In winter, the high southern ridge shuts out the rays of a feeble sun, except for a few hours in the middle of the day; so that the atmosphere is not sufficiently agitated at any season of the year. To this must be added the badness of the waters, which, along the banks of the Upper Rhone are superlatively disgusting." In farther allusion to the same subject, he states that, "it is remarked that cretinism is bounded to certain altitudes above the level of the sea. The Vallais itself, and the ravines or gorges of the mountains by which it is enclosed, are the chief seats of this deformity. All, or almost all, those who inhabit the higher ranges of the mountains overlooking the valleys, are exempt from the malady. This single fact proves that cretinism is owing to a physical rather than a moral cause, or series of causes. There can be no material difference in the moral habits of peasants residing at the base and on the brow of the same mountain. If the former be more subject to goitre and cretinism than the latter, it must be owing to something in the air they breathe, the water they drink, or the emanations from the soil on which they reside. Saussure, Ferrus, Georget, and all those who have personal knowledge on the subject, acknowledge that at a certain height (five or six hundred toises) among the Alps, goitre and cretinism disappear." "In short, we find in the Vallais, and in the lower gorges or ravines that open on its sides, both cretinism and bronchocele in the most intense degrees; as we ascend the neighbouring mountains, cretinism disappears, and goitre only is observed; and when we get to a certain altitude, both maladies vanish." (pp. 56 to 58.) We believe that careful observation of the circumstances under which bronchocele is found to prevail in certain districts of our own country would lead to similar views respecting its origin; and in this manner may be explained the fact, that with us it almost exclusively affects the lower orders, who are of necessity the most exposed to such causes, and to those concurrent circumstances which poverty and ignorance entail upon them. Dr. Reeve, who visited the Vallais in 1805, for the purpose of making personal observations on the causes of goitre and cretinism, remarks that "all the cretins he saw were in adjoining houses in the little village called La Batia, situated in a narrow corner of the valley: the houses being built up under ledges of the rocks, and all of them very filthy, very close, very hot, and miserable habitations. In villages situated higher up the mountains, no cretins are to be seen." (Edin. Med. and Surg. Journ. vol. v. p. 33.) It would be wrong, however, to pass over the observations of the celebrated Humboldt, which certainly tend to throw some doubt upon these views. He observes that, in South America, bronchocele is met with both in the upper and the lower course of the Magdalen river, and on the flat high country of Bogota, 6000 feet above the bed of the river. The first of these regions is a thick forest, while the second and third present a soil destitute of vegetation. The first and third are exceedingly damp, the second peculiarly dry.

In the first the air is stagnant, in the second and third the winds are impetuous. In the two first the thermometer keeps up all the year between 22° and 23° of the centigrade scale; in the third it ranges between 4° and 17°. The waters drunk by the inhabitants of Mariguita, where goitres are the most hideous, are not those of snow, but of springs which flow over granite. He states, also, that the disease is progressively extending itself from the lower provinces to the flat elevated regions of the Cordilleras. (Journ. de Physiologie, par F. Magendie, t. iii. p. 116.)

Ramond, likewise, in his observations on the Pyrenées, informs us that cretinism and goitre exist among these mountains even in greater extent and degree than in the Vallais, and under circumstances of locality very different; namely, in open, well-watered, and well-ventilated valleys. Upon the whole, therefore, we are scarcely warranted by facts in considering that bronchocele has its origin in any one exclusive source; though, as we have already stated, we think it probable that most frequently it is the offspring of a close, stagnant atmosphere, impregnated with moisture and the effluvia of the subjacent soil.

[There is something, at present, inscrutable in the character of the locality which gives occasion to the disease; and in reality we seem to know no more of the immediate cause of this endemic than of that of endemic diseases in general. (See the writer's *Practice of Medicine*, 2d edit. i. 557: Philad. 1844.)]

As bronchocele arises without our being able to trace with certainty its cause, so does it often unexpectedly disappear without any assignable reason, even after resisting all the approved remedies. This has frequently occurred under a change of residence, a circumstance which favours the view that we have considered the most probable respecting the origin of the disease. Alibert states that he has known many ladies in whom the tumour has subsided after a residence of some time in Paris. (Nosologie Naturelle, t. i. p. 473.)

Treatment.—A variety of means have been employed for its cure, both of a local and general nature. The former used to consist of dry rubbing the part; bathing it with cold water; friction with stimulating lotions, liniments, or ointments; mercurial applications, leeches, and blisters, kept open or repeated. Electricity also has been employed, and latterly galvanism, it is said, with some success.

Of the internal remedies, till within these few years, the most celebrated was burnt sponge. This was generally exhibited in doses of ten grains to half a drachm, three times a day, in the form of an electuary, infused in wine, or made into a lozenge, which was kept under the tongue till dissolved, from an idea that, in this manner, its influence was more direct and speedy. It was usual, however, to accompany this remedy with alterative medicines and purgatives, chiefly mercurial; and although we believe the efficacy of burnt sponge, when unadulterated,* to be undeniable, it

* It is stated by Dr. W. Gairdner, that chemists are in the habit of substituting charcoal for burnt sponge, of which an undeniable proof is the fact, that it is sold at a less price than unburnt sponge can be bought for. In this manner Dr. Gairdner explains the inefficacy of this medicine in the hands of British practitioners, whilst it is

might not perhaps be easy to assign its exact share as a remedy when combined with others. That mercurial preparations, internally administered, have in some cases cured the disease, even when burnt sponge has failed, there can be little doubt. There is an instance related by Mr. Davies, of Arelsford, in the 13th vol. of the Medical and Physical Journal, in which two pounds of sponge had been taken without any effect, and yet the tumour entirely disappeared in the course of ten days, while the patient was taking mercury internally for some other ailment. Preparations of soda, potass, and iron; the muriates of barytes and lime; egg-shells, burnt hartshorn, and even burnt toads, have likewise been recommended. Courses of sea-water, or mineral springs, and the use of distilled water, which has appeared to Professor Odier, of Geneva, (who ascribes the disease to the qualities of the water,) to prevent the increase of the swelling, and even to lessen its bulk, have also been advised.

Of all the medicines, however, which have been administered for bronchocele, the substance called iodine is unquestionably the most efficacious, though it may not deserve the name of a specific, which some of its advocates have been inclined to claim for it. Of one hundred and twenty cases, treated by Dr. Manson, of Nottingham, where the disease appears to be endemic, seventy-nine were cured, eleven greatly relieved, and only two derived no relief. (Medical Researches on the Effects of Iodine.) It is now considered certain, that on the presence of iodine in burnt sponge depend the virtues of the latter in the cure of goitre. The discovery of this fact is disputed between Dr. Coindet of Geneva, and his countryman, Dr. Straub of Hofwyl. There is no reason, however, to suspect that either was aware of the other's researches while prosecuting his own. Dr. Straub appears to have been led principally by the similarity of smell between iodine, burnt sponge, and other marine productions, to suspect the existence of the former in these substances. Dr. Coindet, whilst making researches for other purposes, found that the *fungus vesiculosus*, or bladder-wrack, had been recommended by Russell for the cure of goitre; and as it is from this plant, and other species of the same family, that the soda, with which iodine is generally found combined, is extracted, he was led to suspect that the virtues of sponge, likewise a marine production, might depend upon the same active principle; a conjecture which was soon after confirmed by the discovery made by Dr. Fyfe, of Edinburgh, that iodine existed in the ashes of burnt sponge. M. Roulin has found, likewise, that the *accyle de sal*, a South American remedy for the disease, contains iodine. (Magen-die's Journ. de Physiologie, t. v. p. 273.) In whatever manner the question of originality may be decided, it must be admitted that to Dr. Coindet's exertions we are principally indebted for the speedy and extensive adoption of this new medicine. In goitre its effects may be obtained either by local application to the tumour, or by administering it internally. Where the former is suffi-

cient, it is preferable to the latter. The formula recommended by Coindet, and by Professor Brera of Padua, is that of an ointment, composed of half a drachm of hydriodate of potass mixed with an ounce and a half of lard, of which a drachm should be rubbed in over the surface of the swelling, morning and night. Brera, also, uses an ointment consisting of a drachm of pure iodine and an ounce of lard. Of this, the quantity to be rubbed in is a scruple at a time. Dr. Manson uses a liniment, composed of a drachm of the tincture of iodine mixed with an ounce of the liniment sapon. comp., which may be kept in a phial, and the evaporation of the iodine, that takes place in the ointment, be thus, he says, prevented. For internal administration, the preparation in most common use in this country is the tincture. Coindet directs this to be made, by dissolving forty-eight Genevese grains of iodine (forty grains troy weight) in one ounce of alcohol. As, however, the strength of the spirit varies, and it is liable to evaporate, a weaker tincture is preferable, from which the iodine is less likely to be deposited, and thus the deleterious action on the bowels, which has appeared to Dr. Gairdner to be more marked in proportion to the free iodine in the preparation, avoided. Dr. Manson directs the tincture to be made in the proportion of twenty-four grains of iodine to an ounce of rectified spirit; and the dose of this may be from fifteen to thirty drops, three times a-day, taken in some distilled water. The dose of Coindet's tincture is from ten to twenty drops; but Dr. Gairdner, who has had considerable experience in the use of iodine, and has given us an excellent description of its occasional mischievous effects, conceives this to be the most objectionable form in which it is used; and in this Dr. Kolley of Breslau seems to agree with him. (Reflexions, &c. sur l'emploi de l'iod. Journ. Comp. Février, 1824.) Iodine may also be given in the form of pills, containing each half a grain, made, as Brera directs, with elder-rob and liquorice-root. Dr. Gairdner prefers the solution of the hydriodate of potass to any other preparations, for internal use. He directs it to be made by dissolving half a drachm of the hydriodate in one ounce of distilled water; the dose is from ten to twenty drops. Dr. Manson prepares it with twenty-four grains only to an ounce—Coindet with thirty-six. By adding ten grains of iodine to this last, the solution of ioduretted hydriodate of potass is formed, which Coindet considers the safest preparation for internal use. The dose of this should not exceed five drops, three times a day, on its first exhibition. There is an alcoholic, or ethereal tincture also, used by Coindet, which, next to the last, he prefers. Dr. Gairdner states that he has seen reason to believe that bleeding from the arm in plethoric patients accelerates the effects of the medicine, when absorption is slow. Goitrous tumours are subject to sudden augmentation of size during catarrh, or in febrile states of the body, and the efficacy of the local application of iodine seems to be increased in such circumstances by a preliminary application of leeches. Dr. Coster relates a case in the Archives Générales de Médecine, for July 1823, in which galvanism and friction with iodine completely removed a bronchocele, although neither of them

virtues are so palpable and evident at Geneva that not only physicians, but also the inhabitants in general, are convinced of their reality.—Essay on the Effects of Iodine, p. 2, 8vo. London, 1821.

was successful by itself. And there can be no doubt that, when required, it is necessary to improve the general health, in order to afford the remedy a fair chance of success.

When iodine is administered internally, it is necessary to avoid combining it with substances which may decompose it; it should be taken when the stomach is empty, and its effects carefully watched, as it has sometimes produced the most serious and even fatal consequences; though, under proper caution, it may be given with perfect safety. Dr. Kolley, who was himself cured of goitre by means of iodine, after all other remedies had failed, and who has both taken and prescribed it largely, gives us some instructions with respect to the circumstances which have appeared to him to contra-indicate its use. He states that it is improper when there is a disposition to congestion in the head or other internal parts; when febrile or inflammatory symptoms are present; in cases where there is diarrhoea, dyspepsia, or other gastric affection, or hepatic disorder; when there is a disposition to hydrocephalus; and in phthisis pulmonalis, for which it has been extolled as a remedy by some others. (Op. cit.—or *Medico-Chirurg. Review*, Vol. vi. p. 229.) Dr. Gairdner informs us, that so great had been the ravage committed by the imprudent use of this medicine in the Pays de Vaud, that the government of that canton issued an injunction against its sale, excepting under the signature and responsibility of a physician. The mischievous effects which follow its use are generally insidious in their approach. The patient becomes affected with a sense of faintness, tremor, and sinking; dimness of vision, palpitation, and other symptoms of a nervous kind. The degree of tremor, Dr. Gairdner informs us, is sometimes so great, as to present some resemblance to chorea, though the limbs can always be kept steady, when not called on for exertion. More violent effects than these occur at times; symptoms apparently proceeding from the direct and acrid effects of iodine on the alimentary canal, and strongly resembling the Indian cholera:—violent and incessant vomiting, strong spasms of the back and legs, extremely frequent, small, and oppressed pulse, urgent thirst, and excruciating pain of the stomach and bowels; the latter being sometimes violently purged, at other times obstinately confined. For the prevention of all bad effects from the use of iodine, it is an excellent rule to begin with small doses, and increase them gradually, so as never to exceed the minimum quantity required. (Dr. E. Barlow. *Edin. Med. and Surg. Journ.* Vol. xxi. p. 337.) The muscular spasms and the disturbance of the nervous system appear to be more benefited by attention to diet, air, and exercise, than by medicines. Of the latter, all that is required are mild aperient medicines, which, combined with gentle exercise in the open air, a mild, sparing, and nutritious diet, abstinence from wine and other stimulants, and the use of the warm bath, soon restore the patient to health. In the choleric affection, the remedies of much the greatest use are opiates, henbane, or hemlock, together with the warm bath, and mucilaginous drinks. Purgatives and bitters are decidedly injurious. In the second stage, when there appears to be an actual ulceration of the mucous membrane of the

bowels, the pulse, instead of being small and oscillating, becoming firm and bounding, the treatment requires much more discrimination. The diarrhoea, which assumes a dysenteric form, is best treated by the union of opium and aperients. The emaciation which follows the improper use of iodine is rapid and extreme. On some parts of the continent, a wasting of the mamma has occasionally been observed, during its use, even when cautiously administered; and we have ourselves witnessed this effect. Dr. Manson found it, in one case, to excite ptyalism. The external use of the remedy seldom produces any unpleasant effects on the general system; but it sometimes stimulates the arterial vessels of the tumour so powerfully as to produce pain and inflammation. In such cases, it may occasionally be necessary to bleed the patient from the arm, lest the inflammation should extend to the trachea; but, in general, the discontinuance of the medicine, together with fomentations, poultices, and leeches, is all that is required.

[The preparations of bromine, as well as bromine itself, (see the writer's *New Remedies*, 4th edit.: Philad. 1843,) appear to be equally efficacious in the treatment of goitre; but they are not as much employed.]

When both external and internal remedies fail in discussing the tumour, surgical measures have been adopted to destroy or remove it. Of the former, the application of caustics, as recommended by Celsus, is the oldest. This, however, is a dangerous as well as a painful and tedious mode of cure. Hemorrhage, all but fatal, has sometimes occurred from it; and Dr. A. T. Thomson relates an interesting case, in the eleventh volume of the *Medico-Chirurg. Transactions*, in which, from empirical application of quicklime to an enormous goitre, the most dreadful inflammation, delirium, and sloughing ensued. The tumour has sometimes been punctured with a trochar when it contained cysts, or cut into with the scalpel. The latter, it appears, is a very common practice in Denmark; but unless a drain be in this manner instituted in the part, no very permanent benefit can be expected from it; and when suppuration does ensue, dangerous and even fatal symptoms have occurred from the formation of sinuses and sloughing. (*Flajani*, *Colezione d'Osservazioni*, &c. t. iii. p. 283.) Issues, also, have been established in the part, sometimes with success. Their operation apparently consists in breaking down the tumour by the suppurative process, but they may also act by communicating a stimulus to the absorbents. Goitres have been cured by spontaneous suppuration, or by the inflammation and suppuration arising from accidental blows or wounds. It is reasonable enough, therefore, to expect that similar processes artificially excited should be followed by like good effects. When circumstances have rendered such means advisable, the introduction of one or more setons in the tumour is the most effectual mode of accomplishing it, and attended with the least risk of forming sinuses. Several writers of the last century recommended this mode of treatment for goitre, but the attention of practitioners in this country has been principally attracted to it by the Memoir of Dr. Quadri, of Naples, published

in the 10th volume of the Medico-Chirurgical Transactions; and the operation has since been frequently performed in England. Some cases are published in the 11th volume of the Medico-Chirurgical Transactions, and in the 90th number of the London Medical Repository; from which it will appear that the operation is not so uniformly successful and free from danger as Dr. Quadri found it to be. Alibert mentions a case in which a seton produced a partial diminution of the swelling; but two years after it was withdrawn, the tumour became painful, suppurated, fifteen pints of matter were discharged, and six ounces daily for three months after; yet, notwithstanding, the disease was only partially removed. (*Nosologie Naturelle*, t. i. p. 466.) That the success or failure of this remedy is in some measure dependent upon the nature of the swelling is extremely probable, but from what specific difference in that respect the difference of effect may arise we are as yet entirely ignorant. Dr. Quadri states that he has passed a seton sixteen times in as many different directions through the tumour without any untoward accident. In one instance, endeavouring to perforate it pretty deeply, an unusual quantity of blood flowed from the wound, perhaps more than an ounce; and the tumour seemed to swell, as if injected with blood; but the bleeding ceased spontaneously, and he states his conviction, that unless the needle were pushed deep enough almost to touch the semi-form cartilage, the principal trunks of the thyroid arteries would not be injured. He states, also, that the consecutive inflammation is of trifling consequence. When we consider, however, that the blood-vessels of the tumours are frequently very much enlarged, there may, without doubt, be occasional risk of hemorrhage. In two out of the four cases in the 11th volume of the Medico-Chirurgical Transactions, hemorrhage did occur, though not to an alarming extent; and Mr. Samuel Cooper states that fatal hemorrhages have sometimes followed the operation. (*Good's Study of Medicine*, vol. v. p. 322.—*Note*.) It must be admitted, also, that active inflammation excited so near to the trachea may often induce dangerous consequences, especially when the tumour is attached to that part. In one of the cases related in the Medico-Chirurgical Transactions, a patient of Mr. Gunning's, in St. George's Hospital, the operation was followed by fatal sloughing, and there was some appearance of inflammation on the lining membrane of the trachea. In another case, related by Mr. James, of Exeter, which, however, was ultimately cured, there occurred expectoration of purulent matter and lymph, a great degree of orthopnea, suppressed voice, as in laryngitis, and threatening death, until the seton was removed. Dr. Hedenus, of Dresden, informs us that he has seen a patient die of tetanus after the operation. From our own experience, indeed, as well as that of others in this country, we should say that it ought only to be attempted when symptoms urgently demand it. We have, it is true, seen it at times produce but few unpleasant symptoms, though we have witnessed at other times serious consequences from it; so, also, we have seen both successful and unsuccessful cases with regard to the ultimate cure. Of the former,

a case has been reported in the Medico-Chirurgical Review, vol. vii. 1827, treated by Mr. Henry Lyford, of the Hants County Hospital. The tumour, which was of four or five years' growth, and easily moveable, but unusually hard, almost entirely disappeared in less than two months. Dr. Quadri states that it is expedient to retain the seton in the tumour for a considerable length of time, in order to keep up the suppuration, until a cure is accomplished, as well as to prevent the formation of sinuses. When the suppuration ceases, and the wounds are perfectly healed, he has observed the curative process to go on in some cases until the goitre is entirely dissipated. The skin which covered the swelling remains corrugated a short time after the cure, but soon resumes its natural appearance; and the cicatrices left by the seton in a few months present hardly any deformity.

With the view of cutting off the supply of blood by which the tumour is fed, the thyroidal arteries have been tied, and the disease, in some instances, removed by thus destroying the balance between absorption and deposition. Dr. Quadri, indeed, suggests that the effect may have been obtained simply from the increase of absorption, occasioned by the irritation of the ligature, and from the inflammation and suppuration consequent upon the operation.—(*Medico-Chirurg. Transact.* vol. x. p. 26.) But we cannot conceive that such causes are sufficient to account for so disproportioned an effect. The experiment, we believe, was first attempted by Sir William Blizard, and he succeeded in reducing the size of the swelling one-third in the course of a week; but the ligatures having then sloughed off, repeated bleedings took place from the arteries, hospital-gangrene ensued, and the patient was lost. From the circumstances of the case, however, the same event was by no means to be necessarily expected from the operation. Accordingly, in 1814, Professor Walther of Landschut repeated the operation in a case of that particular species of bronchocele which he calls the aneurismal. The patient was a young man, in whom the respiration was much impeded by the swelling, and the upper thyroid arteries were large and pulsated strongly. The left thyroid artery being tied, on the third day after the part of the tumour on that side became less tense, and the throbbing soon ceased. It continued to diminish gradually, becoming at the same time harder, and, as it were, cartilaginous. No febrile symptoms followed the operation, and the wound was completely healed on the twenty-third day. At the end of a fortnight, the left side of the swelling having diminished one-third, the Professor tied the right superior thyroid artery, with a like freedom from any unpleasant consequences. The right portion of the tumour also began to diminish; but, though originally smaller than the left, it did not waste away so completely as the latter, which at last was only one-third of its original size. Two years after, the remains of the tumour produced no inconvenience.—(*Neue Heilart des Kropfes*, &c. 8vo. Sulzbach, 1817.) Another operation of the same kind was performed by Walther in 1820, and with still more complete success. In this patient, also, the tumour was tense, hard towards its centre, and pulsated strong-

ly. The face was pale and tumefied, the respiration obstructed, and deglutition extremely impeded. On exposing the left superior thyroideal artery, it was found dilated so much as to surpass the diameter of a common quill. After it was tied, it became considerably contracted below the ligature, and ceased to pulsate. At the end of seven weeks the wound was entirely cicatrised; deglutition and respiration were performed without any difficulty; the tumefaction of the face had disappeared; the left half of the tumour, originally much larger than the right, was reduced to its natural size; and the patient left the hospital cured.—(London Medical Repository. October, 1822.)

The first apparently successful case of the operation in this country that we are acquainted with, was that of Mr. H. Coates, of Salisbury, published in the 10th volume of the *Medico-Chirurgical Transactions*. The patient was a young woman, in whom the tumour was so large as to render respiration and deglutition extremely difficult, and causing a noise in breathing, which might be heard at a considerable distance. The superior thyroideal arteries were large and pulsated strongly. The left of these vessels was taken up. On the next day there was headach, and some swelling of the neck and side of the head; but these gave way to the abstraction of blood, and in three days all unpleasant symptoms vanished. The wound was completely healed on the fourteenth day. The patient's breathing was much improved, the size of the tumour being reduced nearly one-half; and in less than seven weeks from the operation she was discharged from the hospital quite well. In consequence, however, of an application we made to Mr. Coates for information as to the *final* result of the operation, we are authorized to state that, though the case proceeded extremely well for some time after the patient was discharged and lost sight of, yet the tumour subsequently, he understands, enlarged, and in the end destroyed her by suffocation. Mr. Coates states that he has not repeated the operation in any other case, nor should he be disposed to do so from the result in this instance. Mr. W. J. Wickham, of Winchester, has furnished us with the following notes of a case, in which one of the thyroid arteries was tied, in the Hampshire County Hospital, the operation being followed in like manner by apparent success at first, and failure in the end. He says, "It was the largest bronchocele I ever witnessed, but of the exact measurement I have no memorandum. After the ligature of the artery, the swelling gradually diminished for about six weeks, after which it as gradually regained its former size. It seemed that the decrease of the tumour continued so long as the part of the gland, which had been supplied by the vessel, remained without nourishment; but as soon as the supply was restored by the anastomosing branches from the opposite superior and the two inferior thyroideal arteries, the swelling returned to its former dimensions. Such, I should conceive, would be the case, unless all the thyroideal arteries were obliterated, which it would be a very difficult task to accomplish, if not altogether impracticable, from the depth of the lower vessels. In this case, after the foregoing operation, I introduced a seton through the gland, which was succeeded, at first, by great tumefaction of the

part and alarming difficulty of breathing, but produced afterwards a slight diminution of the swelling. After a few weeks, however, it was necessary to withdraw the seton in consequence of its having occasioned great constitutional disturbance, and ultimately no benefit at all was derived from it. The result of the case, indeed, does not give me much encouragement to attempt a repetition of either plan of treatment on another occasion." Mr. Samuel Cooper mentions, in his *Surgical Dictionary*, that Mr. [Sir B.] Brodie performed the operation in one case without producing any material diminution of the tumour. Mr. H. Earle, however, has been more successful. He has published the result of a case, in which he tied both the superior thyroideal arteries, with great advantage, though not with the effect of completely dissipating the tumour. The patient was a girl of seventeen, in whom the gland was very painful, and so large as greatly to impede respiration and deglutition. Her general health was bad; she suffered much from pain in the head and drowsiness, and complained of pain in her chest, and cough, with foul tongue, and rapid pulse. As the disease did not yield to the usual remedies, she was sent back into the country on account of her general health, but returned some months afterwards with the goitre increased, so as to produce extreme dyspnoea, and totally prevent her from swallowing solid food. The pulmonary affection continued; there was constant headach and drowsiness, and the pulse was 120. As the disease still resisted medicine, and threatened fatal consequences, the operation was determined upon. The right superior thyroid artery was found to be enlarged to the size of the carotid. On tying it, there succeeded intense headach and increased drowsiness, which were subdued by a full bleeding from the arm, leeches to the temples, purgatives, and digitalis. In a few days the tumour was found to be diminished, respiration and deglutition were much less impeded, and the cough had nearly left her. Within a month she was sent home; the circumference of the swelling being diminished three inches and a half. A fortnight afterwards, the tumour remaining stationary, she returned, to have the artery on the left side tied. This was found of the size of the radial artery. No urgent symptoms followed from its being taken up; but the diminution of the tumour was not nearly so great or so rapid as after the former operation. In a month the patient finally left the hospital, with no impediment in swallowing or respiration, and free from cough, the tumour being much softer and smaller. Three months after the operation it was continuing slowly to decrease.—(*Med. and Physic. Journ.* vol. lvi. p. 201, & seq.) From all that we yet know of this operation, we may conclude that it may be performed, perhaps in most cases, with safety; but that it is advisable in all instances of bronchocele is much more than doubtful. It appears not to have been uniformly successful even in reducing the tumour; still less in the complete removal of it. When it is considered, indeed, how largely the thyroid gland is supplied with blood, having four considerable arteries assigned to it; and how soon the place of obliterated trunks is supplied by the collateral branches; the occasional failure of the operation is not surprising, and the permanency

of its benefit, even in apparently successful cases, may sometimes, as we have seen, be questionable. When the urgency of symptoms, however, demands it, and more particularly when the tumour is of a pulsating nature, a dexterous surgeon may probably adopt this with as much safety and prospect of success as any other surgical means of relief.

In some instances the goitrous tumour has been removed, at once, by excision. This, however, will appear to be a most hazardous undertaking, when we consider the number and magnitude of the bloodvessels, and the important nerves adjacent to the tumour, with which it is generally involved; the impossibility of using much pressure in such a situation for restraining hemorrhage; and the risk of wounding the trachea and œsophagus, to which the deceased mass is often adherent. Possibly the removal of the tumour at an early stage of its progress might not be attended with very serious danger. Mr. J. Baillie Fraser tells us, he was informed in his tour through the Himala mountains, that goitre, which prevails in the valleys there, was sometimes cured when early means were taken, and that these consisted in extirpation of the part by the knife. He adds that he saw some persons with the scars from the operation on their throats, and that, in these instances, the cure was complete. (*Journal of a Tour through the Himala Mountains*, p. 349. 4to. London, 1820.) In 1791, Dessault extirpated a tumour of the right portion of the thyroid gland, which was five inches in circumference, and proved to be similar in all respects to scirrhous glands, except that in the centre there was a cartilaginous nucleus. In this case there were no very untoward circumstances, and the patient was dismissed cured on the thirty-fourth day after the operation. (*Dessault's Parisian Chir. Journ.* vol. ii.) The difficulties and danger, however, attending the operation, when the tumour is large, of long standing, and has formed extensive adhesions, are very great. Mr. Gooch relates two cases in which he attempted this mode of cure. In the first he was compelled to desist, before the operation was half completed, in consequence of profuse hemorrhage, which no means were able to stop; and the patient died in less than a week. The second had nearly ended fatally, also, from loss of blood, this dexterous operator being completely foiled in his attempts to stop the hemorrhage by ligatures. The patient's life was only saved by having a succession of persons to keep up a constant pressure upon the bleeding vessels, by means of their fingers, or proper compresses, day and night, for nearly a week. (*Gooch's Medical and Chirurgical Observations*, p. 136.) The operation has been fatal, also, apparently from injury to some of the important nerves in the vicinity of the disease. A woman on whom Dupuytren operated, without losing more than a few ounces of blood, was seized with hurried respiration, sickness, coldness of skin, &c., and died soon after the excision. The operation, however, has accomplished a cure, in some instances even of the most aggravated description. Vogel and Theden performed it with success. Professor Graefe, of Berlin, succeeded in a case where the tumour was so large that he thought it advisable to perform the operation by

instalments, cutting off one side of the gland first, and, after waiting till the wound was healed, removing the other. (In the course of the operation he took up fifty arteries. (Lawrence's Lectures; *Medical Gazette*, vol. vi. p. 719.) But of all who have attempted excision in bronchocele, Dr. Hedenus, of Dresden, has been the most fortunate. It appears that he has performed it six times with success. In one instance the circumference of the tumour was fourteen inches. The operation lasted an hour and a half. Some hours after, there commenced a considerable oozing of blood from all the wounded surface, which it required assiduous care to suppress. After the separation of the ligatures, on the eighth day, there was a considerable hemorrhage, and on the eighteenth day a more serious one occurred in consequence of a convulsive cough. The patient lost two pounds of blood; there was a deadly paleness over his whole body, dimness of sight, loss of speech and hearing, and extreme faintness. By judicious treatment, however, his life was preserved, and he was, at last, dismissed cured. (Graefe's *Journ. der Chir.* B. ii. p. 237. Berlin, 1822; or *Quarterly Journal of Foreign Medicine*. No. 19, p. 317.) A case was published some years ago, in which Klein removed a very large bronchocele, but the patient died upon the operating table. (*Journ. der Chir.* B. i. p. 120.—*Journ. of Foreign Medicine*, vol. ii. p. 380.) In short, judging from the results of the operation, even in the hands of the most judicious and highly skilful surgeons, we may venture to state that it ought scarcely to be attempted when the tumour is of great magnitude, and adheres firmly to the neighbouring structures, and certainly, in no case, until all other means have failed.

Dr. [Sir James] Clark states that Mr. Major informed him of a case in which the tumour was successfully removed by ligature. In another, in which Mr. Major himself adopted that plan, the patient was lost in consequence of hemorrhage, from neglect of the attendant; or rather, he sank under the low fever which ensued from it. (*Op. cit.* p. 111.)

It should be kept in mind by the practitioner, that the removal or sudden subsidence of a bronchocele is sometimes followed by irregular action of the heart, or some other functional disturbance.

BULLÆ, *blains*, an order of cutaneous diseases characterized by an eruption of large thin vesicles, containing a serous or sero-purulent fluid, and succeeded by yellowish or blackish scabs, sometimes by ulcerations.

Syn. *Φλύκταιναί, Δικώδεις φλύκταινίδες, φλύκτιδες*, (*Hippoc. et vet. Græc.*); *Πομφόλυγες* (*rec. Græc.*); *Phlyctænæ*, *Ampullæ* (*Auct. var.*); *Bullæ* (*Plenck*); *Darte plectenoïde* (*Alibert*); *Bulles*, *Ampoules*, *Cloches* (*F.*); *Blasen* (*Germ.*) *Blebs*.

Plenck was the first to found a class upon this form of eruption, for before his time the diseases distinguished by bullæ were comprehended, together with all vesicular affections, under the more general term of phlyctænæ; but not being rigorous in the definition of his class, he included in it phyma, a superficial collection of pus, a species

of paronychia, approaching nearly to the nature of furunculus. Willan had returned to the ancient classification which placed vesicles and bullæ in the same order, from which he was only induced to depart in deference to the well-founded criticism of Professor Tilesius, of Leipsic; and they who have seen much of vesicular eruptions will allow that the learned professor might have found reasons for his distinctions not less in the different nature of the constitutional affections than in their external appearances. But in correcting this error, Dr. Willan did not remove all the objections which might have been made to his arrangement; for, whilst on the one hand he retained, in the order of bullæ, erysipelas, of which vesications are only incidental phenomena, he excluded rupia, of which disease they form the proper elementary eruption. It is therefore our intention to follow M. Bielt, in part of his reform of this classification, leaving pemphigus, pompholyx, and rupia to constitute the order of bullæ.

This elementary form of cutaneous eruption may be produced by external as well as internal causes; and hence bullæ are the ordinary effects of blisters, as of cantharides, ammonia, and many other acrid or rubefacient substances; hence they are caused by burns, scalds, and frost-bites, and are common consequences of friction, pressure, and of distension, as occurs in œdema. The poisons of some serpents are also said to give rise to eruption. But the bullæ arising from the foregoing causes, generally denominated vesications, we leave to our surgical brethren, reserving to ourselves those of spontaneous origin, which observe also a very different progress.

The formation of these last is generally preceded by an elevated erythematous spot, more or less of a bright colour, which, in a certain time, seldom exceeding forty-eight hours, is followed by a small vesicle, which gradually enlarges to a blain. The humour contained in the bulla is in general serous and transparent, but is sometimes sero-purulent, rarely sanguineous. At first the bulla is tense, and the humour may remain a long time accumulated under the epidermis; but it becomes afterwards flaccid, whilst the humour thickens, and often dries into solid scabs, more or less considerable. Or, if situated in a part where the epidermis is thin, the bulla bursts after a few days, and is followed by a thin scab, unless the surface be defended from the air by a portion of the detached cuticle, or any other covering, when it presents a white flocculent secreting covering. In either case the skin gradually provides itself with a new epidermis, or becomes the seat of an ulceration more or less deep.

Though the diseases of this order may exist as acute, they generally present themselves as chronic disorders, eruptions of bullæ following each other in regular succession. As chronic diseases they are never contagious, but generally connected with some disorder of the constitution or the internal organs; hence bullæ are symptomatic of a state of cachexy, of inflammation or irritation of the mucous membrane of the bronchi or the alimentary canal, or of derangements of the function of the liver. They are also observed incidentally in small-pox, the bulla *variolosa* of Plenck.

The pathological condition giving rise to this

form of eruption consists, as far as has been ascertained, in an inflammation of the *rete mucosum*, or upper surface of the cutis, by which a more copious secretion of serous fluid takes place than can be transmitted by the cuticle, thus causing its separation and elevation. In proof of this we may mention that the *rete mucosum* remains adherent to the cutis, and is not detached with the cuticle, as happens when this latter is forcibly torn off. The inflammation which gives rise to the formation of bullæ may be also considered to exist in a higher degree than in erythema, for a higher degree of irritation converts erythema into bullæ.

As bullæ may be dependent upon such different states of the body, it is obvious that their treatment must be various; and therefore we may understand how, in some diseases of this order, the antiphlogistic regimen may be required, whilst, in others, alteratives or tonics may be most advisable, and how, in all the forms, great attention to regimen is always essential.

T. J. TODD.

[CACHEXIA, CACHEXY, CACOCYMY, DYCRASY, literally means "bad habit;" from *κακος*, "bad," and *ἔξίς*, "habit." It has, however, received different acceptations in the history of medicine, and been made to comprise various diseases, which are now more generally separated from it. The acceptation in which it is employed generally at the present day, and always by the author, (see his *Practice of Medicine*, 2d edit. ii. 611, Philad. 1844,) embraces chronic affections, which are induced by some *vice* in the system of nutrition, whether such vice be dependent upon a morbid condition of the circulating fluid that furnishes the pabulum whence the tissues are formed, of the vessels of nutrition themselves, or of both combined. This definition is analogous to, and less liable to objection than, that of Dr. Copland, (*Dict. of Practical Medicine*, art. CACHEXY,) "Depravity of the constitution, without fever, affecting more or less the solids, the circulating fluids, and the secretions."

The chief morbid conditions that fall under cachexis, are serofulosis, tuberculosis, scorbutus, chlorosis, rachitism, hydrops, cancer, and syphilis; but with equal propriety we might class amongst them the morbid results of splenic disease, of lead poison, and many chronic cutaneous affections, in all of which the character of the circulating fluids, or the condition of the function of nutrition, or of both, is modified. In strictness, indeed, of definition, many other diseases might be placed in the same division, which, although seeming to affect primarily particular portions of the frame, implicate, sooner or later, the whole economy.

In order that the tissues shall be duly nourished, the blood must be possessed of appropriate qualities. Should it fail in these requisites, and impress the parts which it bathes abnormally, faulty nutrition must be the consequence. In like manner, if the blood be healthy, and the organs that are concerned in the nutrition of the tissues be morbidly impressed, disease must result; hence, hypertrophy or atrophy may be induced,—in which there may be simply an increased nutritive action in one case, and a diminution of it in ano-

ther; or the nutritive action may, under special circumstances, become so much perverted, that substances may be formed and separated from the blood, which have nothing analogous to them in the economy. These last are cases which are considered by all to belong to cachexia. Under some inappreciable vice in the system, the nutrition of the tissues is so much perverted as to give occasion to various heterologous formations. In some cases, the altered condition of the blood gives rise to a train of phenomena indicating a paucity of fibrin and red globules. The blood is, consequently, imperfectly adapted for the nutrition of the tissues, whose tone is diminished, as indicated by the general appearance of the patient, and by an asthenic condition of all the functions. In other cases, the pravity of nutrition may be evinced by morbid conditions of the cutaneous envelope, or by chronic cutaneous diseases.

In regard to the diseases of the system of nutrition, which are dependent upon some morbid influence or *vice*, as scrofula, cancer, and syphilis, the great indications are much alike. The only mode by which the system can become dispossessed of the vice is by inducing a new condition, which is incompatible with its existence; hence, every effort is made to occasion a change in the circulating fluid by appropriate therapeutical and dietetic agents. These may thus produce a new action in the tissues which they bathe, and break in upon the morbid condition. With this view, recourse is had to those valuable eutrophics—as iodine and its various preparations—which are the gifts of modern chemistry. (*Practice of Medicine*, loc. cit.)

ROBLEY DUNGLISON.]

[CÆCUM, DISEASES OF THE. (See CONSTIPATION.)]

CALCULI, (CHEMICAL COMPOSITION [AND MICROSCOPIC APPEARANCE].)—The term calculus is applied to any solid or unorganized concretions found in the human body. Such concretions have been found in almost all the mucous cavities and canals; in the lachrymal passages; in the mouth, for the tartar in the teeth is certainly of this nature; in the tonsils; in the salivary and pancreatic ducts; in the stomach; in the intestines; in the gall-bladder and biliary passages; in the ramifications of the bronchi; between the prepuce and glans; in the ducts of the mamma; in the vesiculæ seminales; in the ducts of the prostate gland, and in the urinary canals and bladder. Earthy concretions have also been found imbedded in the substance of the brain and other soft parts; within scrofulous abscesses; in cancerous cavities, and in hydatid cysts. The deposition of this earthy matter seems to take place around foreign bodies introduced into the animal frame, as the effect of the irritation which they cause, and probably as the means of rendering them less obnoxious to the living textures. Thus where an extra-uterine fœtus has been long retained, it is usually found more or less encrusted with earthy matter; and when musket-bullets or other projectiles have remained in the human body, their surfaces become covered with a coating of what appears to be phosphate of lime. Even the vascular system is not free from calculous concretions; and small indurated masses have been found

within the cavities of veins, which have thence obtained the name of phlebotolithes.

Chemical Composition of Calculi.—Calculous concretions were noticed by the ancients, and named, obviously from a notion that they were of a stony nature, *λίσθια* by the Greeks, and *calculi* by the Romans. Hippocrates describes the symptoms of calculus in the kidney and urinary bladder with his usual precision. Pliny enumerates a great number of remedies for this dreadful disease, and Celsus describes a method of extracting calculi from the bladder, which Heister praises as excellent. But we look in vain into the writings of the ancients for any description of calculi, or any examination of their nature.

The first person who attempted to speculate respecting them was Paracelsus, though it is somewhat difficult to form an accurate idea of the notions which he entertained on the subject. He seems to have thought that the calculus separates from the liquids of the living body in the same way that tartar is deposited from wine upon the sides and bottom of the wine-cask. This seems to have been the reason that induced him to give the name of tartar to calculi. This tartar, which is apt to be generated in the living body, was in Paracelsus's opinion the origin of most diseases. It differed in its qualities according to the nature of the liquid from which it was generated. He gave it the name of tartar, because it burns the patient like *hell-fire* in severe diseases. It is deposited when the archeus acts with too much impetuosity and irregularity, and when it separates the nutritive principle with too much activity. Then the *saline* spirit unites with the *earthy principle*, which always exists in the liquids, but in the state of *materia prima*; and this union occasions the formation of *tartar* or *calculus*.

The subject of *calculus* was taken up by Van Helmont, in his treatise *De Lithiasi*, which constitutes perhaps the most important and valuable part of all his works. He subjected various urinary calculi to a chemical investigation, and showed that they differed entirely in their nature from the *stony* bodies which occur in the mineral kingdom; from which he drew, as a consequence, that they did not originate from matter contained in food or drink. Tartar, he observed, was deposited from wine, not as an *earth*, but as a crystallized salt; and in the same way the natural salt of urine is precipitated to give origin to a calculus. This precipitation may be imitated by mixing spirit of urine (*solution of carbonate of ammonia*) with rectified spirit of wine. A white precipitate immediately falls, to which he gave the name of *ossa alba*. This view of the subject, which was to a certain extent just, induced Van Helmont to lay aside the name tartar, which had been employed by Paracelsus; and to avoid ambiguity, he employed the term *duclsch*, to denote the state in which the spirit of urine is precipitated when it gives origin to calculous concretions. These views he endeavoured to confirm by an analysis of urine, which was as perfect as could be expected when the experiments were made, and certainly enabled him to approach much nearer the truth than any of his predecessors had done.

No attempt (so far as we know) was made to determine the nature of calculi, or to discover

remedies capable of dissolving them in the bladder without injuring that organ, till the publication of the second volume of *Hales' Vegetable Statics*, in the year 1733. He exposed different calculi to a red heat in a gun-barrel, and found that they yielded a quantity of air amounting to above five hundred times their bulk—a greater quantity of air than most other animal or vegetable substances could be made to yield. This was a decisive proof (if any had been wanting after the experiments of Van Helmont) that urinary calculi are quite different in their nature from the stony bodies belonging to the mineral kingdom. Dr. Hales made several attempts to discover a solvent of urinary calculi, but it is unnecessary to relate them as they were not attended with success.

In the year 1743, Dr. Whytt published an essay to show that *lime-water* was a remedy for the stone. This essay first appeared in the Edinburgh Medical Essays, and was reprinted with them in 1747, and finally published separately in 1752. Soon afterwards Dr. Alston published *A Dissertation on Quicklime*, in which he deduces from his experience that lime-water may have a tendency to prevent the formation of calculi; but that it is incapable of dissolving them when once formed. As neither of these gentlemen made any experiments on the calculi themselves, their observations contributed very little towards improving our knowledge of the nature of these concretions. The analysis of calculi by Slare contributed but little to explain their nature, (Phil. Trans. vol. xvi. 140.) Boyle had subjected them to distillation, and had obtained an oil and a great quantity of carbonate of ammonia.

Such was the state of the chemical knowledge of calculi, when, in the year 1776, Scheele published a set of experiments upon urinary calculi in the *Memoirs of the Stockholm Academy*, (*Undersökning om Blöse Stenen*, p. 327.) He found all the calculi that he examined of the same nature. He could discover in them no sulphuric acid and no lime; but they consisted of a peculiar substance possessing acid properties, and characterized by dissolving with effervescence in nitric acid, and assuming a beautiful pink colour when the solution is evaporated to dryness without the application of too much heat. To this acid the name *lithic acid* was afterwards applied, which by Fourcroy was changed into *uric acid*, in consequence of a remark of Dr. Pearson. Scheele showed that all urine contains this acid. Hence the origin of urinary calculi came to be understood. Whatever has a tendency to throw down uric acid from urine may give origin to a calculus.

To this paper of Scheele an appendix was added by Bergman, in which he stated the result of his own experiments. He detected the uric acid which Scheele had discovered, but found also some lime in all the calculi which he examined. This important paper of Scheele constituted the first step, and it was a material one, towards a full investigation of the nature of urinary calculi.

Hardly any addition was made to the facts ascertained by Scheele and Bergman till the year 1797, when Dr. Wollaston published a paper on *gouty and urinary concretions*, in the *Philosophical Transactions*. In this paper he gave an

account of three species of urinary calculi, quite different in their composition from those described by Scheele. The concretions which appear in the joints of gouty persons, and which had been known to medical men by the name of *chalk stones*, he ascertained to be a combination of *uric acid* and *soda*. To the three new species of calculi he gave the names of *fusible calculus*, *mulberry calculus*, and *bone-earth calculus*.

The *fusible calculi* had been first noticed by Mr. Smithson Tennant, who found, that when urged by the blow-pipe, instead of being nearly consumed, as happens to the uric acid calculi of Scheele and Bergman, they left a large proportion which fused into an opaque glass. This he conjectured to be phosphate of lime mixed with other phosphoric salts of urine. Dr. Wollaston found that this kind of calculus was white, and that it consisted partly of sparkling crystals composed of ammonia-phosphate of magnesia. These crystals had the form of short triangular prisms, having one angle a right one and the other two equal, and terminated by a pyramid of three or six sides. The other constituents of this calculus are phosphate of lime, and a very small quantity of uric acid.

The *mulberry calculus* had been noticed and named before by medical men; but no attempt had been made to determine its nature. The surface is irregular and knotted, bearing a distant resemblance to the mulberry. Dr. Wollaston showed that it is composed of oxalate of lime, mixed with a little blood and other animal matter. Calculi of the same nature are sometimes met with, smooth on the surface, and much lighter coloured. These, from their appearance, were called *hemp-seed* calculi, and were not suspected to be of the same nature with the mulberry, till Dr. Wollaston ascertained their composition.

The *bone-earth calculi* are of a brown colour, and so smooth as to appear polished; they consist of regular laminæ, easily separated from each other. Dr. Wollaston showed that they are composed of phosphate of lime: hence the name by which he distinguished them. Before the blow-pipe this calculus is slightly charred: it then becomes white; and when urged with the utmost heat from a common blow-pipe, it is at length fused. As this cannot be done with the earth of bones, Dr. Wollaston infers that the bone-earth calculi are composed of neutral phosphate of lime; whereas the earth of bones is known to be a sesquisulphate of lime, or a compound of—

1 atom phosphoric acid	4.5
1½ atom lime	5.26
	9.75

Dr. Wollaston, in this important paper, also examined the calculi from the prostate gland, and found them composed of neutral phosphate of lime tinged with the secretion of the prostate gland.

Some years after, a set of experiments on urinary calculi was published by Fourcroy and Vauquelin. They examined no fewer than five hundred different calculi, and were thus enabled to add a little to the important discoveries of Dr. Wollaston, to which, however, they make no all

lusion in their paper. They found calculi composed of urate of ammonia; and in two different calculi they found a small quantity of silica. The animal matter which serves as a cement to the constituents of the calculus, they consider as sometimes consisting of albumen, and sometimes of urea; but it is evident from the way they speak of it that they had not subjected it to a rigid examination.

The next addition to the chemical knowledge of the nature of calculi was made by Dr. Wollaston in 1810, (On a new species of Urinary Calculus, Phil. Trans. 1810, p. 223); by the discovery of a urinary calculus composed entirely of a peculiar substance capable of combining equally with acids and alkalies, and which he distinguished by the name of *cystic oxide*. It is of rare occurrence; only about six or seven such calculi having been hitherto met with.

The labours of Austen, Walther, Brugnatelli, Pearson, Brande, &c., have not added many new facts to those already known; but Dr. Marcet, in his *Essay on the Chemical History and Medical Treatment of Calculus Disorders*, published in 1817, gives an account of two new species of calculi which he had observed. The first, which he received from Dr. Babington, weighed eight grains, and was composed of a substance to which Dr. Marcet gave the name of *xanthic oxide*, from the lemon yellow colour which it forms when acted upon by nitric acid. The other calculus was about the size of a pea, and the substance of which it was composed possessed the characters of *fibrin*. On that account Dr. Marcet gave it the name of *fibrinous calculus*.

In the year 1821, Dr. Prout published *An Inquiry into the Nature and Treatment of Gravel, Calculus, and other Diseases connected with a deranged Operation of the Urinary Organs*; a new and improved edition of which appeared in the year 1825. In this work he treats at large on urinary calculi, and the states of the urine connected with their formation; and has thrown more light upon the subject than any preceding writer.

Such is a short history of the principal discoveries respecting calculi, chiefly of the urinary organs. We shall now take a view of the different calculi which are apt to form in living animals, and point out their nature, and the causes of their formation, so far as the subject has been investigated.

The calculi formed in living bodies are distinguished according to the organs in which they appear. We shall notice them in alphabetical order, dwelling principally on their chemical composition.

1. *Biliary calculi*, formed in the gall-bladder.
2. *Gouty concretions*, formed in the joints of gouty individuals.
3. *Intestinal concretions*, formed in the stomach and intestinal canal of man and the inferior animals.
4. *Ossifications or concretions* which occasionally form in the pineal gland, the salivary glands, the pancreas, the liver, the spleen, the lungs, &c.
5. *Calculi formed in the prostate gland*.
6. *Urinary calculi*, formed in the kidney or urinary bladder.

I. BILIARY CALCULI.—Hard bodies occasionally form in the gall-bladder, which, making their way into the duct through which the bile passes into the intestinal canal, prevent the bile from passing, and thus occasion the well-known disease called *jaundice*. These concretions have received the name of biliary calculi, or gall-stones. Though their existence was known to the ancients, and though they had been imperfectly described by medical men, scarcely any thing was known respecting their nature till they were examined by Poulletier de la Salle, about the year 1784, who found that they were partly dissolved by boiling alcohol, and that the alcohol on cooling deposited a number of brilliant white plates, bearing some resemblance to spermæti. The subject was taken up by Fourcroy in 1785, who compared the matter of gall-stones to the fatty matter into which human bodies had been converted when left in great numbers, piled on each other, to spontaneous decomposition. To this substance he gave the name of *adipocire*; and the same name was applied by him to the chief constituent of gall-stone. In 1814, Chevreul showed that these notions of Fourcroy were inaccurate; that the substance discovered by Poulletier de la Salle in gall-stones was quite different from Fourcroy's adipocire. Chevreul gave it the name of *cholesterine (solid bile)*, and showed that it existed as a constituent in bile. The biliary calculi hitherto described may be divided into three species, namely, *cholesterine calculi*, *mellitic calculi*, and calculi composed of *inspissated bile*.

1. Cholesterine Calculi.—These calculi are not by any means so abundant as those belonging to the second species, if we are to judge from the number which we have ourselves seen. They have a white colour, and a crystallized, shining, lamellated structure. Pretty frequently they have a slight shade of brown, sometimes indeed a decided brown colour, owing doubtless to the matter of bile interspersed through them, but in too small quantity to be visible to the eye, except by affecting the colour of the calculus. These calculi are composed of cholesterine, nearly in a state of purity. The largest we have seen was about the size of a hazel-nut, and very nearly spherical. It is exceedingly light, owing to the low specific gravity of cholesterine.

Cholesterine, when pure, has a white colour, and a silky or pearly lustre. It is lighter than water; it is tasteless and insoluble in water, and possesses little or no smell. Boiling alcohol dissolves about the fifth part of the weight of it, but deposits it on cooling in small brilliant plates. When heated to about 279° it melts, and in a vacuum it may be sublimed without decomposition. It does not combine with potash, nor can it be converted into a soap. According to the analysis of Chevreul, it is composed of—

1 atom oxygen.....	1
37.5 atoms carbon.....	28.125
31.5 atoms hydrogen.....	3.9375
	33.0625

But as it possesses neither acid nor alkaline characters, and is not known to combine in definite proportions with other bodies, we have no means

of determining whether these numbers or some multiple of them constitute the true compositions of it.

2. Mellitic Calculi.—We have given this name to by far the most common species of biliary calculi; and we have named them from the colour, which bears a considerable resemblance to honey, only it is browner. These calculi have always a polygonal shape, occasioned by mutual pressure; for a number of them always exist in the gall-bladder together. We have taken six out of a gall-bladder after death, and the gall-bladder in that case was almost filled. Most commonly they have three blunt edges, and have some resemblance to two low tetrahedrons applied base to base, with their edges and angles rounded off. The mean specific gravity is about 1.061. Their outer surface is smooth, and has a soft feel. When broken, they exhibit a thin outer crust, composed of concentric layers crystallized in small rays inclining towards the centre. These crystals consist of cholesterine. The nucleus has usually the appearance of granulated honey, and consists of inspissated bile.

In the calculi of this species, which we have subjected to analysis, very nearly 19.20ths of the whole was cholesterine. The rest was a mixture of picromel and some other animal matter, which was too small in quantity to admit of a rigid examination.

3. Inspissated Bile Calculi.—This species has a yellow colour, contains little or no cholesterine, but is entirely composed of inspissated bile. So far as our observations go, it is much more uncommon than either of the other two. That it exists, however, there can be no doubt, as Thenard examined several biliary calculi belonging to this species. The gall-stones of oxen are usually of a yellow colour, and consist of the yellow matter of bile mixed with minute traces of bile, which may be separated by water. When thus washed, they are tasteless and insoluble in water and in alcohol. They are used by painters, though their colour is not permanent, but soon changes to a brown.

As all the constituents of biliary calculi exist in the bile, there is no difficulty in understanding how they may be deposited when the proportion of the constituents of that liquid undergoes alteration.

Cholesterine has been rarely found in biliary calculi of the inferior animals; but that it exists in them also is certain; for Lassaigne found the constituents of a biliary calculus from a sow which he examined, as follows:—

Cholesterine	6
White resin	44.95
Bile	3.60
Animal matter	45.45
	<hr/>
	100.00*

II. GOUTY CALCULI.—It is well known that concretions occasionally make their appearance in joints long subject to gout. These concretions, from their colour and softness, have received the name of *chalk-stones*. They are usually small, though they have been observed of the size of an egg. Their nature was first discovered by Dr.

Wollaston in 1797, who proved that they were combinations of uric acid and soda, or composed of *urate of soda*.

Gouty concretions are soft and friable. Cold water has little effect upon them; but boiling water dissolves a small portion. If an acid be added to this solution, crystals of uric acid are deposited on the sides of the vessel. They are completely soluble in caustic potash when the action of the alkali is assisted by heat. When they are treated with dilute sulphuric or muriatic acids, the soda is separated, while the uric acid remains, and may be obtained in a pure state by filtration and washing. When the liquid is evaporated, it yields crystals of sulphate of soda or of common salt, according to the acid used. When the uric acid thus obtained is distilled, it yields ammonia, prussic acid, and the acid sublimate of Scheele (*pyruvic acid*). When dissolved in a little nitric acid, it tinges the skin of a rose colour, and, when evaporated, leaves a rose-coloured deliquescent residuum.

III. INTESTINAL CALCULI.—Concretions of very considerable size are sometimes found lodged in the stomach and intestines; not so frequently in the human body, but very often in some of the inferior animals.

The only intestinal concretions from the human body which we have seen are in the collection of the late Dr. Monro, of Edinburgh, and may still be seen among the preparations belonging to the anatomical class in the University of Edinburgh. They amount to forty-one, and are all very nearly of the same nature, though they differ in size. There are fifteen calculi exactly similar in the collection of calculi made by Dr. Hunter, and now belonging to the University of Glasgow. The largest of these weighs 1057 grains, and as some parts of it are wanting, there can be little doubt that its weight, when entire, was at least 1100 grains. These calculi have a brown colour, and are composed of fibres interwoven together after the manner of felt. They have altogether a certain resemblance to sponge. They feel soft, but are too hard to be much compressed. The specific gravity is about 1.4. One of those in Dr. Hunter's collection has a fruit-stone for a nucleus. In most of those in Dr. Monro's collection no nucleus whatever can be observed. Dr. Monro used to mention, in his lectures, that these concretions had been found in the colon, and that they had all proved fatal. The principal constituent in these concretions is the felted fibrous matter, which was naturally supposed to have been derived from the food. Mr. Clift, of the College of Surgeons, London, conjectured that it might proceed from *oats*. This induced Dr. Wollaston to examine the structure of the oat-seed, and the result fully verified Mr. Clift's conjecture. If the oat-seed be denuded of its husk, minute needles, or beards, forming a small brush, are seen planted at one of its ends. Dr. Wollaston, on examining these needles, and comparing them with similar ones detached from the calculi, satisfied himself of their perfect identity. Hence these concretions were owing to the use of oats as an article of food as oats are employed by the common people of Scotland as a common article of food, we see a reason why these concretions have been observed

* Ann. de Chim. et de Phys. 31,220.

chiefly in Scotland. Mr. Children gives an account of some formed in the human intestines, in Lancashire, where also oat-meal is in constant use by the common people. (Phil. Trans. 1822, p. 24.) The other constituents of these calculi are albumen, common salt, phosphate of lime, and phosphate of soda.

These are not the only calculi which have been found in the human intestines. Mr. E. Brande described some composed entirely of *carbonate of magnesia*, resulting from an excessive and continued use of magnesia for a long time. In one case a collection of several pounds of this substance was found lodged at the head of the colon, which in consequence was much distended. (Royal Institution Journal, i. 297.)

Dr. Marcet describes intestinal calculi voided by the rectum possessing the properties of indurated curd or cheese. (Marcet on Calculous Disorders, p. 127.)

He describes other small granular concretions, which were conjectured by Dr. Wollaston to be the small woody knots which are often found in certain pears; and upon close examination this conjecture was found correct. (Marcet on Calculous Disorders, p. 132.)

Some years ago the writer of this article received from an eminent physician in Birmingham a number of small flattened oval particles, which had been voided by a patient of his. They had all the appearance of seeds, but did not resemble any seed with which we were acquainted. At last, after carrying about the bodies for a considerable time and comparing them with the seeds of every species of fruit which he had an opportunity to inspect, we found that they were the seeds of figs. The patient had been eating green figs, the seeds of which had been voided entire.

Mr. Children gives an account of a very remarkable intestinal calculus which destroyed the life of John Chambers, a young carpenter at Clithero in Lancashire, who had been in the habit of eating large quantities of unripe plums, and of swallowing them together with the stones. Three concretions were formed in the arch of the colon, having a plum-stone for a nucleus, which in a short time destroyed his life. These concretions, together with some others collected by Mr. Barlow and Mr. Coultate; surgeons in Lancashire, which are deposited in the Museum of the Royal College of Surgeons, London, appear, from Mr. Children's description, to be intermediate between the *outen* concretions in the collection of Dr. Monro and Dr. Hunter, and the triple phosphates, which occur so frequently in the intestines of the inferior animals. They were laminated, and composed of alternate layers of the felted fibres of the oat and the triple phosphates. The following table exhibits the constituents of one of these concretions as determined by Mr. Children:

Animal matter, chiefly gelatin.....	25.20
Resin.....	3.90
Ammonia-phosphate of magnesia....	5.16
Phosphate of lime.....	45.34
Fibres of the oat.....	20.30
	99.90*

The calculi found in the intestines of the infe-

rior animals were examined with much care by Fourcroy and Vauquelin many years ago. They describe the following varieties:

1. **Biphosphate of Lime Calculi.**—They are composed of concentric layers, and very brittle. They redden vegetable blues, and are partially soluble in water.

2. **Phosphate of Magnesia Calculi.**—These concretions are described as semi-transparent and of a yellowish colour. Their specific gravity is 2.160. They are laminated. They are doubtless very uncommon. We ourselves have never had an opportunity of seeing any of them.

3. **Ammonia-phosphate of Magnesia Calculi**—said to be very common. Their colour is grey or brown, and they are composed of crystals diverging like rays from a centre.

4. **Fungous Calculi.**—These concretions are composed of pieces of the *boletus ignarius*, disposed in layers, and cemented by animal matters. These pieces had of course been swallowed by the animals in whose intestines they were found.

5. **Hairy Calculi.**—These are found in the stomach and intestines of cows and sheep. They consist of balls of hair felted together, and generally coated externally with a very thin crust of animal matter. The hair had obviously been licked by the animals from their companions, and had been felted by the action of the stomach and intestines. There are several of these concretions in the collection of Dr. Hunter belonging to the University of Glasgow. The same collection contains enormous calculi composed almost entirely of phosphate of lime; but as there is no history attached to them, we have not ventured to describe them, because we do not know from what animal, or from what part of the animal, they were obtained.

6. In the same collection are five or six of the celebrated oriental *bezoars*, once so much sought after as medicines of approved efficacy. They are all smooth and polished, and have a greenish colour. They are small and round, and long, so as to have a considerable resemblance to a cylinder rounded off at the ends. Three of these bezoars, sent by the Schah of Persia to Bonaparte, were found by Berthollet to be composed of fragments of wood. Another kind of these bezoars (probably artificial), analysed by Fourcroy and Vauquelin, was found composed chiefly of resin.

IV. **OSSFIFICATIONS.**—Concretions are apt to appear in various glands of the living body. These consist constantly of phosphate of lime and animal matter; or of a mixture of phosphate and carbonate of lime and animal matter. In some rare instances they consist almost exclusively of carbonate of lime and animal matter. The seats of these *ossifications*, as they may be called, are the pineal gland, the salivary glands, the pancreas, the lungs, the liver, and the spleen. The concretions coughed up from the lungs usually contain some carbonate of lime, and in some rare cases seem to be nearly destitute of phosphate of lime.

V. **CALCULI OF THE PROSTATE GLAND.**—[*Prostatal Calculi.*—Prout.] Calculi occasionally form in the prostate gland, sometimes in great numbers at a time and of small size, but occasionally in smaller numbers, and of a size nearly as large as that of a hazel-nut. Often they do not

* Phil. Trans. 1822, p. 23.

exceed the size of the head of an ordinary sized pin, and they are rarely larger, judging from those which we have seen, than a pea. These calculi were first examined by Dr. Wollaston, who found them composed of phosphate of lime, mixed with more or less animal matter. Dr. Prout informs us that he has met with calculi from the prostate gland containing a considerable proportion of carbonate of lime. The writer of this article has met with five or six which contained very little earthy matter, but which were composed chiefly of a substance having considerable analogy to cystic oxide.

These calculi, when small, are nearly spherical, and have a yellowish brown colour: those of a large size are smooth and polished, and have the appearance of porcelain; precisely similar, indeed, to the phosphate of lime calculi formerly described. Dr. Prout is of opinion that these porcelaneous calculi always originate in abscesses of the prostate gland. But there are not a few of them in Dr. Hunter's collection of such a size that they could not possibly have been deposited in any cyst of the prostate gland. These calculi sometimes give little uneasiness, and are not suspected till after death.

[The composition of all calculi of the prostate, according to Dr. Prout, (*On the Nature and Treatment of Stomach and Renal Diseases*, Amer. edit., from the 4th revised Lond. edit. p. 448, Philad. 1843,) is nearly the same,—that is, they consist chiefly of phosphate of lime, a little carbonate of lime, and animal matter. In different instances, the relative proportions of the phosphoric acid to the lime and the carbonate of lime appear to vary considerably.]

URINARY CALCULI.—The constituents of urinary calculi, so far as we know at present, are the following substances:—

1. Uric acid.
2. Urates of ammonia.
3. Urates of soda.
4. Phosphate of lime.
5. Ammonia-phosphate of magnesia.
6. Carbonate of lime.
7. Silica?
8. Cystic oxide.
9. Xanthic oxide.
10. Colouring matter of urine.
11. Purpurate of ammonia.
12. Fibrin.
13. Mucus.
14. Urea.

These substances seldom appear insulated or constituting each a whole calculus. In general several of them appear together, either mixed or constituting alternate layers. To enable us to form correct notions respecting the way in which they make their appearance in the urinary organs, it will be requisite in the first place to make a few remarks upon urine.

Urine, as is well known, is a liquid secreted from the blood by two large glands called the kidneys, possessing a remarkable structure which has been minutely described by anatomists. The quantity of urine voided daily differs very much in different individuals, depending in some measure on the quantity of drink and upon the state of the skin. But perhaps two pounds avoidupois

or 14,000 grains approaches somewhat to the general average. It is transparent, has a light amber colour, and, when voided, has an aromatic odour, which has been compared to that of violets. As it cools, this aromatic odour leaves it, and another succeeds, well known under the name of *urinous*. In two or three days this smell is succeeded by another, which has a considerable resemblance to that of *sour milk*. It has a disagreeable bitter taste, and a specific gravity which varies very much; but which may be stated as vibrating between 1.010 and 1.020; though in certain diseases it rises as high as 1.050, or sinks as low as 1.003. [According to F. D'Arcet (*L'Expérience*, No. lv., Aug. 1838), it varies between 1.001 and 1.060. Dr. Thomson (*British Annals of Medicine*, p. 5, Jan. 1837) found its specific gravity in an individual from 50 to 60 years of age, and in perfect health, to bear the average 1.013;—the lowest specific gravity being 1.004, and the highest 1.026: (see the writer's *Human Physiology*, 5th edit. i, 294: Philad. 1844.)]

It reddens vegetable blues, owing probably to the presence of a little urate of ammonia, and to some biphosphates which it always holds in solution. If we add to healthy urine a few drops of any acid, and set it aside for some time, small red coloured crystals are deposited. These consist of uric acid tinged by some colouring matter. If we evaporate a quantity of healthy urine to one half its natural bulk, and then mix it with nitric acid, and set it aside in an open vessel, a number of beautiful crystals in plates make their appearance. They have a light yellowish brown colour and a silky lustre, and consist of *urea* combined with nitric acid.

The presence of sulphuric acid can be detected in urine by means of a solution of chloride of barium; muriatic acid may be detected by nitrate of silver; and phosphoric acid by nitrate of lead; the white precipitate thrown down by which, as far as it is a phosphate, being again dissolved by the addition of nitric acid. Lime may be detected by means of oxalate of ammonia. The quantity of magnesia in urine is so small that it is scarcely possible to detect its presence by re-agents. But if a quantity of healthy urine be left for two or three weeks in a cylindrical glass vessel, the mouth of which is covered with paper, and then be poured out, we shall find attached to the sides of the glass a number of small transparent crystals consisting of four-sided prisms with square bases. These crystals constitute a double salt composed of

One atom phosphate of ammonia 6.625

One atom phosphate of magnesia 7

The formation of these crystals proves evidently that magnesia exists in urine, though only in minute quantity. Urine also contains potash, soda, and ammonia; the last of which may be detected by the smell, if we add caustic potash to urine concentrated by evaporation over sulphuric acid in the vacuum of an air-pump. If we continue this evaporation nearly to dryness, crystals of sulphate of potash and sulphate of soda make their appearance in it, proving that both potash and soda enter into the constitution of urine. The following table exhibits the constituents of

healthy urine according to Berzelius's analysis, which is the latest that we have.

Water	93.300
Urea	3.010
Uric acid	0.100
Mucus	0.032
Lactic acid, lactate of ammonia, &c.*	1.714
Sulphate of potash	0.371
Sulphate of soda	0.316
Phosphate of soda	0.294
Phosphate of ammonia	0.165
Chloride of sodium	0.445
Sal-ammoniac	0.150
Earthy phosphates, with a trace of fluorid of calcium	0.100
Silica	0.003
	100.000

Besides these substances, which form constant ingredients of healthy urine, this liquid in different diseases has been found to contain albumen, fibrin, and red globules of the blood; nitric acid, purpuric acid, oxalic acid, carbonic acid, benzoic acid; cystic oxide, sugar, bile, pus, and doubtless also xanthic oxide, though that has not yet been ascertained by observation.

Of these different constituents of urine there are only two that it will be requisite to describe particularly in this place. These are urea and uric acid.

Urea, when pure, is a transparent colourless substance, having a pearly lustre and crystallizing in four-sided prisms. Its taste is feeble; but it leaves a sensible coldness on the tongue like nitre. Its smell is slight, but peculiar, and quite different from that of urine. When exposed to damp air it deliquesces, but does not seem to be decomposed. The specific gravity of its crystals, as determined by Dr. Prout, is 1.350. At 60° water dissolves more than its own weight of it, and the solution may be exposed to the air without undergoing any change, provided it be pure; but if it be contaminated with the smallest quantity of foreign matter, it is speedily converted into carbonate of ammonia. Boiling water dissolves any quantity of it whatever. Alcohol of 0.816 dissolves at 60° about the fifth part of its weight of it, and at a boiling heat more than its own weight; but when the liquid cools, the excess of urea separates in crystals. When mixed with the caustic alkalis or alkaline earths, and heated (provided water be present), it is decomposed and converted chiefly into carbonate of ammonia. A number of curious facts, respecting the relation existing between urea and cyanogen have lately been discovered, which throw considerable light upon the occasional existence of prussic acid in urine,—a fact which seems pretty well established; but it would lead us too far from the subject of calculi to state them here.

[By the aid of the microscope, the presence of a very minute proportion of urea may be ascertained. If its aqueous or alcoholic solution be evaporated, and then a little nitric or oxalic acid be added, delicate silky crystals of nitrate or oxalate of urea are perceptible. The evaporation

* The writer of this article has in vain endeavoured to ascertain the presence of these bodies in urine.

should be performed on a glass slide, and the subsequent crystallization be examined by the microscope. (Dr. Griffith, *Practical Manual*, &c., p. 17, Lond. 1813.)]

Uric acid, when pure, is a white, tasteless substance, existing either in powder or in minute crystals, which seem to be four-sided prisms. It has no smell. According to Dr. Henry, it is soluble at 60° in 1720 parts of water; but Dr. Prout could not dissolve it in 10,000 times its weight of water.† It dissolves readily in a solution of caustic potash or soda, from which it may again be precipitated in a white powder by the addition of almost any acid. It dissolves in nitric acid with effervescence, when assisted by heat. When the solution is gently concentrated, crystals of erythric acid form in it. When the liquid is evaporated to dryness, a beautiful pink sediment remains, which is a characteristic of this acid. On one occasion we have seen uric acid converted into urea by digestion in nitric acid. The experiment was made by a surgeon who wished to determine the nature of a calculus which he had extracted. The result not being satisfactory, he brought both the calculus and the substance into which he had converted it, to the writer of this article. The calculus was the common uric acid calculus, mixed apparently with muriate of ammonia. The substance into which it had been converted was urea. The surgeon could not give a satisfactory account of the process which he had followed, and we attempted in vain to repeat it successfully.

Uric acid combines with the different bases, and forms salts nearly insoluble. The urate of ammonia is the most soluble; it dissolves in about 480 times its weight of water, and the solution has the property of reddening vegetable blues. If we put a quantity of healthy urine under the exhausted receiver of an air-pump over sulphuric acid, and allow it to evaporate spontaneously, a sediment of urate of ammonia gradually attaches itself to the sides of the vessel in which the urine is. This seems to prove that in urine the uric acid is in the state of urate of ammonia.

[Uric or lithic acid is always crystalline. As occurring in urine, the crystals are always coloured. Their varieties of form are endless; and they are either separate, or combined in clusters. When separate, the outlines are either rhomboidal, square or rectangular; and all their varieties, according to Dr. Griffith, (*op. cit.*) are explicable by assuming them to be derived from the right rhombic prism. When examined by polarized light, the crystals of lithic acid develope splendid colours.

Urate or lithate of ammonia is almost always amorphous. The radiating needles, seen upon its surface have been described as composed of superlithate of ammonia; but Dr. Griffith states, that

† The probability is that both of these statements (incompatible as they may at first sight appear) are substantial correct. Dr. Henry probably digested uric acid in water of 60°, and evaporated a given weight of this water to dryness in a moderate heat, and weighed the uric acid remaining. Dr. Prout, on the other hand, digested one grain of uric acid in 10,000 grains of water without being able to dissolve it. The first experiment shows the quantity of uric acid which water can dissolve when the attraction of aggregation is destroyed; the second the power which water possesses to destroy this attraction of aggregation.

he has not obtained enough to enable him to speak positively on this point.]

Let us now take a view of the different urinary calculi, that we may see what light our knowledge of the urine will throw upon their formation.

1. **Uric acid Calculi**, [*Lithic acid Calculi*.]—The uric acid calculus is by far the most common of all, and to judge from the number of calculi which the writer of this article has had an opportunity of inspecting, at least two-thirds of the concretions formed in the kidney or urinary bladder owe their origin to the deposition of uric acid, either in a pure state, or combined with ammonia. As healthy urine contains urate of ammonia to the amount of about 1-813th part, and as this salt requires about 480 times its weight of water to dissolve it, we see at once, that, if by any derangement in the digestive organs the quantity of urate of ammonia in urine should be tripled, a portion of it would of necessity be thrown down, as the urine would not be sufficient to hold the whole of it in solution: for the urate of ammonia would amount to 1-271st part of the urine; so that about three-eighths of it would precipitate. Calculi composed of urate of ammonia are always small, and seem nearly peculiar to children. They are undoubtedly to be ascribed to the existence of an excess of urate of ammonia in the urine, which is a very common consequence of indigestion, proceeding either from the use of an excessive quantity of food, or of food which does not agree with the constitution of the child.

Whenever a free acid makes its way into the urine, uric acid constantly precipitates, and may give origin to a calculus unless it be voided along with the urine. Now, as there is always a quantity of free muriatic acid in the stomach, and frequently also acetic acid, it is easy to see how these, when they become excessive, may make their way to the urine, and occasion a precipitation of uric acid.

It is probable that most of these calculi have their origin in the kidney, from which they are not displaced till they have gained some size; for if either urate of ammonia or uric acid were to be precipitated in the bladder, as they would be in the state of a powder or of minute crystal, they would probably be voided along with the urine. But, after a nucleus has lodged in the bladder, it is easy to see how it increases in size; because the uric acid, &c., as precipitated, is deposited on its surface, and adheres to it.

Calculi composed of uric acid are generally of a brownish red or fawn colour, but occasionally approaching to the colour of mahogany. The surface is often smooth, but not unfrequently finely tuberculated. This kind of calculus is usually composed of concentric laminæ. Its fracture generally presents an imperfect crystalline texture, but sometimes an earthy one; in which case its colour is lighter, and it usually contains a mixture of urate of ammonia.

Before the blow-pipe this calculus blackens, emits a smoke having a peculiar colour, and is gradually consumed, leaving a minute quantity of white ash, which is generally alkaline. It is completely soluble in caustic potash, and precipitated again by any acid in the form of a white granular powder. When a fragment of it is

mixed with nitric acid, and heated on a watch-glass, it dissolves with effervescence; and if the solution be evaporated to dryness, the residue assumes a beautiful pink colour.

This is by far the most common species of calculus. The number of calculi composed of uric acid alone, or only slightly mixed with other bodies, in the collection of Dr. Hunter, deposited in the Hunterian Museum belonging to the University of Glasgow, amounts to ninety-eight. Of these, sixty-seven are tuberculated on the surface. The largest of them measures three inches in length, and weighs 2340 grains. Another weighs 1817 grains. Most of them are composed of concentric laminæ, chiefly distinguishable by difference of colour, and in the density or looseness of texture. Some of them contain a small compact nucleus of uric acid; others not.

The uric acid calculi, quite smooth on the surface, in the same collection, amount to twenty-three. No other difference between these and the tuberculated calculi can be pointed out, except the appearance of the surface. Several of them are crystallized, and they consist of laminæ like the others. In some of the internal laminæ, tubercles can be distinctly recognised.

There are eight uric acid calculi in the collection, of a much whiter colour and more chalky texture than the others. Probably they contain urate of soda. One of these contains a piece of bright iron as a nucleus.*

Calculi of urate of ammonia [or lithate of ammonia] are so rare that their existence has been denied altogether. There is not one of them in the collection of calculi in the Hunterian Museum belonging to the University of Glasgow; but the writer of this article has had an opportunity of inspecting and subjecting to a chemical analysis a considerable number of such calculi. The late Dr. Monteath, surgeon in Glasgow, had a high reputation as an operator for the stone. He had preserved all the calculi which he had extracted, and among them there were no fewer than seven consisting of urate of ammonia. Most of them had been extracted from infants between the ages of two years eleven months, and nine years, though one was from a man of forty. It was dark-coloured, and in layers, and about the size of a wren's egg.

They were all small, but sufficiently large to be subjected to analysis without any great diminution of their size. The diameter of the largest was one inch and five-eighths.

Urate of ammonia calculi have a clay colour; the surface is in most cases smooth, but sometimes tuberculated. The stone is composed of concentric layers, and the fracture is very fine earthy. Before the blow-pipe it usually decrepitates strongly. It is much more soluble in water than uric acid calculus,† and when heated with caustic potash gives out a strong smell of ammonia. Liquid carbonate of potash or soda readily dissolves the urate of ammonia calculus, although they are incapable of dissolving uric

* Most of these calculi have been varnished. This is the reason why the iron has remained bright.

† It is not unlikely that the calculus originally examined by Scheele was composed of urate of ammonia. This would account for its solubility, which he found much greater than that of uric acid calculi ever is.

acid calculi. The reason of this is, that a double decomposition takes place; the carbonic acid and ammonia unite together, and make their escape, while the caustic alkali combines with the uric acid. Two of these calculi consisted of urate of ammonia alone; two had a nucleus of uric acid, while the external part was urate of ammonia; and three were mixtures of uric acid and urate of ammonia.

Urate of ammonia calculi are certainly rare. They seem to be mostly confined to infants, or at least to persons under puberty. They occasion a degree of irritation in the patient scarcely credible. The opening or shutting of a door, or the least noise or motion, produces a paroxysm of the most distressing kind.

Uric acid exists very frequently as the nucleus of a calculus, the greatest part of which consists of other ingredients; showing clearly to what cause the origin of the disease must be ascribed.

2. Mulberry or Oxalate of Lime Calculi.

—Next to the uric acid, we conceive that the oxalate of lime constitutes most frequently the nucleus of urinary calculi. This calculus is usually of a dark brown colour, approaching to that of dried blood. Its surface is very rough and tuberculated. It is usually hard and compact, and, when cut through, exhibits an imperfectly laminated texture. Mulberry calculi commonly approach the spherical form, and are never very large. The diameter of the largest in the Hunterian collection belonging to the University of Glasgow, is two inches. It weighs 1323 grains. Before the blow-pipe this calculus expands into a kind of white efflorescence, which, when moistened and brought in contact with turmeric paper, stains it red, owing to the lime being deprived of its acid, and rendered caustic by the heat. When pounded, it dissolves slowly in muriatic or nitric acid; and the oxalate of lime may be again thrown down by ammonia.

There is a variety of this calculus called *hemp-seed calculus*, from some resemblance which it bears in colour and lustre to hemp-seed. It is remarkably smooth and pale-coloured, and always of a small size. A number of these hemp-seed calculi usually exist in the bladder at once.

[Oxalate of lime, when present in the urine, occurs in crystals, whose form is a very flat octohedron. As they lie upon the field of the microscope, they appear to have a rectangular or sometimes a square outline. When dry, they seem to have a smaller square placed within the larger, whose sides are opposite the angles of the latter. Sometimes, they appear in the form of dumb-bells. By polarized light the dumb-bells give the most splendid colours, whilst the octohedrons produce very little, sometimes no alteration. (Dr. Bird and Dr. Griffith, in *op. cit.*)]

As oxalic acid is not a constituent of healthy urine, it is not easy to conceive to what alteration in the blood or in the functions of the kidney its formation is owing. Probably the appearance of this acid is the consequence of the mode of living. From a paper by Mr. R. Smith, of Bristol, entitled *A Statistical Inquiry into the Frequency of Stone in the Bladder in Great Britain and Ireland*, it appears, that in the collection of calculi belonging to the Bristol Infirmary, amount-

ing to two hundred and eighteen specimens, about five-twelfths, or almost one-half are either composed entirely of oxalate of lime, or contain at least a nucleus of that substance. Of the one hundred and eighty-seven calculi belonging to different practitioners in Manchester, described by Dr. Henry, about one-fourth are either composed of oxalate of lime, or contain it as a nucleus. In Dr. Hunter's collection belonging to the University of Glasgow, the number of calculi composed altogether of oxalate of lime amounts to only two. But those which contain a nucleus of oxalate of lime amount to fifteen. Of these, ten contain a nucleus of oxalate of lime, while the outer lamina is uric acid. Five have a nucleus of oxalate of lime, while the outer crust is triple phosphate. In three of the five there are three laminae; 1. a nucleus of oxalate of lime; 2. a thick lamina of phosphate of lime; 3. a thin crust of triple phosphate.

We can draw no conclusion from their numbers, because Dr. Hunter has left no documents by which the localities from which he procured his calculi can be authenticated. As he did not himself practise as a surgeon, it is obvious that his collection must have been made by presents from other persons; and being a great favourite with his pupils, who were settled in almost every district of Britain, it is probable that he drew his supplies indiscriminately from the whole island.

3. Phosphate of Lime Calculus, [*Bone-earth Calculus*.]

—This calculus is generally of a pale brown colour, and its surface is smooth like porcelain, so as to appear highly polished. It is very regularly laminated. The laminae are usually thick and very easily separated from each other. The shape is mostly oval, and the size is sometimes very considerable. We have seen one taken out of the bladder, after death, of such a size that it must have nearly filled it. It does not fuse before the blow-pipe. It dissolves readily in muriatic acid, without effervescence, and is precipitated undecomposed by caustic ammonia.

Judging from the statements of Mr. Brande, Dr. Marcet, Dr. Henry, and Mr. Smith, who have described the constitution of no fewer than 823 calculi, this calculus in a pure state is exceedingly rare, and generally of a small size. The number of calculi composed entirely of phosphate of lime, in Dr. Hunter's collection, is 43. The largest is 2.8 inches in length; but it is not certain that it was from a human bladder. It weighs 2142 grains. The finest of these calculi is composed of five laminae, easily separable, and quite smooth and polished on the surface.

There are 11 calculi in the same collection, composed chiefly of phosphate of lime, but the outermost coat of which is the triple phosphate. Thus the whole phosphate of lime calculi in this collection amount to 54, which approaches to one-fourth of the whole. But we are not certain that some of these may not have been from some of the inferior animals. The number containing a nucleus of phosphate of lime and an external coating of the triple phosphates is small, not amounting to a tenth part of the collection. There is not a single calculus in which a nucleus of phosphate of lime is followed by a lamina of uric acid or oxalate of lime.

As phosphate of lime (or at least *biphosphate of lime*) exists in urine, though in exceedingly minute quantity, there is no difficulty in conceiving how it might be deposited. Whatever has the property of rendering the urine alkaline, will of necessity precipitate phosphate of lime from it. For example, if the nature of the uræ were so much changed that it should be converted into carbonate of ammonia, which happens out of the body whenever it is heated in contact with potash or soda and water, it is obvious that phosphate of lime would be thrown down.

4. Ammonia-Phosphate of Magnesia Calculi.—[*Ammoniaco-magnesian phosphate calculi; triple phosphate of magnesia and ammonia calculi.*] These are always nearly white. The surface is commonly uneven, and covered with minute shining crystals. The texture is not at all, or very imperfectly laminated. This calculus is soft, and easily broken and reduced to powder. But it is said sometimes to be hard and compact, and when broken, exhibits a crystallized texture, and is somewhat transparent. There is a remarkable calculus of this kind in the Hunterian Museum, belonging to the University of Glasgow. It was taken from the bladder after death, which it completely filled. It was sent to the museum by Dr. King, of Irvine. It is an oval stone, constituting a pretty exact cast of the bladder. Near the centre it is a little smaller, indicating a stricture of the bladder in that place. The length of this stone is five inches and a half. Its circumference where thickest is fourteen inches and one-sixteenth; but at the stricture only ten inches. Its weight is one pound fourteen ounces and eight grains avoirdupois. It is white and crystallized on the surface, bearing some resemblance to agalmatolite. It is composed of a nucleus of uric acid, having a brown colour, and composed of many concentric laminae. The external crust is ammonia-phosphate of magnesia, mixed with some animal matter. This calculus is the largest which the writer of this article has ever seen. Before the blow-pipe this calculus gives off the odour of ammonia, and at length melts with difficulty. It gives out ammonia when treated with caustic potash, and is very easily dissolved by very dilute acids.

It is a rare thing to meet with a calculus composed entirely of ammonia-phosphate of magnesia. In the Hunterian collection belonging to the College of Glasgow, which consists of 225 urinary calculi and about 75 intestinal calculi, biliary calculi, and calculi belonging to inferior animals, there is not a single specimen of this calculus in a state of purity. But mixed with phosphate of lime it is by no means uncommon, and then constitutes what Dr. Wollaston called *fusible calculus*. It is usually white and friable, somewhat like a mass of chalk. It is sometimes very large. It fuses very easily before the blowpipe, and dissolves with great ease in dilute muriatic acid. There are fourteen such calculi in the Hunterian collection. The largest is three-fifths of an inch in length, and weighs 1758 grains. One of these calculi contains a piece of lead about the size of a crow-quill, and more than an inch long, which had served as a nucleus. A second has a nucleus of tin. Besides these fourteen composed entirely

of the mixture of the two phosphates, there are seventeen calculi in the same collection having a nucleus of phosphate of lime, but whose external coat is the fusible calculus. It is curious that this external coat, which is usually much more abundant than the nucleus, is not concentric with it. The internal nucleus with which the calculus has obviously originated is frequently within a quarter of an inch of the outside of the calculus on one side, and more than an inch from it at the other side. It is obvious from this, that the accumulation of the fusible part of the calculus must have been very rapid.

As biphosphate of magnesia exists in urine, and as it becomes insoluble whenever the second atom of acid is saturated with ammonia, we can easily see that there ought to be a deposit of ammonia-phosphate of magnesia whenever the urine becomes charged with ammonia. Ammoniacal urine usually indicates a broken constitution; and it is remarkable that in such urine the quantity of earthy phosphates always increases enormously. Hence it happens that the fusible calculus frequently forms the outermost coat of large calculi, and that whatever may have been the original state of the urine when the calculous deposit began to be formed, it ultimately terminates, unless the irritating cause be removed, in the urine becoming alkaline, and the consequent deposition of the fusible calculous matter. Perhaps this may be owing in some cases to improper medical treatment; for Dr. Prout mentions calculi which he had examined, the outer crust of which consisted of urate of soda. In such cases the patient seems to have been subjected to a course of alkaline medicines till the urine was impregnated with an excess of soda. This occasioned the deposition of urate of soda, and would ultimately have led to the deposition of the triple earthy phosphates, and probably to the increase of their quantity.

[The bi or sesqui-basic triple phosphate of magnesia and ammonia, is composed of minute elegant stellæ. It is seldom found as a natural deposit, but may often be detected in urine which has become alkaline by keeping. The neutral phosphate is found in the form of beautiful prisms. Sometimes the angles are replaced by facets. These crystals are recognized by their transparency, absence of colour and peculiar forms. When examined by polarized light, the neutral phosphate produces the most brilliant colours. The stellar bi-basic triple phosphate produces little or no effect with polarized light. (Griffith, *op. cit.*)]

5. Carbonate of Lime Calculi.—These calculi are not very rare in the inferior animals, though they are very uncommon in man. Mr. Smith describes some which he had met with that bore a close resemblance to the mulberry calculi, and yet consisted of carbonate of lime. (Med. Chirurg. Trans. xi. 14.) Dr. Prout mentions some small calculi which he had seen composed almost entirely of carbonate of lime. They were perfectly white and very friable. (Prout's Inquiry, p. 93; [and *On the Nature and Treatment of Stomach and Renal Diseases*, Amer. edit. from the 4th revised Lond. edit. p. 448: Philad. 1843.]) In Dr. Montearth's collection, mentioned before, there was a small calculus, which had been extracted from a man in the 26th year of his age. It was white,

but not friable, nor did it stain the fingers; it was composed of nearly one part of carbonate of lime and two parts of phosphate of lime. There was a very small internal nucleus composed of bright crystals, having the aspect of ammonia-phosphate of magnesia. This is the only calculus that we have seen having a nucleus of ammonia-phosphate, and the outer crust of which consisted of other constituents. Yet as the whole calculus was calcareous, it can hardly be considered as an exception from the general rule.

The carbonate of lime calculus is easily detected by the property which it has of dissolving in muriatic acid with effervescence, and the neutral solution is abundantly precipitated by oxalate of ammonia.

6. Cystic Oxide Calculi.—This calculus has a yellowish white colour, and its surface, which is commonly smooth, exhibits a kind of crystallized appearance. It is not composed of distinct laminae, but appears as one mass, confusedly crystallized throughout its substance. The fracture exhibits a peculiar glistening lustre, like that of a body having a high refractive density. When in small fragments, it is semi-transparent. This calculus is very rare, only four or five specimens having yet been recognized. When treated by the blow-pipe, it gives out a peculiar and characteristic odour. It is very easily dissolved both in acids and alkalis, and crystallizes with both.

[Cystic oxide generally crystallizes in delicate six-sided and sometimes in quadrilateral plates. At times, the crystals are crenate at the margin, with a dark nucleus, and often irregular laminae are perceptible on the surface. The effect with polarized light is various; sometimes colour is developed, but often not.]

7. Xanthic Oxide Calculi.—Of this very rare calculus only a single example has been hitherto observed. It was given to Dr. Marcet by Dr. Babington, who had it from one of his patients; but nothing farther is known respecting its history. It had an oblong spherical shape, and weighed about eight grains. Its texture is compact, hard, and laminated; surface smooth, colour cinnamon brown, and much heightened by adding caustic alkali to the calculus in powder. Before the blow-pipe it splits in pieces, burns black, and is consumed, leaving a minute particle of white ash. When distilled it yields a fetid ammoniacal liquid, from which carbonate of ammonia crystallizes. It is mostly soluble in boiling water when in fine powder, and the solution reddens vegetable blues. On cooling the greatest part again subsides in white flocks. It dissolves both in acids and alkalis, though much more readily in the latter than the former. When its solution in nitric acid is evaporated to dryness, the residue has a bright lemon yellow colour. This residue is partly soluble in water, to which it communicates its colour. Thence the reason of the name xanthic oxide, by which Dr. Marcet distinguished it. It is insoluble in alcohol, ether, and oxalic acid, and very sparingly soluble in acetic acid. (Marcet's Essay on the Chemical History and Medical Treatment of Calculous Disorders, p. 95.)

8. Alternating Calculus.—This, as the name imports, may consist of different layers of any of the preceding species. Hence its appear-

ance may be very varied. The nucleus is usually uric acid or oxalate of lime; and the outermost crust is not unfrequently composed of triple phosphate. We have in the preceding account stated the different alternations, and the order in which they occur in the calculi belonging to the Hunterian collection in the College of Glasgow.—There was an alternating calculus in the late Dr. Monteat's collection, which deserves to be noticed. It was oblong, being 1.75 inches long, and 1.375 inches broad where widest. It was composed of three distinct substances. The nucleus was oxalate of lime, not however pure, but mixed with a little phosphate of lime, and with distinct traces of uric acid. The second layer was composed of uric acid mixed with some phosphate of lime. The outermost coat consisted of phosphate of lime mixed with a little uric acid. This outermost coat was divided into three distinct layers, each of them composed of the same materials. This calculus was not only composed of alternating coats, but each coat was a mixture of two or more constituents. Indeed, this mixture of different ingredients in the same coat is a very frequent occurrence in calculi. The most common mixture is that of urate of ammonia with the phosphates. In such cases the urine was undoubtedly alkaline; and such a state, when it continues, is very apt to occasion a redundancy of earthy phosphates, which of course would be neutralized and precipitated by the alkali present. This alkali, it may be presumed, is most commonly ammonia.

9. Fibrinous Calculus.—This calculus was sent to Dr. Marcet by Sir Astley Cooper. It was about the size of a pea, and had a yellowish-brown colour, somewhat resembling that of bees'-wax. Its surface was uneven, but not rough to the touch; its texture rather fibrous than stratified, and the fibres seemed to radiate from the centre. When heated it took fire, swelled out, and burnt like an animal matter. It was insoluble in water and muriatic acid; but it formed a soapy solution when boiled with caustic alkali, from which it was precipitated by muriatic acid. Nitric acid dissolved it with difficulty. When boiled in very dilute acetic acid, it swelled to a great size, and was at last dissolved; and prussiate of potash, when added to the solution, threw down a yellow precipitate. These characters lead to the conclusion, that the calculus in question was composed of *fibrin*. (Marcet's Essay, &c., p. 101.) This kind of calculus is very rare, having been observed only in the case of a gentleman between fifty and fifty-five years of age, who passed in succession three such calculi.

Such is the nature of the different calculi to which the urinary organs of man are liable. The mulberry calculi are the most difficult of explanation, as they consist of a salt which does not exist in healthy urine at all; yet they are not uncommon, the mulberry calculi in Dr. Hunter's collection amounting to one-thirteenth of the whole. But by far the most common calculus is the uric acid one. They amount, in the collection of Dr. Hunter, to five-elevenths of the whole; and they are still more numerous in the collections which have been described by others. In Dr. Monteat's collection, which consisted of about thirty calculi, all of which he had extracted himself, no fewer

than ten-thirteenths, or rather more than three-fourths of the whole, consisted of uric acid or urate of ammonia.

There is reason to believe that, when uric acid is deposited, the urine is *acid*; a state which is very apt to follow indigestion, or excess in eating and drinking.

The phosphate of lime calculi are generally considered as rare, and it is supposed that they are always small in size. If any conclusion can be drawn from the number in Dr. Hunter's collection of calculi, they amount to very nearly one-fourth of the whole. Some of them are very large; but as there is no catalogue nor history accompanying this collection, we cannot be sure that some of them are not from the inferior animals. Yet, as the calculi of the inferior animals are in this collection arranged in a separate drawer, it seems to follow that all the calculi in this part of the collection were considered by Dr. Hunter as human calculi.

The fusible calculi usually indicate a broken constitution. Hence this matter commonly constitutes the last coat of those calculi that have been long in the bladder, and which have been taken out after death. The calculi belonging to this class in Dr. Hunter's collection amount to nearly one-seventh of the whole. But if we take the phosphate of lime and the fusible calculi together, they constitute two-fifths of the collection. Probably they may be nearly as numerous as the uric acid calculi; but as patients afflicted with them frequently die, many of them are not extracted at all, and thus the number appears much less than it ought to do; whereas the uric acid being a deposit which is apt to be formed in a state of comparative health, the operation is much more frequently had recourse to, and of course their numbers appear much more formidable than those of the phosphates. [See, on the chemical history of urinary concretions, Dr. Golding Bird, in *Guy's Hospital Reports*, vii. 175.]

THOMAS THOMSON.

CALCULUS. (PATHOLOGY AND TREATMENT.)—The calculi which are found within the urinary organs are, of all those enumerated in the preceding article, the most important to the practitioner, and they have long attracted a large share of attention from medical men.

Urinary calculi are formed by the diseased action of the vessels which secrete the urine, or by a deposition from urine in a morbid state. They are also formed by the mucous membrane of the bladder, which sometimes secretes an altered fluid abounding in phosphate of lime; just as many of the concretions enumerated take place in other mucous cavities.

In considering the formation of urinary calculi, there are certain chemical facts which require to be stated before we can explain how precipitations from the urine occur. When any acid, even the carbonic, is added to healthy urine, a precipitation of lithic acid after a short time takes place; the acid thus added seizing upon the small proportion of ammonia in combination with the lithic acid, and by means of which it was held in solution. (Dr. Prout on Diseases of the Urinary Organs, 2d edit. p. 12, [and on the Nature and Treatment of Sto-

mach and Renal Diseases, Amer. edit. p. 163: Philad. 1843.]) Thus we see how the presence of any uncombined acid in the urine will produce a lithic deposit, and give rise to calculous disease, or augment a calculus already in existence. The acid which seems most commonly to be the primary cause of lithic deposits, is the muriatic, and its source the stomach, where it abounds in most cases of indigestion.

On the other hand, by adding ammonia to healthy urine, a precipitate is produced, consisting partly of phosphate of lime, and partly of triple phosphate of ammonia and magnesia: part of the alkali uniting with the excess of phosphoric acid, which held the lime in solution, while another portion combines with the phosphate of magnesia, and forms a salt of very sparing solubility. Hence we perceive the connection which exists between ammoniacal urine and the deposition of the phosphates. The ammonia, thus performing so important a part in calculous disease, seems to be chiefly derived from the decomposition of urea, which is effected readily by the presence of the fixed alkalies and alkaline earths, and by various other substances. These remarks will serve to explain in what way precipitations from the urine do take place independent of a morbid excess of lithic acid, or of lime and magnesia; but it is by no means to be inferred that the excess of these constituents of urine is not respectively the immediate cause of a great majority of calculous cases.

When a calculous nucleus has been formed, if it do not escape by the natural outlet, it will receive from the urine by which it is washed successive additions of solid matter. It does not appear, however, that in all such cases there is a continual increase of the stone; for we often find it to consist of many distinct concentric laminae, varying in thickness, and sometimes also in composition. It is, besides, obvious that the occurrence of a deposit will depend on the condition of the urine, which may be, and frequently is, so healthy that it lets fall no concreting matter. Calculi have been known to exist in the bladder for many years, yet without acquiring an extraordinary size, which they must have done had a continual increase been taking place. The mechanical process of the formation of calculi is sufficiently demonstrated by dividing them accurately through the centre; thus exhibiting their nucleus and the successive layers of which very many of them are composed. The nucleus is either itself a concrete formed by the kidney,—in two cases out of three lithic acid,—or some extraneous body which has found its way into the urinary cavities. The most common of such foreign bodies is a clot of blood; at other times the nucleus has been a fragment of a bougie, a small hair, a portion of lint introduced through the wound in lithotomy, a bit of straw, a musket-ball, a pin, a bodkin, and even a filbert. By such dissections of calculi we are enabled to trace out with accuracy the history of their formation, to mark the changes which the constitution of the urine underwent during the progress of the disease, and to satisfy ourselves that considerable intervals must have occasionally existed between the successive deposits.

Urinary calculi vary exceedingly in their size, form, and tenacity. Some calculi do not equal a

millet-seed in size, while others have been found so large as to fill up the entire cavity of the bladder. Mr. Earle has described a very large stone which had been extracted, but with a fatal result, by the celebrated Cheselden. Its weight was 18½ ounces, its circumference in the large axis was 11½ inches, in its short axis 10 inches. Dr. Charles Preston relates in the *Philosophical Transactions*, that he saw, at La Charité, in Paris, a stone which weighed 51 ounces. The patient died under the hands of the operator. Mr. Harmer, of Norwich, extracted from the bladder a stone which weighed 15 ounces, and had a diameter of 4½ inches by 3½. The patient recovered, but a fistulous opening remained. (*Gooch, Surg. Observat.* p. 54.) In the case of Sir David Ogilvie, Mr. Cline performed the operation, but could not extract the stone. (*Philos. Trans.* 1810.) After death it was found to measure 16 inches in its longest diameter, and 14 in its shortest, and to weigh 44 ounces. The Breslau collection contains an account of a stone found in the bladder after death, which weighed 72 ounces. (*Bresl. Sam.* vol. ii. p. 434. 1724.) Kesselning relates that he saw, in Morand's Museum at Paris, a stone which weighed six pounds three ounces; and the model of another which was still larger. (*Haller, Dissert. Chir. t. iv.* p. 251.)

By far the largest calculus which we have ourselves seen is one presented to the Hunterian Museum at Glasgow, by Dr. King, of Irvine. It was taken after death from the body of a carter, who had for many years laboured under the disease. Its form is irregularly egg-shaped, with a slight constriction near the middle; its greatest circumference is $14\frac{1}{8}$ inches, its shortest 10 inches. It has unfortunately been broken, but it is now so carefully cemented together by means of plaster of Paris, that its appearance is in no way injured. The weight of the calculus as it now lies, together with some fragments kept for examination, has been ascertained by Dr. Thomson to be one pound fourteen ounces eight grains avoirdupois. It consists of two substances: one resembling light brown indurated earth, and forming the great mass of the stone; the other an incrustation of white closely crystallized matter, which envelops all but one or two spots. The surface of this crystallized portion presents numerous short elevated lines and small indentations, corresponding apparently to the minute wrinkles of the mucous membrane with which it lay in contact.

Urinary calculi are usually spheroidal, and their surface is sometimes remarkably smooth, often covered with minute crystals, occasionally tuberculated, or beset with sharp projections. Calculi of the kidney, when of large size, sometimes present a complete cast of the dilated cavities of that gland, and have the appearance of corallines. When several stones are contained within a cyst or pouch, their surfaces become adapted to each other, and the whole often forms one globular cluster. Instances are recorded where calculi have occupied the neck of the bladder and prostatic portion of the urethra, moulding themselves to the form of the cavity, and allowing the urine to drain away by their sides. (*Ballingall, Ed. Med. Chir. Trans.* vol. ii.) and several histories

are to be met with of grooved (*Blancard, Anat. Prat. Cent. i.* Ob. 91. *Walter, Mus. Anat.* vol. i. p. 31) and even perforated calculi. (*Schurig, Litholog.* p. 371. *Blancard, Anat. Pract. Cent. ii.* Obs. 34.) Many calculi are so hard that they cannot be penetrated without great difficulty, while others are so loosely agglutinated that the pressure of the forceps in extraction readily crushes them into a substance like mortar. In other cases the calculous matter has never coalesced into a solid, but remains in a soft state, like newly-mixed plaster of Paris.

In reference to the medical history of calculi, they may be conveniently divided according to the situation in which they are found; into renal, vesical, and urethral. A fourth description of calculus found in the genito-urinary organs is the prostatic; but there is reason for believing that it is not derived from the urine.

1. RENAL CALCULI.—It is an observation as old as Pernelius, and it may be traced even higher, that all urinary calculi not formed on foreign bodies introduced into the bladder, originate in the kidney; and if we except phosphatic concretions, some of which appear to be formed in the bladder, the doctrine appears to be substantially correct. We will not attempt to describe in what exact mode a calculus is first formed in the kidney, nor is it likely that we shall even attain to more than a probable conjecture on this subject. As crystals of lithic acid have been found in the tubuli uriniferi, and even in the cortical part of the kidney, (*Wilson, Lect. on the Urinary Organs*, p. 213, 8vo. 1821.) there is good reason to believe that in many instances the material of calculus concretes almost at the moment of its secretion. If such solid granules be retained within the channels of the kidney, it is obvious that they must become the centres of attraction for other particles of concreting matter to arrange themselves around; and as they increase in size, they will serve, by their irritation, to derange the actions of the organs in which they are detained, and thus occasion the secretion of a morbid fluid, abounding in the materials of calculous concretions. Many dissections have shown the great size to which renal calculi may attain, and the extraordinary tenuity to which the secreting organ which surrounds them may be reduced; and that too in some cases without destroying its secretory function. A remarkable instance of such a calculus occurred in the person of a natural daughter of Sir Richard Steele. No nephritic symptom took place until shortly before her death, when severe pain was felt in the region of the right kidney, fever followed, and speedily proved fatal. A calculus of oxalate of lime, weighing 7½ ounces, was found in the right kidney, which was so thinned by absorption as to be reduced to a mere membrane. In this instance the stone could be felt during life through the loins, inducing the belief that the kidney had become ossified. (*Catal. Museum R. Coll. of Surg. Lond.* Note by John Hunter.)

Mr. Cline used to mention in his lectures that he had been able to detect the presence of calculus in the kidney of a very thin person. But such are extreme cases; and many instances are recorded, where, although renal calculus had been

long in existence, no disease of the kidney was suspected during the lifetime of the patient. The symptoms are in general obscure, and rarely enable us to ascertain satisfactorily the presence of stone in the kidney. Among these may be enumerated, a feeling of weight and dull aching in the loins; sharp pricking sensations in the region of the kidney; obstinate pain, in some instances, at the scrobiculus cordis; frequent fits of vomiting; bloody urine, especially after exercise which shakes the body; numbness, cramp, pain, or œdema of the corresponding thigh; and, finally, occasional attacks of inflammation of the kidney. Attacks of this nature sometimes destroy the patient by their violence, but much more frequently end in the discharge of pus from the kidney, which escapes by the natural passages; while the patient gradually wastes away, and after much suffering from inflammation, or perhaps ulceration of the bladder, at length dies exhausted. It is from this propagation of disease to the bladder that frequent painful micturition comes to be a symptom of calculus of the kidney. In some rare instances the inflammation has produced thickening of the surrounding parts, and led to the formation of abscesses, which have presented in the loins and formed fistulæ, giving issue to the urine, and occasionally to small calculi. Cases are recorded in several of the older authors, where stones of considerable size were extracted by the incision of such fistulæ. Hence surgeons have been emboldened to propose and sometimes to perform the operation named nephrotomy, for the removal of renal calculi; but no distinctly detailed and well-authenticated case has come to our knowledge, where, without the previous existence of abscess of the loins, a calculus has been successfully removed by this operation. (See Mr. Hobson's relation of his own case, *Philos. Transact.*, abridged, vol. iii.) Nor is it likely that the pelvis of the kidney could be safely approached with the knife without the previous security of that matting of the parts which must occur before an abscess can make its way to the surface of the loins. When a stone has been formed in the kidney, its weight, and the current of the urine which is constantly passing off, naturally tend to carry it down through the ureter; but it may be detained by the deep situation in which it has concentered, or by some prominent points of crystal, which serve to fasten it to the soft surface on which it lies; or, after it is loose, its size may be such as to prevent it from entering the ureter. In some instances the calculus has lain in the orifice of that tube, and remained there as a plug, allowing the urine in part to escape, yet keeping, at the same time, the pelvis and infundibula generally distended, and in this manner dilating these cavities gradually to a great extent; causing absorption of the substance of the kidney, and reducing it at length to a mere capsule, having many cells communicating one with another. When the distended and attenuated kidney is seized with inflammation, pus is formed, the interior receives a lining of albumen, and the gland becomes like the cyst of a large chronic abscess. When the stone is very small, it occasionally passes along the ureter without producing any sensible effect; but in general the system feels the influence of the unwonted im-

pressions which it induces. The patient is usually seized with nausea and vomiting; a feeling of alarm takes place, with cold chills and smart shivering; pain, often agonizing, shoots from the loins down to the fold of the thigh, and thence along the limb. The pain is usually felt on the inside of the thigh; but in the recent instance of a lady who passed an irregular pea-like calculus of oxalate of lime, the pain stretched from the loin, by the crest of the ilium, along the outside of the limb. In men, the passage of a calculus along the ureter is generally marked by the retraction of the corresponding testicle, and sometimes even by inflammation of that gland. It is remarkable that, amid all this commotion, the circulation is usually unaffected. The pulse is calm and regular, and the skin nearly of natural temperature; thus proving that the symptoms are occasioned by a powerful impression on the nerves, and are wholly independent of inflammatory disease. But here, as in other cases of strong nervous impressions, inflammation will arise in consequence of this prolonged operation. Should the calculus be arrested in its progress down the ureter, all the symptoms become aggravated, inflammation in general speedily sets in, and, if not subdued, cuts off the patient. The greatest danger in such cases arises from the stone filling up the canal of the ureter, and obstructing entirely the passage of the urine; thus forcibly distending the cavities of the kidney, and inducing suppression of the secretion, which has been known to occur in both kidneys where only one of the ureters was obstructed. (*Brodie, L. Med. Gazette.* April 16, 1831.) It might be supposed that the ureter would in some cases become so distended above the impacted stone as to burst; but if this ever occur, it is certainly an uncommon accident. Several circumstances render its occurrence unlikely; one of the first effects of the pressure of the confined urine is to act mechanically on the secreting organ, and diminish or altogether suspend its functions; absorption of the aqueous part of the fluid also takes place, which relieves the distension of the cavities: while fortunately the ureter is very dilatable, and its contents are not urged forward by the spasmodic action of powerful muscles, as when retention of urine arises from obstruction of the urethra. The ureter is well known to be capable of great dilatation, when the current of urine is obstructed; it has sometimes been found as large as the small intestine, and elongated so as to have a zigzag form. Cases have even been met with where the capacity of the ureter is said to have equalled that of the bladder. The consequences of suppression of urine and of its absorption are low delirium, coma, and death. (See *ISURIA.*) A fatal result may also follow the retention of calculi in the ureter in a more gradual manner, by the occurrence of inflammation, ulceration of the ureter, and escape of the urine into the adjoining cellular tissue. In some rare cases of stone in the ureter, abscess has occurred, followed by fistulæ opening in the groin or lumbar region, and giving issue to the urine. Frank relates a case where a calculus was thus discharged from the left ureter. In many instances, although a calculus be detained in the ureter, its form is so

irregular, or the relaxation of the tube is such, that the urine escapes by its sides, depositing new matter on its surface, and augmenting it far beyond the size capable of being transmitted along the ureter. The deposition of calculous matter under such circumstances is greatest above and below, thus giving the stone an oblong or cylindrical form. Sometimes one calculus only is found in the ureter; sometimes there are many smaller ones; and instances are recorded where its channel was found entirely filled up with gravel. A calculus has not unfrequently passed along the ureter until it reached the point where that tube pierces the coats of the bladder obliquely, and has there been arrested. Its extremity projecting into the bladder has been felt by the sound, and lithotomy performed for its extraction, which, to the credit of surgery, has in more than one instance been successfully accomplished. (*Le Dran*.—*Dessault*.)

2. **VESICAL CALCULUS.**—If the calculus, happily, drop into the bladder, there is a cessation for a time of all urgent symptoms; and should its size permit, it is expelled through the urethra. In the female, where the urethra is short and easily dilated, the calculus is usually discharged; and hence the greater rarity of stone in the bladder among women. Even when the stone has rested in the female bladder, and grown to so great a size as to fill up and form a cast of the partially contracted organ, its pyramidal form has enabled it to pass by gradually dilating the urethra; and it has been expelled with throes resembling those of parturition. Calculi of extraordinary size are recorded, in the Philosophical Transactions and other publications, to have been discharged by females in this manner.

In males, the length and narrowness of the urethra, and the spasmodic action of the muscles which embrace it, render the expulsion of a calculus from the penis much more uncommon than its passage through the ureter. In very few cases is a calculus forced through the male urethra without considerable suffering, and sometimes an incision is required to relieve the patient. Retention of urine for a longer or shorter period usually occurs. In one instance, where the recent formation of a catheter, puncture of the bladder became necessary, and was successfully performed through the rectum; the small calculus being expelled when the congestion and irritation of the parts had subsided. Retention of urine in infants has not unfrequently arisen from calculus sticking in the urethra, or plugging up its internal orifice. The practitioner, therefore, ought to be aware of the possibility of such an occurrence, and have recourse to the necessary method of ascertaining and removing the obstruction. A curved probe will often suffice, or a slender gum catheter may be introduced, and the water drawn off. If relief be not speedily given, the bladder inflames, constitutional symptoms arise, and the little patient is soon carried off. Many instances are recorded in which symptoms of calculus existed from birth. A male child, mentioned by Mr. Wilson, (*Wilson*, Lectures on the Urinary Organs, p. 210.) was unable, from his birth, to retain his urine; and, dying before he had completed seven months, a

stone as large as a garden-pea was found in the bladder. Brendelius relates that two infants, one two days old, the other eight, passed calculi before death, and calculi were also found in their bladders. (*Brendelius*, Program. de Calculis Vesic. et ceteris Natal.; also, *Observ. Anat.* Dec. iii. ob. 1.) *Loeske* found a calculus in the kidney of a new-born child. (*Loeske*, *Obs. Anat.* Chir. Med. p. 39.) *Fischer* relates that a boy, in his twelfth week, after suffering excruciating pains, passed a calculus by the urethra as large as a date-stone. (*Haller*, *Disp.* Chir. t. iv. p. 79.) Hence we are warranted in believing that urinary calculi are sometimes formed during the fetal state.

Should the calculus be retained in the bladder, which in the male most commonly happens, it receives a gradual addition of substance, and becomes a source of greater and greater irritation. Although the existence of stone in the bladder cannot be fully ascertained without its being felt by an instrument introduced into that organ, yet there are many symptoms which, when they concur, afford strong presumptive evidence of the fact. When a calculus is loose in the bladder, it is liable to constant changes of position, which usually occasion sharp pain; and in evacuating the urine, the stone is apt to fall upon the internal orifice of the urethra, causing sudden stoppage and severe straining. After smart exercise or jolting of the body, the urine is generally mixed with blood, from the abrasion of the mucous membrane, which is loaded with red vessels, and resembles during life the richest vermilion-coloured velvet, as we have seen in a case of eversion through a vesico-vaginal fistula.

The appearance of blood in the urine would be much more frequent in cases of calculus, were it not for the protection afforded by an increased secretion of mucus, which acquires in this disease an unnatural degree of viscidness; thus enveloping the calculus, and shielding the tender surface of the bladder. A copious secretion of glairy mucus is a constant attendant on the advanced stages of calculus, and also on diseased prostate and other prolonged irritations of the bladder. It is to be observed that this mucus is seldom passed in a separate state, but generally diffused and suspended in the urine, from which it gradually subsides, and coalesces into a gelatinous viscid mass, which adheres to the bottom of the vessel, even when it is inverted. When this separation has taken place within the bladder, it is voided with difficulty, and often plugs up the urethra, and causes a temporary retention of urine. The colour of the mucus varies according to the degree of irritation and the length of time it has existed. From being clear it changes to grey, then to greenish yellow; and at length, when the mucous membrane has become extensively diseased, it is largely mixed with purulent matter. The character of the mucus is alkaline, even when the urine is decidedly acid; and it is justly considered as the source of many of those deposits and spongy concretions of phosphate of lime which are found in the bladder.

The agony of a fit of stone is generally known; consisting of excruciatingly painful efforts to expel the urine, during which the abdominal muscles, the diaphragm, the muscular coat of the blad-

der, and the levator ani are all in a state of strong spasmodic action, and alternate but brief relaxation. From time to time this straining forces out a few drops of scalding urine, while part of the contents of the rectum are perhaps expelled at the same time with eversion of the bowel; but from neither is the least alleviation of suffering obtained. A vivid and accurate picture of the miseries endured in a case of calculus is exhibited in a paper by Dr. Marcet, where the patient has described his own feelings, (*Med. Chirurg. Trans.* vol. x.) and if we are to give implicit credit to the histories of the blacksmith of Amsterdam, (*Tulpius. Obs. Med. l. iv. c. 31.*) and the cooper of Königsberg, (*Walther. Thes. Med. Chirurg. Obs. Cur. p. 195, ob. 60.*) who cut into their own bladders and extracted the stones, we shall have the strongest of all evidence that the sufferings from calculus are sometimes beyond human endurance.

The chief cause of all this agony seems to be the contact of the calculus with the sensitive internal surface of the neck of the bladder; at once irritating the parts to spasmodic contraction, and blocking up the passage of the urine; for the patient often finds that by reversing his posture, or perhaps resting on his head and shoulders, he obtains relief. The pain in the bladder shoots to the anus, the loins, down the limbs, and is felt in an especial manner at the extremity of the urethra, which causes boys affected with calculus to seize and pull at the penis. Hence elongation of the prepuce comes to be a symptom of stone, and the swelled and softened state of the little patient's fingers shows how often they are bedewed with urine. The ramifications of pain in a fit of stone are various and extensive, and in some cases reach even to the heel or sole of the foot; a fact which we have noted also in ulceration of the bladder. A reference to the multiplied connections of the lumbar plexus and the distribution of the great sciatic, the ultimate ramifications of which are sent to the sole of the foot, will serve to explain the great extent to which the pain of calculus shoots.

When a calculus is of great size, it is less liable to alter its position and is therefore usually productive of less irritation; the excruciating pain is commonly exchanged for a distressing sense of weight at the neck of the bladder. Calculi occasion comparatively little uneasiness when they are supported by the moderate contraction of the bladder within its upper fundus behind the pubes; and when they get into fixed situations, as behind an enlarged prostate gland, or in cysts formed by the protrusion of the mucous membrane between the bundles of the overgrown muscular coat. This state of overgrowth of the muscular tunic of the bladder occurs in calculus, as in all diseases of that organ where frequent and long-continued but ineffectual efforts are made to expel the urine. Instances are occasionally met with when several, sometimes many stones are found separately lodged in such pouches in the same bladder; and preparations of this description are to be seen in most pathological collections. A stone, which had been distinctly felt by the sound, has sometimes been thrown into one of these cavities; thus an end has been put to the irritation,

and it has eluded the examination of the sound, inducing the belief that there was no longer a calculus in the bladder. Both the formation of pouches in the bladder, and the enlargement of the prostate gland, are to be considered as consequences of the irritation of calculus; and they illustrate, in a striking manner, the operation of that conservative principle by which even the uncontrolled progress of diseases produces changes which tend to the relief of the patient. A still more remarkable proof of the same fact is afforded by those cases where calculi have ulcerated through the coats of the bladder, and have been discharged from the body, sometimes through the walls of the hypogastrium, at others into the rectum, and in other instances into the vagina. Caumont and Deschamps relate cases of the first, (*Journal Générale de Méd. t. 27, p. 353, &c.*; an. 1806, No. 124.) and Johnstone of the second, (*Johnstone, Mem. Med. Soc. Lond. iii. p. 536.*) In Mr. Johnstone's case, the patient, after years of suffering from the usual symptoms of stone, at length discovered pieces of gravel in his stools, which Mr. Johnstone was confirmed were urinary concretions. From that time all the painful feelings ceased, and the patient recovered perfectly, without any fistula remaining. A female, who, at the age of twelve, got rid of a pretty large calculus by ulceration into the vagina, is now, after ten years, in good health, but still suffering under vesico-vaginal fistula, (*Edinb. Med. and Surg. Journ. vol. xxi.*) It is probable that in such cases the stone had become imbedded in a pouch before ulceration commenced, otherwise it would have extended more widely over the internal surface, and proved fatal.

The occurrence of ulceration of the mucous membrane of the bladder is one of the last in the series of changes produced by calculus; and if the patient has withstood all the other exhausting circumstances of the disease, this seldom fails to put a period to his sufferings. In such prolonged cases the bladder after death exhibits various degrees of organic injury; the mucous membrane is extensively eroded, the ulceration sometimes reaching to the other coats of the bladder; or abscess has formed under its peritoneal covering. The internal surface is in many places lined with a layer of coagulated albumen, which is often encrusted with calculous matter. Such deposits appear never to fasten on the organized textures themselves, but on a layer of albumen which forms the medium of attachment between them. The urine is probably, in most cases, the source of this incrustation; but it may also be derived from the internal surface of the bladder, in the same way as earthy concretions are formed within the cavities of abscesses.

The effects of calculus in the bladder are not limited to that organ, but extend to the ureters and kidneys. The pressure of the urine, unable to escape by the urethra, dilates the ureters and cavities of the kidneys, and the latter often exhibit marks of inflammation, and are sometimes found suppurated, or small depôts of pus are discovered under the peritoneal covering.

The long-continued irritation of a calculus in the bladder, or indeed within any of the urinary organs, produces a change in the constitution of

the urine, which loses its acid character, begins to abound in the phosphates, and at length becomes ammoniacal. In undergoing this change, the urine first deposits the lithate of ammonia, then the ammoniaco-magnesian phosphate, and the phosphate of lime. This morbid condition of the urine, termed the phosphatic diathesis, takes its rise under various other circumstances of impaired nervous energy of the kidneys and bladder, besides those connected with the wasting effects of protracted calculous disease. Thus injuries of the spinal cord; continued irritation of the urinary cavities from diseased prostate gland and strictures of the urethra; immoderate sexual indulgences; disordered health, and general irritability induced by excessive mental anxiety and fatigue; all have the effect of occasioning the phosphatic diathesis. Dr. Prout has satisfactorily shown that all varieties of calculus converge to this point, and ultimately end in the deposition of the phosphates. In proof of the correctness of this opinion it is sufficient to trace the progress of a long-continued calculous case, and to inspect the successive laminae of which urinary calculi of long standing are generally composed. The formation of the phosphatic diathesis affords a clear indication that the constitution is breaking down under the sufferings of the disease, and requires that the question of a surgical operation should be considered without delay.

3. URETHRAL CALCULI.—Calculi which have commenced their passage along the urethra may be detained in their way, and become imbedded in the side of the canal, where they will continue to receive new additions from the urine which washes over them. In this manner urethral calculi have occurred, and on many occasions they have attained a considerable magnitude. Their general situation is in the perineum, where they are found forming a hard prominent tumour. In some instances a single stone is contained in a cyst communicating with the urethra; in others there is a pouch filled with numerous small many-sided calculi, which have evidently lain closely packed together. On one occasion we witnessed the extraction of a stone from the perineum, which was as large as a pullet's egg, and consisted of two portions, one of them having its rounded extremity fitted into a cavity in the other. Mr. Sisley, in the Philosophical Transactions, gives an account of a calculus weighing five ounces two drams, which was expelled through a dilated urinary fistula at the upper part of the scrotum, (Phil. Trans. vol. xli. p. 351.) In an instance which came under our own observation, eighteen stones, varying from the size of a mustard-seed to that of a horse-bean, many of them polyhedrons, were removed from a cyst forming a hard tumour behind the scrotum, and communicating with the membranous portion of the urethra. The examination of one of these stones showed it to be composed chiefly of phosphate of lime deposited in concentric laminae, from which and the yellow polished surface which they almost all possessed, we were led to believe them of prostatic origin. The following is probably to be referred to the same source. A case of very large perineal calculus, supposed to be of twenty years' growth, is related in the Philosophical Transactions, (Phil.

Trans., abridged, vol. iii. :) a sharp angle of the stone was found to have penetrated the rectum. Its form was irregular, and it consisted of two parts, one jointed into the other.

The symptoms produced by calculi in the urethra, or in pouches communicating with it, are those of urinary irritation, and occasionally retention of urine; but they seldom attract much attention until the external tumour has become considerable.

4. PROSTATIC CALCULI.—Small calculi are frequently found within the ducts and in abscesses of the prostate gland: sometimes they are contained in one cavity, at others disseminated in separate cells through the thickened substance of the gland. Their surface is occasionally rough, more frequently smooth and of a porcelain-like polish—their colour yellow or light brown—their size varying from a mustard-seed to that of a hazel-nut. Their chemical composition, unlike that of urinary calculi, is always the same. It appears that they are produced by the mucous membrane of the prostatic ducts, or by the suppurating surfaces of abscesses of that gland; and are not secreted by the kidney, or deposited from the urine, and therefore cannot in strict propriety be termed urinary calculi. They may, however, readily become the nuclei of such stones, either from the urine having access to them while imbedded in the gland, or by their getting loose and escaping into the bladder. Prostatic calculi have often been found after death, where no symptom had indicated their presence; more frequently they cause some degree of irritation at the neck of the bladder, particularly when the urine is voided; and if any portion of such calculus project beyond the orifice of the duct or abscess, it will be felt by a sound entering the bladder. The instrument in these cases frequently forces the small stone deeper into the cavity, and thus prevents it from being touched by the sound in several subsequent examinations, however dexterously conducted. It appears probable, from some of the cases referred to under the head of urethral calculi, that those of the prostate, when accumulated in great numbers, or of large size, occasionally form tumours in the perineum, or penetrate into the rectum.

CAUSES OF URINARY CALCULUS.—The importance of acquiring a knowledge of the causes from which urinary calculi arise, must be apparent to every one who considers that it affords the only means by which we are enabled to prevent the formation of this disease, the most painful in the catalogue of human maladies, and its recurrence after the sufferings and hazards of lithotomy. Calculus is more common in temperate than in warm or very cold climates: it is much more incident to early years than to any other period; and to old age more than to the prime of life. Among those beyond middle age, it occurs more frequently in persons of sedentary habits than in those who lead an active life; and in those who indulge in luxurious living much more than in the temperate and abstemious. Hence there has long been observed a marked connection between a calculous and a gouty tendency. But although the rich, the luxurious, and the indolent are at a certain age more prone

to calculus than other classes, the poor and the destitute in early years enjoy no immunity from it; for the ill-fed and half-clothed children of the manufacturing and labouring population are frequently afflicted with stone. All authors who have written on this subject concur in stating, that females are greatly less subject to calculus than males, notwithstanding their more sedentary habits. The more temperate and regular modes of female life are less productive of the calculous tendency; and the absence of the prostate gland, and the short dilatable urethra of females, enable them much more readily to expel such calculi as have formed.

Much persevering research has been directed, by a succession of writers, to ascertain the comparative prevalence of calculus in different parts of the British islands, and among different classes of society. Ireland is still admitted to furnish very few instances of calculous disease; and there certainly are strong grounds for this opinion, although we have no doubt that the state of society in that island opposes many obstacles to the acquisition of a full knowledge of the facts on this subject. Scotland, which had been set down as affording a very small number of calculous cases, is now ascertained to have been quite underestimated. (*Mr. Hutchinson in Med. Chir. Trans. vol. xvi.*) The large manufacturing town of Paisley appears, from the very accurate returns furnished by Dr. M'Kinlay, (*Ibid.*) to be almost as productive of calculous cases as Norwich itself, having yielded, in the ten years from 1820 to 1830, eighteen cases of lithotomy in a population of probably 42,000. Both Mr. Hutchinson and Dr. Yelloly (*Dr. Yelloly in Phil. Trans. 1830*) seem to us to have estimated the population of Paisley too low; but making allowance for this, and some abatement also for admitting into the enumeration private as well as hospital operations, it must be granted that calculus is of comparatively frequent occurrence in that town. In further support of this opinion, it appears, from information kindly furnished to us by Dr. M'Kinlay, that the number of cases of lithotomy between 1810 and 1820 was probably greater than in the subsequent decade; and that, although no operation has occurred since his report, several cases of calculus in every respect favourable for lithotomy, are now (July 1831) known to exist in Paisley.

The comparative prevalence of urinary calculus in different parts of England has been elucidated by the inquiries of many able writers, from Dr. Dobson downwards. The number of hospital operations has been assumed by all of them as the basis of calculation; therefore the result must be considered as only a distant approximation to the truth; for the number of cases of lithotomy will not always preserve the same proportion to the real number of calculous cases, but will vary according to the dexterity, enterprise, and reputation of the surgeons of the place. Thus in Norwich, where distinguished operators have existed as far back as the beginning of the eighteenth century—witness the epitaph on the tomb of the ecclesiastic Havers—not a case of calculus can occur in the city or neighbourhood without being speedily detected, and probably operated on;

while in many other districts, cases of stone are allowed to proceed for years unrelieved, and perhaps wholly unsuspected. The celebrity of an hospital surgeon, or his own exertions to obtain reputation, will often bring to him cases from very distant quarters, some of which may be assumed in calculation as belonging to the district where he resides. Frank (*Frank, De Curand. homin. morb. De Calculo*) tells us that, previous to the arrival of the celebrated Venetian lithotomist Pagola at Vienna, calculus was deemed rather uncommon in that metropolis, and only one or two operations were performed annually; but after the surgeons had acquired experience and dexterity from his example, the operation became frequent, and the cures numerous. He adds, that calculus was believed to be very rare in Lithuania, until the establishment of the surgical clinic at Wilna; but that now the surgeons who are skilled in the art of sounding find the disease but too common.

Norwich appears to be more productive of calculous cases than any other part of Great Britain, yielding one hospital case of lithotomy for every 21,000 inhabitants. On the other hand, the city and county of Hereford appear to be wholly free from calculous disease: from 1775 till the date of Mr. Smith's statistical inquiry (1818), no patient suffering under calculus had applied at the Infirmary; and Mr. Smith could not learn that lithotomy had ever been performed within the bounds of the county, (*Medico-Chir. Trans. vol. ii. p. 20.*) which, it is worthy of remark, is noted for its cider, a beverage hitherto supposed to be favourable to the production of calculus. Thus we have the two extremes of the great prevalence, and the apparent non-existence of calculous disease, in different districts of England. It has been supposed that the diet of the inhabitants of Norfolk is a main cause of their liability to calculus—a favourite article of food being hard boiled, ill fermented, greasy dumplings. These, no doubt, are likely to cause indigestion, and thus give rise to lithic acid deposits. To this it has been objected, that many cases of calculus occur in that district at so early an age that diet can have no influence in their production: but the diet of the nurse is known uniformly to affect the infant at her breast.

Mr. A. C. Hutchinson has shown in several able papers, that calculus is of particularly rare occurrence among seafaring people; and the hospital returns of the British army prove also that calculus is very seldom met with among our soldiers. [Sir William Burnet, having caused the returns of the British naval hospitals, at home and abroad, from April 1830 to Nov. 26, 1836, to be carefully examined, with reference to this point of medical statistics, it was found that the only instance of the kind was one of renal calculus in the hospital at Malta. The average number of seamen and marines voted annually by the British Parliament, during the period mentioned, including 2000 boys, was 30,000.] The information which has been obtained by Dr. Yelloly respecting the armies of France and Russia, shows likewise that calculus is a rare disease among the military of those countries. In explanation of these facts, it ought to be remembered

that none are admitted into either navy or army out the robust and active; and that their services are chiefly limited to that middle period of life when calculus is very rarely observed to originate among the labouring classes from whom soldiers and sailors are drawn. But, after taking this fairly into account, we are not disposed altogether to deny the greater immunity from calculus enjoyed by individuals of both land and sea forces; and we think that this serves to confirm, what other observations clearly show, that a full supply of wholesome food, good clothing, active habits, and regular exercise, all tend to prevent the formation of calculus. The state of the digestion and of the cutaneous perspiration must be admitted to exert a powerful influence on the secretion of urine; for when the stomach habitually abounds with acid, the urine rarely fails to exhibit in excess a similar condition; and the perspiration influences, in a remarkable manner, the quantity of lithic acid contained in the urine, as the experiments of Dr. Wilson Philip have satisfactorily shown. (*Wilson on Urinary Gravel: 1792.*) Probably free perspiration is a principal cause of the infrequency of calculus in warm climates. The connection between calculous disease and a dry and harsh state of the skin, or even scaly eruptions, has long been remarked. In the case of Horace Walpole, it was observed that a cutaneous eruption, to which he had been many years subject, yielded to the alkaline remedies which relieved his calculous symptoms.

The tendency to calculus appears in many instances to be hereditary, like the kindred disease of gout. Dr. Prout and Dr. Yelloly both relate remarkable facts in proof of this opinion; and we are inclined to ascribe to the hereditary nature of calculus a part, at least, of that extraordinary tendency to the disease which has long existed in certain districts. Hitherto we have been unable to discover those local peculiarities of soil and situation which favour the formation of calculus; but if we admit its hereditary nature, we have obtained a key to some of those continued anomalies, which otherwise appear incapable of explanation. It is clear that, in a district where calculus is well understood, and lithotomy often successfully performed, a greater number of calculous individuals will be preserved to propagate their race, than in districts where the operation is most commonly fatal. And it is not beyond the range of probability that individuals who have come from distant quarters to some hospital of great repute, for the purpose of submitting to lithotomy, may settle in the city or its neighbourhood after the completion of their cure.

It has long been a popular opinion that hard waters are favourable to the production of calculus, and one of our latest and best writers on the subject expresses the same belief. The effects of such waters are diuretic, and sometimes slightly purgative, and they are apt to disorder delicate stomachs; but it is very doubtful whether the earthy salts which they contain contribute in any more direct manner to the formation of calculus.

[In the great valley of Chester county, in Pennsylvania, where limestone abounds, a case of stone is of rare occurrence. According to Dr. Thomas Harris, of Philadelphia, a respectable physician,

who had been in extensive practice there for twenty years, had never seen a case of it. (*The writer's Practice of Medicine, 2d edit., ii. 42: Philad. 1844.*)]

Injuries of the back have been remarked to produce a morbid condition of the urine, usually a change to an alkaline state; and cases of renal calculus have been distinctly traced to accidents of this nature; several very interesting examples of which have been related by Mr. Earle (*London Med. Chir. Trans. vol. xi.*) and Mr. Wilson. (*Lectures on the Urinary Organs.*) Such injuries influence the function of the kidney in different ways. A general concussion of the spinal cord, or a blow on the spine in the region of the kidney, will enfeeble its powers by diminishing the nervous energy distributed to it, and thus induce a morbid condition of the urine: such injuries will also tend to weaken the expulsive powers of the bladder, and by preventing it from ever being completely emptied, lead to the decomposition of the urine, and hence to the deposition of the phosphates. A blow on the kidney itself is likely to prove a cause of calculous disease, by the immediate effects of the concussion deranging the action of the organ; and by small extravasations of blood, which cause irritation as foreign bodies, and furnish nuclei for future concretions. Although clots of blood have often been found in the centre of calculi, it is obvious that blood has very frequently been effused within the kidney, yet no calculus has followed; the blood being washed away before it had time to cause that irritation of the urinary organs which disorders the urine and occasions deposits. For it is in this manner that extraneous bodies introduced into the bladder become incrustated with calculous matter,—causing in the first instance by their irritation a derangement in the secretion of the kidney, and then furnishing a solid inorganic substance to which the deposit may attach itself. In such cases the deposit is almost uniformly composed of the phosphates, but instances are met with where it is formed of lithic acid; as an example of which, we may mention a calculus in the museum of William Hunter, where this substance has formed a concretion, as large as a plum, around a fragment of iron.

Strictures of the urethra and enlargements of the prostate gland prove causes of calculus by the irritation which they produce on the urinary cavities, and by their subsequent effects on the general health, as well as by the obstruction which they present to the complete evacuation of the bladder.

Treatment of Calculus.—In the treatment of calculous disease, several different and highly important objects demand the attention of the physician—to correct the calculous diathesis and prevent the formation of stone—to facilitate the expulsion of calculi when formed—to relieve the sufferings of the patient, and delay the progress of the disease—and to point out the period when a surgical operation offers the best means of relief.

When calculus has been observed in several members of the same family, or in successive generations, it is to be presumed that a strong tendency to the disease exists in their constitu-

tion; and precautions are therefore to be adopted against its development. For this purpose, active habits ought to be encouraged, and the digestion preserved in as vigorous a state as possible; the diet being nutritious, but not heavy or acescent. A healthy state of the skin should be promoted by the use of the flesh-brush, by warm clothing, and occasional warm baths. Even a residence in a warmer climate during the early years of life, may, under certain circumstances, be advisable. On the first appearance of any thing unnatural in the urine, it ought to be carefully examined, for the purpose of adopting that plan of treatment which its chemical constitution requires.

The morbid states of the urine arrange themselves under the two great heads of the predominance of acid, and the predominance of alkali or alkaline earths. The acid diathesis is chiefly prevalent in infancy, and at the commencement of the decline of life; and in the early stage of most calculous diseases. It may be truly said to be by far the slightest deviation of the two from the healthy condition of the urine; for the function of the kidney has been satisfactorily shown to be an acidifying process; and the acid state of all healthy urine is proved by the change which it produces on litmus paper. The morbidly acid condition of the urine exists under various forms; from that in which lithic acid is deposited as a flocculent precipitate, or red gravel, to that where a calculus of lithic acid is receiving from day to day new additions of size. The urine in this diathesis, when first voided, is usually clear, not very plentiful, and is of a bright coppery colour. It occurs under circumstances apparently the most opposite—in the ill-lodged, half-starved, half-clothed child of the artisan or labourer, in connection with loose chalky stools, feeble digestion, and a pallid aspect,—as well as in the pampered plethoric adult, who enjoys the pleasures of a luxurious table and all the comforts of a modern house. The digestion of the latter individual is strong, but his stomach is overtaxed, and unable to accomplish the duty which is daily imposed on it: his countenance is florid, his frame robust, and his habit probably gouty. In both of these cases there is frequent acidity of the primæ viæ, but much greater in those of the luxurious liver than in the child: the difference, however, is more than compensated in the latter, by the harsh unhealthy state of the skin, which executes its function imperfectly, and leaves an additional task to be performed by the kidneys. Guided by these views, our first object in undertaking the cure of the child should be, to have him warmly clothed, comfortably lodged, and supplied with a nourishing diet, containing a moderate proportion of animal food. Excess in this article seems to dispose to the secretion of lithic acid. The medical treatment is to be commenced by a mild laxative of castor oil, or rhubarb and magnesia; and in many instances great benefit will be derived from small repeated doses of hydrarg. cum creta, or minute doses of calomel. After this, alkalies and tonics ought to be given for the purpose of correcting the acidity of the primæ viæ and of the urine, and of improving the powers of digestion. Rhubarb, gentian, calumba, and cinchona, may be enumerated as the best tonics; and of the fixed

alkalies, potass is to be preferred to soda; for the lithate of potass is a very soluble salt, while the lithate of soda is so much the reverse, that it forms the *chalk-stones* of gout, and has been found by Dr. Prout to constitute occasionally a considerable portion of a urinary calculus. Although the fixed alkalies are usually employed, cases of the acid diathesis do occur, both in children and adults, where the stomach is enfeebled, and where ammonia will prove more beneficial. The volatile alkali has also the advantage of determining to the skin, which it is of great consequence to bring into a healthy state. This is the description of calculous cases which are so often met with in manufacturing districts, and which seem to have led Dr. Yelloly to suppose that there was a connection between the scrofulous and the calculous diathesis.

[It is affirmed by Dr. A. Ure, (*Provincial Medical and Surgical Journal*, July 17, 1841, p. 317.) that hippuric acid is found in the urine after benzoic acid has been taken, and that the quantity of uric or lithic acid is thereby diminished. He hence inferred, that the uric acid is converted into the hippuric; and as the hippurates are more soluble than the urates, it was suggested by him, that benzoic acid might be advantageously exhibited in lithuria or in cases of predominance of uric acid. The observations of chemists have not, however, established this. On the contrary, they have shown, that although the benzoic acid appears to be converted into the hippuric, there is no diminution in the quantity of the uric acid. (Liebig, *Animal Chemistry*, Gregory & Webster's edit., p. 316, Cambridge, U. S., 1842; and Professor Booth and Mr. Boyé, in *Proceedings of the American Philosophical Society at the Centennial Celebration in Philad.*, May, 1843.)]

In the instances in which a calculous tendency is combined with fulness of habit, a mode of treatment in many respects the reverse of that now described becomes requisite. A spare regimen and more active habits ought to be recommended; blood should be taken by cupping from the loins, or from the arm by venesection. Calomel should be given freely over-night, and followed next morning by rhubarb with magnesia, or Rochelle salts. The cure is to be completed and confirmed by the employment of alkalies and biters, and by a rigid adherence to a system of moderate living and regular exercise.

Under the head of acid diathesis may be arranged, not only deposits of lithic acid, but those also of oxalate of lime and cystic oxide. It has been ascertained from the examination of calculi, that the lithic acid diathesis and that of the oxalate of lime alternate with each other, thus showing their near alliance and mutual convertibility. The cystic oxide diathesis, on the other hand, appears to be exclusive in its nature, all concretions of this kind being of remarkable purity: it is, however, sometimes followed by a deposition of lithic acid; and this, like the other species of urinary calculi, terminates in producing the alkaline or phosphatic diathesis.

The general principles of treatment in this class of calculous diseases, is, certainly, to counteract the acid tendency by the use of alkaline remedies,

but to this there are many exceptions. In the lithic diathesis it has sometimes been found very serviceable to produce a copious discharge of that acid, by the exhibition of turpentine combined with laudanum. Dr. Prout has employed, with advantage, the muriatic acid in cases of oxalate of lime diathesis; by which means he succeeded in converting it into that of the lithic acid, and thereby procured great relief to his patient. This eminent physician, who has so ably illustrated the various forms of urinary disease, and to whose writings the author of this article is so much indebted, proposes a similar practice in the cystic oxide diathesis, recommending the muriatic acid to be given wherever the state of irritation will permit, for the purpose of keeping the cystic oxide in solution, and establishing in its place the lithic acid diathesis.

[Liebig (*op. cit.*) and Wöhler ascribe oxalic acid to the oxidation of uric acid; and the former affirms, that it is a common occurrence in France, when patients, suffering from calculous complaints, go to the country, where they take more exercise, the compounds of uric acid, which were deposited in the bladder during their residence in town, are succeeded by oxalates, in consequence of the increased supply of oxygen. If these views be correct, it would seem, that country air might be injurious; but the matter cannot be regarded as established. (The writer's *Practice of Medicine*, 2d edit., ii. 49: Philad. 1844.)]

Should a calculous tendency appear to be connected with injury of the kidney, or a diseased state of that organ, the employment of counter-irritation, and especially of setons in its neighbourhood, is distinctly indicated; and their beneficial effects have been placed beyond doubt by the observations of Mr. Earle. (Lond. Med. Chir. Trans. vol. xi.)

When a gouty disposition coexists with a calculous tendency, the colchicum, in combination with the means already described, ought to be had recourse to; but if the bladder already contain a calculus, we cannot with safety push this medicine to its full effect on the bowels, which in cases of simple gout and rheumatism is often found beneficial.

In the alkaline or phosphatic diathesis, the naturally acid condition of the urine is exchanged for an alkaline state; and the deposits now consist of the phosphates. This is a much more formidable deviation from health than that which we last considered, for it arises as a consequence of other disease, and is usually connected with a shattered state of the constitution. Our first object ought to be, to ascertain the cause from which the phosphatic diathesis has arisen, and to remove or palliate it as far as we are able. The spinal cord should be relieved by counter-irritation, varying, according to circumstances, from a galbanum plaister to a seton or a caustic issue—the effects of diseased prostate alleviated by such means as we possess; and if the symptoms have arisen from calculus in the bladder, its early removal by operation presents the only mode of effecting a cure. A free air, gentle exercise, and a mild nutritious diet, ought to be prescribed; and the tone of the digestive organs restored by means of the mineral acids, bitters, and astringents. The

acids have been supposed to exert a direct influence on the urine, and there is no doubt that they do pass the kidneys unchanged; but their chief beneficial effects in the phosphatic diathesis are accomplished by influencing the organs of digestion. The sulphuric, nitric, and muriatic acids, have all been employed; and the last has been found most generally useful. Among the bitters and astringents the *uva ursi* and *parcira brava* have deservedly obtained a preference. Medicines which cause a copious secretion of lithic acid, such as the turpentine, the seeds of the *daucus sylvestris*, and *alchemilla arvensis*, might be supposed to prove beneficial when an opposite diathesis was known to prevail; and cases do occur in which they are found serviceable: but in the greatest proportion of such diseases, the irritation of the urinary organs is so great as to render their employment improper. Indeed, it is obviously of little consequence to induce for a time a free secretion of lithic acid, without also improving that shattered state of health with which the morbid condition of the urine is generally connected. It is worthy of remark that such remedies are powerfully diuretic; now in the phosphatic diathesis the urine is almost always superabundant, at times excessive, which forms another objection to their employment. This tendency to an unnatural increase of the urine, and the irritation, anxiety, and pain attending the alkaline diathesis, point out opium as a valuable remedy; and here, as in other states of prolonged suffering, it has proved truly a blessing. Among the various forms in which this drug may be administered, perhaps the best are the black drop, Battley's liquor, and Dover's powder. Other anodynes, as *hyoscyamus*, *conium*, and *bella-donna*, may be employed under less urgent symptoms; and they often produce very excellent effects.

Although mercury is certainly entitled to a place among the causes of the phosphatic diathesis, and is therefore, on general principles, to be avoided, yet under certain circumstances mercurials are productive of great benefit. Dr. Prout has well remarked that in children whose urine deposits the phosphates, repeated doses of calomel and rhubarb are exceedingly useful; without doubt, by correcting the disordered functions of the digestive organs: and in cases of excessive irritation of the urinary cavities we have found the full operation of calomel and opium signally beneficial. The existence of the phosphatic diathesis is so generally combined with a morbid state of the alimentary canal—the stools being too pale, or too dark, or yeasty—that it is quite obvious laxatives and alteratives must be given; but drastic purgatives, and even free purging, are to be avoided on account of the tenesmus which they are apt to occasion. The great importance of attending to the feelings of the patient under this form of calculous diathesis, and of removing when it is possible every source of care and anxiety, is sufficiently obvious. Relief from the irritations of business and the fatigues of study is equally required; and a change of scene and air, when the patient can be moved, is productive of great benefit.

Such are the modes of treatment which appear

to be best adapted to correct the two principal forms of calculous diathesis, whether the morbid condition have recently arisen, or be combined with the existence of stone.

When symptoms indicate that a calculus is passing from the kidney to the bladder, the physician is usually called under circumstances of great anxiety and alarm. In such cases, although the pain be urgent, it is not always necessary to abstract blood: it is a remedy, however, which ought to be kept in view, and employed on the slightest appearance of a tendency to inflammation. In the robust and plethoric, venesection is a wise measure of precaution, and will have a useful effect as a relaxant: even in persons of a less vigorous frame, when inflammation threatens, the immediate relief obtained by bloodletting renders it preferable to cupping and the application of leeches. During the passing of a calculus, all the various methods of allaying pain are sometimes required;—warm fomentations, bags of hot salt, hot poultices, the warm bath, and anodynes in every various form and mode of exhibition. Some difference of opinion may exist as to the propriety of giving diluents freely in such cases, so as to produce an increased secretion of mild urine; but it does not appear likely that a copious flow of urine will in any case prove hurtful; for if the calculus be not too large to pass, the increased current of fluid will certainly render the process more easy; nay, there is reason to believe, that by exposing a calculus to the constant washing of any aqueous urine, some of those spiculæ which detain it in its passage may be dissolved or worn away. Should the calculus be so smooth and so impacted in the ureter that no urine can pass, the probably fatal result is not likely to be much hastened by the use of diluents.

When the calculus appears to be delayed in the ureter, a brisk purgative of rhubarb and sulphate of potass, followed by an enema, will be found to facilitate its progress. After the renal calculus has dropped into the bladder, free dilution with bland liquids or pure water ought to be persevered in to a still greater extent; and brisk purgatives of castor oil, or rhubarb and sulphate of potass repeated at intervals. Should the small stone still be retained, its removal should be attempted by dilatation of the urethra. By such means we shall often succeed in ridding the patient of what would entail torture on his future days, or bring his life into hazard by the operation of lithotomy.

When a calculus is lodged in the bladder, and there is no longer any prospect of its expulsion by the urethra, the exertions of the physician are chiefly limited to the two objects of lessening the sufferings of his patient and preventing an increase of the stone. The general treatment is to be conducted on the principles already laid down for the management of the prevailing diathesis, whatever that may be; since by such means we shall be most likely to accomplish the two objects stated above. The irritation of calculus in the bladder is in most cases remarkably relieved by the administration of alkalies in the acid diathesis, and of acids in the phosphatic; but the soothing effects of the alkalies in the former of these cases, is by far the more striking and uniform. Nay, the power of the alkalies to allay the irritability

of the urinary apparatus seems not always limited to those cases where the acid diathesis prevails; and it is worthy of remark that their efficacy is not diminished by combining them with the vegetable acids.

Gentle exercise on foot, frictions, shampooing, warm clothing, great attention to the diet and to the state of the bowels, are all necessary in the management of calculus of the bladder. Straining at stool, whether from a confined state of the bowels or the smart operation of medicine, is to be carefully avoided; therefore only the mildest laxatives should be used. Castor oil is perhaps of all others the best; but a combination of the colocynth pill with hyoscyamus and a small proportion of opium often answers remarkably well. Under the agony of a fit of stone, the warm hip-bath, heat applied in various other ways, hot opiate fomentations, and anodynes in suppository and injection, are our chief means of relief. Considerable benefit has also been obtained from a clyster, composed of half an ounce of oil of turpentine mixed with yolk of egg, and diffused in a pint of thin warm starch.

Long before the chemical nature of calculi was accurately ascertained, physicians conjectured that they might be dissolved while in the body, by means of internal medicines; and the opinion was supported by the great and speedy alleviation of suffering which calculous patients often derived from alkaline remedies: hence the belief became general, and various nostrums were offered to the public as certain solvents of the stone. The most celebrated of these was the alkaline solvent of Mrs. Steevens, who obtained from the British Parliament five thousand pounds for the publication of its ingredients. As both alkalies and acids, when thrown into the stomach, are found to make their appearance in the urine, they are without doubt fitted to produce some alteration in calculi within the bladder; but their action in most instances seems to be exceedingly limited. When alkaline lixivia have been long persevered in, they seem to have had the effect of rendering calculi very brittle, (Dr. Henry, Lond. Med. Chir. Trans. vol. x.) and in some instances to have caused exfoliations of their superficial laminae. On examining the bladder of Horace Walpole, who had taken lime-water and soap for nine years, with great relief, some exfoliations from two of the calculi were observed. (Philos. Trans. vol. 1. p. 206.)

Dr. Marcet also gives a similar testimony, regarding a case where alkalies had been used with benefit for ten years. (Marcet on Calculous Diseases, p. 151.) In a case which fell under our own observation, where the fixed alkalies had long been employed, the patient passed many fragments of concentric layers of calculus, which were soluble in liquor potassæ; and he was for some years before his death, which occurred at an advanced age, nearly free from urinary irritation. When the alkalies have been exhibited for a considerable time in a case of lithic calculus, a superficial admixture of the phosphates with the acid is found to have taken place; and when this treatment is continued still longer, the whole surface has been found coated over with the same salts. In one instance related by Sir Everard Home, (On the Diseases of the Prostate Gland, vol. ii.) where the

alkalies had been followed after a time by an aggravation of symptoms, the stone, when extracted, was found beset with spicular crystals of the triple phosphate. The relief from the irritation of calculus procured by the employment of alkaline remedies has in some instances been so great, as to lead to the belief that solution of the stone had actually taken place; but on dissection it has been found that the prostate gland was enlarged, and the calculus lying in the cavity behind it, and thus prevented from falling against the sensitive orifice of the bladder. In the administration of the alkalies, it must ever be kept in view, that the tendency of all calculous cases is towards the formation of the phosphatic diathesis, and that the employment of the alkalies will necessarily hasten the period of its occurrence; when the phosphates will be deposited in abundance, and the calculus will receive a more rapid increase than before. A vigilant attention, therefore, is required to prevent the establishment of this diathesis, which will readily be accomplished by abandoning the use of alkalies, and having recourse for a time to acids. A phosphatic diathesis thus artificially induced, is, without doubt, much more manageable, and the probable result far less dangerous, than when it arises in the natural progress of disease, and in connection with an impaired constitution.

[In France, the Vichy waters, which are highly alkaline, have been celebrated, and their properties have been canvassed by scientific observers, whose opinions are worthy of all attention. It would not appear, that the destruction of calculi by this water is effected merely, or perhaps principally, in the way of solution, but that it is accomplished in a very considerable degree,—especially as regards those of the triple phosphates,—by a kind of disintegration of their component particles. When calculi consist of the oxalate or the phosphate of lime, mingled with lithic acid, lithate of ammonia, or the triple phosphate, the Vichy water is said to attack and disintegrate them rapidly. This water contains a large amount of pure carbonic acid, and nearly a drachm and a half of the bicarbonate of soda in every thousand drachms of the menstruum. (See the writer's *Practice of Medicine*, edit. cit. ii. 86.)]

Proposals have been made to dissolve calculi by injecting appropriate fluids into the bladder; but the trials hitherto made with alkaline solutions have shown that the bladder will not bear them of sufficient strength to act effectively on calculi of lithic acid. On the other hand, loose concretions and amorphous deposits of the phosphates, and of carbonate of lime, appear, from some late experiments of Mr. [Sir B.] Brodie, to be capable of being gradually removed from the bladder by a weak solution of nitric acid, sent in a stream through that organ, by means of a double catheter of pure gold. (London Medical Gazette, June 18, 1831.) This prospect is highly gratifying, and we trust the practice will prove as successful as the most sanguine can anticipate; but it must be remembered that cases of this description are in general complicated with such derangement in the general health, and so much disease of the bladder, that nothing beyond a palliation of symptoms can be looked for.

[Mr. S. Elliot Hoskins (*Proceedings of the Royal*

Society of London, No. 56.) has endeavoured to discover some chemical agent which is more energetic in its action on certain varieties of human calculi, and less irritating when injected into the bladder. With this view he suggests the employment of weak solutions of some of the vegetable supersalts of lead, such as the supermalate, the saccharate, the lactate, &c.; but he gives the preference to an acid saccharate—the nitro-saccharate of lead. This salt must be moistened with a few drops of acetic or of its own proper acid, previous to solution in water; and the decomposing liquid should not exceed in strength one grain of the salt to each fluidounce of water. The chemical effects of these decomponents Mr. Hoskins has tried out of the body, and the results are certainly encouraging. More recently, Dr. A. Ure has suggested an injection of carbonate of lithia; and, as urate of lithia is the most soluble salt which the uric acid forms, it has been thought by him an advisable injection in cases of the lithic acid calculus. Dr. Ure has not, however, tried it: moreover, the carbonate of lithia is extremely scarce; but he suggests the importance of its preparation to the pharmaceutical chemist.]

In all cases of calculus in the bladder, the patient experiences most ease when there is a plentiful secretion of urine, which, by distending the bladder, prevents the stone from being grasped in the muscular contractions of this organ. It also probably preserves in solution what might otherwise form a new deposit on the stone; and therefore a free use of thin demulcent liquids, as barley water, arrow-root, gruel, decoctions of prunes and raisins, and of the fibrous roots of the leek, are often productive of great relief to the calculous patient. But this system of dilution is obviously not adapted to all cases; for, as we remarked above, the phosphatic diathesis is not unfrequently attended with a superabundant secretion of urine; and in such cases any increase of the quantity would still prove more distressing.

Although we cannot remove a stone from the bladder by the internal administration of drugs, surgery has invented various methods by which this object may be accomplished. The most ancient is that of cutting into the bladder, and extracting the stone through the incision; and to this the name of lithotomy has been given. The mortality from this operation has always been considerable, and uniformly very great in the hands of the inexperienced and unskilful. The proportion of deaths to recoveries has varied exceedingly in different hospitals; but it is gratifying to be enabled to state that, over the island generally, it has of late manifestly diminished; a result which we are inclined to ascribe to the more general diffusion of surgical skill. In the Norwich and Norfolk Hospital, the total rate of mortality in all ages and sexes, from the opening of the institution in 1772, has been only 1 in 7.29. Dr. Yelloly, who has made this statement, (*Philos. Trans.* 1829.) adds, that of late it has been reduced to 1 in 8.6. The following tables, constructed by Dr. Yelloly, (*Philos. Trans.* 1829.) from the records of the hospital up to June 1828, exhibit the comparative results of lithotomy at different ages and in the two sexes. The data here are more extensive, and the success is greater, than in any other British hospital.

TABLE I.

Age or Sex.	Opera- tions.	Cured.	Died.	Mortality.
Both sexes.....	649	560	89	1 in 7·29
Males.....	618	531	87	1 in 7·1
Females.....	31	29	2	1 in 15·5
Both sexes.				
Under 14.....	292	272	20	1 in 14·6
14 and upwards.....	357	288	69	1 in 5·17
14 to 40.....	155	140	15	1 in 10·33
40 and upwards.....	202	148	54	1 in 3·74
14 to 50.....	196	171	25	1 in 7·84
50 and upwards.....	161	117	44	1 in 3·56
Under 16.....	317	294	23	1 in 13·78
16 and upwards.....	332	266	66	1 in 5·03

TABLE II.

Age.	Opera- tions.	Cured.	Died.	Mortality.
Infancy to 10.....	255	237	18	1 in 14·16
10 to 14.....	37	35	2	1 in 18·5
14 to 20.....	62	55	7	1 in 8·85
20 to 30.....	47	42	5	1 in 9·4
30 to 40.....	46	43	3	1 in 15·33
40 to 50.....	41	31	10	1 in 4·1
50 to 60.....	92	69	23	1 in 4
60 to 70.....	63	43	20	1 in 3·15
70 to 80.....	6	5	1	1 in 6

These tables present several results deserving of particular notice. The rate of mortality between the ages of 30 and 40 is only 1 in 15·33, while the decade immediately above gives 1 in 9·4, and that below 1 in 4·1. Hence it may be inferred that this small proportion of deaths is an accidental anomaly, which will not be found to correspond with the results of a more extended experience. In respect to the rate of mortality in the two sexes, and before and after puberty, Dr. Yelloly's tables coincide completely with the general observation of medical men. The mortality in males is more than double what it is in females; and the mortality before puberty is very much less than at any period after that age. The operation of lithotomy in females is now almost wholly superseded by the process of dilatation, which may be said to be wholly without danger; therefore, if in future calculations the results of the total cases of lithotomy do not appear proportionally more fatal than at present, it will obviously amount to a real diminution of deaths. The low rate of mortality before puberty is chiefly to be ascribed to the facility of reaching the bladder, owing to the small depth of the perineum, and to the imperfect development of the parts; which are greatly less vascular and less sensitive than after that age. Therefore it may be safely assumed as a rule, that whenever a calculus is ascertained to exist in the bladder, at almost any age before puberty, lithotomy ought to be performed as soon as

convenient. A disordered state of the health, unless the bladder or kidneys be actually ulcerated, forms no sufficient objection; for we have known the lateral operation performed on an infant of two years and a quarter, though in a sickly and very feeble state, with the effect of speedily restoring him to sound health. The operation by being delayed becomes, after puberty, one of increased difficulty and danger; and a long train of suffering is inflicted on the patient, while organic changes are taking place in the urinary organs which will ultimately render any operation altogether nugatory. It would seem as if the operation of lithotomy often produced a change in the constitution, for it is rare that the disease is known to recur after the extraction of a calculus. This has been remarked by different writers, and particularly by the late Mr. Martineau of Norwich, a very distinguished lithotomist. He observes that scarcely a case occurs in which the complaint returns; and when a second operation has been required, he believes that it may generally be traced to the stone having been broken, and a fragment left in the bladder. (Medico-Chirurg. Trans. vol. xi. p. 413.) The propriety of performing lithotomy at a more advanced period of life admits of more question. Its difficulties and dangers are greatly increased. Many circumstances may then render it unwise to put life in hazard by an operation; and the patient has arrived at those years when he may be supposed likely to pursue with steadiness that plan of regimen and medicine which will render his sufferings more tolerable, and, in all probability, prevent the increase of the stone. So soon, however, as the phosphoric diathesis is fairly established, whatever be the period of life, medicine and regimen become of uncertain efficacy, even in the hands of the most skilful; and extraction of the calculus affords the only prospect of permanent relief to the patient.

A second method of removing calculi from the bladder is by detrition, or what has been named lithotrixy; in which the stone is seized by an instrument introduced through the urethra, excavated and crushed, and the debris washed out of the bladder by injections and the natural flow of the urine. The first attempt of this nature was made by Colonel Martin, of the Indian army, who introduced an exceedingly delicate saw through a cannula into the bladder, and wore down a calculus which it contained. Some years after this, Mr. Elderton invented an instrument for the same purpose; and more lately M. Civiale, M. Leroy, and the Baron Heurteloup have carried the plan into effective practice by a variety of ingenious instruments, and succeeded completely by this method in removing stones from the bladder. The number of cases to which lithotrixy can be applied is very limited; for the bladder and prostate gland must be healthy, and the patient of a very tolerant temperament, to admit of its being carried into operation. The principal evils which are apt to attend this mode of procedure are, inflammation of the bladder, and retention of small fragments of the stone, which may at no distant period renew the disease.

A third method of removing calculi from the bladder is the dilatation of the urethra; but it is

limited excepting for small stones, to female cases; to which it is now ascertained to be so perfectly suited, that it has in a manner wholly superseded in that sex the operation of lithotomy. It is worthy of remark that dilatation of the female urethra for this purpose is an operation as old as Franco and Fabricius Hildanus, and that it was practised with great success by Proby, of Dublin, in 1693. (See Dr. Molineux in Philos. Trans. abridged, vol. iii.)

Prostatic Calculi.—Calculi in the prostate gland very often remain for a great length of time without causing any irritation, and in that case it is much better not to disturb the patients by attempts to extract them; but should they give trouble, the usual methods of allaying irritation of the bladder ought to be had recourse to, and surgical aid called in. The forceps of Sir Astley Cooper has often been used with success; at other times such calculi have been extracted by incisions made through the rectum or through the perineum.

[CANCER. (See SCIRRHUS.)]

CARDIALGIA. (See GASTRODYNIA.)

CARDITIS. (See PERICARDITIS.)

CATALEPSY, (derived from the Greek *καταλαμβάνω*, to seize,) is applied to a very rare form of disease, characterized by the sudden suspension of consciousness and of voluntary motion, the muscles continuing steadily in that state of contraction in which they happened to be at the instant of the attack,—and yet readily admitting of, and retaining any other position of the body and limbs, however inconvenient, in which they may be placed at the will of the by-standers.

The extreme rarity of this affection has caused its existence to be doubted by several distinguished physicians, and amongst these, by Cullen, as he never happened to meet with any instances of it which were not feigned. There are now, however, a sufficient number of well-authenticated cases on record to render its existence unquestionable.

The attack is sometimes announced by certain precursory symptoms, as lassitude, palpitation, headach, confusion of intellect, stiffness in the neck, or pain and slight cramps in the limbs; but more generally it is instantaneous, the sudden rigidity of the trunk and limbs, the suspension of the senses, and temporary interruption of the exercise of the intellectual faculties, having been preceded by no premonitory stage. The patient retains the posture of body and the expression of countenance which he chanced to have at the moment of seizure; and by this combination of fixed attitude and unvarying expression, presents the air of a statue rather than that of an animated being. The eyes continue either fixedly open or shut, as they happened to be at the commencement: whilst the pupil, though usually dilated, contracts on the approach of a strong light. The balance between the flexor and extensor muscles is so perfect, that any new position given to the head, trunk, or extremities, by an external force, is easily received and steadily maintained. This passive energy of the muscular system, permitting the body to be moulded into almost as great a variety of attitudes as if it were a figure of wax

or lead, is the distinguishing characteristic of the disease.

Catalepsy is an intermittent disorder, unaccompanied by fever, and recurring in paroxysms of various duration; more generally of only a few minutes, but occasionally of several hours, or even days. The length of the intervals is equally liable to variation, and seems to depend in a great degree on the recurrence of the peculiar exciting causes.

The return to the natural state is usually rapid, almost instantaneous, accompanied by heavy sighing, and generally by a complete restitution of all the faculties both of body and mind. Occasionally, however, pain and confusion of head, with a sense of fatigue in the limbs, are felt for some time after. There is no recollection of any thing which occurred during the fit, and the half-finished phrase which was cut short by the seizure, has been said to be taken up and completed on the instant of recovery.

During the paroxysm the countenance is for the most part little altered, though it has in some cases been slightly suffused, indicating, along with the more forcible pulsation in the carotid arteries, an increased determination of blood to the brain; whilst in other cases, on the contrary, the face has been observed even paler than natural. But these irregularities in the circulation, as well as frequent inequalities in the distribution of the animal heat, are in a manner common to all nervous affections. The respiration and action of the heart are often little affected, though in some cases the former has been observed to be much embarrassed from the extension of the spasmodic state to the muscles concerned in inspiration; and the pulse has occasionally manifested a considerable deviation from its natural force and frequency, more usually tending to an increased quickness and diminished strength.

Such is *true catalepsy*. But the disease does not always appear in so perfect a form: more frequently, indeed, its attacks are of a partial nature, the senses not being altogether obliterated, and the individual continuing conscious of every thing passing around him, though utterly unable either to move or to speak. This is the *catochus* of most nosologists. Of this spurious or partial catalepsy a very remarkable instance is recorded in Duncan's Medical Commentaries, vol. x. A woman was on the point of being buried alive in a trance, and endured all the horrors of seeing her own body prepared for interment; for though in the perfect possession of all her senses, she was unable to move a muscle or give the slightest indication of life. Galen has recorded a similar instance of total loss of the power of voluntary motion, whilst the consciousness continued unimpaired: and the author of the *Philosophy of Sleep* endured in his own person an apparently similar affection, to which he has given the title of *day-narc*. In another class of cases, the patients, having still a certain degree of consciousness, are able to move one hand or limb, and to swallow food when put into their mouths.

Ecstasy is a disease nearly allied to, and by some authors treated of under the head of epilepsy; and so often do these disorders run into one another, that of those nosologists who have sepa-

rated them, no two agree on their diagnostic signs. According to Dr. Mason Good, ecstasy is sufficiently distinguished by the inflexible rigidity of the muscles, whilst consciousness, as in catalepsy, is for the most part suspended. An instance of this kind occurs in the first volume of the Medical Observations, in the case of a woman of fifty, who was daily seized, for some years, with a rigid contraction of all the muscles of the body, and such a profound sleep that nothing could awaken her: she remained thus from sun-rise to sun-set, and then recovered, took her food, and continued awake all the night, but relapsed again into the same state every morning. The greater number of systematic writers, however, place the distinguishing characteristics of ecstasy in a high degree of mental excitement, co-existing with a state of unconsciousness to all surrounding objects, the limbs being often quite relaxed. The fit is for the most part induced by deep and long-sustained contemplation of some subject capable of awakening an exalted enthusiasm; and during its continuance the patient often speaks with earnestness, prays with fervour, or sings with much pathos and expression. Vivid dreams or visions of an extraordinary nature occasionally occur, and are so firmly impressed on the memory that they can be minutely detailed afterwards. But there is much reason to suspect that a majority of these latter cases have been counterfeited. Dr. Chisholm has recorded a remarkable and apparently genuine instance in a young female, where ecstasy alternated with mania; the limbs becoming relaxed, and the patient beginning to sing in a most touching manner as often as the maniacal state recurred. To us, catalepsy and ecstasy seem to be mere modifications of the same morbid state: thus Sauvages gives a case in which the first part of the paroxysm consisted in violent declamation and gesticulation, and loud singing, the girl being quite insensible to external objects; whilst in its termination, the fit had all the characters of true catalepsy.

As to the danger of catalepsy, though we have the high authority of Boerhaave for estimating it fatally, yet subsequent and more numerous observations prove that death during the fit is a rare occurrence; and where such a termination has ensued, it has usually been from the affection being complicated with or passing into other diseases, as apoplexy, mania, &c. Rostan met with one fatal case where inflammation of the lung co-existed, and Pinel another which terminated in apoplexy. Forestus has been cited by Sprengel, in his History of Medicine, as an authority for instances of fatal catalepsy attacking simultaneously a great number of soldiers at the siege of Metz; but any one who reads his narrative must feel satisfied that both Forestus and Sprengel have fallen into error in applying the term to such cases, and that the sudden deaths attended with rigidity were simply the result of intense cold in their exposed night quarters. Forestus in a subsequent passage particularizes the case of a horseman, who being frozen to death on the saddle, continued to maintain his seat, and rode, statue-like, into the camp, still firmly grasping the reins and his weapon. He supposes that in such cases 'he cold merely predisposed to catalepsy, and that

the maintenance of the erect posture and the firm contraction of the muscles, were sufficient evidences of remaining vitality; but this is evidently a gratuitous assumption. It was probably from such cases as these that Hoffmann came to the strange conclusion, that as catalepsy occurred most frequently in winter, it must depend on congelation of the nervous fluid.

Amongst the predisposing causes are, a highly nervous temperament, and whatever tends to increase the susceptibility of the nervous system. Of this nature are all such causes as are calculated directly to weaken the body, or to act powerfully on the mind; the depressing passions, as violent sorrow, continued anxiety, unrequited love; intense and long-sustained application of mind. Both sexes, and children as well as adults, have afforded instances of it; but females, and especially those who have a tendency to hysteria and hypochondriacism, melancholia or mania, are the most frequent subjects of these attacks. The late Dr. Gooch met with an exquisitely marked case of catalepsy supervening to puerperal melancholia, in a female debilitated by repeated miscarriages. The trunk, as she lay in bed, being raised to an obtuse angle, retained this painful posture; the limbs remained in any position in which they were placed: when set on her feet, the slightest push threw her off her balance, and no effort was made to regain it. The eyes were open, and the pupil, though dilated, contracted on the approach of a strong light. Of these attacks she had three, each lasting several hours, and recurring at the intervals of one and two days. The case afterwards resumed the form of melancholia and terminated favourably. This, which is one of the latest, best authenticated, and accurately detailed cases of the disease on record, is delineated with all the graphic power for which this distinguished physician was remarkable.

To the head of exciting causes may be referred strong mental emotions, as terror, suppressed rage, protracted meditation on deeply exciting subjects, &c. Fernelius mentions the case of a student who was seized whilst at his desk, and continued during the fit, with his pen in his hand, and in a fixed attitude of intense application. Bonetus gives the case of a soldier, who having deserted his colours, on being apprehended shortly afterwards, was so terrified that he lost the power of speech, became as immovable as a statue, and apparently unconscious of every thing around him: after continuing in this senseless state twenty days, during which he took no food, nor had any natural evacuation, he expired.

General plethora, suppressed evacuations, repelled eruptions, worms, and other sources of irritation in the digestive organs, are reckoned among the occasional causes of this disease.

The paroxysm is sometimes induced by very trifling circumstances, as a sudden noise, a slight contradiction, an unexpected visit, or a passing fit of anger or impatience.

Catalepsy is closely allied to the comatose diseases, apoplexy, carus, lethargy; and accordingly we find it classed by Cullen under the order Comata, genus apoplexia cataleptica. To epilepsy also, it is nearly related, as we find this disorder

occasionally assuming the cataleptic form, or the diseases alternating.

But in far the greater number of authentic and fully detailed cases, catalepsy has appeared to bear the strongest affinity to hysteria; and, indeed, in some of these seems to have been merely one of the innumerable forms of this Protean disorder. In support of this view we find that females and hypochondriacs are by far the most frequent subjects of both these affections; that they occur in similar constitutions, viz., those characterized by a high degree of nervous mobility; that they are convertible into each other; and finally, that they are susceptible of relief from similar modes of treatment.

In illustration of this opinion we shall briefly mention a case of catalepsy, which we witnessed some years since. The patient, a young woman of eighteen years, having been cruelly treated by a man who was under promise of marriage to her, and received a slight wound in the head and some bruises in the breast, was seized with severe and repeated fits of catalepsy. These were usually preceded by headach, vertigo, and tinnitus aurium. During the continuance of the paroxysm she remained perfectly insensible to surrounding objects; the breathing was considerably affected, and the pulse rather quick and small; the pupils were dilated, the face assumed the expression of a smile; and the limbs steadily maintained any position in which they were placed. The duration of the fits was from five to ten minutes, and they recurred very frequently in the course of the day. After each attack, pain in the præcordia, headach, and a general sense of uneasiness were complained of. In the intervals the intellectual functions were usually unimpaired, though on some occasions a slight degree of stupor was observable. After the disease had existed some weeks, the fits were occasionally accompanied with screaming and struggling. She now suffered from severe lacerating pain at the epigastrium, increased by pressure, and accompanied with difficulty of respiration, pain in the small of the back and in the right lumbar region, and subsequently some difficulty in voiding the urine, and frequent constipation. The most usual appearance of the paroxysms now became that of sound sleep, and their recurrence was much more frequent. The menstrual flux was not interrupted. The fits daily assumed more and more of the hysterical form; and by the use of aperients, local and general bleeding, and counter-irritants to the spine, ceased altogether in about two months from the commencement of her illness. The transition from well-marked catalepsy into hysteria was so remarkable in this case, as to leave little doubt of the close affinity, if not the identity, of the two diseases. The case of Helena Renault, recorded by Sauvages, seems to have partaken of the nature of catalepsy, hysteria, and epilepsy conjointly—all ceased on the spontaneous return of the menses.

One of the most remarkable cases given by M. Petetin in his treatise on catalepsy, if it be at all worthy of credit, would seem to fall rather under the head of animal magnetism, or lucid somnambulism, than true catalepsy. He asserts, not merely that consciousness and the power of

voluntary motion were abolished, but that the functions of the senses were transplanted into the epigastrium and into the extremities of the fingers and toes; so that when objects of taste, smell, &c. were applied to these parts, they were as accurately appreciated as they would have been by the tongue, the nose, &c. in the natural state. Strange to say, these and some still more startling facts do not rest solely on the authority of M. Petetin; he is supported in his assertions by other and equally respectable testimony:

Diagnosis.—The diagnosis of catalepsy from asphyxia, syncope, apoplexy, and apparent death, usually presents little difficulty. The suspension of the circulation and respiration, the flexibility of the limbs, and the colour of the face or lips, sufficiently distinguish asphyxia; while syncope is readily recognised by the three former circumstances co-existing with paleness of the countenance. In apoplexy there is usually paralysis of one side of the body and flexibility of the limbs, whilst stertorous breathing and congestion of the face are common attendants. To discriminate between catalepsy and apparent death is often a matter of less facility, and more than one case is on record in which individuals in the state of trance have narrowly escaped being buried alive. In such instances the disease must have existed in a very intense form, and been accompanied with paleness, suppression of the pulse, weak respiration, and a cold skin; and here the stiffness of the limbs might be very readily mistaken for that rigidity of the muscles which characterizes the dead body. But as the pulse and respiration are never quite extinct in catalepsy, the use of the stethoscope to the region of the heart, or even the application of the finger over the seat of any of the larger arteries, will enable us to detect the one; whilst the exploration of the lungs by the same instrument, and the holding of a polished mirror over the mouth of the patient, so as to intercept and condense the pulmonary exhalation, will leave us in little doubt as to the existence of the other. The expression of the eyes and of the whole physiognomy might perhaps occasionally afford us additional assistance, as would also a knowledge of the previous state of the health, the mode of attack, and other circumstances of the case. If, after all, there shall still remain even the shadow of a doubt, we must wait for the indubitable evidence of incipient putrefaction.

Numerous instances of a state in some degree resembling catalepsy having been feigned, are on record, some of which have resisted the infliction of the severest modes of investigation. One of these stood out against the shower bath, electricity, and a variety of other energetic kinds of treatment, but was detected by the pulse of the individual being found to rise, when a proposal for applying the actual cautery was made within his hearing. Another young soldier resisted measures of still greater severity, such as the thrusting of pins under his finger-nails, scalping and trephining the head, &c. and persisted in the deception till he obtained his discharge; immediately after which he was seen in perfect health, and engaged in active occupations about his father's house. John Hunter, as Mr. Abernethy used to relate in his lectures, proposed to detect

cases of feigned catalepsy by appending a weight to the arm, and after some time suddenly cutting the string by which it was attached: if any resiliency of the limb took place, he considered it a proof that additional force had been voluntarily exerted for the sustaining of the additional weight, and that, consequently, the powers of the mind were not really suspended. But even this would scarcely be conclusive, as it seems to leave the natural elasticity of the muscles altogether out of the account. Indeed, after making all due allowance for what practice and a firm determination can effect, we much doubt whether the peculiar state of the muscular system which exists in perfect catalepsy could by any effort of the will be successfully counterfeited, or whether very painful postures of the trunks and limbs could be long supported without the occurrence of such a tremor in the muscles as would reveal the deceit. And accordingly we find that impostors rarely attempt an imitation of perfect catalepsy, but content themselves with the easier task of assuming a state of profound insensibility coupled with relaxation of the muscles.

Morbid anatomy has hitherto thrown little or no light on the nature of this curious affection. As it is rarely fatal, few opportunities of dissecting such cases have occurred; and in those few, though the brain and nervous system have been carefully examined, no morbid changes have for the most part been discovered. Still, if we are to adopt the axiom of some modern French pathologists, namely, that every change of action implies a change of structure, we should conclude that such morbid alterations, though inappreciable by our senses, must needs exist. In science, however, such dogmatical assertions, with nothing but vague analogy for their support, are misplaced. The converse of the proposition, or that change of structure necessarily implies a previous change of action, might be maintained with at least an equal show of reason. The great truth that the nervous system generally gives the initiative both to disorder and disease, has of late years been too much lost sight of. The younger Pinel has attributed the symptoms to an inflammation of the spinal marrow; but this does not rest on a sufficient basis of observation to entitle it to much credit; nor, indeed, is it probable, *à priori*, that an affection, the attacks of which commence and terminate so instantaneously, and which have been known to recur at various intervals during a period of many years, should have inflammation for their cause. A temporary state of irritation and congestion of the cerebro-spinal system, would seem to be more consistent with some of the phenomena, and to give an equally satisfactory explanation of the remainder. As the disease seems to be often induced by sympathy with the stomach, intestines, or uterus, the ganglionic system is probably also not unfrequently implicated.

As to those theories which propose to explain the singular symptoms of catalepsy by a supposed excess, deficiency, or immobility of the nervous fluid, though supported by the authority of high names, they are surely unworthy of notice in the present state of physiological science. We know little of the mode of action of the nervous system,

and still less of its irregularities: a candid confession of ignorance in such a case is infinitely more favourable to the advancement of knowledge than the reproduction of such gratuitous hypotheses.

In the treatment of this disease the chief indications are, to subdue general plethora when it exists, by venesection and other depletions, and to obviate irregular determination of blood to the brain and spinal chord, by the use of leeches or cupping in the neighbourhood of these important organs; or (as some continental practitioners, guided by the old theory of derivation, prefer,) to a more distant part, as the feet or thighs. The existence of headache, confusion of ideas, and flushing of the face; or of pain, and tenderness on pressure in the course of the spine, will leave us little doubt as to the propriety of these measures. Counter-irritation in the form of blisters, issues, or moxa will subsequently be called for.

The state of the stomach, bowels, and liver must be carefully investigated, and every effort made to counteract any irregularity in their functions. From the well-known influence which these organs exert over the nervous system through the medium of sympathy, the importance of this part of the treatment cannot be too much insisted on; but generally speaking, our object should rather be to keep up the natural action of the alimentary canal, than to stimulate it to excessive secretion by drastic medicines, as the local irritation and the constitutional exhaustion induced by such means would, in many cases, tend to exasperate the nervous symptoms. The existence of general plethora will, however, justify the use of free and long-continued catharsis; and Dr. Cheyne, in his valuable work on Comatose Diseases, has signalized the utility of aloetic purgatives in such cases.

A careful examination must also be made into the state of the uterine functions, and if not duly performed, every measure taken to restore them to their natural state. In those cases partaking largely of the nature of hysteria, the operation of cupping over the loins or the occiput, along with large turpentine enemata, should not be neglected.

In the intervals of the fits, exercise, diversified amusement, country air, and a mild diet should be insisted on. Sauvages records instances of the disease being removed by a milk diet and country air alone.

In those cases which appear to be purely nervous, the cold shower bath, if not peculiarly disagreeable to the feelings of the patient, and tonics, should be tried. But above all things the undue excitement of the feelings and of the intellect must be cautiously avoided.

During the paroxysm, the application of cold, in the form of ice or evaporating lotions, to the head, provided there be any proof of determination to the brain, and the immersion of the feet into a warm stimulating foot-bath, are perhaps the only measures we should put in practice. Valerian, ammonia, musk, assafetida, and other antispasmodics, both in draughts and enemata, are usually employed, with the view either of warding off or shortening the duration of the fit, but generally with no very marked advantage.

The older writers recommend ligatures to the limbs, and assiduous friction with stimulant liniments; but if the seat of the disease be, as we have every reason to believe, in the brain or spinal chord, little can be expected from such means. Electricity and galvanism have also been suggested, and are said in some instances to have cut short the attack. In the Dictionnaire des Sciences Médicales, it is recommended to direct all our efforts to rousing the dormant sensibility of some one organ; and a case is given from the *Ephemerid. Naturæ Curios.* where this was done with success: but the mode of effecting it there alluded to is one which, we believe, few practitioners in this country would venture to recommend. M. Petroz has occasionally known music to exercise a singular influence over the paroxysm, diminishing it materially both as to duration and intensity.

Should the attack end in apparent death, the importance of the immediate employment of artificial respiration is obvious; and indeed, in any of these cases where the action of the heart and lungs is greatly depressed, we should not be justified in neglecting it. In similar circumstances the application of moderate warmth and the free access of pure air are of the highest moment.

W. B. JOY.

CATAMENIA. (See MENSURATION. See also AMENORRŒA, DYSMENORRŒA, MENORRHŒA.)

CATARRH, PULMONARY.—Every disorder of the mucous membrane of the bronchi has been included under this name. Thus Laennec makes the term generic, applied to the several species, *the mucous* (acute and chronic), *the suffocative*, *the pituitous*, *the dry*, and *the convulsive catarrhs*. But as the etymology of the word (*κατὰ, deorsum, ἴτω, fluo,*) has relation rather to the secretion than to the pathological state of the diseased membrane itself, it is better to reserve the term for those forms of the disease in which unnatural secretion is the only constant or appreciable phenomenon. We have accordingly included under the head bronchitis all those affections of the bronchial membranes which are in any appreciable degree inflammatory, except hooping-cough, which will be found in its place. The cases, therefore, excluded from that head that require consideration under the name of catarrh, are those which Laennec denominates the *pituitous* and the *dry catarrh*, and this rather from want of another term, than from the aptness of the term employed.

Both the pituitous and the dry catarrhs attack the nasal as well as the pulmonary mucous membrane, and, like the inflammatory influenza, frequently pass from one to the other. According to the extent of the membrane affected, they may amount to a very trivial or a very serious malady; and when they affect extensively the bronchial membrane, they constitute the disease in a great number of the cases which are commonly called asthmatic.

1. PITUITOUS CATARRH.—This form of catarrh is distinguished by the secretion of a thin, colourless, glairy liquid from the bronchial membrane. This flux comes on in paroxysms, attended with dyspnoea and cough, which are relieved by the

expectoration of a liquid, "frothy on the surface, and underneath like the white of egg diluted with water." Such a secretion frequently attends bronchitis when it attacks persons of lax habit of body; and, in fact, those cases which have been called *pneumonia notha* seem to owe their peculiar character to the pituitous secretion that occurs in them. It is sometimes likewise present in cases of œdema of the lungs, and the first stage of phthisis. It does occur also idiopathically, and as such we have to consider it here. It is either acute or chronic. In its acute form it sometimes commences as a common cold, but with a sensation of oppression and dyspnoea greatly disproportioned to the slight febrile symptoms. The attacks are sometimes of short duration, passing off entirely in the course of a few hours, after the expectoration of a quantity of the fluid before described, which sometimes amounts to several pints. Not unfrequently they assume a periodic character, coming on twice or three times a day, the symptoms in the intervals generally disappearing entirely. Sometimes this affection is combined or alternated with what Laennec terms dry catarrh, and the tough pearly mucus characterizing the latter is often seen in the expectorated matter. The stethoscope discovers a variety of sibilant and bubbling rhonchi in the chest, often resembling the chirping of birds, whilst during the paroxysm the sound of respiration is impaired. The chest sounds well on percussion. During the intervals the same rhonchi are present, but in a much slighter degree, and the respiratory sound resumes its distinct character. The examination of those who have died during a paroxysm of pituitous catarrh discovers little or no trace of inflammation in the bronchial membrane. It is sometimes a little thickened and softer than natural, from the infiltration of serum; often perfectly pale; and any blushes or striæ of red that may occasionally appear are very slight, and of trifling extent. These circumstances, and the fact that it attacks most commonly those of weakly habit, languid circulation, and little disposed to inflammatory symptoms, seem to indicate that it is rather of the nature of a *profusivum*, arising from want of tone in the vessels, than an inflammation. The effects of remedies and the nature of the predisposing causes confirm this supposition. It most commonly arises in persons who have for a long time suffered from disordered digestion, whether arising from habits of excess, or from natural weakness of the digestive powers. In certain individuals a form of pituitous catarrh sometimes happens during the summer months, and it is commonly attributed to an inhalation of the effluvia of hay-fields, whence it has gained the name of hay-fever or hay-asthma; but this is apparently more of the nature of influenza. After one attack, pituitous catarrh is extremely apt to recur; alterations of temperature or irregularities of diet being sufficient to re-excite it. When it has once established itself, like most other serous fluxes, it is very difficult to remove; for the habit of occasional profuse secretion being acquired, it frequently does not yield on the removal of the original exciting causes. Laennec remarks, that it is common in gouty subjects advanced in age, and in whom the gout has become milder and

less regular. The importance of pituitous catarrh varies much according to the state of the individual whom it attacks. When it seizes a subject enfeebled by present or previous disease, it may prove fatal in a few hours. Again, its long continuance, when it has by habit become established in the system, sometimes wastes the body, and brings on disease of the heart, pulmonary œdema, or some other loss of balance among the vital functions, that leads to the extinction of life.

In other instances, where the body is strong, or the disease slight, it may go on for years, injuring the comfort rather than the general health of persons even far advanced in life. Andral records an instance in which a sudden and temporary attack of pituitous catarrh, with very profuse discharge, was attended with the removal of a hydrothorax. We have before remarked that it sometimes is excited by miliary tubercles in the tissue of the lungs; and in all cases where the constitution of the subject, irregular resonance of the chest on percussion, with bronchophony, and constancy of cough and pituitous expectoration (not in paroxysms), indicate this lesion, the prognosis must be more unfavourable.

The treatment of pituitous catarrh must be considered in relation to the paroxysms, and likewise to the disposition to them. The indications during the paroxysm are to facilitate the removal of the redundant secretion, and to prevent its further effusion. The means which we employ under the name of expectorants, have probably, in some instances, both these effects, but in a very uncertain degree, and rarely in a manner available in these cases. Ipecacuanha, whether as an emetic, or in a nauseating dose, is perhaps the one from which most advantage has been derived. It is best to obtain at first its emetic effect, and afterwards to repeat it in such quantities as will keep up a slight sensation of nausea. The power which this remedy has in restraining hemorrhages is probably of the same character which renders it useful here: but it is extremely difficult to say whether this is from any direct action on the affected vessels, or from its general effects on the circulation. Tartar emetic, in large doses, which Laennec found effectual in two cases of an alarming aspect, probably has a similar mode of action; and from what we know of its effects in peripneumony, it seems difficult to avoid attributing it to a sorbefacient power. The lobelia inflata would perhaps more properly than these come under the class of expectorants. Of its utility in pituitous catarrh we have the testimony of practitioners of great sagacity and experience. The tincture has been given in doses of fifteen or twenty-five minims every two or three hours, with marked effect in relieving the dyspnoea. As has already been remarked, (see CHRONIC BRONCHITIS,) it is a medicine that must be watched, and stopped or diminished if vertigo or nausea show that its effect on the system has been produced.

Of evacuants, which it may be necessary to resort to, to divert the determination from the pulmonary vessels, those which produce watery discharge are to be preferred to bleeding, which is seldom admissible, and only where there is marked plethora of the system. Diaphoretics and diure-

tics, if they can be brought to act, will have a tendency to shorten the paroxysm. Antimony and ipecacuanha, as already recommended, will best fulfil the first effect, and squill may be used with advantage as a diuretic. Drastic purgatives are not generally useful, often injurious; but those of a milder kind may be given with advantage; and when irregularities of diet have been the exciting cause of the paroxysm, a free evacuation of the bowels may contribute most materially to its removal.

In many cases these means are of but little avail; and when they do abridge or remove a paroxysm, they are scarcely effectual enough to prevent its recurrence. Strengthening the system by a mild but tonic regimen, removing disorder of the digestive organs, and the adoption of every means calculated to improve the general health and strength, often succeed better in curing pituitous catarrh than any remedy directed against the disease itself. The diet should be mild and nutritive, consisting chiefly of farinaceous food and plain meat. The hours of eating should be regular, and the quantity moderate. All spirituous and fermented liquors are best avoided, and liquids of all kinds should be taken sparingly. Coffee made by infusion is the best beverage, and seems positively useful in some cases in preventing the recurrence of the paroxysm. To strengthen the digestive powers, calumba, rhubarb, or some other bitter may be given; and in some cases the sulphate of quinine, with a mineral acid, will be found of good effect. But the safest and most efficacious tonics, are country air of a bracing quality, such as that of Brighton, and the cold shower or plunge bath. Regular exercise is highly necessary; and that on horseback is generally the most suitable. It is of importance to attend to the clothing, that it be sufficient to prevent the cuticular exhalation from being checked by occasional winds.

2. DRY CATARRH.—This disease is more recognised as an asthmatic than a catarrhal affection. In fact, the term catarrh is not by any means appropriate in a disorder that is unattended with flux; and but for the absolute want of another term, it should not be employed. The pathological state of the membrane, however, does not so much differ, as the nature of the secretion, from that in the disease just described. There appears to be a passive or venous congestion in the mucous membrane of the bronchi, which neither in its nature nor effects resembles inflammation. An improved nomenclature, founded on pathology, is much to be desired; but it may be doubted whether it be expedient to frame one until our knowledge of pathology itself be much more extended and definite than at present.

The symptoms of dry catarrh vary much according to its extent. In its slightest degrees it occurs in those individuals who, without any other derangement of health than a slight shortness of breath felt on exertion, expectorate every morning a small portion of tough mucus of a pearly grey colour. Sometimes, however, there are cough and dyspnoea, which, coming on in paroxysms, assume the form of asthma, each fit terminating with an expectoration of pellets of the same dense mucus. Occasionally there is a tole-

rably copious pituitous secretion at the same time; but this is uncertain, and bears no relation to the severity of the preceding fit, which seems to be connected with the formation of the thick mucus. Sometimes there is little or no cough; and the dyspnoea, or rather shortness of breath, may continue for months, or even years, without other symptoms. If an attack of bronchitis supervene, there is generally an aggravation of the dyspnoea, sometimes amounting to a fit of asthma. Laennec, who is the only writer who has given a distinct account of this disease, remarks, that it most commonly attacks gouty persons, those affected with cutaneous eruptions, and those disordered by long excesses; and he considers the slight and dry coughs frequently attendant on various functional disorders of the abdominal viscera, and which are generally called nervous, to arise from a degree of dry catarrh.

The physical sign of this disease is a suspension of the sound of respiration in the part affected, while the corresponding part of the chest sounds well on percussion. This arises from a tumefaction of the bronchial membrane, which either of itself, or assisted by the pellets of thick mucus before described, more or less completely obstructs the caliber of one or more of the tubes. When the obstruction is not complete, a dull whistling or clicking sound accompanies the breathing; and a cough or forcible inspiration may sometimes discover the same sounds where in ordinary breathing the air does not enter. According to the extent of the bronchi thus affected, the severity of the disease will vary; but in all cases the expectoration of the thick mucus brings with it some relief of the dyspnoea. Andral records two cases in which a fatal asphyxia was caused by such obstructions occurring in one of the great bronchi, and which no efforts of coughing were able to remove; but these are to be considered as accidental rather than as common cases.

On anatomical examination, the membrane of the bronchi affected is found tumefied, and of dull red or violet colour, but without softening or ulceration. These circumstances, together with its duration, seem to indicate this affection, although occasionally originating in inflammation, to be of the nature of passive congestion, with interrupted secretion. Although not frequently in itself a dangerous disease, dry catarrh often much aggravates the symptoms of any other affection attacking the chest; and is in itself apt to induce the organic change called emphysema of the lungs.

The congestion of the mucous membrane constituting dry catarrh, chiefly occurs, like other congestions, in those persons in whom some functional derangement has injured the balance of the circulation, and impaired the tone of the extreme vessels. Disordered digestion, imperfect secretion of the bile, and irregular alvine excretion, are the most common of these derangements; and, although they do not always give notable and direct evidence of their existence, the success attending treatment calculated to remove them is so efficacious in relieving the affection in question, that it should be adopted in all severe cases of dry catarrh. It is unnecessary here to particularize the treatment alluded to; but it may be observed that a proper regulation of the diet, to the

exclusion of rich, irritating, or acescent articles of food, and all fermented liquors; the promoting regular alvine evacuations of proper colour by the aid of small doses of blue pill and ipecacuanha, followed by castor oil, saline, or other mild aperients; and afterwards giving tone to the stomach and system by a judicious administration of tonics;—all these measures, as the circumstances may require, may be resorted to with the greatest advantage, and are often more successful in the permanent relief of the dyspnoea or asthma of dry catarrh than any measures directed against the disorder itself.

Laennec remarks that the means found useful in chronic bronchitis and other forms of catarrh, make no impression on this, and are only indicated when any of these are combined with it. The indications are, to remove the congested state of the bronchial membrane, and to facilitate the expectoration of the dense portions of mucus that obstruct the tubes. Bloodletting, blisters, and evacuants in general, have not the effect on congestion that they have on inflammation; and the state of the system is generally not such as to make the trivial benefit that may result from them equivalent to their weakening effect; but the same objection cannot be urged against dry cupping, which Laennec recommends; and friction of the chest with rubefacient substances, the occasional short application of a blister, wearing a pitch-plaster, or any of those means that may excite the superficial circulation without weakening the system, may be resorted to in most instances with more or less temporary relief.

With these measures we may properly combine such expectorant medicines as may fulfil the second indication, namely, to facilitate the expectoration of the thick mucus, which by obstructing the bronchial tubes becomes a principal cause of the dyspnoea. As Laennec remarks, we may effect this by any means which will diminish the glutinous tenacity of this matter; and he conceives that we possess medicines capable of attenuating the secretions and rendering them more liquid, in the mild or very dilute alkalies. He recommends either almond soap, in form of pills, with the patient's meals, to the amount of ʒss. to ʒi. a day, or the carbonated alkalies in doses of from twelve to thirty-six grains. He likewise made use of baths, both salt water and alkaline, made with four ounces of a carbonated alkali. He considered sulphur baths serviceable in cases complicated with herpetic diseases. To the efficacy of alkaline medicines in dry catarrh we can add our testimony. We have already spoken of their utility in other bronchial affections besides those accompanied by a viscid secretion. But in these their effect is more marked and unequivocal, and far from being so inexplicable as Laennec seems to consider it. The power of alkalies and acids to change the quality of the urine is well ascertained; and whether it be by an effect on the whole mass of blood, or by the agent passing immediately to the kidneys, it is quite certain that an acid or an alkaline quality may at pleasure be communicated to the urine by repeated doses of the corresponding medicine given by the mouth. Now it is not indulging a supposition too chemical, to consider that the formation of thick tough

mucus is incompatible with an alkaline state of the fluids, since alkalies exert a remarkable solvent power on mucus. Then it must be held in view, that the beneficial effects of alkalies are not limited to the removal of the viscid secretion; but by likewise establishing a liquid secretion from the diseased membrane, they tend very much to relieve the congested state of its vessels. To increase this effect, it is advantageous to combine with the alkalies, squill, ammoniacum, or some other stimulating expectorant. The liquor potassæ is the form of alkali to which we give the preference; and we have found ten minims or more, with the same quantity of tincture of squills and ℥ss of the tinct. camphoræ comp. in ℥i of water, of more efficacy than any other combination in dry catarrh. Where languor of the circulation and tendency to spasmodic asthma are present, a preference may be given to combinations of ammonia and ammoniacum; and if the liquor potassæ should ever appear to irritate the stomach, castile soap, as recommended by Laennec, may be substituted. Inhalation of the vapour of water, alone, or with camphor or some other aromatic matter, would probably avail more here than in other cases of pulmonary catarrh; but we have no experience on this point. Finally, we must again insist on the importance of attending to the state of the other functions, and do all in our power to remove the disposition to local congestions, by keeping free the secretions, and giving tone to the body by cold baths, frictions, and regular exercise.

C. J. B. WILLIAMS.

CATHARTICS. By cathartics are meant substances which accelerate the peristaltic movement of the intestinal canal, and promote the evacuation of its contents. They operate locally on the intestines; but their influence is extended to the neighbouring viscera, and, in many instances, to the whole system. When their action is confined to the intestinal canal, they prove beneficial by restoring its natural function. Their stimulus is often extended to the stomach, causing its contents to be propelled into the duodenum; and they promote and increase the flow of bile and of the pancreatic fluid, by stimulating the excretory ducts of the pancreas and the liver.

The kidneys, the bladder, and the uterus, are also influenced by the action of cathartics; the secretion of the first is generally diminished by their continued exhibition, as the fluids which they cause to be discharged by the bowels would have been excreted by the kidneys. The uterus suffers by contiguity.

Cathartics differ with respect to the part of the canal on which they act: some particularly stimulate the duodenum, promoting the discharge of the bile through the biliary ducts; as, for instance, calomel and jalap; others, as aloës, exert their action on the colon and rectum; while a third class, the saline and oleaginous purgatives, increase the peristaltic movement of the whole intestinal tube, and therefore operate quickly. No satisfactory explanation of the cause of this difference of action has yet been advanced; but the knowledge of the fact is of great importance in a practical point of view.

Cathartics are said to act *generally*, when,

besides the evacuations of the bowels, they also cause a copious discharge of serous fluid from the general circulating mass: the suddenness of this abstraction, combined with the quantity of the fluid discharged from the exhalents, produces a powerfully sedative effect on the whole frame: the force and velocity of the pulse are lessened; excitement is diminished, and febrile and inflammatory action is overcome, or, at least, greatly lessened. In some instances, indeed, as when elaterium is administered, the discharge of watery fluid is so excessive, that alarming and even fatal effects have resulted. If purging be long continued, the chyle is evacuated; and hence, in protracted diarrhoea, the blood loses its red colour, the surface of the body becomes pallid, and symptoms of exhaustion supervene.

Cathartics excite the general action of the absorbents, and on this principle is explained the removal of extravasated fluids: even solid matters, the product of disease, are sometimes removed by active purging; an effect attributable to a law of the system, by which a great discharge of serum is followed by a corresponding increased action of the absorbents.

Some cathartics cause purging when they are only applied to the skin; thus, if a cataplasm of rhubarb be laid upon the pit of the stomach of a child, the bowels will be emptied; and aloës, applied to any abraded surface, produce the same effect on the rectum as if the medicine had been taken into the stomach. This may be taken advantage of when patients obstinately refuse to swallow medicines, as occasionally occurs in childhood, and frequently in insanity. On the same principle, placing two or more drops of croton oil on the tongue purges briskly, when the powers of deglutition are suspended, and injections do not fulfil the intention of the practitioner.

Although the *primary* influence of cathartics, that of exciting the alimentary canal, is shared by all of them, yet they differ considerably in their *secondary* effects. Some operate quickly; others very slowly: some produce nausea, griping, and tenesmus; others operate with little sensible impression: some cause one copious evacuation only; others repeated stools. The doses, also, in which cathartics are administered, greatly modify their action: some, when given in large doses, only slightly increase the peristaltic motion of the bowels; others, when given in minute doses, produce numerous watery stools with great irritation; and some act so violently as occasionally to excite inflammation. Cathartics have been accordingly divided into laxatives, purgatives, and drastic cathartics.

1. **Laxatives** are partially digestible substances, which gently stimulate the inner coat of the intestinal tube, and moderately quicken the peristaltic action. They merely remove irritating matters from the bowels, and thereby diminish what is termed the tension of the system, and abate the disposition to febrile action; they are on this account employed in cases in which active purging would prove detrimental. Some laxatives owe their effects to a mechanical property; as, for example, bread made of flour which has not been bolted or freed from all the bran, proves aperient, owing to the little spiculæ of the horny

testa of the grain which have been left in the flour. The distension of the stomach by a large quantity of fluid is often followed by evacuation of the bowels. But many laxatives owe nothing to their physical properties: this is the case with manna, sugar, honey, the pulp of the cassia fistularis, the juice of ripe subacid fruits, malted grain, fermented liquors, bland fixed oils, sulphur, magnesia and subcarbonate of magnesia, and some other substances.

2. **Purgatives** are indigestible substances, which, taken into the stomach, or introduced into the rectum, irritate the coats of the intestines and augment their peristaltic movement. The action of purgatives is, therefore, merely an increased degree of that of laxatives; but besides augmenting the peristaltic action of the intestinal canal, they stimulate their secreting surfaces, so that an increased quantity of fluid is secreted by the intestinal exhalents.

The necessity of employing purgatives is founded on the same circumstances which demand the use of laxatives; and as their operation also reduces the powers of the system, they are indicated in diseases of excitement, in which the mere evacuation of the alimentary contents is a secondary consideration. In continued torpor of the bowels, giving rise to an accumulation of feces in the larger intestines, more active stimulants than simple laxatives are requisite; and hence in such cases purgatives are employed.

Purgatives are procured both from the organic and the inorganic kingdoms of nature. Among those belonging to the first are classed substances the effects of which depend,—1. on an *acid principle* blended with a fixed oil, as in castor oil; 2. on a *stimulant volatile oil* combined with resin, as in the balsam of copaiba, and the various turpentes; 3. on *resin* in union with *extractive*, as in jalap, rhubarb, and aloë's; or with cathartine, as in senna leaves; or veratria with fecula, as in colchicum. Among the inorganic purgatives, the most active are, 1. compounds of the oxides of metals combined with different acids, constituting salts; for instance, sulphate of magnesia; the sulphate and the phosphate of soda; the tartrate of soda and potassa; the sulphate, bisulphate, tartrate, bitartrate, and acetate of potassa: 2. oxides of metals in combination with vegetable matter, as in the mercurial pill, or with magnesia, or with chalk, as in the preparations termed, *hydrargyrum cum magnesia*, and *hydrargyrum cum creta*: 3. chlorides, as that of soda, and the submuriate of mercury.

3. **Drastic Cathartics** are also indigestible substances, which operate in the same manner as purgatives, but with greater energy, and affect the nerves of sensation more than either laxatives or purgatives; frequently causing griping, or tormina, nausea, and vomiting. This influence, however, on the sensitive nerves is not essential to the fulfilment of the intention for which drastic cathartics are administered. Drastic cathartics are chiefly derived from the organic kingdom of nature, and consist generally of resinous and resino-extractive matters: for example, scammony, colocynth, gratiola, gamboge, white hellebore root, croton oil, the root of the common dock, *rumex obtusifolium*, tobacco, and elaterium.

One drastic purgative only, the precipitative sulphuret of antimony, is derived from the inorganic kingdom.

Although cathartics have been described as belonging to three genera, yet it is impossible to mark the limits where the one set terminates and the other commences; for all, with a few exceptions, may be arranged under one head, the difference depending rather on the energy of their action than on any specific or peculiar mode of operation. The effects, indeed, of cathartics, depend on such a variety of circumstances, that laxatives may operate in some cases with violence, and a mild and scarcely sensible action may follow the administration of the most drastic cathartics. What are the circumstances that thus so powerfully modify the operation of this order of medicines?

We may first mention *quantity* as modifying the operation of cathartics; and this is so obvious as scarcely to require any comment. The rule, however, is not general; as some drastic purgatives, for example, elaterium and croton oil, exert their full influence in such minute doses that it is impossible to reduce their action to that of a laxative. On the other hand, some laxatives, as sugar, manna, and magnesia, cannot, in any dose, be brought to operate as drastic cathartics. The second circumstance influencing the operation of cathartics is *mechanical division*. The resinous purgatives, when coarsely powdered, cause griping and even tenesmus; while, in a state of more subtle division, they operate with little sensible effect; a circumstance at variance with the law which regulates the degree of action of most other substances. Thus, if camphor be combined with colocynth, the purgative property of the gum resin is increased; but at the same time its influence on the sentient nerves is greatly diminished: and the same effect is produced by the union of camphor with senna. By such a combination, the colocynth is rendered more soluble; but in the case of the senna, the activity of which is augmented even when the camphor is added to the decoction, some other explanation must be sought for. The third circumstance modifying the powers of some cathartics is *light*, operating on impalpable powders. Thus, if powdered rhubarb be kept in a glass bottle, the portion on the side of the bottle exposed to the light loses both its colour and its activity, while that on the opposite side retains both unaltered. The last circumstance which we shall notice as influencing the operation of cathartics is *combination*. Thus in cases of spasm, the operation of a cathartic is promoted by its combination with opium; and under all circumstances, mixture,—as for example, the mixture of sulphate of magnesia and bitartrate of potassa, of infusion of senna and camphor mixture, and compounds of the resinous cathartics and camphor, and the union of calomel with jalap, scammony, gamboge, colocynth, or rhubarb,—promote the action of purgatives, and cause cathartic substances to operate with more certainty than when taken alone.

Cathartics differ in the time necessary for the production of their effects; some operating in a few hours, others requiring from eight to twelve. These differences depend, in some degree, on the

solubility of the substances in the fluids of the alimentary canal. Thus the saline purgatives operate most quickly; the resinous require the longest time. It is probable also that their action in different parts of the intestinal canal, is, in part, to be ascribed to their different degrees of solubility. Some, as jalap, are very soluble in the fluids of the duodenum, and act immediately on that portion of the canal; others dissolve more slowly, and act on the lower intestines; whilst others, as, for instance, calomel, acquire activity from meeting with acid in the stomach and undergoing a chemical change. This rule, however, is not without exceptions: thus aloës is more soluble than jalap, yet it operates chiefly on the colon and rectum; and even when applied to an ulcer on the surface, its influence is still exerted on the large intestines. A knowledge of the time required for the operation of different cathartics is useful in a practical point of view, as it enables us to adapt our remedy to the urgency of the case: the saline purgatives, owing to the rapidity of their operation, are well adapted to acute diseases, especially those of a febrile and inflammatory character; the resinous, from the tardiness of their action, are better calculated for chronic affections.

Cathartics differ in their ultimate effects upon the system. In general they induce a subsequent costiveness; and this is supposed to depend on the evacuation of the fluids of the intestines being so considerable, that some time is requisite to replace them; but it is more probable that it is the result of that law of the constitution which determines that every increased action must be followed by a state of inactivity or collapse. The more general, also, the action of a purgative, the more likely is costiveness to follow: an exception, however, must be made, as relates to castor oil, which, when given daily, operates in such a manner, that the dose may be gradually reduced to a few drops, and yet the effect of a full dose be maintained. Saline purgatives, owing to their operation on the whole intestinal canal, often leave a greater sluggishness of the bowels than existed before their exhibition. Rhubarb, also, has this effect: but on the contrary, those resinous cathartics which operate on the lower portion of the canal, induce a more open state of bowels.

In the administration of cathartics, some attention must be paid to the following circumstances:

1. Cathartics are more necessary and serviceable in warm than in cold climates; owing, not only to the greater vitiation of the contents of the bowels and the augmented secretion of bile in high than in low temperatures; but to the great determination of fluids to the skin in warm climates favouring the formation of scybala. As to the influence of season, it is an old maxim that purgatives should be given in the spring and autumn: and it is true that more inflammatory diseases prevail at those seasons than at other periods of the year; but the custom ought not to be followed by persons in health, as it is apt to induce a habit which may prove hurtful.

2. The constitution of the patient must be attended to. Cathartics are more required by persons of a melancholic than those of a san-

guine temperament, the bowels being generally more torpid in the former than the latter. There is an exception, however, to this rule in women, who, although they are more commonly of a sanguine temperament, yet are generally more disposed to costiveness than men; they do not however bear the operation of purgatives so well. In pregnancy, and during menstruation, drastic purgatives should not be administered, nor should cathartics of any kind be freely employed in states of debility. In attending to this rule, however, it must be recollected that debility may arise from very opposite conditions of the system. Where any idiosyncrasy exists, connected with the operation of cathartics, it should not be disregarded, as much injury may follow the employment of certain kinds of purgatives in such instances: thus, in some individuals a dose of rhubarb will cause convulsions closely resembling those of epilepsy; in others the smallest quantity of calomel will produce alarming syncope. The readiness with which ptialism is induced in some individuals by the last-mentioned medicine is also a circumstance which sometimes requires consideration.

3. Although a costive state of body is to be strictly guarded against in childhood, yet it is certain that children bear the action of cathartics worse than adults. On account of the depressing effects of saline purgatives, those of a warm character are the best adapted for aged persons.

4. Cathartics ought not to be too frequently taken, as, by the excitement they produce in the mouths of the hepatic and pancreatic ducts, they cause a hasty, irregular, and imperfect secretion of bile and pancreatic juice, which is highly injurious to the digestive function.

5. As a general rule, cathartics are inadmissible in inflammatory states of the alimentary canal which have gone on to ulceration.

6. The nature of a cathartic determines the period of the day in which it should be administered: if it require a long time to operate, it should be given at bed-time; if it act quickly, in the morning: thus saline purgatives, senna, castor-oil, croton-oil, and elaterium, are best administered in the morning; the gum resins, sulphur, and calomel, in the evening. But the action of a cathartic may at any time be quickened by copious dilution with warm aqueous fluids.

7. During the operation of a purgative, it is necessary to distinguish carefully those appearances of the alvine discharges which are the results of disease from those produced by the cathartic. Calomel always causes the evacuations to appear unnatural; and, if it be requisite to ascertain their real aspect, the use of the medicine must be suspended for a few days. During the operation of colchicum the stools are of a bilious appearance; during that of full doses of saline purgatives, daily repeated, they assume a peculiar colour; and the effect of elaterium is to produce stools resembling water in which meat has been partially boiled.

With respect to the peculiar action of cathartics, it is necessary to make a few remarks.

Among the laxatives, honey is apt to gripe and to prove flatulent, and the older it is the more likely are these effects to follow its administration. Cassia-pulp, which is now seldom employed alone

in this country, produces nausea, flatulence, and griping. Tamarind-pulp, although an agreeable laxative, yet operates too gently to render it useful when given alone; it is, therefore, usually combined with neutral salts. The same observation applies to manna. Olive-oil operates as a mild laxative in doses of f.ʒii. Sulphur, whether in the simple sublimed state, (the sulphur lotum of the pharmacopœia,) or in that of a hydrate, (sulphur præcipitatum,) is a mild but certain laxative, well adapted to cases of habitual dyspnœa, in which it is of much importance to keep the bowels open: and in hemorrhoids it is preferable to purgatives, not only on account of the mildness of its operation, but because it produces soft, easily moulded stools, which pass from the rectum without irritating the highly sensitive piles. It may be given daily, in doses of from ʒss. to ʒiiss., combined with gr. x. or gr. xv. of magnesia, until its odour is manifested on the skin, when its employment should be intermitted for a few days. Magnesia and its carbonate operate with some degree of energy when they meet with much acid in the stomach. The pure magnesia is usually preferred to the carbonate, on account of the inconvenience produced by the extrication of the carbonic acid of the latter in the stomach. Both of them, when they do not act freely as laxatives, are apt to accumulate, and form concretions in the stomach, if taken daily for some length of time; hence, in such cases, it is proper occasionally to clear out the bowels by means of a brisk cathartic. Magnesia, besides exercising its laxative influence, allays the irritability of the stomach; it is consequently useful in the dentition of infants and children, at which periods of life there is both much irritability, and a prevailing acescency of the stomach. The dose of the magnesia is from gr. xv. to ʒii. for an adult; that of the carbonate from ʒi. to ʒii.: when it is taken alone, the best vehicle is milk.

Among the purgatives no animal substances are found; and the vegetable products, although they may be in some degree digestible substances, are not dietetical. They may be noticed according to their effects. Castor-oil, which seems to be intermediate between fixed and volatile oil, owes its properties to an acrid principle which is obtained, mingled with bland oil, by the expression of the seeds of the ricinus communis, and is more or less active according to the degree of temperature employed in the process; that now generally employed is expressed in India without heat. From its quick and mild operation it is peculiarly adapted for children, puerperal women, and all cases in which it is necessary to procure the evacuations with little constitutional disturbance. As its effects are not influenced by combining it with opium, it is generally preferred to other purgatives in colica pictonum and calculous affections. None of the purgatives can be so much relied upon for overcoming habitual costiveness as castor-oil, given daily for some weeks, gradually reducing the dose until less than half a teaspoonful be taken; after which the bowels generally continue to act without farther artificial assistance; even its occasional administration leaves the bowels in a relaxed state. The tendency of castor-oil to nausea is a disadvantage, but it is counteracted by

the addition of an aromatic. The dose for an adult, to produce a full operation, is from f.ʒiv. to f.ʒiiss.

The terebinthinate purgatives, for example the balsams, as they are incorrectly termed, of copaiba and of Gilead, common turpentine, Chian turpentine, and Canada balsam, are stimulant in proportion to the extent of the dose. In doses of f.ʒi., rubbed into an emulsion with mucilage of gum, balsam of copaiba affords much relief in hemorrhoids; and owing to the determination which it induces to the kidneys, acts in some respects as a counter-irritant. It may be administered in the form of pills, by mixing it with one-sixteenth of its weight of calcined magnesia, and exposing this mixture to the air until it acquires a consistence fit for forming it into pills. The other turpentines are most commonly exhibited in the form of enema, in torpid conditions of the bowels, and in the sinking stage of some febrile diseases, particularly in erysipelas of a malignant kind. Under such circumstances the dose is from f.ʒi. to f.ʒiv., rubbed up with mucilage and manna. In some habits the turpentines are apt to cause an eruption on the skin, closely resembling eczema; in which case their use should be discontinued.

The resinous purgatives, jalap, aloës, and rhubarb, operate variously according to circumstances of extent of dose, combination, and the state of the patient. In a moderate dose, for instance, from gr. xii. to ʒss. of the powder, jalap operates effectually without griping; in larger doses it gripes, and produces copious watery stools; and when given in an over-dose it excites hazardous inflammation of the mucous membranes. It operates chiefly through the medium of the nervous system; for when it is injected into the veins it does not act on the bowels, although when it is combined with lard and rubbed on the skin it causes brisk purging. The fineness or coarseness of the powder, also, modifies the operation of jalap; and it is probable that its augmented activity, when united with bitartrate of potassa and other neutral salts, is in part owing to the aid which they afford to its comminution. In conjunction with calomel, the activity of jalap is increased, owing to the calomel aiding its stimulant influence on the hepatic duct in the duodenum. The watery extract operates mildly, and is on that account well adapted to children; the resinous extract gripes violently and displays all the characters of a drastic cathartic without purging much. With respect to the state of the patient—in nervous and irritable habits jalap operates too violently; whereas in languid and torpid individuals its purgative influence requires to be aided by other cathartics. Jalap is chiefly useful as a general purgative in febrile affections connected with an increased action of the liver, and a more than natural discharge of vitiated bile into the duodenum.

Aloës is a warm stimulating purgative, exerting little action on the duodenum and small intestines, but affecting powerfully the colon and rectum, a peculiarity which has been erroneously attributed to the little solubility of the aloës in the fluids of the intestinal canal permitting it to pass nearly through its whole length before it is sufficiently dissolved to exert its purgative influence.

In small doses, for instance from g. v. to gr. x. , aloës does not induce an attack of hemorrhoids, which, however, is not an unfrequent result of large doses. It has been found useful in the dyspeptic affections of cold and languid habits, particularly of the sedentary and hypochondriacal. In combination with calomel or blue pill, or with alkalies, it has been found more beneficial in jaundice than when given alone, notwithstanding the opinion of Cullen, (*Materia Medica.*) that nothing is obtained by combining aloës with other substances. From the influence of aloës on the rectum it is generally thought to be an improper medicine in pregnancy; but Dr. Denman has remarked that the lower class of people use aloës on account of the cheapness of the medicine, and because it can be conveniently administered in the form of pills without any bad effects in such cases. (Introduction to the Practice of Midwifery.) The addition of camphor to aloës renders its operation both milder and more certain.

Rhubarb is one of the most useful of the resinous purgatives, acting chiefly through the medium of the nervous system, a fact demonstrated by the effects of its application in the form of cataplasm to the surface; for were it absorbed, the colouring matter would be detected in the urine, which is not the case; yet the application of such a cataplasm purges briskly.

Senna owes its purgative property to a peculiar principle, discovered by MM. Lassaigue and Feneulle, called *cathartina*. This principle is dissolved by water at a temperature of 96° , which takes up little of the extractive and other matters on which the gripping quality of senna is supposed to depend; an infusion, therefore, made with distilled water at this temperature, purges without griping. When the infusion is kept ready-made and exposed to the air, the cathartina is decomposed and the extractive oxidized. Senna is a useful and very general purgative, there being scarcely any disease in which purgation is indicated, where it may not be administered. The purgative power of the infusion is greatly augmented by the addition of camphor mixture, or of the decoction of guaiacum: it is seldom given alone; but some of the adjuncts frequently prescribed with it, such, for example, as magnesia, rhubarb, and the carbonates of alkalies, destroy its active properties.

Notwithstanding the virulent effects of colchicum when given in an over-dose, it is an efficacious and valuable purgative; operating chiefly on the duodenum, and, by stimulating the excretory ducts of the liver and the pancreas, producing copious bilious stools; diminishing febrile action, and allaying pain. To these effects we may ascribe the beneficial influence of colchicum in gout and rheumatism. It may be demanded, why do not other purgatives equally relieve these diseases? We reply,—present us with one that will act as decidedly on the hepatic and pancreatic ducts, and we will equally rely on its powers. The wine is the best form of the medicine, because the acetic acid in it is sufficient, in conjunction with the alcohol, to take up the whole of the veratria, and is not enough to determine its action chiefly to the kidneys, which is the effect of the vinegar of colchicum.

The inorganic purgatives are principally neutral salts. The most commonly employed of these, sulphate of magnesia, purges freely without griping; but as it frequently causes flatulence, it requires in most instances to be conjoined with aromatics, or some warm bitter infusion, such as that of cascarilla. It operates chiefly on the duodenum; and it is to its presence that many of the mineral purging springs, as those of Kilburn, Cheltenham, Moffat, Seidlitz, and others, owe their active properties.

Soda is the basis of at least three purgative salts, the phosphate, sulphate, and muriate. The phosphate, on account of its similarity to common salt, and the mildness of its operation, is well adapted to children and delicate persons: it acts moderately in doses of from ʒiv. to ʒii. Before the introduction of the sulphate of magnesia, sulphate of soda was the most commonly employed purgative: it is now less used. Its nauseous taste is readily and effectually covered by citric or tartaric acids; and when a purgative is required to lessen rapidly the mass of the circulating fluids, none answers more effectually than a combination of three parts of sulphate of soda, and one part of bitartrate of potassa. Sea-water owes its purgative influence to a combination of muriates, of which that of soda is predominant. All the salts of soda operate upon the whole length of the intestinal canal, stimulating the orifices of the exhalent vessels, and, consequently, causing serous discharges in the form of thin watery stools: they are, therefore, well calculated for cases of febrile excitement, and those in which there is a tendency to plethora. Their influence on the exhalent vessels also promotes absorption, for the action of the exhalents cannot be augmented without a corresponding increased action of the absorbents. In prescribing the salts of magnesia and of soda, it is important to understand the variation of their action produced by various combinations. Thus, the addition of sulphate of magnesia quickens greatly the action of infusion of senna; while, for those who can scarcely bear the operation of purgatives, the sulphate should be combined with bitter or aromatic infusion, or even with sulphate of iron, as circumstances may direct; and this rule holds good, also, respecting the others.

The salts of potassa are more diversified in their action than those of magnesia and soda. The sulphate and bisulphates of potassa are useful adjuncts to rhubarb and aromatic bitters in dyspepsia, accompanied, as it usually is, with torpid bowels. The dose of the sulphate is from gr. x. to ʒii. , that of the bisulphate ʒss to ʒii. It must be recollected that the sulphate is decomposed by tartaric acid and converted into the bitartrate; hence it cannot properly be prescribed with infusions of tamarinds, nor with the infusion of senna with tamarinds of the Edinburgh Pharmacopœia. As a purgative, the neutral sulphate is supposed to extend its action beyond the intestinal canal; and, therefore, it is generally selected in cases of obstructions of the mesenteric glands. In combination with aloës, it has been found to answer well in cases of jaundice, in dyspeptic affections, and in habitual costiveness. The tartrate and bitartrate of potassa differ consider-

ably in their mode of operation. The former is a mild and efficient purgative, operating without griping; and it has, also, the property of lessening the griping quality of senna and scammony. It acts on the whole of the intestinal tube; and, as it operates rapidly, it is well suited to cases requiring the aid of a quick and effectual purgative. The average dose is from \mathfrak{z} i. to \mathfrak{z} iv. It is perhaps the best purgative that can be prescribed, to assist the effect of a large dose of calomel given at bed-time; thus, from \mathfrak{z} i. to \mathfrak{z} ii. of tartrate of potassa, in \mathfrak{f} ℥iss of infusion of senna, administered in the morning, after a dose of calomel taken on the preceding night, operates rapidly, and sweeps away the bile which the calomel has brought from the liver. The bitartrate operates more on the exhalents of the smaller intestines than the tartrate, producing watery stools, flatulence, and, in some persons, griping. From its property of acting on the exhalents, it is advantageously prescribed in cases of ascites and other dropsical accumulations; hence its continued use is productive of emaciation, and to this property, also, may be ascribed its utility in cases of plethora and obesity. As it is not very soluble, it may be given either in the form of powder or of electuary, combined with jalap, scammony, or sulphur. The acetate of potassa in small doses operates as a diuretic; but in doses of from \mathfrak{z} ii. to \mathfrak{z} iv. it purges freely, if the surface of the body be kept warm. It is, nevertheless, much inferior to any of the other saline purgatives.

With respect to the mercurial oxides and salts, the mercurial or blue pill and calomel may be regarded rather as preparatives for active purgatives than as purgatives themselves; they operate chiefly by stimulating the gall-ducts, when given in full doses; and as alteratives, improving the biliary secretion and increasing it, when the liver is in a torpid state. The hydrargyrum cum creta operates also mildly; but it is seldom employed except in cases requiring the aid of a mild alterative, or as a purgative for children in whom there is much acescency of stomach, and in whom there are, at the same time, glandular obstructions. When calomel is intended to operate as a purgative, it should be given in much larger doses than are usually prescribed: in such doses, for example, as from gr. x. to gr. xv. it lessens the irritability of the stomach when this is excessive, combines with, renders more fluid, and detaches the viscid mucous secretions adhering to the small intestines, and augments the vascular and capillary circulation in the mucous coat of the colon and rectum.

During its administration it has been said that the aspect of the alvine discharges is rarely natural; the medicine should, therefore, be frequently intermitted for a few days, in order to ascertain the real state of the abdominal secretions.

The last division of cathartics, the *drastic purgatives*, consist, almost entirely, of organic products, involving some very active principle. Their operation is commonly attended with griping; and in some instances the effects are so violent, that, unless they be closely watched, much mischief may result from their employment. They exert a powerful influence on the exhalents and

absorbents, and merit more justly the name of hydragogues than any other set of purgatives. Amongst them, colocynth is supposed to owe its cathartic power to a peculiar principle which has been named *colocynthine*; but this is uncertain. Colocynth operates chiefly on the larger intestines; and, as with aloes, this happens even when it is applied to an ulcer on the surface of the body. When given in substance, the violence of its operation should be moderated by triturating it with gum or farinaceous matters. It is most usually administered in the form of extract, in doses of from gr. vi. to gr. xv.; but the aqueous decoction is milder in its effects than the extract. The resinous drastic purgatives most commonly employed are scammony and camboge. Scammony is a powerful griping cathartic. It is generally combined with calomel, and is one of those substances the acrimony of which is greatly modified by combining with it sulphate of potassa. From its activity, it is well adapted for removing the scybala that frequently remain, for a long time, in the cells of the colon in maniacal cases; and in combination with calomel and sulphate of potassa, it aids greatly in removing ascariides from the rectum. The dose is from gr. v. to gr. xv.; it is advisable generally to conjoin with it a drop or two of some volatile oil; and when the bowels are irritable, if it be ever proper in such a case to prescribe a drastic purgative, the watery emulsion of scammony, allowed to settle and deposit the resin, will answer the purpose, as it operates with sufficient activity without griping. Camboge is more drastic than scammony, and frequently excites vomiting when given alone, even in moderate doses. It is usual to combine it with calomel, soap, rhubarb, or sulphate of potassa. The average dose is from gr. iv. to gr. viii. The drastic character of the root of black hellebore as a cathartic was well known to the ancients, and one of their chief resources in the management of mania: but it may be doubted whether it possesses any superior advantages over other active cathartics in that disease, or even as a hydragogue. One of the most active of the drastic cathartics is, undoubtedly, the expressed oil of the seeds of the croton tiglium. Like castor oil, it is the solution of an acrid principle in a bland oil, in the proportion of forty-five parts of the former to fifty-five of the latter. The acrimony of this principle is so great, that the oil operates briskly by merely applying a single drop of it to the tongue; nevertheless it seldom excites nausea or vomiting, and rarely griping. In maniacal cases, in visceral obstructions, in dropsical accumulations, in delirium tremens, in apoplexy, and in all cases requiring ample and prompt evacuations, the oil of tiglium may be prescribed with advantage. The best mode of using it is to rub it up with sugar, as an oleo-saccharum, in the almond emulsion; or to dissolve it in alcohol, as recommended by Dr. Nimmo.

The last of this class of cathartics which it is requisite to notice is elaterium, a vegetable product, which owes its activity to *elatin*, a peculiar principle discovered by Dr. Paris,* and the most

* Dr. Clutterbuck first discovered the fecula now called elatin.—See his paper in the Medical Repository, quoted by Dr. Paris.—EDITORS.

powerful purgative agent yet known, as it constitutes one-twelfth only of the weight of elaterium, of which one-eighth of a grain only is required to produce brisk purging. Elaterium, when properly managed, is an excellent drastic hydragogue. Sydenham employed it successfully in dropsy; but it fell into disrepute from the indiscreet use made of it, until Dr. Ferriar, of Manchester, restored it to practice for the cure of hydrothorax. In administering it, the strength should be supported with moderate stimuli, particularly ammonia, capsicum, or camphor: under every circumstance the utmost caution is required in its administration, and no practitioner ought to prescribe it unless he is able personally to watch its effects. The average dose to an adult is one-sixth of a grain; and this should be repeated every sixth hour, until copious stools are procured.

Among the inorganic drastic purgatives, the only substance requiring to be noticed is the precipitated sulphuret of antimony, which, however, is employed merely as a component of the compound calomel pill. It is a violent but very uncertain cathartic.

CEPHALÆA, CEPHALALGIA. (See HEADACH.)

CHEST, CONTRACTION OF. (See PLEURITIS.)

CHEST, EXPLORATION OF.—The methods employed by physicians for *exploring* or physi-

cally examining the external parts of the chest, with the view of discovering or discriminating the diseases of this cavity, are the following:—*inspection, manual examination, mensuration, auscultation, percussion, succussion*. The three latter methods have been fully discussed in the article AUSCULTATION; it therefore only remains to notice the three former in this place.

The relationship of the external to the internal parts is much more easily ascertained in the case of the thorax than the abdomen, owing to the less complexity and greater fixedness of the contents of the former cavity. The thoracic viscera are few in number, and their boundaries are, in general, accurately defined. In the state of health they cannot vary their position; and their displacement is produced by only a small number of well-defined causes, the chief of which are preternatural growths, or the accumulation of fluids within the cavity of the chest, encroachment of the abdominal viscera from below, or alteration of the solid walls of the chest, chiefly from distortion of the spine.

In the article EXPLORATION OF THE ABDOMEN, the importance of knowing the topographical relations of the external and internal parts of the great cavities was pointed out, and also the means of rendering this knowledge more precise by the aid of artificial subdivisions of the anterior of the body. The principles adopted in dividing the whole trunk of the body are there explained; and the figures in pages 26 and 27 exhibit a repre-

Fig. 4.

- i. The left subclavian vein.

sensation of the thoracic regions along with those of the abdomen. We must, therefore, refer the reader to those figures, while we now proceed verbally to define the regions which belong exclusively to the chest.

All the regions, as is explained in the article referred to, are bounded by direct lines drawn from fixed and conspicuous points on the surface of the body, and which lines are either vertical or horizontal. The vertical lines having relation to the chest are eight in number, and run as follows:—1. along the middle of the sternum from its upper to its lower extremity; 2. from the acromia extremity of the clavicle to the external tubercle of the pubes (right and left); 3. from the posterior boundary of the axilla, or inferior edge of the latissimus dorsi, to that point of the crest of the ilium on which it falls vertically (right and left); 4. along the spinous processes of the cervical and dorsal vertebræ; 5. along the posterior or spinal border of the scapula, from the clavicular transverse line to the mammary transverse line. The horizontal or transverse lines are four in number, and are as follows:—1. around the lower part of the neck, sloping downwards to the upper end of the sternum anteriorly, and to the last cervical vertebra posteriorly; 2. around the upper part of the chest in the line of the clavicles; 3. around the middle of the chest, crossing the nipples anteriorly, and touching the inferior borders of the scapula behind; 4. around the lower part of the chest on the scyphoid cartilage.

- c. The aorta.
- e. The ascending colon.
- f. The small intestines.
- g. The descending colon.
- h. The caput coli.
- i. The spleen.
- k. The kidney. — l. The trachea.

By these imaginary lines the trunk is divided into three horizontal and eight vertical bands, and their intersections form, in all, sixteen compartments or regions, of which two are superior, four anterior, four lateral (two on each side), and six posterior. They are named as follows:—*superior regions*—humeral (right and left); *anterior regions*—subclavian (right and left), mammary (right and left); *lateral regions*—axillary (right and left), subaxillary or lateral (right and left); *posterior regions*—scapular (right and left), intrascapular (right and left), subscapular or superior dorsal (right and left).

In the figures introduced into the present article, to which we particularly call the attention of the student, an attempt has been made to impress still more strongly on the mind topographical relations of these external artificial subdivisions with the viscera within. In consequence of their introduction we shall greatly abridge the remarks on these relations which would otherwise have been necessary. In studying them it is necessary to keep constantly in view the figures in p. 27, and the explanation of the regions which accompanies them.* In fig. 4 and 5 the outlines of the viscera are delineated on the surface of the body; and in fig. 6 and 7, the regional lines of the surface are drawn on the viscera exposed in situ.

The natural boundaries of the two great organs

* As belonging all to the same series, we have continued the numeration of the figures begun in the former article.

contained in the chest scarcely require to be pointed out. Separated from each other by the mediastinum, which at its lower part includes the heart, the two lungs are in contact with the solid walls of the chest in every other point, and rest on the diaphragm below. The heart rests on the diaphragm on the left side of the sternum, and extends upwards beneath this bone midway to the upper part of the chest. Both lungs descend much lower on the sides and back than on the fore part of the chest, on account of the position of the diaphragm, which stretches upwards from behind forwards, so as to form an acute angle with the spine. The lungs are consequently prolonged downwards, in very thin lappets, behind, and reach much lower than persons not very well versed in anatomy are apt to believe. It is not unusual to find painful affections of the dorsal pleura referred to the kidneys. An opposite mistake is occasionally committed on the fore part of the body, affections of the liver and stomach being referred to the lungs or heart, because the site of the pain is considerably above the margin of the ribs. We do not allude to those sympathetic pains which in dyspeptic cases radiate far within the true boundaries of the chest, but to pains fixed in the organs themselves.

The general shape of the lungs corresponds with that of the cavity in which they are placed. The right lung is larger than the left, but does not descend so low anteriorly, owing to the position of the liver on that side. The upper lobes of the lungs rise as high as the first rib and clavicle, and in the space between the last-mentioned bone and the anterior edge of the trapezius muscle the pulmonary structure is undefended by any bony or thick muscular covering, and consequently lies very near the surface.

I. Inspection.—By inspection of the chest we mean in this place the ocular examination of the chest freed from covering; and it is by this alone that the actual configuration of this cavity, whether natural or morbid, can be ascertained with certainty.

The relative size of the cavity of the chest varies considerably in different individuals even of the same age, sex and stature. This is a circumstance of much practical importance, more especially in relation to prognosis. A very small chest not merely predisposes to diseases of the lungs, but renders them, when they occur, more dangerous. It even tends to enfeeble the constitution generally, by diminishing the energy of the respiratory and circulatory functions, and may thereby become a source of aggravation of many diseases which have not their seat within the chest.

A well-proportioned chest should be large in all directions, more particularly in its antero-posterior and lateral directions. Sometimes we see great disproportion in this respect overlooked from imperfect examination. Generally speaking, the cavity of the chest is proportionally smaller in women than in men; and this natural conformation is commonly increased by the use of stays; often it is aggravated in an extreme and most injurious degree. The effect of stays tends to diminish the capacity of the chest chiefly in two ways; first, in its transverse diameter, by compressing it

in every point towards the axis of the trunk on its lower half; and, secondly, in its vertical diameter, by forcing the diaphragm upwards before the compressed abdominal viscera. In these cases, although the longitudinal extent of the proper cavity of the chest is greatly diminished, the external bony compages of the thorax is often lengthened, the lower ribs being forced downwards towards the pelvis. When this happens, the usual topographical relations of the external and internal parts are often greatly altered; and mistakes in diagnosis are only to be prevented in such cases by careful examination of the body freed from its coverings, and by the habit of inspecting bodies, so distorted, after death. Another very frequent cause of alteration of the natural configuration of the chest in women is distortion of the spine. Every experienced practitioner is aware of the great frequency of this affection among young women educated at boarding-schools, or subjected to sedentary employments. The effects of this change in the natural direction of the spine in altering the shape of the chest are well described by many of our recent surgical writers; but they are still too imperfectly known by practitioners in general. The real nature of such cases can only be ascertained by inspection, more particularly of the back.

It is, no doubt, by inspection that we can judge most accurately of the condition of the respiratory function generally; but it is not necessary to have recourse to this expedient in order to ascertain the mere frequency or quickness of the inspirations and expirations. This we can do by merely watching the respiratory sounds; and the signs and indications thence derived for the purposes of diagnosis, prognosis, and practice, belong more to the general subject of diagnosis than to the physical exploration of the chest. But it is impossible to ascertain the degree of mobility of the whole thorax relatively with that of the abdominal parietes, or of one side of the thorax relatively with the other, without inspection; and such knowledge is often of much importance. In certain inflammatory diseases of the chest, as pleurisy, more particularly when both sides are affected, the walls of the thorax often remain nearly unmoved, respiration being carried on almost entirely by the diaphragm and abdominal muscles. In this case the abdominal movements are quick and extensive, while those of the chest are the reverse; such a condition of the respiration has been termed *abdominal*. When inflammation exists in the abdominal cavity, the thoracic parietes are preternaturally mobile, while those of the abdomen are inactive: in this state the respiration is said to be *thoracic*. It is only by inspection also that we can ascertain certain conditions of the mere surface, which are, however, often of importance to diagnosis. Of this kind are œdema of a portion of the chest, the relative width of the intercostal spaces, their degree of prominence, &c.

But it is by enabling us to ascertain partial contractions or dilatations of the chest, not dependent on spinal distortion, that inspection is most useful. In some cases, these partial alterations of shape extend to both sides, but they are much more commonly confined to one. In phthisis which has been very slow in its progress,

and when tubercles exist in both lungs, as usually happens, we find both sides of the chest contracted, particularly in the subclavian regions. In asthma, on the contrary, both sides are usually considerably dilated, more particularly about the middle of the chest, and rendered much more convex both before and behind. In old asthmatics this configuration of the chest is sufficiently conspicuous, even when the body is covered. Its presence is always a proof of the permanent dilatation of the pulmonary cells, and, generally, of an incurable disease.

But the alteration of configuration produced by disease in the chest is much more generally confined to one side; and the diseases in which this change occurs are chiefly pleurisy and pneumothorax. In acute pleurisy, when the effusion is at all considerable, the affected side is perceptibly dilated; and Laennec assures us that he has often observed this effect on the second day of the disease. The eye readily detects the dilatation when it does not exceed half an inch in the whole semi-circumference of the chest. In chronic pleurisy, when the accumulation of fluid is very great, the affected side is often very considerably dilated: the disease, however, frequently exists without any dilatation. In pneumothorax the affected side is often much dilated; and here, as in simple empyema, we sometimes see the intercostal spaces elevated to the level of the ribs, or even above this. Some of the same diseases which produce dilatation of the chest, occasion at other times a contraction of it, either generally or partially. Contraction of one whole side of the chest is a frequent result of pleurisy, the side being diminished in all its dimensions, the ribs being pressed together, and the intercostal spaces consequently nearly abolished. Partial contraction or dilatation of the chest, permanent or temporary, is still more common than a similar condition of the whole side. When not dependent on distortion of the spine, it may always be regarded as a sign of disease within the chest, either now or formerly existing. By far the most common cause of partial contraction of the chest is circumscribed pleurisy. In the history of the individual diseases—phthisis, hydrothorax, pneumonia, pleurisy, empyema, pneumothorax, &c.—the significance and value of the foregoing signs will be more particularly pointed out.

II. Manual Examination.—There are only a few circumstances relating to the physical condition of the chest which cannot be ascertained without the direct application of the hand. Of this kind is soreness or tenderness of the surface. Much tenderness of the surface of the chest on simple touch usually indicates an affection of the external parts, either of the skin or muscles, as in the rheumatic affection termed *pleurodynia*. It is, however, sometimes produced by internal diseases, as when a collection of pus in the pleura is making its way outwards by perforation of an intercostal space. When, however, considerable pressure is made in the intercostal spaces, pain is very frequently experienced in pleuritic affections, more particularly of a chronic kind. In chronic pneumonia, also, and in phthisis, when the lungs, as frequently happens, are adherent to the costal pleura, the same effect is frequently observed: and

in cases of this kind we have often found much uneasiness produced by even the gentlest percussion, more particularly if made without the pleximeter.

A preternatural degree of temperature of any part of the surface of the body has been always considered indicative of disease of the particular part, or of those which lie beneath it.* The same rule is, no doubt, equally applicable to the diseases of the chest; but although the fact may be so, it is interesting more as a pathological phenomenon than as a means of diagnosis, as it scarcely ever exists where we are not provided with more certain indications. In acute pleurisy and pneumonia, and yet more in the complication of these, pleuro-pneumonia, the external surface is often much increased in temperature; and this fact was taken advantage of by Avicenna as a means of detecting the part affected. For this purpose he proposed to apply wetted cloths upon both sides of the chest, and concluded that the side on which the cloth dried soonest, on account of the greatest heat, was that in which the inflammation existed.

Manual examination discovers the presence and degree of muscular robustness, obesity, or emaciation, also oedema, emphysema, &c. with much greater certainty and accuracy than mere inspection: it also enables us to judge of the natural degree of thickness of the thoracic parietes, a circumstance sometimes of considerable importance in appreciating the value of other signs derived from different methods of physical exploration.

[If the hand be applied to the chest whilst a healthy person is speaking, a vibratile tremor, called *vocal vibration* or *vocal fremitus*, is felt; which, at times, is scarcely or not at all perceptible, but at others is very marked, especially in those whose voice is grave. In persons with weak or shrill voices, it is absent altogether, and hence is not felt in children, and is very often absent in women. It is more marked, according to Dr. Stokes, (*On Diseases of the Chest*, p. 497: Lond. 1837.) on the right than on the left side; in front than behind; behind than laterally; is scarcely perceptible in the infra-clavicular, and still less so in the interscapular sub-regions. This fremitus is heard not only when the person speaks, but often when he coughs; rhonchi and friction sounds can also be appreciated in the same manner. (Walsh, *The Physical Diagnosis of Diseases of the Chest*, p. 16, Amer. edit.: Philad. 1843.) The writer has often been struck with the difference in the vocal fremitus of the two sides of the chest, where one lung has been affected with tubercular or other consolidation, and the other not. (See ASCULTATION OF THE VOICE.)]

III. Mensuration.—This process is confined chiefly to ascertaining the comparative size of the two sides of the chest, which relation it ascertains with much greater preciseness than either of the two former methods. It consists simply in measuring the superficial extent of the chest by means of a piece of tape stretched over it from certain fixed points. As the contraction or dilatation may be in both the transverse and

* Et ubi in corpore caliditas aut frigiditas, isthic morbus est. *Hippoc. Aph.* 39, sect. 4.

vertical directions, it is necessary, if we wish to be extremely precise to make two admeasurements, one from the spine to the sternum, the other from the top of the shoulder to the lowest rib. In general, however, the transverse admeasurement is all that is requisite. In measuring the two sides, we must be careful to apply our tapes in a precisely similar manner to each side. In ascertaining the transverse extent, we first make our measurements after a complete expiration, and then after a full inspiration. It will thus frequently be seen that, although little or no difference is found between the two sides in the former case, it is very considerable in the latter,—the chest on the diseased side not at all expanding during inspiration, and probably expanding even more than in the state of health on the sound side. This effect is rendered particularly striking by fixing the *middle* of the piece of tape on the spine, and allowing the two ends to rest somewhat loosely on the sternum, so as to be moved by the motions of the chest: on the patient taking a deep breath, the end on the sound side is seen gradually to recede from the sternum, while that on the diseased side either remains stationary, or recedes to a very small extent. In cases of contracted chest succeeding acute pleurisy, in which a cure has been effected, it is interesting to watch, month by month, the gradual expansion of the contracted side. In such instances we have been accustomed to supply the patient with a marked piece of tape, and have been gratified to prove by this means, at certain intervals, the progressive return of the chest to its natural size.

[The average result of the most accurate measurements of the chests of 20 persons not labouring under disease of the lungs, gave, according to Dr. Stokes, (*op. cit.* p. 498,) for the right side 17.86 inches; and for the left 17.23, or more than half an inch in favour of the right lung. Of these, the most capacious chest measured 22 inches for the right, and 21.50 for the left. In one case only, the left side was larger than the right, and in three the sides were symmetrical. In the case in which the left side was more developed, the man was left-handed, and the biceps measured half an inch in circumference more than the right. Of 20 measurements made by the writer—ten of males and ten of females, none of them labouring under disease of the lungs, the average in the case of the males gave 17.47 inches for the right side.—16.92 inches for the left;—in that of the females, 15.2 inches for the right side, and 15.1 for the left. (*Præctice of Medicine*, 2d edit., i. 390: Philad. 1844.)

The two sides of the chest are affirmed to be of unequal dimensions in about five-sixths of healthy subjects; a mean excess of about half an inch existing on the right side in right-handed individuals; whilst in left-handed persons the left side sometimes measures more, or more frequently the same as the right. (Walshe, *op. cit.*)]

It has been endeavoured to ascertain the capacity of the chest, or rather of the lungs, on another principle, namely, by ascertaining the quantity of air the lungs were capable of containing. This method was proposed by the late Mr. Abernethy. It is obvious that it does not lead to the same results as mensuration of the external sur-

face of the chest; this latter giving the capacity of the containing, the former the capacity of the contained parts. Mr. Abernethy's method consists in making the patient take as deep an inspiration as possible, and then expire through a bent tube communicating with an inverted jar containing water. The quantity of water displaced by the air is a measure of the capacity of the lungs to contain air. A person in good health with sound lungs is able to displace six or eight pints; and if the amount be greatly less than this, as for example, only one-third or one-quarter, it may be inferred that the lungs are either obstructed by disease of their own substance, or compressed from without. "Muscular debility or spasm," says Mr. Abernethy, "may occasionally make the result of this experiment doubtful, yet in general, I believe it will afford useful information." (*Essays*, Part. II. p. 157.) In this judgment we agree with Mr. Abernethy.

A more simple test of the capacity of the lungs, founded on the same principle, has been proposed: (*Edin. Med. Journ.* vol. xxxviii. p. 453.) It consists in measuring the comparative length of time occupied in making a complete expiration after a complete inspiration. With the view of proving that the expiration is continuous, the patient is desired to *count* from one upwards, as far as he can, slowly and audibly; and the number of seconds during which he is able to count, without drawing breath, is noted by a watch: the number of seconds is considered a proportional sign of the quantity of air expired, and consequently of the lungs. Dr. Lyons, who proposes this method, says that the most healthy individual will not continue counting beyond thirty-five seconds; but in this he is certainly mistaken, as any of our long-winded readers may prove by personal experiment. In confirmed phthisis, Dr. L. says, the period of expiration never exceeds eight, and is frequently less than six seconds; while in pleurisy and pneumonia it may range from four to nine. This test is of much easier application than Mr. Abernethy's, but it is much less accurate: it is liable to variation from many causes, but still, like Mr. Abernethy's, it may be occasionally useful.

JOHN FORBES.

CHICKEN-POX.—The terms chicken-pox and swine-pox seem to have been in use in England from a very early period, to express those lighter cases of eruptive disorder, which, bearing a general resemblance to small-pox, yet differ from that disease in the mildness of the accompanying fever and the shorter duration of the eruption. Morton, the contemporary of Sydenham, introduced the term chicken-pox into scientific nomenclature, and it is now so universally adopted that it is proper to inquire what are the pathological characters of the disease thereby designated. Is the chicken-pox allied to small-pox? Does it arise from the same contagion? Does it give security against small-pox? Can it be communicated by inoculation? These questions have been argued for the last hundred years, and the opinions of pathologists are still far from being made up concerning them. It is obvious that before we can undertake to establish the diagnostic characters of chicken-pox, we must have pre-

viously fixed the distinguishing features of small-pox. On this account it is proposed to defer the regular consideration of the former until the latter disease has been described. A brief sketch, however, of the eruptions commonly known in England as the *chicken-pox*, may find a place here.

This term is familiarly applied to all those eruptive complaints, in which, after a brief attack of fever, the skin is covered, generally or partially, with vesicles or imperfect pustules, which run through their stages of maturation and decline in three, four, or, at furthest, five days, the attending constitutional symptoms being very slight, without any threatening of danger. Such disorders are very common. They are met with in infancy and mature age. They often appear to prevail epidemically. Dr. John Thomson, of Edinburgh, believes that the whole of them are modifications of small-pox, and the result of the variolous virus. Other pathologists, again, consider that under the term *chicken-pox* are included different kinds of disease, analogous to each other in their progress and termination, but differing in their causes and in their earlier phenomena. This latter is the opinion, which, after very careful consideration of the subject, will be adopted here. Accordingly, the reader will find under the head of SMALL-POX (*Modified*) a description of that class of cases which are characterised by imperfect pustulation, occurring chiefly in adults, and preceded by two or three days of fever; while under the head of VARICELLA LYMPHATICA he will look for those which have for their chief features a sudden eruption of vesicles, preceded by little or no fever, and occurring almost exclusively in the periods of infancy and childhood.

GEORGE GREGORY.

[CHLOASMA. (See EPHELIS.)]

CHLOROSIS, from $\chiλωρός$, green; the disease known by the designation *green-sickness*. This singular affection is chiefly incidental to female youth; it occurs sometimes, however, in the age of childhood, not unfrequently in married women, and occasionally in the young and delicate of the male sex; and in these several cases it assumes modified forms, which will be carefully described in the sequel.

History and Symptoms.—Chlorosis steals upon the patient very insidiously. It has pretty distinctly three stages; the incipient, the confirmed, and the inveterate. It may be characterized, in general, as uniting a morbid paleness of the complexion, tongue, and general surface, with recurrent pain of the head or of the side, generally the left; palpitation, fluttering, breathlessness, nervousness, and frequently attacks of hysteria, with some tendency to loss of flesh and œdema.

The first stage or period of chlorosis is usually little observed by the patient or friends. There is a slight paleness, or a little fading of a wonted florid complexion, and the patient is only a little more languid and listless than usual, the ordinary amusements or occupations, whether mental or bodily, being accompanied by fatigue, the nights restless, the mornings heavy. With these changes, however, there is invariably a confined state of the bowels, a deranged condition of the stomach,

a tainted breath, a white and pasty tongue, and a morbid appetite; and there is recurrent headach, pain of the left side, palpitation, &c. The catamenia are supposed to flow as usual, but an attentive inquiry discovers, that with the complexion, the uterine discharges also lose their colour.

In the second or confirmed stage, every morbid appearance, every symptom is aggravated; the countenance, the prolabia, the tongue, the gums, the internal parts of the cheeks, the conjunctiva, the general surface, and especially the fingers and the finger-nails, become absolutely exanguious, sometimes with a pearly, sometimes with an icterode hue; the eye-lids are sometimes slightly œdematous, especially in the morning; the tongue, besides being pale and exanguious, is œdematous and impressed with the teeth; sometimes slightly loaded, sometimes morbidly clear, and glossy in various parts; the teeth are apt to decay; the skin becomes gradually rather dry; a singular change takes place eventually in the finger-nails, which become brittle and easily split or break off, so that frequently a pin can scarcely be taken out of the dress. An equally remarkable change is also occasionally observed in the hair, which becomes dry and harsh, frequently splitting, and not remaining "in curl;" the ankles become tumid, and more and more œdematous. With the accession and progress of these symptoms, the catamenia are found to become more and more scanty and pale, and then to disappear; the bowels continue constipated, with or without alternations of diarrhœa; the stomach is oppressed after eating; there are various forms of pica or morbid appetite, as for pickles, magnesia, cinders, &c.

With this state of things there is frequently one predominant symptom, which absorbs the attention of the patient and friends, and sometimes even deludes the medical practitioner. This symptom is sometimes a violent recurrent headach; sometimes pain of the side, especially the left side, just under the mamma; sometimes palpitation of the heart; sometimes cough; in other cases these symptoms vary and interchange, and there is frequently every variety of affection comprised in hysteria. This predominant symptom frequently leads to the idea of *arachnitis*, of *pleuritis*, of *disease of the heart*, or of *incipient phthisis*.

Chlorosis is frequently complicated with hæmatemesis and mœna, and with epistaxis. In the latter affection the blood occasionally scarcely tinges the linen on which it drops.

There is also frequently in this disease the peculiar affection designated by Dr. Willan, the erythema nodosum, and of which an account will be given in its proper place.

The second stage gradually passes into the third, in which some degree of emaciation is added, the œdema assumes a more or less aggravated form of anasarca, and a proportionate degree of danger now attends the complaint.

It frequently happens, from the insidious character of this affection, and from the severity of the predominant symptoms, that the case is mistaken for one of an inflammatory character. The affection of the head, the pain of the side, the palpitation of the heart, have severally led, in

many instances, to an abstraction of blood, equally inappropriate and useless, if not absolutely injurious and dangerous.

The distinction is not always easy. One of the best sources of the diagnosis, in doubtful cases, is the degree of susceptibility to faint from the detraction of blood. This circumstance, added to the general symptoms and to the inefficiency of those remedies which are adapted to the case of inflammation, is an important criterion of pains which are not inflammatory. (See BLOODLETTING.) The quantity of blood which has been unwittingly detracted, and the number of leeches and of blisters which have been uselessly as well as needlessly applied in some of these cases, are quite extraordinary.

[Singular phenomena are afforded by chlorosis on auscultating the blood-vessels. One of these has been termed *bruit de diable*, in consequence of its resemblance to that of the *diable* or humming-top of children. It is heard most frequently along the carotid and subclavian, and, at times, in the crural arteries; but never to the same degree. Commonly, it is heard on one side only. M. Raciborski (*New and Complete Manual of Auscultation and Percussion*, translated by H. Fitzherbert, p. 139: Lond. 1835,) affirms, that during a year and a half that he had punctually attended the clinical wards of M. Bouillaud, he had observed the *bruit de diable* more than thirty times, and had not met with a single chlorotic patient that was without it. It would appear, that this sound is connected with a predominance of the watery portion of the blood, but the precise mechanism of its production is not very intelligible.

From an analysis of 88 cases of anæmia, in which there was a continuous or intermittent sound heard over the carotids, M. Andral (*Hématologie Pathologique*, Paris, 1843,) has endeavoured to establish a ratio between a diminution in the amount of globules and such sound. Of the 88 cases, the *souffle* was continuous in 56; intermittent in 32. Of the 56 cases, in which it represented the *bruit de diable*, in 28, the proportion of globules was not above 80, and descended as low as 21. The results of his observations showed, that in different persons the arterial *souffle* does not always appear with the same degree of depression in the proportion of globules. He thinks, that the following rules exist on this subject. *First*. When the ratio of globules has gone below 80, the *bruit de souffle* exists in the arteries continuously. To this law he has not seen an exception. *Secondly*. When the globules remain above 80, the *bruit* may still exhibit itself; but it is no longer constant. It is still heard when the proportion of globules varies between 80 and 100; and occasionally when it is above 100.]

Causes.—The most usual exciting causes of chlorosis are delicate and sedentary habits: the predisposing causes are those peculiarities of the constitution involved in the lymphatic temperament. From the influence of one or both of these causes, chlorosis frequently prevails amongst young persons of the same family; and when the female part of a family suffers in this manner, a slight degree of the same or of a similar affection is frequently traceable in the males, denoted by

unwonted pallor of the lips, and an œdematous condition of the tongue.

The influence of such habits in such a temperament as has been described, is first seen in a confined state of the bowels; the colon becomes loaded, and the functions of the other digestive organs, with the processes of assimilation and sanguification, become deranged.

In an early stage of chlorosis the catamenia are observed to become pale and scanty, and eventually they cease. This circumstance has led to the opinion that the peculiar condition of the generative organs, about the age of puberty, had much influence in inducing the state of chlorosis. Dr. Cullen contends that the retention of the catamenia in these cases "is to be referred to a certain state or affection of the ovary;" but this he does not "pretend to explain." Dr. Hamilton, in his admirable work on Purgative Medicines, has argued against this notion so satisfactorily as to leave little for subsequent writers to do. It is quite obvious, on carefully tracing the succession of symptoms, that the first link in the chain is constipation, and that the subsequent links are the effects of the continued operation of this cause.

In some manufacturing districts, chlorosis and some affections strictly allied to it, may, from the habits of the people, be justly said to be endemic. In manufacturing towns, in Nottingham, for instance, the youthful and almost the infantine parts of the population are engaged during many hours of the day bending over the tambour or lace-frame. The baneful influence of the want of air and exercise, and of a sedentary occupation, are speedily visible in the pallid and icterode states of the complexion, and in the listless manner of these youthful sufferers. The bowels first become confined and loaded; the appetite repels simple food; the breath becomes tainted; the gums become swollen and pale, and the teeth decayed. This state is gradually followed by the other appearances and affections observed in chlorosis.

Servants, and especially cooks, are particularly liable to chlorosis. But the delicate and inert habits of the rich not less frequently lead to this affection.

In all there is the same torpor of the bowels, the same defective digestion, assimilation and formation of blood.

Pathology.—Amongst the series of morbid changes induced in chlorosis, is an impaired condition of the blood itself. This fact is particularly noticed by M. Andral in his *Anatomie Pathologique*, t. i. p. 87. The quantity of serum is proportionately augmented, that of the crassamentum diminished. This appears to be the true source of the pallor characteristic of this disease, and of the greater or less deficiency in colour and in quantity of the catamenia. This is also most probably the cause of many of the symptoms of chlorosis which resemble, in so many respects, the case of anæmia from actual loss of blood. The same circumstance is also the cause of two events occasionally observed to take place in cases of chlorosis; namely, *delirium* or *mania*, and *suicidal death*.

[In addition to the diminution in the proportion of the clot to the serum in the blood of chlorosis,

it is deficient, as before remarked, in red corpuscles; hence, probably, the diminished temperature of the surface; the pallor and waxy appearance, as well as the want of colour in the catamenia, and the pale stain which the blood, in cases of chlorotic epistaxis, leaves upon linen. In two well-marked specimens of chlorotic blood, observed by Dr. B. Babington, (*Art. Blood, Morbid Conditions of the, in Cyclop. of Anat. and Physiol.*) it contained 871 and 852 parts of water in the 1000, instead of 780, the healthy proportion; and the colouring matter amounted to 48.7 and 52 respectively, instead of 127. The albumen and salts were in the usual proportion. As a general rule it may be inferred from the experiments of Messrs. Andral and Gavarret (*Annales des Sciences Naturelles*, Dec. 1840, & Mars 1841,) the proportion of red corpuscles is diminished, whilst that of the fibrin remains the same; so that the clot, although small, may be firm. Owing to the diminution in the proportion of red globules, whilst the fibrin remains the same, the blood of chlorotic patients is not unfrequently buffy. (See, on all this subject, the writer's *Practice of Medicine*, 2d edit. ii. 632: Philad. 1844.)

In two cases the writer has witnessed complete mania in chlorosis. One of the patients speedily recovered; and the other was conveyed to a distant hospital, and died from the effort.

Four cases of chlorosis in which death took place suddenly have fallen within the writer's knowledge. In one of these a careful post-mortem examination was made. The patient having been confined to bed for a few days with cold, became much better, and was in good spirits; after having sat up for a quarter of an hour, and talked cheerfully, she suddenly became faint, gasped, and expired. On examination, some effusion was found in the ventricles of the brain, in the pericardium, and the left cavity of the pleura, the right cavity being obliterated by adhesion; the lungs were gorged with serum; the heart was large; the liver much enlarged; the hands were of an ivory whiteness; the ancles were slightly œdematous; and there was abundance of adipose substance. The blood was pale and aqueous, and the clots formed in the large vessels were small and light coloured.

The occurrence of sudden death in some affections termed nervous, and deemed innocuous, is a fact which has not been sufficiently noticed. The writer has been informed of several such cases within the last two years. He suspects that the patients have been chlorotic and bloodless, and that the case is like that of sudden death occurring after great loss of blood.

Treatment.—The remedies for chlorosis are principally mild but efficient aperient medicines and chalybeates. It is important, in the first place, to remove any load from the bowels by an ample dose of medicine, such as an ounce of the oleum ricini. Afterwards, pills consisting of two grains of the Barbadoes aloes and the same quantity of the sulphate of iron, taken daily during dinner, are most efficacious, and indeed, in the writer's experience, almost specific.

It is sometimes useful to interpose a draught of the tinctura and infusum rhei with manna; at other times, senna and the Epsom salt are required

to move the bowels sufficiently. In other cases the warm water enema is necessary to ensure the due effect of the aperient medicines.

Other forms of the chalybeates are also occasionally advantageous, and especially the ammoniuret in the form of tincture, and the carbonate.

A mild, light, nutritious diet must be enjoined with these medicines; and a system of moderate exercises, in the free open air, especially riding on horseback, must be enjoined, carefully avoiding fatigue. The general surface, but especially the feet, must be kept warm.

It is often necessary to employ some distinct remedy for the pain of the head or of the side; and a blister is the best. The palpitation also occasionally demands a remedy, and the tinctura hyoscyami relieves this symptom. Leeches, and, *à fortiori*, general bloodletting are highly injurious, perpetuating the constitutional disease.

Chlorosis is frequently produced, and frequently aggravated or protracted by some mental cause. It is important that the physician should at least be aware of this fact; he may then sometimes be enabled to remove an obstacle to the recovery of the patient, which, whilst it existed, might frustrate all his efforts.

The remedies for chlorosis may be enumerated thus: the aloetic chalybeate; mild nutritious diet; exercise and air; horse-exercise and the sea-breezes are also highly useful.

Many other remedies have been proposed for chlorosis; but, in the writer's opinion, they are both inefficient and unnecessary. Those which have been enumerated have seldom failed to remove the disease; whilst the other forms of aperients and chalybeates have appeared far less efficacious. The well-known Griffith's mixture, the mistura ferri composita, and the precipitated carbonate of iron, are of this character.

[At the present day, the subcarbonate of iron is employed perhaps more than any other. The protocarbonate is also used in the form of the Pilulæ Ferri Carbonatis of the Pharmacopœia of the United States, of 1842. They are the pills of Vallet, so called after their proposer; but they have not appeared to the writer to possess any advantage over the subcarbonate. The citrate and the iodide of iron have likewise been used of late with benefit in this affection, (*New Remedies*, 4th edit. p. 274 and p. 290.) If the blood be examined after iron has been given for some time, the proportion of the red corpuscles will be found to have augmented.]

A disease similar to chlorosis, which yields to similar remedies, occurs in infants and children, and might for the sake of distinction be termed *leucosis*, from λευκός, *white*. The lips and cheeks are of a waxy pallor; the tongue, the hands, and the general surface are perfectly exanguinous; and there is extreme feebleness. A few grains of rhubarb with one-fourth of a grain of the sulphate of iron, given twice a day, with a light nutrient diet, and the fresh air, and attention to warmth, speedily restore the little patient to its wonted strength and colour. This affection has been little noticed. If neglected, it sometimes takes the patient off with symptoms resembling those of hy-drencephalus.

A disease similar to chlorosis also occurs in

married females. This affection sometimes, but not always, arises from actual loss of blood; the late Dr. Gooch has designated such a case *acute chlorosis*. More frequently an exanguious condition of the system arises from a defective assimilation and formation of blood. The aloeic chalybeate is the remedy of greatest efficacy in restoring the hæmatisis.

The occurrence of chlorosis in the delicate of the male sex has been noticed by Dr. Hamilton, Sir Gilbert Blane, and others, and will become familiar to all who study this affection with attention. It has been already stated that in families in which chlorosis prevails amongst the females, a similar affection seems to attack the males. In some such instances the writer has seen chlorosis in its most marked character in the male sex. It is removed by the aloeic chalybeate.

MARSHALL HALL.

CHOLERA.—This word is generally supposed to be derived from $\chiολη$, *bilis*, and the authority of Celsus is ordinarily quoted in support of this etymology. There is, however, an obscurity in the passage usually referred to in the works of this writer, which renders it doubtful whether he means that bile or the forcible manner in which it is ejected has given origin to the name of the disease; for the Greek word $\chiόλερα$ signifies a water-spout as well as the disorder of which we are treating, and it has been suggested that the adjunct *morbus*, so frequently annexed to it, when employed in the latter sense, was thereby rendered necessary for the purpose of due discrimination. However this may be, it is manifest from passages of different writers, especially from one of Celsus himself, that the words $\chiολη$ and *bilis* had a much more extended sense than our word bile, being by no means restricted to the secretion of the liver, but applied to any liquid discharge from the intestines. By Trallian the word is derived from $\chiόλαος$, *intestina*.

The disease being one of frequent occurrence at certain seasons in various climates, and its symptoms being of a very manifest nature, it early attracted the attention of medical writers. It is mentioned at some length by Hippocrates (*Epidem. lib. v.*), who divides it into the moist and dry species, an arrangement which has been adopted by some much more recent authors. Celsus has a chapter upon it (*cap. xi. lib. iv.*) in which its symptoms are detailed with his accustomed accuracy, brevity, and elegance; and notice is taken of the occasional occurrence of a watery and a white discharge, circumstances which recent events have invested with considerable importance. He regards it as a highly dangerous disease, and speaks of the deaths produced by it as of sudden occurrence. Aretæus treats of the disease, and is rather minute in his description of the discharges. The matter vomited is at first, he informs us, like water, and the alvine dejections are liquid and stercoraceous; whilst, if long indigestion has been the exciting cause of the disease, the discharges are at first *piluitous*, then bilious. Of more modern writers, our own Sydenham treats of the disease with that accuracy of observation and practical good sense which are his chief characteristics as a writer. He regards cholera as having in this

country an epidemic prevalence only during the months of August and the early part of September, and declares that any occasional case which may occur at another season, however similar to the epidemic in character, is in its nature essentially distinct from it. Morton (*Pyretologia*, p. 16, &c.) and Torti (*lib. iii. cap. i. p. 124.*) have described cholera as appearing in an intermitting form and curable by bark.

The disease is placed in the class *fluxus* and order *alvifluxus* of Sauvages; in the class *neuroses* and order *spasmi* of Cullen, and very appropriately in the class *caliaca* and order *enterica* of Dr. Good.

The following definition will probably comprise every case really belonging to the genus cholera:—vomiting, purging, spasms, prostration and collapse, or any four of these symptoms occurring simultaneously or in a succession more or less rapid.*

For practical purposes it seems sufficient to consider cholera as divided into two species, ordinary cholera and the epidemic or malignant disease; such deviations from the common type of these disorders as are occasionally met with being indicated in the course of the article; [after which, some remarks will be made on cholera infantum.]

I.—COMMON, OR SPORADIC CHOLERA.—Ordinary cholera may be thus defined:—vomiting and purging, the discharges during great part of the course of the disease containing generally a large proportion of bile; pain in the stomach and intestines; spasms, especially of the muscles of the abdomen and lower extremities, and prostration. If collapse occur, it takes place after the disease has endured some time apparently, as an effect of the great discharge, spasm, and irritation.

Besides these distinctive marks of the disorder, there is generally found great inflation of the stomach and bowels; the fluid vomited is frequently enormous in quantity, consisting at first of the food in the stomach, and subsequently of matters variously coloured from light brown to dark green, and expelled with great force; and the stools, the appearance of which indicates during the greater part of the course of the disease, the same redundancy of biliary secretion as is denoted by the matters vomited, are generally copiously and forcibly expelled, though sometimes sparingly and with difficulty. The dark appearance here attributed to the discharges in ordinary cholera must be considered as generally applicable only to this disease as it occurs in our own and other temperate climates; for a white appearance of such matters had been remarked as an occasional circumstance, by Celsus and various other physicians, in the warmer regions long before the occurrence of the epidemic which has recently attracted so much attention. At the commencement of the attack the skin is generally warm and dry; but after a few hours its temperature falls considerably below the standard of health, and it is bedewed with a cold and clammy moisture. The tongue is dry and the thirst excessive; the urine scanty and high-coloured; the pulse rapid, and generally small and irregular; and the spasms which affect

* This definition is modified from that of Dr. Macann.

the muscles of the abdomen and of the inferior extremities, and occasionally those of the hands and arms, recur at short intervals, and are attended with great pain. After the disease has continued some time, the countenance appears anxious, ghastly, and shrunk; the voice is feeble and interrupted; the sense of exhaustion is extreme, and in severe and protracted cases the tendency to fainting is great and alarming.

Ordinary cholera in temperate climates is not very often fatal; yet it is a dangerous disease, and one which requires much attention on the part of the practitioner. The approach of death is denoted by the continuance of the vomiting and purging, especially of the latter; by hurried breathing; a countenance either of a purple hue, or pale, anxious, and contracted; a feeble and fluttering pulse, and coldness of the extremities and surface generally. Cessation of the vomiting and purging; warmth of the skin; the pulse approaching the surface with a diminution of its frequency; the restoration of a tranquil expression to the countenance, and the recruiting of the powers of the patient from a state of oppression and exhaustion, indicate recovery.

It not unfrequently happens that for some days after the subsidence of vomiting, purging, spasms, and other violent symptoms mentioned, the patient feels some uneasiness in the epigastrium and other parts of the abdomen, which is increased on pressure. The pulse is at the same time sharp and frequent; the tongue always dry, and either red and glazed, or covered with a brown fur; there is great thirst with complete inappetency, and occasionally nausea, and the bowels are generally costive, though they may be readily excited to action by laxative medicine if the stomach can be made to retain it, the discharges procured being usually of a dark green appearance. These symptoms, which denote gastro-enteritis supervening on the high degree of irritation of the lining of the digestive canal, require diligent attention; for some cases in which they had been overlooked have proved fatal, though the patients had previously emerged from a state apparently more urgent and dangerous.

Diagnosis.—The factitious disorder produced by an irritating poison, and the epidemic species of the disease, are the only affections of the system with which there is any risk of our confounding the form of cholera at present under discussion. The distinction from the latter affection we shall endeavour to point out in a subsequent part of the article. Professor Christison (*Treatise on Poisons*, p. 93, et seq.) places some reliance on the respective duration of cases of fatal cholera and of poisoning from the irritants, as a ground of distinction between them. He informs us that death from irritant poisons is seldom delayed beyond two days and a half, and frequently happens within thirty-six hours, sometimes within twelve hours, or even less; whilst death from cholera at any time is rare, but within three days very rare indeed, though it may occur in twelve hours. This statement itself shows that the comparative duration of these affections furnishes no secure means of distinguishing them; and our experience tells us, besides, that death from cholera within three days, or even in twelve hours, is much

less rare than this able writer supposes. Another discriminating test pointed out in the *Treatise on Poisons*, the sanguinolent vomiting which attends cases of poisoning, we fear is not more tenable than the preceding; for though a rare, we know from observation that it is not an unexampled accompaniment of cholera.

Though these circumstances, the duration of the disease when fatal, and the presence or absence of sanguinolent vomiting, seem insufficient to distinguish the two affections, yet the conclusion to be arrived at is, that the diagnosis between cholera and poisoning may in many cases be formed from symptoms alone; and certainly, that no observing practitioner would be long at the bedside of a patient who had swallowed an irritating poison in a dose likely to prove fatal, without discovering that he had something different from natural disease to contend with. It is true that he might not have evidence of the fact sufficient to establish it in a court of justice, but his conviction would be such as to excite him to an examination calculated to elicit satisfactory legal testimony. The sense of burning in the throat, extending thence down the œsophagus to the stomach, is dwelt upon by the sufferer in a way that is never observed in cases of cholera, in which the patient complains of intense pain, but never dwells upon this burning feeling as constituting the chief source of his sufferings, though he may acknowledge its existence if questioned. Besides, as Professor Christison justly observes, it is certain that the sense of acridity or burning sometimes remarked in cholera never begins before the vomiting, whereas in many cases of poisoning, though certainly not in all, it is the first symptom. It may be remarked, too, that it is often stated by the sufferer to have occurred either immediately or shortly after the swallowing of something.

Nature of the Disease.—The first effect of the application of the cause of cholera seems to be a violent irritation of the mucous lining of the stomach and small intestines, which is propagated to the liver either by continuity along its ducts, or by sympathy between organs whose actions are so intimately associated. Some writers, reversing the order here stated, consider the liver as the part first affected, and the manifest disorder of the digestive canal to be the effect of the derangement of that organ. The order first mentioned seems more in accordance with the agency of the usually assigned causes of the disease, with its phenomena, the effects of remedies upon it, and the appearances on dissection. The irritation is extended, it would appear, not merely to the liver, but likewise to the spinal marrow; at least the parts supplied with spinal nerves are the seat of violent spasms. The state of the heart's action at the onset of the disease, before exhaustion can be supposed to have resulted from the mere effect of the discharges, renders it probable that it is affected through the medium of the ganglionic nerves or spinal marrow. Whatever view may be taken of the structures primarily affected in cholera, it seems beyond all question that those we have enumerated are the parts principally concerned in producing its symptoms.

Appearances on Dissection.—When the

disease is rapidly fatal, there is no discernible lesion of structure; but if death occur after the lapse of some days, and especially if it take place from the gastro-enteritis which has been described as supervening on cholera, the mucous lining of the stomach and small intestines is found more or less strongly injected.

Causes.—This disease was supposed by Sydenham to be peculiar to the month of August, and it certainly in this country occurs more frequently during this month than any other; but it may be observed at any season of the year when a warm atmosphere during the day alternates with a considerable degree of cold at night. As might be supposed from this statement, its most frequent exciting cause is exposure to the chill of damp or cold air after unusual heat. On the same principle, drinking cold water when the body is heated has occasionally produced an attack. Cases occur, too, in consequence of taking food or liquid calculated to irritate the stomach and bowels. Malaria has been supposed to be a cause of the disease; and this opinion derives a great degree of probability from its appearing at the season when autumnal intermittents and remittents prevail, and the fact that many cases of sub-continued or slightly remitting fever, and even of ague, have been observed, which commenced with symptoms identically similar to those of cholera, (*Medical Essays, by J. Brown, M. D., p. 38*). A remarkable example of the malarious origin of the disease occurred at a school at Clapham, in August, 1829. A very foul drain, or cesspool, was opened, and its contents were thrown into a garden adjoining the school. A day or two afterwards one of the boys was attacked, and in two days more twenty others out of the total of thirty. The disease appears to have considerably resembled the Indian epidemic, the evacuations being much less tinged with bile than is usual in the ordinary cholera of temperate climates. Two cases terminated fatally. It was held by the highly respectable medical authorities assembled on the occasion, that the effluvia from the putrid matter had produced the disease, (*Searle on Cholera, and Orton, p. 415*).

Treatment.—The counsel ordinarily given is to defer the employment of medicine for some hours after the commencement of the disease, limiting our endeavours during this period to the administering diluents, such as gruel, thin chicken-broth, beef-tea, barley-water, &c.; but even if the patient's earnest appeals for relief would allow of this delay, it seems more than questionable whether it would be justifiable; for some time has generally elapsed before medical aid is obtained, and the cases must be rare indeed in which more powerful agents than those mentioned may not be employed at the time of our arrival, and are not, in fact, demanded.

Opium is the remedy which, from its well-known effects in other diseases, would naturally present itself to the mind of the physician as likely to allay the irritation; and it is in reality the best which he can employ. In mild cases, it is often found to be the only medicine required; but in more severe attacks it may be advantageously conjoined with calomel, the combination of these medicines having an excellent effect in allaying

gastric and intestinal irritation. In slight cases, a grain of opium, or a proportionate quantity of laudanum, may be given every second hour till relief be obtained. In those which are more severe, two or three grains of calomel, combined with a grain of opium, may be given at the same interval till three or four doses shall have been taken; or, the calomel being administered in pill, a draught containing a proportion of laudanum or black-drop, equivalent to a grain of opium, may be exhibited along with it.

Subsidiary measures should accompany the employment of these medicines. The diluent drinks already mentioned should be given at intervals to allay the urgent thirst of the patient, but in small quantities, lest they excite vomiting. Hot fomentations to the abdomen are well calculated to afford relief; and the patient, if not much exhausted, may remain for a quarter of an hour in a bath of 100°, if it can be obtained. It must be observed, however, with regard to the warm bath, that in the epidemic disease the most experienced practitioners decline its employment where there is much collapse, on account of the distress it occasions, and, indeed, from the positive mischief arising from the necessity of removing the sick from the horizontal position: *dry heat* is now generally preferred in those cases, and it will be proper to keep this fact in view in our treatment of the ordinary species, when the exhaustion is considerable. A large blister to the epigastrium, previously fomented with hot vinegar, is frequently useful in relieving the vomiting and internal irritation; or sinapisms are sometimes advantageously employed to produce the same effect more rapidly. Scalding the epigastrium, or, as it is called, the warm-water blister, is the prompt mode occasionally employed in the cholera of the east; but there is reason to apprehend that it would prove abhorrent to the feelings of patients in this country, and would be deemed a needlessly severe treatment of ordinary cholera.

Should there be considerable exhaustion, indicated by coldness of the skin and feebleness of the pulse, diffusible stimulants, such as brandy, ether, and ammonia, should be given in small quantities. Draughts composed of carbonate of magnesia, aromatic spirit of ammonia, compound tincture of cardamoms, and laudanum, are frequently well retained by the stomach, and have a good effect in such a state. Strong beef-tea may be given, if the stomach become tranquil, in small quantities at short intervals, alternately with brandy and water.

General bleeding is neither required nor perhaps admissible, in the course of the symptoms of what may be strictly termed cholera in a temperate climate; but even during such symptoms either there is occasionally such permanent tenderness of the epigastrium, perceived in the intervals of severe pain, vomiting, and spasm, as induces us to conclude that the irritation of the digestive canal has passed into inflammation; or the glazed or furred state of the tongue, the intensity of the thirst, the sharpness of the pulse, and general uneasiness of the patient, without the existence of permanent pain, may lead us to the same conclusion. In either case the application of a dozen or eighteen leeches to the epigastrium

will be attended with much benefit. After the leeching, a large emollient poultice may be applied, followed, on the total subsiding of the oozing from the leech-bites, by the application of a blister to the epigastrium.

In the gastro-enteritis, described as sometimes occurring after the cessation of the actual symptoms of cholera, general bleeding may be performed to the extent the patient's strength will admit, not only with safety, but with great benefit. Leeches and blisters to the abdomen, and mild mercurials, particularly hydrargyrus cum cretâ in doses of three or four grains every fourth hour, till some affection of the mouth is perceived, will be found the best subsidiary remedies.

Cholera frequently leaves the patient in a state of extreme debility, which should be sedulously watched, for persons have occasionally died suddenly, when supposed to be recovering from the disease, apparently from exhaustion. The horizontal posture, and mild and nutritious diet, consisting of sago with milk, beef-tea, or chicken-broth, with bread or biscuit, animal-jelly, &c. are the appropriate remedies. If the bowels are costive, they should be moved by enemata; for all the symptoms of cholera have been reproduced, three days after their subsidence, by so gentle an irritant to the digestive canal as a dose of rhubarb.

We had proposed to ourselves to terminate here all that it appeared to us necessary to say under the present head; but we are bound towards the profession to admit that the details which had been laid before us, previously to the manifest appearance of the epidemic disease in this country, through the channels of medical journals, of sporadic cases which occurred in various parts of England during the autumn of last year (1831), preclude the possibility of our hesitating to acknowledge a perfect identity between the group of symptoms in some of those cases, and the symptoms of the choleric stage of the malignant epidemic form in which cholera has of late years committed such ravages. The fullest details are given in several instances, and by persons of whose accuracy we cannot have the remotest doubt. Respecting a case in the seventh regiment at Hull, which proved fatal on the 11th of August, after an illness of sixteen hours and a half, and in which the assemblage of symptoms held to be characteristic of Indian cholera were so very strongly marked, we may state that the gentleman who forwarded the details to the journal in which they appeared has sent us his name, and pledges himself for their fidelity. In this case there were the *blue skin, the total absence of pulsation in the extremities for some time before death, the sodden appearance of the fingers, the coldness of the tongue, the change in the voice, and the suppression of urine*, all which are so particularly dwelt upon by innumerable authorities as peculiarly marking the cholera spasmodica.

II.—EPIDEMIC, OR MALIGNANT CHOLERA.—Long prior to the appearance of the present epidemic in the Delta of the Ganges in 1817, and its subsequent diffusion over so large a portion of the globe, extensive and destructive visitations of cholera had been noticed by various writers. One of these, we learn, occurred in Europe at the close of the seventeenth century; but most of them

originated in the east, and limited their devastations to that quarter of the world. The indefatigable Mr. Scott has quoted, from the Madras Courier of 1819, a letter, which suggests the opinion that a description, though certainly a very obscure one, of a disease resembling that which now prevails, is to be found in a Hindoo work of great antiquity; and cites instances of the epidemic prevalence and great fatality of cholera from the time of Bontius, in 1629, to the present century; but the description of these epidemic visitations has not always reached us in so detailed a form as to enable us to judge correctly of their identity with what has been recently observed: enough, however, may be gleaned to prevent our denying this identity in some instances; indeed, it is impossible not to be struck with the resemblance which certain of the more accurately reported of these examples—especially one which occurred at Ganjam, in 1781—bear to that now existing. But this much seems certain, that, however cases in previous visitations may have resembled in character those of the prevailing disease, no recorded epidemic of cholera has equalled this in the wideness of its diffusion and the amount of its ravages, or has preserved its character and intensity so little influenced by climate and temperature.

The question of the identity of the disease which now prevails in Great Britain and on the continent of Europe, and that which ravaged Hindostan, having been settled in the affirmative, at least as regards certain of their most important practical points, by the various respectable physicians who have witnessed both diseases, we may assume that much of the valuable information transmitted to us from India, respecting the nature and treatment of the malady which raged there, is applicable to that which is now committing its ravages in Europe.

1. **Symptoms of Cholera in India.**—The disease generally makes its attack in the night, or towards morning, with vomiting so excessive, that the whole contents of the stomach appear to be discharged; and nearly at the same time the bowels are copiously emptied, as though all the solid matters in the intestinal canal were evacuated. In some cases a watery purging precedes the vomiting by some hours; but they more frequently occur simultaneously. After the first copious discharge, the patient experiences a distressing feeling of exhaustion and faintness, with ringing in the ears and giddiness. The subsequent discharges from the stomach and those from the bowels do not differ from each other in appearance, excepting as the matters ejected from the stomach may be tinged by medicines or other ingesta: they are generally watery, colourless, and inodorous, and are compared in their appearance to barley-broth, or more frequently to rice-water. Sometimes they are like milk, occasionally yellowish, greenish, like muddy water or yeast; but the "conjee-stools," as they are emphatically termed, which consist of albuminous flakes floating in serum, or discharges of pure serum, are of the most frequent occurrence. The dejections sometimes take place without effort or uneasiness, but occasionally very forcibly, with simultaneous vomiting, spasm, and sinking of the pulse. This

violent action of the alimentary canal is not of long continuance, the powers of the system being unable to support it: hence the vomiting and purging generally cease some hours before death; but in some cases a discharge of serum takes place from the rectum on any movement of the body till the fatal close.

In most cases, some time after the commencement of this affection of the intestinal tube, but in others previously to it, spasmodic contractions of the muscles of the fingers and toes are felt, and these affections gradually extend along the limbs to the trunk. The spasms are imperfectly clonic or convulsive, with infrequent relaxations, are attended with great pain, and leave for some days afterwards a degree of stiffness in the affected muscles. The pulse is from the first small, weak, and accelerated; and after a certain interval, but especially on the accession of spasms, or severe vomiting, it sinks suddenly, so as to be speedily lost in the external parts. The length of time during which a patient will live in this pulseless state is remarkable. In a case related by Dr. Kellett, the pulse was gone within three hours from the attack, yet the man lived twenty-two hours in that state. On the cessation of spasm and vomiting, and sometimes apparently from the exhibition of remedies, the pulse will return in the extremities for a short time, and again cease. The skin is cold from the commencement of the disease, and as it advances, becomes gradually colder, and is covered either with a profuse sweat or a clammy moisture. The state of its circulation and its insensibility are sometimes strongly denoted by the following circumstances: leeches will not draw blood from it; blisters and other vesicatories will not act; and even the mineral acids and boiling water produce no effect, and some patients are not even sensible of their application. In Europeans the colour of the surface is often livid; the lips and nails present a blue tint; and the skin of the feet and hands becomes corrugated, and exhibits a sodden appearance, as if from long immersion in hot water.

With these symptoms coexist violent pain of the intestines, with a sensation of writhing and twisting there; heartburn, which the sufferer compares to a fire consuming his entrails; excessive thirst; anxiety, with inexpressible uneasiness about the præcordia; hiccup; jaetitation; and, notwithstanding the actual coldness of the surface, and even of internal parts which are accessible to the touch, the tongue for instance, a *sense* of heat which impels the patient incessantly to throw off the bed-clothes. The breathing is much affected, being performed either more slowly than usual, sometimes for instance, in the advanced stage, only at the rate of seven respirations in a minute, or the inspirations are short and sudden, with violent pain from spasm of the diaphragm; the voice being feeble, hollow, hoarse, and interrupted. The eyes are sunk in their orbits; the corneæ flaccid, the conjunctivæ frequently suffused with blood; the features of the face collapsed; and the whole countenance wears a cadaverous aspect. The secretions, those of the skin and intestines excepted, are generally suspended. The functions of the mind are undisturbed almost to the very last moment of existence.

The approach of recovery is denoted by the rising of the pulse, the return of heat to the surface, inclination to natural sleep, diminution or cessation of vomiting, purging, and spasms, and, after an interval, the re-appearance of bilious stools, urine, and saliva.*

Regarding the above as a picture of the general type of a disease rather variable in character, we shall proceed to relate the more striking deviations from the ordinary form which were observed in India.

Instead of the exceedingly sunk state, there was a marked excitement, with a hot and dry skin, and a pulse of considerable force, in several instances throughout great part of the course of the disease. (Madras Reports, p. xxv.) This in some cases arose from the early exhibition of stimulants, but in others it appeared to be an essential part of the disorder. These cases yielded most certainly and readily to treatment; and hence, many of them having been subdued without the occurrence of sinking or debility, it was a matter of doubt whether this description of disorder really belonged to the epidemic; but that it did so was placed beyond all question by some of the more protracted cases degenerating into the ordinary low form.

The most fatal variety of the disease was denoted by the slowness of the commotion in the system: there was no vomiting; hardly any purging, perhaps there were only one or two stools; with no perceptible spasm; no pain of any kind; a mortal coldness with arrest of the circulation coming on from the beginning, and the patient dying without a struggle within three or four hours. Several instances were heard of, at Hoobly and other places, of natives being struck with the disease, whilst walking in the open air, and who, having fallen down, retched a little, complained of vertigo, deafness, and blindness, and expired in a few minutes. Mr. Scott informs us that this most deadly form of the disease frequently manifested itself in local epidemic visitations, which were often observed in India, all the cases occurring at the same time in a given district partaking of the same peculiarity of character.

The collapsed form of disease first described is that which has been most frequently observed. In fatal cases its duration varies from four to eight hours; whilst in those which terminate favourably, a result often apparently due to early medical assistance, the patient may be restored to perfect convalescence in a period ranging from twenty-four to forty-eight hours. But in many cases considerable disturbance of the system intervenes between the period of collapse and restoration to health, or this disturbance may itself cause death. The Indian reporters mention two forms of this disorder. In the one, with some excitement in the system, the bowels continue to discharge, for many days, first brown and watery, then dark, black, and pitchy stools, sometimes with blood, and with peculiar pains in the bowels, particularly in the rectum. The other

* Scott's Reports on the Epidemic Cholera; Anderson on Cholera, E. M. and S. Journal, vol. xv. p. 324; Christie on Cholera and the Pathology of Mucous Membranes; Annesley's Sketch of the Diseases of India, &c.

a distinct febrile form, we shall describe in the language of the Bengal Report :—

“The fever which almost invariably attended this second stage of the disease (in Europeans), partook much of the nature of the common bilious attacks of these latitudes. There was a hot dry skin, a foul deeply-furred tongue, parched mouth, thirst, sick stomach, restlessness, watchfulness, and quick variable pulse, sometimes with delirium and stupor, and other marked affections of the brain. Generally, when the disorder proved fatal in this stage, the tongue, from being cream-coloured, became brown, and sometimes black, hard, and more deeply furred; the teeth and lips were covered with sordes; the state of the skin varied, chills alternating with heats; the pulse became extremely quick, weak, and tremulous; hiccough, catching of the breath, great restlessness, and deep moaning succeeded; and the patient soon sunk, incoherent and insensible, under the debilitating effects of low nervous fever, and frequent, dark, tarry, alvine discharges.”

A consecutive fever, similar to this, we learn from Drs. Russell and Barry, is of more frequent occurrence in Russia than in India. The following description of it we owe to these gentlemen :—

“After the blue cold period has lasted from twelve to twenty-four, seldom to forty-eight hours or upwards, the pulse and external heat begin gradually to return, headach is complained of, with noise in the ears, the tongue becomes more loaded, redder at the tip and edges, and also drier. High-coloured urine is passed with pain and in small quantities, the pupil is often dilated, soreness is felt on pressure over the liver, stomach and belly; bleeding by the lancet or leeches is required. Ice to the head gives great relief. In short, the patient is now labouring under a continued fever, not to be distinguished from ordinary fever. A profuse critical perspiration may come on from the second or third day, and leave the sufferer convalescent; but much more frequently the quickness of pulse and heat of skin continue, the tongue becomes brown and parched, the eyes are suffused and drowsy; there is a dull flush with stupor and heaviness about the countenance much resembling typhus, dark sordes collect about the lips and teeth, sometimes the patient is pale, squalid, and low, with the pulse and heat below natural, but, with the typhous stupor, delirium supervenes, and death takes place from the fourth to the eighth day, or even later, in the very individual, too, whom the most assiduous attention had barely saved in the first or cold stage. To give a notion of the importance and danger of cholera fever, a most intelligent physician, Dr. Reimer, of the Merchant-Hospital, informs us, that of twenty cases treated under his own eye, who fell victims to the disease, seven died in the cold stage, and thirteen in the consecutive fever.”*

The same gentlemen state, as the result of their observation, that the following are the points of difference between the European epidemic and that of India :—

“First, the evacuations, both upwards and

downwards, seem to have been much more profuse and ungovernable in the Indian than in the present cholera, though the characters of the evacuations are precisely the same.

“Secondly, restoration to health from the cold stage, without passing through consecutive fever of any kind, was by far more frequent in India than here (St. Petersburg), nor did the consecutive fever there assume a typhoid type.†

“Thirdly, the proportion of deaths in the cold stage, compared with those in the hot, was far greater in India, according to Dr. Russell’s experience, than here.

“Fourthly, the number of medical men and hospital attendants attacked with cholera during the present epidemic, in proportion to the whole employed, and to other classes of society, has been beyond all comparison greater here than in India under similar circumstances.”

Dr. Kier of Moscow, gives the following description of the consecutive or secondary morbid state. “A second ordeal now begins, sometimes as severe, and frequently not less fatal, though more slowly so, than the first; this is probably the effect of the morbid changes which have been induced during the first period of the disease. The appearance of the complaint is now entirely changed, inasmuch that one who had not seen the patient during the first period, or been told of the symptoms, could not possibly know that he was suffering from the epidemic. I have observed the disease in this, its second period, to assume four forms: the first, an inflammatory, or rather sub-inflammatory state of the stomach and bowels, most frequently the latter, sometimes conjoined: the second, inflammatory irritation of the lungs, with pain of the chest, cough, viscid expectoration, and fever, appearing as a critical metastasis of the disease: the third, bilious or bilio-nervous fever, with suppuration of the parotid glands; in one case, with axillary suppurating bubo, towards the end of the fever, an inflammatory irritation of the lungs took place, ending in vomica: and the fourth, a congestive sub-inflammatory state of the brain and spinal chord. This last, as was natural to expect from the nature and seat of the affection, proved by far the most dangerous and most frequently fatal form of the second period: it appeared generally to supervene after the purging, vomiting, and cramps had been relieved, and the external heat in some degree restored; the pa-

† If we compare the symptoms attributed to this consecutive fever by Drs. Russell and Barry, with those quoted from the Bengal Reports, the difference between this stage of the respective epidemics does not appear very striking: the epithet *typhoid* seems almost equally applicable to both. Varieties were observed in the disease as it prevailed in the different Indian presidencies, and likewise between that which existed in Hindostan and Ceylon, perhaps as considerable as those now observed by these intelligent physicians. In regard to what is stated in the extract referred to, relative to the greater frequency at Petersburg of the secondary “typhoid,” or, as more commonly designated in India, low bilious symptoms, we confess that we observe a discrepancy when we read a subsequent part of the same Report, in which Drs. Russell and Barry state, “Convalescence from cholera has been rapid and perfect here, as is proved by the following fact. The Ministers of the Interior had given orders that all convalescents, civil as well as military, at the General Hospital, should be detained fourteen days. We inspected about two hundred of these *deterius* some days back, with Sir J. Wylie, and found them in excellent health, without a single morbid sequela.”

* Report of Drs. Russell and Barry to C. C. Greville, Esq., published among other papers, by authority of His Majesty’s Most Honourable Privy Council.

tient complained of pain in the back, between the shoulder-blades, or in some other part of the spine, sometimes along its whole tract; he appeared sleepy to such a degree that at first I was disposed to attribute this state, in part at least, to the effects of the opium given in the first period. But I was soon convinced that the cause of this symptom, and of another strongly characteristic of this form of the disease, namely, the filling of the vessels of the sclerótica with red blood, was a congestive sub-inflammatory state of the brain and spinal chord. This striking symptom at first began to show itself in the inferior part of the globe of the eyes; it gradually increased, and little by little reached the upper part, while the eyes turned upwards, exposing the lower part gorged with blood. The state of the patient generally ended in a complete coma, and proved fatal a few hours afterwards.*

Besides the various and appalling symptoms which indicate general derangement of the action of the solids, there are appearances in the blood drawn during the collapsed stage, showing that the fluids feel the influence of this formidable disease. These appearances are very uniformly expressed by the terms dark, black, or tarry, in regard to colour, and by thick, ropy, syrupy or semi-coagulated, in respect to consistence. This change in the condition of the circulating fluid is fully proved to be in the ratio of the duration of the disease; the blood at the commencement seeming to be nearly or altogether natural, and more or less rapidly assuming a morbid state as the malady advances. This condition was less conspicuous in cases of cholera ushered in by symptoms of excitement, than where the collapsed state of the system had occurred early; and in certain rare cases it was not observable at all, and the blood flowed readily from the vein; but the reverse was the fact, both with respect to its condition and the manner of its flowing from the arm, in an immense majority of instances. In general, after a certain quantity of dark, thick blood had been drawn, its colour became lighter, its consistence less thick, and the circulation revived, such appearances always affording grounds for a proportionably favourable prognosis. There is some discrepancy in the accounts transmitted to us of the mode in which this diseased blood coagulates. In some instances, we learn, the coagulation is rapid, whilst in others it is slow and imperfect. Reporters are unanimous in declaring it deficient in serum, and destitute of the buffy coat. The latter is occasionally observed in cases attended with re-action, in which the blood is not black and thick. (Madras Report, p. xxx. &c.)

The discharges from patients suffering under this disease were subjected to experiment by Dr. Christie. The secretion consists of two substances, the one a transparent serous fluid, the other an opaque coagulum; the former perfectly soluble in cold water, the latter quite insoluble. These matters being submitted to the action of re-agents, the fluid part was found to be pure serum, and the coagulated portion fibrin. The secretion, therefore, as the author remarks, has a composition similar to that of the blood deprived of its colouring matter; but the serum is in

much larger proportion to the fibrin than in that fluid.

Chemistry has been occupied in researches into the composition of the blood and of the secretions in this disease since it has extended into Europe. Mr. Herman, of St. Petersburg, who regards free acetic acid as an essential constituent of the blood when in a healthy state, finds a deficiency of it in that of choleric patients. This gentleman, like our Indian practitioners, has observed that the crassamentum bears a larger proportion to the serum in this disease than in health; and this increased relative quantity of crassamentum was found to be in direct proportion to the intensity of the disease. The fluids voided by stool and vomiting contained, he informs us, besides water, some acetic acid, a small quantity of osmazome, salivary matter, butyric acid and mucus. They very much resemble gastric juice, but do not contain any free muriatic acid. In the alvine discharges, the quantity of butyric acid is greater than in the fluid voided by vomiting; and they contain, besides, some albumen, a fetid, oily matter, and a small admixture of bile.*

2. Character of the epidemic as it appeared in Sunderland in 1831.—Thus far our account of this formidable malady has been derived from the very valuable mass of information with which we have been favoured by our medical brethren in India, and the many intelligent men who have witnessed its ravages on the continent of Europe. Circumstances having brought it under our own observation, we shall endeavour to convey succinctly to the reader the results of our experience, prefaced by a few reflections on the character and designation of the disease, which this experience has suggested to us.

A question has been repeatedly discussed, but without having been so far settled as either to lead the profession to feel satisfied with the name first given to the disease, or to adopt a designation more consonant with its nature, viz.—can it properly be considered as belonging to the genus cholera? or is its character so much more closely related to that of fever as to render it advisable, consistently with accuracy of arrangement and precision of nomenclature, to place it among febrile disorders, and give it a designation more corresponding than its present one with its new nosological position. The vomiting, purging, spasms, and prostration which are generally considered as the pathognomic symptoms of cholera, belong equally to a certain stage of this disease as to the ordinary form; and, in addition to this argument, it may be urged that only a strong affinity could have led men so intelligent as our Indian practitioners unanimously to designate it by the term cholera. It is true, that if we limit our view to one stage only of the disease, the former reason is forcible; but if we embrace, as we ought to do, all its parts as we witness them in Europe,—if we consider that the choleric symptoms, if not fatal, prove but the commence-

* Letter to Dr. Todd, (Medico-Chirurgical Review, July, 1831, p. 285.)

A specimen of the intestinal discharge from a child three years old, labouring under the disease, with which we furnished M. Magendie when he visited Sunderland, was analysed by that gentleman; and he informed us that it contained albumen and mucus, and was *alkaline*.

ment of a series of changes to which a yone who witnessed them alone would give the appellation of fever, and which men of great experience in the disease have declared they could not distinguish from typhus—if we observe, too, that long before this epidemic excited attention, symptoms strikingly resembling those of cholera had been observed to form the initiatory stage of certain malignant fevers.* — we are disposed to admit that it is in reality a fever, and that to designate it merely cholera is to take a part for the whole, and to give to the inexperienced, as far as a name can give it, an erroneous idea of the disease. At the same time it would be advisable to mark its relation, a relation which it unquestionably possesses, to the disease from which it is dissociated, and to apply to it the trivial epithet *choleric*. Consequently with these views, we should advise that the name suggested by Dr. Johnson, *epidemic choleric fever*, be in future adopted as its designation.

The argument against this change derived from the universal employment of the other name by our Indian practitioners, is not of much force; for it is manifest, from many circumstances, that in Hindostan, the disease, in the majority of instances, consisted of the cold stage only, many reporters not at all advertent to the consecutive fever; and Mr. Jameson alone, in the Bengal Reports, treats of it at any considerable length. So rare indeed was it, that we have met with Indian physicians of no inconsiderable experience in the disease, whose observation it had escaped altogether. It should be remarked, too, that Mr. Jameson declares the febrile stage to have been rare and slight among natives in general; but that it frequently occurred in Europeans and natives of robust and athletic make. It would appear, that, in proportion as the disease has receded from its original source, it has been undergoing more and more a transmutation into a febrile character. Drs. Russell and Barry, it will have been remarked, state that restoration to health from the cold stage, without passing through consecutive fever of any kind, was by far more frequent in India than at St. Petersburg, a statement which, while it asserts the increased frequency of fever, certainly implies that restoration to health sometimes takes place without its occurrence. Now we can positively assert that we have not met with a single case in England, in which fever did not intervene between the choleric or cold stage and restoration to health; and the result of inquiries we have addressed to individuals the most observing and most familiar with the disease in this country, has proved that their experience has coincided with our own. It is true that in some cases this fever has been slight, but the choleric stage has been so likewise; for we have always observed a correspondence in intensity between these stages.

Were we to attempt a definition of epidemic choleric fever, the following, according to our experience, would comprise its distinctive symptoms.

After watery diarrhœa, or other generally slight

indisposition, vomiting and purging of a white or colourless fluid, violent cramps, great prostration and collapse,† the last occurring simultaneously with the vomiting and cramps, or shortly after them. Should the patient survive the last train of symptoms, a state of excitement and fever supervenes.

We can convey a correct idea of the disease only by dividing it into three stages, *the incipient, the cold or choleric, and the febrile*: the division is a natural one, according with the character of the disease.

1. Symptoms of the Incipient Stage.—In an immense majority of instances, diarrhœa has been the prominent symptom of this stage. Jaundice and lassitude, and occasionally nausea and vertigo coexisted with the disorder of the bowels, and sometimes certain of these symptoms may have appeared without it; but its occurrence has been so common, that we have treated few cases in which it has not preceded the more formidable symptoms. On examining the discharges, if we have an opportunity of doing so shortly after the occurrence of the diarrhœa, they will be observed to be fecal and bilious, but we shall find that they subsequently bear the serous character of those which occur after the choleric stage is fully formed; they are passed copiously and without much griping; the feeling of debility which attends them is great, and this diarrhœa is so exhausting, that we have met with patients, especially those advanced in life, in whom a considerable degree of collapse had occurred, with a feeble pulse scarcely exceeding fifty, before the accession of vomiting and cramps. The natural tendency of this purging, is, we believe, to pass into the choleric stage; but the transition has frequently occurred shortly after some dietetic error, either as to quantity or quality of food, or after exposure to cold. The commencement of the purging has sometimes preceded by several days the accession of the choleric stage, and occasionally only by eight or ten hours; but forty-eight hours has been its mean duration, calculated from a great number of instances. We have dwelt the more on this incipient stage from a conviction, the result of considerable observation of the disease, that subsequent symptoms might often be prevented, and life preserved, by the early and appropriate treatment of the diarrhœa.

[The premonitory symptoms, consisting of more or less derangement of the digestive functions, with diarrhœa to a greater or less extent, were generally termed *cholericæ*. The appellation was also given by some, both to the premonitory and to the incipient stage.]

2. Symptoms of the Cold or Choleric Stage.—Our description will be more intelligible if we divide into two periods this very important stage, which has in truth given its name to the

† By collapse, in this definition, is meant the feebleness or almost the arrest of the circulation; the death-like appearance, the coldness, shrinking, and occasional blueness of the surface, which may in other diseases be observed after they have existed some time, and as the powers of life are passing away; but which occur in what we shall call the cold or choleric stage of the epidemic, in a short time after its commencement, as though they formed an essential part of it. The degree and early accession of this collapse, and the white discharge are the only distinctive marks that we are aware of between this stage of the epidemic and ordinary cholera.

* For further information on this point consult Dr. Negri's Letter to Dr. Barry; Morton, Pyretologia, pp. 16, 33, 81; Forti de Febrilibus, lib. iii. cap. l. p. 124; and Med. Essays, by J. Brown, M. D. pp. 37-39.

disease, and, by its fearful symptoms, has engrossed such general attention, that the facts of its being but part of a series of changes has been too often lost sight of.

First period.—The time of invasion has been, as in India, in a great majority of instances, from two to four o'clock in the morning. The patient is attacked with uneasiness of the stomach, occasionally amounting to pain, to which speedily succeeds vomiting of the characteristic fluid so frequently described; and, if diarrhoea have preceded, which in almost all the cases that have fallen under our observation has been the case, a purging of the same fluid, the fecal contents of the canal having been previously expelled. The vomiting is rarely full and effectual, consisting rather of apparently unsatisfactory retchings than of a full discharge of the contents of the stomach; but sometimes these contents are expelled forcibly, as if squirted from a large syringe. The discharges from the bowels are occasionally scanty, but much more frequently they take place copiously and forcibly. Simultaneously with the vomiting, or not unfrequently before this symptom has occurred, cramps take place, and the agony which attends them constitutes great part of the sufferings of the patient, who incessantly entreats that friction may be applied to the parts they affect. However soon our visit may be made, the pulse will generally be found to be feeble and frequent; the skin in point of heat below the healthy standard; the countenance shrunk, and, if not livid, pallid; and the respiration hurried, if not checked, as it frequently is, by spasm of the diaphragm and intercostal muscles. The circulation sinks remarkably, and sometimes appears momentarily to cease, on every occasion of severe vomiting or spasm.

Second period.—The mean duration of the preceding period varies from about eight to twelve hours; the vomiting and spasms then either totally subside or recur at much longer intervals, and the patient sinks into a state of extreme collapse. The pulse at the wrist is scarcely or not at all perceptible; the surface is universally moist and cold, excepting as heat is imparted from without, for the instant that the hands or other parts are exposed, they become of an icy coldness; blueness, if it exist at all,—but it is by no means an uniform symptom,—is now conspicuous on the face and hands, which last have the shrunk and soddened appearance so generally described; the tongue is moist, and, if not actually cold, at least cooler than natural; and the voice is of that mingled huskiness and feebleness which strikes the ear so peculiarly. In this condition there is little suffering, excepting from the sense of weight and oppression at the præcordia, of which the patient complains much; for even should spasms occur, they are now too feeble to excite much pain; the respiration is slow; the conjunctivæ, especially in their inferior hemisphere, are frequently injected with dark-coloured blood; and the insensibility of the stomach is so great, that the most powerful stimulants may be given and retained without the organ being apparently more sensible of their presence than if it were a lifeless pouch. The urine is suspended throughout the

whole course of a choleric stage so intense as we have described.

However hopeless such a state might appear, we have seen more than one patient emerge from it by the powers of the constitution, to have a faint chance for life in a very bad form of fever, after all the efforts of art had proved ineffectual for bringing on reaction. We have seen this apparently spontaneous transition into the febrile stage take place after the patient had remained for many hours without any perceptible pulse at the extremities.

Premising that the danger in the cold stage, and the degree and malignancy of the subsequent fever, are in proportion to the collapse which is observed in this stage, we shall depict one of the lighter cases which occurred during the epidemic, remarking that the shades of intensity in the disease are so infinite that its intermediate degrees must be supplied by clinical observation.

In one of the milder cases extreme collapse does not take place. Whether by the powers of the constitution, or the remedies employed, there is a subsidence, after a period varying from eight to twelve hours, of the cramp and diarrhoea; the patient becomes calm and composed, but appears rather low and sunk; the stomach remains irritable, occasionally retaining, occasionally rejecting, food or medicine administered; the skin becomes of a moderate warmth, but yet is cooler than natural, and a good deal of adventitious heat is required; the pulse emerges to a condition of moderate force, without much frequency, being probably about eighty, and soft; the urinary secretion, if it has been suspended during the spasmodic period, which it is not always in the milder cases, is restored; after the lapse of a few hours, should vomiting occur, bile is perceptible in the matters vomited, and, generally by the assistance of calomel or other laxatives, bilious stools are discharged.

The transition from such a case is into a mild inflammatory fever, generally with some affection of the head; from which the patient recovers in a few days, by measures to be subsequently adverted to.

3. Symptoms of the Febrile Stage.—The preceding stage, in most instances, makes a very gradual transition into the present one. After the patient has remained in the collapsed state probably for a considerably longer time than the medical attendant expected, some degree of warmth will be found returning to the surface, which for a variable period, perhaps for a couple of days, has been almost of icy coldness; and the pulse is proportionably developed, being very perceptible at the wrist, generally about eighty, and soft; the vessels of the conjunctiva gradually become distended with blood; or if those of the inferior hemisphere have been so during the stage of collapse, the distension now diffuses itself over the whole membrane; the patient, who on his attention being roused is perfectly sensible, complains of severe pain in the head, of a sense of giddiness, and that the light distresses his eyes. The tongue in this early stage is clean and moist; the bowels are readily acted upon by medicine, and the discharges are feculent, and though somewhat

clayey, contain a proportion of bile; but the urinary secretion is sometimes either not restored, or is considerably deficient for a day or two after the establishment of fever. In the progress of the fever the tongue becomes black, and sordes accumulate about the teeth; the eyes become more and more injected; the intellect more and more torpid, though still the patient can be roused to answer questions, and even may make one or two sensible remarks on his condition; but the instant the conversation ceases, the eyes are turned up in the orbit, exposing through the half-closed eyelids the red scleroticæ, and the patient is in a state of profound stupor: the urinary secretion is now established, and the urine, which at first was dark-coloured and cloudy, is now limpid and pale; the alvine discharges are darker coloured than at first; and throughout the disease there is a deficiency of vascular action and of temperature, which we have not observed to the same extent in typhus or any other fever. However flushed the countenance may appear, and it is often very considerably so, the temperature of the surface is below the healthy standard, and we have not often found the pulse above ninety. *Typhoid* is not an inappropriate designation of the condition we have endeavoured to describe; but we think that an individual who had once watched the progress of such a case would run no risk of confounding it on future occasions with typhus;—the deficiency of vascular and calorific power; the peculiar vascularity of the eye; the absence of subsultus and inuttering delirium, (for though delirium occasionally occurs during night, the condition of the intellect is throughout much more one of torpor than of irregularity,) would be the marks by which he would discriminate the two affections.

The duration of such a febrile stage as we have described is from a week to ten days. Its termination has been in a considerable majority of instances, which have fallen under our observation, fatal. The brain has appeared to us to be the organ mainly affected, and by this view our treatment has been chiefly guided, though at the same time the condition of the intestinal canal has not been neglected.

In another form, and one which supervenes on a minor degree of collapse than the preceding, the symptoms do not differ from those described above, excepting that there are indications of greater excitement, more warmth of surface, and more force and frequency of pulse. Depletion could be more freely practised, and it was altogether a more tractable form of disease.

The mildest and most tractable type of the febrile stage was denoted by symptoms of general but moderate excitement with epigastric pain on pressure, headach, and giddiness; the tongue being at the same time either clean, with a disposition to become dry and glazed, or slightly white and furred; the skin warm; the pulse free and forcible; the urine high-coloured, and the thirst considerable. In such a case there is little or no confusion of thought or delirium, and the eyes are not injected. We need scarcely remark that examples of this mild and tractable type of the febrile stage occurred after a choleric stage, in which the symptoms of collapse had been inconsiderable, in which the urinary secretion had not

been suspended, or which had not always been attended with vomiting, a symptom occasionally wanting in slight cases.

The writer met with but one example of considerable affection of the thoracic organs, and this occurred in a case in point of general character not unlike the form last described, though somewhat more collapsed. The affection was bronchial, and was relieved by a copious expectoration of very dark-coloured sputa,—the patient recovering.

In the preceding sketch of the febrile stage, it will be understood that, as in the case of the choleric stage, we have not attempted to depict all the various shades of intensity in which the disease manifested itself. The extremes are given: to have essayed to describe all the intermediate degrees would have swelled the article beyond reasonable limits, and would have proved a burthen to the memory of the reader, rather embarrassing than beneficial at the bed-side.

The varieties in the different stages which we have left to be discerned clinically by the reader were, it ought to be remarked, essentially the same in character with the forms we have depicted, differing only from them and each other in shades of intensity more or less minute; but there were cases observed in Sunderland, as in India, of which the character constituted so considerable a deviation from the ordinary type, that our description would be incomplete did we pass them unnoticed.

In one such deviation from the usual type, the discharges were bilious during the choleric stage, which, in fact, could not be discriminated from an attack of ordinary cholera; a mild and tractable form of fever ensued, and the patient recovered. One case of this kind occurred under the following circumstances. The wife died of what was then designated malignant cholera. The order for prompt funerals did not at that time exist; and on the day of her interment, three days after her death, the husband sickened of the form of disease we are now describing, and recovered after a few days of fever.

We witnessed a solitary example of a form of disease which has been particularly described by Mr. Orton, as being occasionally intermingled with the customary type of the malady in India. In our case there were trismus, and spasms of the muscles of the throat so violent, that, till they were allayed by bloodletting, swallowing was impracticable; and when it could be performed, it was done with an effort resembling that with which a patient in hydrophobia swallows water, after having, by a strong mental effort, brought himself to make the attempt in spite of his abhorrence of it. It ought to be remarked, however, that there was no dread of water, nor any characteristic symptom of hydrophobia—the resemblance was merely in the manner of swallowing. The patient was in an excited state throughout the disease, which was of twenty-four's duration, till within two hours of death, when collapse occurred. The complaint commenced with vomiting and purging; the matter vomited we were informed was colourless; that discharged by purging we learned was at first rather yellow; but the intestinal discharge which we saw, after the com-

plaint had lasted some hours, was colourless and mucous. This being a solitary case of the kind, and fatal in the stage which we considered as corresponding with the choleric stage of the ordinary type, we had no opportunity of ascertaining whether any or what form of fever would ensue.

3. **Prognosis.**—The danger of the disease is in all cases, we believe, to be estimated from the degree of collapse attending the cold or choleric stage. In India, it was remarked that the cases in which the spasms and vomiting were the most violent were by no means fraught with the most peril, and what we have seen of the disease enables us to bear testimony to the accuracy of the remark; for when we have heard attendants exulting in the cessation of the spasms and the facility with which the stomach retained medicine or food, and have felt at the same time the pulseless wrist and the cold and clammy hand, we have seen in these apparently favourable omens only the natural progress of the disease from a bad condition to one still worse. Whether we are to dread a fatal result in the cold or the excited stage, the intensity and duration of the collapse in the former of these stages are the measure of the danger; for if the patient die in this stage, he dies of collapse, and if he survive it and pass into the state of fever, the character of this fever is malignant and dangerous in proportion to the same collapse.

4. **Diagnosis.**—From ordinary cholera the cold stage is to be distinguished, as it appears to us, by the peculiar character of the discharges, which has been sufficiently dwelt upon, and by the degree of collapse and its early occurrence. Cases have been adverted to, which, at least in the choleric stage, could not be discriminated from ordinary cholera, excepting perhaps from their taking place at a season of the year when ordinary cholera is never observed; but it may be remarked that no one would infer the existence of the epidemic from such cases, though he might be disposed to acknowledge that they belonged to it, if cases less equivocal were simultaneously prevalent, and especially if they originated under the circumstances mentioned in the preceding page.

Notice has been taken of sporadic cases which have occurred in several parts of the kingdom during the last year, and which have been reported in various publications. We have already stated our opinion as to the perfect identity of the group of symptoms in certain of these cases, and those which characterise the choleric stage of the epidemic. These cases have generally been fatal as cases of cholera, and probably on this account have attracted attention and been reported; and hence what we should consider the *experimentum crucis* by which their essential alliance to the epidemic, as it has manifested itself in this country, or difference from it can alone be proved,—the intervention, or otherwise, of fever between the cold stage and recovery,—is necessarily wanting. We have been favoured by a gentleman of high character and attainments (Dr. Fenwick, of Durham) with a report of two cases regarded, at the time they occurred, as aggravated cases of the ordinary disease; both took place in the interior, under circumstances in which there was not the slightest ground to expect contagion,

and previously to there being any suspicion of the existence of the epidemic in this country. In one, the symptoms bore, unquestionably, a considerable resemblance to the choleric stage of the epidemic, but no fever supervened. The symptoms of the other shall be given in the words of the writer.—“The total, or nearly total suspension of the secretion by the kidneys; the watery vomiting and stools; the severity of the spasms; the shrunk and corrugated state of the skin on the hands and feet, and the blueness of his nails, persuade me that his disease was of the spasmodic type. In him, moreover, a slow fever succeeded the original symptoms, and long retarded his recovery.” We need not remark that we would not attempt to discriminate between such a case as this and examples of the epidemic, believing their character to be identical. This case occurred in the beginning of July, 1831.

There is a certain form of the febrile stage, that which supervenes on a choleric stage, attended with extreme collapse, which the deficiency of the temperature and the circulation, the congested state of the conjunctiva from the very commencement of the fever, and the peculiar torpor of the intellect, would enable, as it appears to us, the observer to discriminate from any fever which we are in the habit of witnessing in this country, provided he saw the patient early and watched him throughout; but in the majority of instances the diagnosis can only be correctly drawn by coupling the preceding history of the case with the existence of fever, and with its character.

5. **Appearances on Dissection.**—The external appearance of the body closely resembles that which has been noticed during life: the solids are shrunk, the surface is livid, the skin of the hands and feet is corrugated, the nails are blue, and the fingers often rigidly contracted. There is no evidence of any unwonted tendency to putrefaction, nor any characteristic fetor from the abdominal cavity.

In the *head* are found marks of congestion, and even occasionally of extravasation. Such appearances were not of uniform occurrence in the dissections performed in Hindostan, but they were found very constantly in those made by Dr. Davy, in Ceylon; and Dr. Keir, of Moscow, discovered in the Russian disease the blood-vessels of the brain and its membranes more or less turgid with blood, particularly towards the base, with a fluid effused into its convolutions, and more or less of serum in the lateral ventricles.

In the *thorax*, the pleura and pericardium are found, as the serous membranes generally are in this disease, perfectly healthy, with the exception occasionally of an unusual dryness. The lungs are sometimes in a natural state, but more frequently gorged with dark-coloured blood, so as to resemble liver or spleen; or they have been found collapsed on each side of the spine, leaving the thorax nearly empty. This latter appearance Dr. Pollock, of the fifty-third regiment, explained by supposing gas to be extricated within the cavity of the pleura; but the thorax having been opened in such cases under water, and no air having been found, Mr. Scott is disposed to ascribe it to a contractile power exerted by the viscus, sufficient to overcome the atmospheric pressure. Both sides

of the heart are in general distended with dark blood, and the bronchi are frequently filled with mucus.

In the *abdomen*, the vessels of the liver are often much congested, and pour forth blood copiously when incisions are made into the organ; but this congestion is not uniformly found; the gall-bladder is turgid with black bile, and its ducts are sometimes constricted and impermeable, though occasionally in an opposite state. The peritoneum is often quite healthy, but the portion investing the alimentary canal has frequently an inflamed appearance from the exceedingly loaded state of the blood-vessels. This congestion is sometimes so great as to give the appearance of gangrene; but by drawing the finger over the surface, innumerable small veins may be found running in every direction, as in a preparation nicely injected, and the texture is found to be resisting and firm. This portion of the peritoneum, however, occasionally bears marks of actual inflammation, especially if the patient has lingered long before death. It then presents a thickened appearance externally, and its colour varies from a pale vermilion, through all the deeper shades, to a dark purplish hue; the former being chiefly remarkable on the surface of the duodenum and jejunum, the latter on the ileum where it terminates in the cæcum. At other times, the whole alimentary tube, instead of this congested state, presents a blanched appearance both internally and externally. The omentum is sometimes healthy; at others, it presents the same appearance of extreme vascularity as the peritoneal surface of the alimentary canal.

The following appearances are discovered on laying open the stomach and intestinal tube. A white, opaque, and viscid substance is found adhering to the surface of some portions of the mucous membrane; and in many cases it is so abundant in the intestines as completely to fill parts of them of a greater or less extent. The stomach and portions of the intestines are filled with a transparent or turbid serous fluid, and frequently the viscid matter mentioned above is found intimately mixed with the serous fluid, or floating in it in the form of flakes. The mucous membrane, except when inflamed, which it not unfrequently is, has an unnatural whiteness, is often soft and pulpy, and in general—especially in the stomach and small intestines—can be easily detached by scraping, in the form of a thick pulp, from the subjacent coat. These appearances are sometimes more or less partial; but some of them are generally found throughout the whole extent of the tube. They extend in some cases to the mucous membrane of the bladder and ureters, and have been found in two or three instances in that lining the bronchi.

In one case only in India was the state of the spinal marrow examined; and in that, strong indications of inflammation were detected in its sheath; the case, however, was in some degree a mixed one. But Dr. Keir found, at Moscow, the blood-vessels of the vertebral column and spinal chord more or less loaded with blood, which was sometimes effused between its arachnoid and dura mater; partial softening of the substance of the spinal chord was sometimes met with, and marks

of inflammatory congestion in the larger nerves were detected.*

The dissections performed in Sunderland have generally furnished results corresponding with those obtained elsewhere.

In the *head*, venous congestion of the brain and its membranes has been the most uniform and prominent appearance. Serum has been found in the ventricles of the brain and at its base; but in many cases this has been in small quantity, not exceeding that frequently observed after diseases in which no affection of the encephalon was supposed to exist. In some cases, especially those in which death took place in a protracted stage, but occasionally in a rapid disease, fibrinous depositions existed between the membranes.

In the *thorax* the lungs have uniformly been found more or less gorged with blood, though in many cases the engorgement was in the posterior part, and probably resulted from position. These organs were generally crepitating, and free from structural change. Softness or flabbiness of the heart has been noticed in several instances, and both its cavities and the venæ cavæ and coronary vein have been distended with dark-coloured blood.

In the *abdomen*, the liver has been found gorged, but occasionally its condition was natural. The gall-bladder was generally distended, and the ducts were constricted, so that the viscus could not be emptied by pressure; but in some cases they were pervious. The abdominal veins have been found generally distended; but in several instances, the vena portæ and meseraic veins have constituted an exception to this rule, having been found empty. Vascularity and pulpiness of the mucous lining of the stomach have been frequently noticed; but the former has often been slight in degree, and observers have felt disposed occasionally to attribute it to the exhibition of mustard or other stimulants; whilst the latter has by no means been invariably found. The lining of the intestines has been found in many parts vascular and pulpy; but these appearances are not invariable, both lesions having been found wanting, and the pulpiness more frequently than the vascularity. The peculiar secretion has generally been found in the intestines.

The kidneys have been observed to partake of the general congestion of the venous system. The bladder has generally been found contracted, and either empty or containing a small quantity of urine. In the case mentioned, which was attended with trismus and other peculiarities remarked in India, but not in other examples of the disease in Sunderland, it was considerably distended.

No softening or other disease of the spinal marrow, a little venous congestion excepted, was discovered in the few examinations of this organ made here.

In concluding this rather unsatisfactory portion

* Madras Reports, pp. 32, 34. *Anderson on Cholera Morbus*, Edinburgh Medical and Surgical Journal, vol. xv. *Christie on Cholera*, p. 47. *Annesley, Diseases of India*, 2d edit. p. 106, et seq. *Account of the Appearances after Death observed at Moscow*, drawn up by Dr. Keir.

of our subject, we cannot refrain from expressing a conviction that symptoms during life throw much more light on the nature of the disease and its appropriate treatment than appearances after death.

6. Nature of the Disease.—Many writers of great talent have preceded us in this very intricate branch of the subject, and much ingenuity has been displayed in the endeavour to trace all the phenomena of the choleric stage, which has been the principal subject of investigation, to a change in one part of the system. But it must be remarked that there is little accordance among medical reasoners as to the part of the body in which the phenomena of the disease are presumed to originate; for the nervous system generally, the ganglionic portion of it exclusively, the blood itself, and the lining of the digestive canal, have each found advocates equal in ability to plead their cause.*

The diversity of these views is a proof of the intricacy of the subject; and probably also, since they have all emanated from observing and ingenious men, an evidence of the variable nature of the disease; each reasoner being perhaps influenced by that portion of the general phenomena of the epidemic which predominated in the cases it was his lot most frequently to witness. Their partial nature, too, may be in a considerable degree ascribed to the unfortunate influence of the expression, *proximate cause*, as a substitute for the more comprehensive term, *essence* or *nature* of the disease, on medical reasoning. Even those who affect to use it as an equivalent term for *nature of the disease*, are yet insensibly influenced by the words they employ. Amidst the crowd of phenomena presented to their notice in certain maladies, they often assume, on very insufficient grounds, that some one fact is the original of all others, and this they invest with the title of *proximate cause*.

If the facts related respecting epidemic choleric fever are compared with the explanations offered of them, it will be found that each medical reasoner has attributed the commencement of the phenomena of the disease to an affection of some part of the frame, which affection unquestionably exists in a very great number of instances, but neither with that uniformity nor with that priority of time which can warrant us in concluding that it was the cause of all the other symptoms. It seems a rational supposition that the remote cause of a disease may act, in some instances, first on one, in others on another part of the system, from some local weakness or peculiarity of individual constitution, or from some speciality in the mode of application of the cause; and yet that the disease shall retain in each case such a resemblance to a common type as shall prove its identity. It is likewise supposable that the remote cause may make a simultaneous attack on more than one organ or part of the system. Complex diseases, such as fever, appear to furnish examples of both these cases. The real philosophy of medicine seems to consist in ascertaining the actual state

of the system of which symptoms are the signs; and if we can proceed through the medium of these signs and post-mortem appearances, to one sole change in one organ, the treatment is simplified, and science and art are gainers. But there are diseases, and this seems to be one of them, in which we meet with a variety and complexity of pathological conditions, all of importance, and all to be kept in view in their treatment. It is true that of these conditions some may arise from others according to known physiological laws, as dark-coloured blood from impeded respiration, and it is right thus to explain them when possible; but the uniform endeavour to trace all to one primary change, or rather, as is more frequently done, to assume one change to be primary, and all other morbid states to be but emanations from it, is not only unphilosophical, but is too apt to tinge our practice with undue partiality.

Whilst we deem that no one writer has attained, either by inferences drawn from symptoms, appearances after death, or both, a knowledge of the affection of any one organ in cholera which can be properly termed a proximate cause whence all the other phenomena arise; or acquired precise ideas respecting the nature of the affection of many organs which manifestly participate in the disorder; it is gratifying to acknowledge that their labours have thrown much light on the condition of many parts, and that very great practical good has resulted from the information thus obtained.

That the nervous system generally, and especially the ganglionic and spinal nerves, and the spinal medulla itself, are affected, is manifest from many symptoms; but whether this affection arises from a direct impression of the remote cause of the disease on these organs, or from irritation propagated from the alimentary canal along the ganglionic nerves to the spine, we are ignorant. Dr. Kier's able researches have shown that in some fatal cases inflammation of a portion of this system has existed; but its precise pathological condition in cases which terminate favourably remains yet to be ascertained; and it must be remarked, too, that in fatal cases this inflammation has not been always detected. The state of the sanguiferous system is very remarkable: but here too we must feel some doubt whether the feebleness or almost complete arrest of the heart's action is a primary effect of the cause of the disease, or, as suggested by Mr. Bell, arises from the affection of the ganglionic system; or, again, whether it results, through the medium of this system, from the condition of the alimentary canal. Is the dark appearance of the blood to be explained by the feebleness of the action of the right ventricle, as a consequence of which but little blood is transmitted through the lungs and exposed to the influence of the air? According to this view, which is suggested with diffidence, the imperfection of the respiratory process will arise from the same cause as in congenital malformation of the heart, such as the persistence after birth of the foramen ovale, or the aorta arising from both ventricles, in which a very small proportion of the whole mass of blood is oxydized. This hypothesis explains readily the dark appearance of the blood, its accumulation in the great veins of the viscera, the coldness and lividity of the skin, and the imper-

* These are Dr. Kennedy and Mr. Orton for the first, Mr. Bell for the second, Mr. Annesley and others for the third, and Mr. Christie, with Roche and other French writers for the last.

fection of the respiratory process, which has been so ably illustrated by Dr. Davy. This gentleman was the first to show that the air expired by patients in the choleric stage is colder and contains less than the usual proportion of carbonic acid; and that this is the case even when the breathing is full, free, and rapid. The explanation offered is confirmed by an observation of Mr. Ellis, in his experiments on respiration, that "as the circulation declined, so likewise did the emission of carbon, and, consequently, the production of carbonic acid." The thickened consistence of the blood receives a ready explanation from the loss of its serous part by the abundant discharge from the inner intestinal surface.

There are two morbid conditions of the lining of the digestive canal. In one it is in a state of manifest inflammation: in the other it is white and pulpy, and easily detached from the subjacent coat. Is this latter condition the result of a disorganizing inflammation which has itself passed away, or must we be content to describe the action which has produced it by the very unsatisfactory and vague expression, disturbance of the function of nutrition? This is a question rather of general pathology than one connected solely with this disease; but it is one as yet undecided. The affection of the alimentary canal is essential and primary, if any part of the disease is so; and it were vain to attempt to trace it to a morbid condition of any other organ or system of organs.

[The German and French physicians have paid considerable attention to an eruption of isolated granular pimples, chiefly met with in the two lower thirds of the ileum, which is said to exist in the vast majority of cases. Owing to this eruption, MM. Serres and Nonat gave the disease the name *psorocenteria*. (Art. *Cholera*, par A. Nonat, in *Dict. des Études Médicales*, tom. iii. p. 416; Paris, 1839.)

Examination of the blood of a choleric patient by M. Andral. (*Hématologie Pathologique*, Paris, 1843.) showed that there was no augmentation of the fibrinous element, as is observed in severe phlegmasiæ of the digestive tube. The proportion of fibrin was 3·3; of globules 118; and of solid matter of the serum 88.]

The general suspension of secretion, which is complete only when the collapse is extreme, appears to result from the disorder of those systems, the nervous and vascular, on which this important function depends. The apparent anomaly presented by the continuance of the cutaneous and intestinal discharges amidst the general suspension of secretion, is well explained by Mr. Bell's distinction between this function and exudation or exhalation. (*Treatise on Cholera Asphyxia*, p. 56, 57.)

Were we to endeavour to illustrate in a few words the nature of cholera by examples drawn from analogous diseases, we should say that its choleric stage presented in a more intense degree the initiatory collapsed symptoms of certain bad fevers before re-action had taken place, combined with excessive gastro-intestinal irritation; whilst the febrile stage bore a very close resemblance to such fevers after the establishment of re-action, or in many cases was, at least in external character, perfectly identical with them.

That the whole series of phenomena results from the action of a morbid poison on the body, there can be no doubt; but as yet, as in the case of other fevers, we are ignorant of the precise nature of the primary change effected by it in various organs or systems; and it is to be feared that till more accurate ideas are attained respecting the pathology of fever in general, this ignorance will remain. In the febrile stage, we would remark, there are indications by no means equivocal, of inflammatory affection of the brain, and occasionally of other organs, the analogy to fevers in general being in this respect preserved. Were we to judge solely from what we have ourselves observed of the commencement of the disease, we should consider the alimentary canal to be the part of the frame which first felt the influence of the poison; but we should consider the condition of the nervous and vascular systems much too intense in degree to be merely sympathetic of the state of the stomach and bowels. Many cases, moreover, which have been reported from abroad, particularly from India, lead to the opinion, that in various instances the nervous system is primarily affected.

5. Proportionate Mortality.—The mortality during the early prevalence of the epidemic in India in 1817 and 1818 was very great, but either from the abatement of the intensity of the disease, or from the improvement of the method of treatment adopted by our medical men, or, as is more probable, from the co-operation of both these circumstances, it was subsequently very much reduced. There is no disease in which unassisted nature seems more powerless than this. We learn from the report to the Medical Board at Bombay, that there is reason to believe that of 1,294 cases which received no medical assistance, every individual perished; and it is added, that it is not ascertained that any case has recovered in which medicine had not been administered. From this appalling statement, it is gratifying to humanity to turn to the following records. According to the documents collected by the Madras Medical Board, the number of deaths caused by it in the army of that presidency during 1818 and the four subsequent years, was 4,430, of which 695 occurred among the European troops, and 3,735 among the sepoys. The number attacked was 19,494, namely, 3,664 Europeans and 15,830 natives. The average strength of the army during the period included in the reports being 10,112 Europeans and 73,254 natives, it follows that in five years 23½ per cent. of the troops were attacked, and that of these 22¼ per cent. were carried off, or 5½ per cent. of the whole force of the army. This statement, though sufficiently distressing, is still a proud monument to the skill of the medical men employed, and to medical science in general.

We hear, in different situations, of rates of mortality infinitely lower than this. Dr. Burrell, surgeon of the 65th regiment, reports, for instance, from Seroor, that out of sixty cases he lost four, being at the rate 6·6 per cent.; whilst Mr. Crow, at the same station, makes the mortality much less, declaring that the disease is not fatal in more than one in a hundred of those who are early succoured. Dr. Burrell found, too, that of a cer-

tain description of cases, those attended with violent spasms, he saved eighty-eight out of ninety. (Bombay Reports, p. 68, &c.) In taking these estimates into consideration, we must always recollect, however, that in epidemics there is often a very wide difference in the gravity of the disease at different points or in different years,—indeed, sometimes at nearly the same point and in the same year; so that when we hear of an extremely small loss in proportion to the number attacked, long experience does not permit us to doubt that in such a case the type of the disease has been very mild.

The ravages of the disease in civil life, amid a comparatively unorganized population, where prompt assistance could not always be rendered to the sufferers, furnish a considerable contrast to this statement from the British army, and strongly confirm the opinion expressed, of the importance of early treatment in a malady so rapid in its course, and in which the efforts of nature are so impotent.

At Busheer, in the Persian Gulf, we learn from Moreau de Jonnés, that in 1821 a sixth part of the inhabitants perished; and at Bassora, in the same year, Mr. Rich informs us that eighteen thousand died, of whom fourteen thousand perished within a fortnight. The number attacked in Moscow from September 1830 to January of the following year, was 8,130, of which perished 4,385, or 54 per cent.* In the small town of Redischef, of eight hundred sick, we learn from Dr. Reimann, that seven hundred died in one week. The greatest success which has attended the treatment of the disease in the Russian empire, so far as the records have reached us, occurred in the district of Orenburg, the number attacked being 3,590, of whom 865 perished, or about 24 $\frac{1}{10}$ per cent., a result creditable to the vigilance of the Russian government, and to the skill and care of the medical men employed. The treatment adopted was that of our Indian practitioners; bleeding, calomel, opium, warmth, and friction.†

The disease having, there is every reason to think, run its course through the town in which these observations were written, it may not be uninteresting to mark the amount of ravage which it has inflicted.

The town comprised under the general name of Sunderland consists of three parishes, viz.

	Inhabitants.
That of Sunderland, containing....	17,060
Bishopwearmouth.....	14,825
Monkwearmouth and its immediate dependencies, in all which the disease existed.....	8,850
Total.....	40,735

This computation is exclusive of certain out-townships, to which the disease did not extend.

The total number attacked with epidemic choleric fever out of this population from its manifest appearance on the 26th of October to its cessation in the middle of January, was 534, of whom 202

perished. These deaths are computed, with all the accuracy which the parish registers and other sources of information permit, to have occurred in the following proportions:—

In Sunderland.....	156
In Bishopwearmouth.....	21
In Monkwearmouth.....	25
Total.....	202

From this statement it is manifest that, if the disease pursue the same course elsewhere that it has done in Sunderland, the danger to a population is to be estimated less from their numbers than from various circumstances in their condition, and particularly from the proportion which the labouring class bears to the rest of the community; for the parish of Sunderland, in which the mortality was in so much higher a ratio to the population than in the other parts of the town, is that in which the proportion of the labouring poor is greatest; though their situation is by no means so comparatively wretched as persons unacquainted with the habits of the labouring class in general, (and especially of that portion of it dwelling in sea-port towns,) and consequently destitute of the means of accurate comparison, have taken pains to describe. Besides the smaller number of the labouring class residing in Bishopwearmouth, there are various circumstances, such as its situation being higher, its streets wider and better ventilated, &c. which probably contributed to its proportionate exemption from the disease. Of the small number of its population who suffered, it must be remarked, moreover, that a large proportion lived in an inconsiderable part of the parish, at its outskirts near the river, called Ayre's Quay, inhabited almost exclusively by the labouring class. In this small locality nine out of the twenty-one deaths occurred. It should be observed, too, that in Monkwearmouth, situated on the north bank of the Wear, the disease was confined almost exclusively to the lowest, dirtiest, and most populous district, situated near the river, called *the shore*.

It is a fact of some importance that of the victims of the disease, seven only, so far as we have been able to discover, were, in point of situation in life, at all above the labouring class.

A simple calculation shows that the mortality amounted to one in two hundred and one and a fraction of the whole population in which the disease prevailed; that of Sunderland was as one to about a hundred and fifteen of its population; that of Bishopwearmouth as one to seven hundred and six, and exclusive of Ayre's Quay, as one to somewhat more than one thousand; and that of Monkwearmouth as one to three hundred and fifty-four.

There is nothing very alarming in such a rate of mortality as we have described; it is high on the number attacked, but low on the amount of population: and the former circumstance and the rapidity of the disease will probably be found to constitute its most appalling features, if its course elsewhere in this country resemble that observed here. Other epidemics which visit us exceed it, whether we regard the number or the quality of victims, in the amount of evil inflicted; but none is to be compared with it in fatality in proportion

* Memoir of Dr. Loder, physician to the Emperor at St. Petersburg, dated January 1831, and read at the Academy of Medicine at Paris.

† Substance of a report published by the Supreme Medical Board of Russia.

to the number attacked, or in the rapidity with which it accomplishes the work of destruction.

Our friend Dr. Ogden has furnished us with the following calculation, which is interesting provided the results of similar calculations made elsewhere in this island correspond with it; for it will thus be shown that in one point of some importance, the proportion of the sexes attacked, the disease here observes a course directly the reverse of that witnessed elsewhere in its progress.

Cases of cholera, known to be such, buried at Sunderland between the 28th of October and 23d of December:—

AGE.	MALES.	FEMALES.	TOTAL.
15 and under	12	13	25
From 15 to 50	14	33	47
Above 50	37	36	73
	<u>63</u>	<u>82</u>	<u>145</u>

Besides showing that at the period of middle life the number of female victims of the disease is double that of males, and that at the two extremes the numbers are as nearly equal as possible, this table shows how large a proportion of aged persons the whole amount of mortality comprises, these constituting more than one-half of the total of deaths.

The preponderance of attacks in females over

those in males at the period of middle life is probably to be explained partly in the manner suggested by Dr. Ogden, that the dress of the latter sex furnishes a better security against cold than that of the former; and in part by the circumstance that males at the working period of life are better nourished than females, being frequently the only members of families of their class of society who partake of animal food.

For obvious reasons, we abstain from any statistical details connected with neighbouring towns in which the disease is, at the time this is writing, only in progress.

[From some estimates made in England by Sir David Barry, it would appear that 38.5 per cent. of the cholera patients died. In 1832, probably 5000 perished in London, and in Great Britain somewhat more than 20,000. In Paris, during the epidemic of 1832, more than 18,000 fatal cases are said to have occurred. In the Russian provinces, the mortality was 58.6 per cent. In Naples, it was estimated at six to ten. In Palermo, it was dreadful. Of a population of 150,000, about 30,000 of whom, it was supposed, left the town at the breaking out of the complaint, 25,000 died, or about a fifth part of those who remained. In some of the towns of the United States, the mortality was taken as accurately as was practicable. It is thus stated by Professor Jackson, of Philadelphia:

Places.	Population.	Cases.	Deaths.	Ratio of cases to population.	Ratio of deaths to cases.	Ratio of deaths to population.
Quebec,	32,000	5783	3292	1 in 5+	1 in 2.5	1 in 10.5
Montreal,	28,000	4285	1853	1 in 6.5	1 in 2.5	1 in 15+
New York,	240,000	5547	2782	1 in 25.3	1 in 2	1 in 15.5
Philadelphia,	160,000	2314	935	1 in 70	1 in 2.5	1 in 173.2

From the epidemic at Paris, attempts have been made to calculate the probability of death and recovery in Asiatic cholera. From these it would appear, that the daily rate of mortality, in the first 12 hours, was 16 per cent.; in the next 12 hours, (12-24,) 37 per cent.; in the 2d day, 11 per cent.; in the 3d day, 8 per cent. The mortality of cases of cholera, in Paris, was 49 per cent. The force of mortality attained its maximum in cholera by the 21st hour, (18-24 hours;) the maximum intensity of smallpox being attained in days 10-15; of phthisis, in 6-9 months. The danger of cholera decreases as the time advances: the longer a cholera patient lives, the more likely is he to continue to live. Half the deaths happen in 24 hours.

The following table by Mr. W. Farr shows the probability of recovery from the severer attacks of cholera at the end of 12 hours, and of one, two, and three days:

Cases.	To recr.	To die.	Probability of recy.
0 hours, 10,000	5093	4907	.509 nearly 1 to 1
12 " 9185	5093	4088	.555 — 1.3 to 1
1 day, 7616	5093	2523	.669 — 2 to 1
2 " 6793	5093	1700	.750 — 3 to 1
3 " 6091	5093	1198	.839 — 4 to 1*

6. Extent of Diffusion, and Causes.—On the first branch of this subject we cannot be wrong, so frequently have its details been presented to the public, in assuming considerable

knowledge on the part of our readers; or in referring those who may wish for more minute information than is ordinarily possessed or than we have space to give, to the admirable chronological table of M. Moreau de Jonnés. The present epidemic originated in the district of Nuddea, and perhaps in some other parts of the Delta of the Ganges, about the end of May or the beginning of June, 1817. It did not during that year extend beyond the territory of Lower Bengal; but in 1818 and the early part of 1819 it diffused itself throughout the extreme length and breadth of the Indian peninsula, moving in lines more or less diverging, and attacking in succession places generally more remote from the seat of its origin, (though striking deviations from this rule were occasionally observed,) and situated in various directions from it; but leaving untouched many districts placed between its lines of movement. Its progress along the lines it selected was wonderfully uniform, being for some successive months at the rate of about one degree in a month. As early as 1818 it extended itself beyond the boundaries of Hindostan into the Burmese empire and other territories of Eastern Asia, and, making gradual progress through these extensive realms, reached China in 1820, and in the following year visited the numerous and populous islands situated in the Indian Archipelago. The Isle of France suffered its invasion in 1819, and some

* [Practice of Medicine, i. 143.]

cases occurred in the same year at one point in Bourbon, in which island it has not since appeared. In 1821 it extended along the shores of the Persian Gulf, and during this and the following year spread through parts of Arabia, Persia, Mesopotamia, Syria, and Judea, and closely threatened Europe. It appeared in the Russian territories in 1823, at Saillon, Ghillan, Orenburg, and Astracan; but its further northern and western progress was for a time arrested. It, however, re-appeared in Orenburg in 1828, and again in 1829, and in 1830 advanced through the southern provinces of the Russian empire, till it reached Moscow on the 28th of September of that year. Its subsequent progress through Russia, Poland, the Austrian dominions, the north of Germany, and in England, is too familiarly known to render it needless that we should present its details to the reader.

The space traversed as yet by this extraordinary epidemic may be conceived from the following simple calculation. The Philippine islands form (so far as is known) the eastern, and Mauritius the southern, boundary of the disease. The former lie in east longitude 125° , and the latter is in south latitude 20° . Archangel is the most northern, and the vicinity of Edinburgh the most western point to which it has extended. The former is in north latitude 64° , the latter in west longitude 3° . Hence it is manifest that the disease has passed over 128° of longitude and 84° of latitude.

[On the 26th of October, according to the above account, it first appeared in Sunderland; in January 1832, it was in Edinburgh; and on the 10th of February, in London. Its progress in every town in the British islands visited by it has been accurately traced by Professor Graves, of Dublin, (*Dublin Journal of Medical Science*, January, 1840; reprinted in the *American Medical Library*, vol. iii.: Philadelphia, 1840.) It is singular that there, as elsewhere, it left a number of places untouched, and others were but slightly affected.

Cholera first appeared in Paris in March, 1832, and, with great rapidity, various parts of France were attacked. From England the disease soon passed to Ireland, and appeared in Dublin in March, 1832. On the 8th of June, 1832, it was first seen on this side of the Atlantic in Quebec; and on the 10th it appeared at Montreal. On the 21st of June, it suddenly and unexpectedly appeared in New York,—all the intermediate cities on the seaboard of the provinces of New Brunswick and Nova Scotia, and of the States of Maine, Massachusetts, and Rhode Island, remaining wholly exempt. On Thursday, July 5, the first decided case manifested itself in Philadelphia. This city suffered much less than Montreal, Quebec, and New York. The disease spread in various directions, visiting Albany, Troy, New Brunswick, and Rochester, in July; Baltimore, Washington, and Boston, in August. During the same months, it was prevalent in several parts of New Jersey and Delaware. About the 1st of October it suddenly broke out at Cincinnati, and nearly simultaneously at Madison, Louisville, and St. Louis; and by the latter end of the month, it reached New Orleans. Leaving the Ohio, it

visited Tennessee, Illinois, Indiana and Kentucky, —Lexington, Maysville, and some other towns, suffering severely. During the same year, the disease visited Campeche, where it was exceedingly fatal,—4000, out of a population of 20,000, falling victims to it. It also visited the Havana early in 1833, but never reached any other West India island; nor did it extend to Guiana, Demerara, or any of the embouchures of the great South American rivers, Amazon, Orinoco, or La Plata. In 1834, it revisited many of the cities of this country, which had previously suffered, and spread to others that had been left untouched; yet singular cases of entire immunity were met with. Two of these may be mentioned as examples. Fredericksburg on the Rappahannock, and on the great road from Washington to the South, may be said to have escaped almost wholly; and whilst the disease was prevailing at Richmond, and the inhabitants of Charlottesville, and of the University of Virginia, in its vicinity, were daily expecting a visitation, not a case occurred, although travellers daily arrived from the afflicted city in the public stage. Philadelphia and Baltimore both suffered again, but not severely, in 1834. Charleston also was visited, with most of the southern towns. The disease recurred, indeed, at intervals, for a year or two, but ultimately disappeared, not to return, unless the same endemic-epidemic influences should exist, which favoured its progression previously. In like manner it occurred at Marseilles and Toulon in 1835; at Naples in 1836; and at Bona in 1837. Marseilles was attacked, for the third time, in the same year, and it re-appeared in the autumn at Berlin, Prague, and Danzig. The number of persons attacked in the Lombardo-Venetian States, in 1836, was estimated at 100,000, of whom 55,000 died. In the latter part of 1837, the inhabitants of the British metropolis were alarmed by the appearance of cases at Limehouse, which were pronounced by some to be genuine Asiatic cholera; but, by others, to be emanations from “alarmist cholera-hunters.” The disease, if it existed, never certainly became epidemic. (See the writer’s *Practice of Medicine*, 2d edit. i. 132: Philad. 1844.)]

The questions naturally occur, what agent first generated the disease? and what has subsequently diffused it over so large a portion of the globe?

The first question must be answered by a simple statement of the facts, that it originated in the district mentioned after an unusual disturbance of the seasons with respect to alternations of heat and moisture; that it made its appearance at the commencement of a rainy season, so excessive that the Gangetic Delta was converted into a sheet of water; and that the very first point in which it was observed was the district of Nuddea, noted for the endemic prevalence of cholera, where the whole year had been rainy, and during every week of April and May (it began to manifest itself in the latter month) there had been a succession of thunder-storms. From this district it appeared to diffuse itself over the rest of Hindostan, its progress throughout the country being accompanied, as Mr. Orton informs us, by circumstances somewhat similar to those which attended its origin.

The second part of the question cannot be dismissed so lightly. As is well known, the doubt and difficulty regarding the subject exist chiefly with respect to the share which *contagion* has had in its diffusion; and this question we shall endeavour to discuss as succinctly, and certainly as dispassionately and fairly as possible. That our opinion, in the course of the investigation, has fluctuated, we feel it no discredit to avow. This fluctuation was either prior to the appearance of the disease in this country, or to our having it a sufficient length of time under observation to enable us to attain a settled conclusion; and when we show the conflicting nature of the evidence from which, under the circumstances mentioned, a conclusion was to be drawn, it will be manifest that fluctuation or total scepticism must have been its result. As this evidence consists of facts already before the public, we shall, for the sake of brevity, rather refer to than detail them, classing them, as nearly as their nature admits, according to the very precise rules laid down by Dr. Alison for discriminating the operation of contagion.

1. Strong evidence of a disease being contagious is furnished by its appearance in communities previously healthy shortly after the arrival of persons from infected districts, who are themselves suffering under the disease, or who sicken of it soon after their arrival. A striking example of this sort is related in the Madras Report of the appearance of the disease at Jaulnah, after the arrival of a detachment there from Nagpore, then infected, and its subsequent diffusion from the former place to the towns of Malligaum and Hydrabad, and various villages.

Other cases, though few so striking as this, might be selected from the Indian records, but we prefer referring to examples which occurred in the Russian epidemic. In the fortress of Razüpna, in that of Iletsk, and, towards the close of the epidemic, at Caramala-Gubeerra, all in the government of Orenburg, the invasion of the epidemic coincided, in point of time, with the arrival in them and sickening of persons coming from infected places. It should be remarked, however, that in these cases communication was not always traced between the individuals subsequently and those first attacked; and in the case at Razüpna, it is distinctly mentioned, that of the individuals who visited the man first seized on his arrival from Orenburg, then infected, not one took the disorder.*

Into the opposite scale, that of the non-contagionists, may be thrown facts which tend to prove that it has originated in districts previously healthy without any ascertained communication with infected persons, and that, on the other hand, the most ample intercourse has existed on various occasions between healthy and infected communities without the former having participated in the disease. Its introduction into the city of Orenburg in 1829 was not only not traced to communication from an infected district, but a conjecture that it might have been introduced either by the

caravan which arrives from central Asia at midsummer, or by the Kirghis, a semi-barbarous Tartar horde, from whom the government of Orenburg is separated by the river Oural, was, if not disproved, rendered in the highest degree improbable.†

“When the disease attacked the sixth regiment at Colabath in July, 1828,” says Mr. Assistant-Surgeon Spence, of the 52d regiment, “its commencement was a remarkable proof against its contagious nature. It was in the midst of the rainy season, and not a case had been seen for months either in or near Bombay, when Assistant-Surgeon Campbell, in paying his evening visit to the hospital, found an old soldier, who had been under treatment some time for hepatic affection, suddenly seized with cholera. He went to the opposite extremity of the building for the purpose of consulting with the surgeon, and found him busily employed with another man, who had been almost simultaneously affected. Now it is physically impossible that these two individuals could have received the disease by contagion, because that which does not exist cannot have issue.” The disease proceeded with unabated violence till it destroyed sixty men and several women. (Taken from Mr. Spence’s MS.; since published in the Medical Gazette.)

The following example of personal intercourse between the healthy and infected without communication of the disease, is taken from Mr. Annesley’s Sketch of the Diseases of India. Cholera attacked the field force stationed at Shalligaum in Kandiesh, and raged with great violence among the corps posted on the left of the line, while the 17th battalion of native infantry, who were posted on the right of the line, were exempt from it, though they had constant communication with the other men.

2. The gradual diffusion of a disease through a limited community, those near the sick being first attacked, and others in succession in proportion to their proximity, is strong evidence of a disease being contagious. But this evidence has rarely been furnished by cholera; the general statement from India, indeed, is of a totally opposite nature; for we learn that, on its appearance in any place, numbers are simultaneously attacked, and that, after committing unheard-of ravages for a short period, its cessation is as sudden as its invasion. One example, however, resembling in some degree this gradual diffusion, is given in the Russian reports, and this is furnished by the staff-physician, Dr. Schimanski, with regard to the extension of the disease at Iletsk. He says he was able to trace the progress of the disease in the first eight cases, thus:—The husband of the woman, (a soldier’s wife,) from Orenburg, was taken ill three days after her; and about the same time, also, two girls who lived in the immediate neighbourhood of the soldier, and who visited him soon after his arrival from Orenburg: the aunt of these girls, who nursed him, was next attacked; and from her it passed to her own two sons. (Edinburgh Medical and Surgical Journal, No. cviii. p. 130.)

3. There is no circumstance connected with the disease on which the information received from

* On the Asiatic cholera as it appeared in Russia in the years 1829 and 1830, by Dr. J. R. Liechtenstadt. (Translated in the Edinburgh Medical and Surgical Journal, No. cviii.)

† Ibid.

different quarters is more contradictory than the comparative liability to it of attendants on the sick and other members of the community. From India the testimony on this head is so conflicting that no conclusion can possibly be drawn from it: a state of complete scepticism is that in which it leaves the mind of an honest inquirer after truth. That from Russia is not of a much more decisive character; such as it is, we shall present it to the reader.

During two months, observes Professor Lichtenstadt, while the disease prevailed at Orenburg, and two hundred and ninety-nine patients were admitted with cholera into the military hospital, the personal attendants on the sick remained entirely exempt from the disease. They consisted of one hospital assistant, six pupils, as many Baschkir lads, and fourteen hospital servants, in all, twenty-seven; and their duties were to perform bloodlettings, apply leeches, poultices, and frictions, and administer baths and the like, so that they were compelled to be constantly breathing the exhalations from the bodies and clothes of the sick, as well as to touch and handle them. The washerwomen of the hospital likewise escaped; a class of individuals, who, it is well known, are extremely apt to suffer from contagious diseases.

On the other hand, Drs. Russell and Barry inform us, "that the number of medical men and hospital attendants attacked with cholera during the present epidemic, in proportion to the whole employed, and to the other classes of society, has been beyond all comparison greater here (St. Petersburg) than in India under similar circumstances; twenty-five medical men have been already seized, and nine have died out of two hundred and sixty-four. Four others have died at Cronstadt, out of a very small number residing in that fortress at the time the disease broke out there. Six attendants have been taken ill at a small temporary hospital behind the Aboucoff." With regard to this last circumstance, it is not stated, as in another report by the same gentlemen (not published) bearing date 4-16 July, that "in the great Aboucoff hospital, where there were no cholera patients, but to which a temporary cholera hospital was attached behind the building, ten persons residing within the area of the establishment had been severely attacked up to the 12th instant (N. S.) with cholera." This leaves a very different impression, and not being aware of what is meant by "the area of the establishment," we cannot form an opinion how it may or may not bear towards the side of contagion. In the last-mentioned report, those gentlemen also state, that in the Military General Hospital, in which four hundred cholera patients had been admitted from distant quarters, up to the morning of the 13th, "one attendant had been attacked." But one attendant where so many cases had been treated!

These specimens, taken from an immense mass of foreign evidence, will suffice to show its conflicting nature on points essential to the decision of a much litigated and very important question. There are certain branches of the subject, such as the immunity apparently afforded by seclusion, which we have designedly omitted; partly be-

cause they were unavoidably exposed to sources of fallacy, and the testimony regarding them was of the same conflicting nature as the specimens which we have already presented to the reader; and partly that we might preserve space for an examination of the question, how far the general progress of the disease favours the opinion that human intercourse has been the instrument of its diffusion; and for the narration of certain facts illustrative of the general question which have fallen under our observation.

The progress of the disease on the great scale having been tolerably regular both geographically and chronologically, — that is, its having passed from country to country without leaving inter-jacent countries untouched, and those infected having been so in some proportion, in point of time, to their distance from its original source, — has been appealed to by two parties as evidence of the accuracy of their opinions; the one seeing in it a proof of a continuous stream of epidemic influence flowing from the point where the disease originated; the other a transport of the malady by human intercourse from the same source. To the opinion of a flow of epidemic influence, have been objected, and apparently with justice, the slowness of the progress of the disease; that it has extended its territory in spite of the opposition of continued and violent monsoons; and that, notwithstanding a degree of general regularity of progress, there have been anomalies observed in its course, such as its having left districts untouched whilst all around them were suffering, utterly irreconcilable with the opinion advanced. On the other hand, circumstances have been observed, which render it almost equally questionable whether contagion has been the sole instrument of its diffusion.

It has been asserted by the advocates of the exclusive operation of this principle, that the disease has always been found to move in the line of human intercourse, and it must be acknowledged that, whilst so migratory an animal as man inhabits the earth, it cannot well do otherwise; but if it is meant to be asserted that its diffusion has been in proportion to the intercourse between infected and healthy districts, the assertion is by no means supported by facts. Its appearance at Madras, for instance, whither according to this doctrine it ought to have been conveyed almost three months earlier by trading vessels from the infected districts, was simultaneous, as Mr. Bell informs us, with its origin in parallel latitudes in the interior. It did not reach Ceylon, to which, on the contagious principle, it ought to have been conveyed at a much earlier period, by shipping from infected points of the coast, until it had previously gained the nearest point to it on the continent, about Adam's Bridge, and had been long prevailing on both coasts of the peninsula. (*Orton on Cholera*, 2d edit. p. 332.) Unfrequented villages have been observed to suffer the invasion of the disease as early as the marts of intercourse and commerce; thus, from a statement of Mr. Orton, it seems to have reached some villages on the north bank of the Cavery, — detached from any frequented road, and considerably to the eastward of Trichinopoly, — quite as soon as this large and frequented town, whither it appeared

to have been imported by a company of sepoys. (Ibid. p. 331.)

Its movement along *navigable* rivers has been dwelt upon as evidence that human intercourse has been the means of its diffusion; and it is an argument of some force in showing that such intercourse may have occasionally been instrumental in effecting it: but when we are informed by Mr. Orton that the disease manifested this predilection for the course of rivers in the peninsula of Hindostan, "where navigation is scarcely carried on, even to the most trifling extent, on any river, and scarcely an instance can be mentioned of a great road running on the bank of a river, for they almost all cross them," we must acknowledge that more weight has been attached to the argument than it is calculated to bear.

The disease, in its general course, has manifested a preference for one line of movement, and has rejected another, though there has been no striking difference in the amount of human intercourse between the two directions to explain the preference and rejection. Its progress in a north-western direction across the European continent has been briefly described, and is fully known to the reader. For three years it prevailed in the Ottoman territories bordering on the Levant; and it would appear, without any deficiency in the productive (or at least destructive) force of those germs of which we have recently heard so much; for in November, 1822, it numbered 4000 victims in eighteen days in Aleppo; yet it has not penetrated into Turkey in Europe, and other extensive realms on the shores of the Mediterranean. Assuredly this could not arise from want of means of transport, and few will be disposed to ascribe it to the perfection of the quarantine department of the Sublime Porte. Since its appearance in this country a similar predilection has been displayed; for we find it at this instant a hundred and forty miles to the north-west of Sunderland, whilst six miles south is the extreme distance to which it has reached in that direction; and from the point which it attained, Seaham Harbour, after attacking eight persons and destroying three, it has since vanished.

A circumstance which may be urged against the exclusive operation of contagion, (and it is against attributing too much to one principle alone that we are arguing,) is the unusual prevalence of disease, bearing a considerable relation to epidemic choleric fever, which generally occurs prior to the appearance of this in any given locality. The facts which might be mustered in proof of the antecedence of such disease are far too numerous and consistent to be accidental. Ordinary cholera, sporadic cases not distinguishable from the epidemic, excepting by the isolated manner in which they occur; epidemic diarrhoea; gastric and intestinal fever, have been observed in so many situations and by so many individuals, from 1817 to the present instant, to have been the precursors of the disease, that there cannot be a reasonable doubt of the accuracy of the observation. During the last year the prevalence of these affections in various parts of this country has been matter of familiar remark among medical men, and many of them have very properly taken care to record their observation. (See *Dr. Burne's*

Dispensary Reports, in the Medical Gazette for July 2d, and July 16, 1831.) In this neighbourhood, what Mr. Orton felicitously terms the skirts of the approaching shower were manifest long before the epidemic made its formal inroad. Ordinary cholera was most unusually prevalent; whilst cases of disease, certainly not distinguishable by symptoms from the epidemic, occurred on the 5th, 8th, 14th, and 27th of August; and cholera continued to be very prevalent and severe throughout September. The cases which occurred in August were not matters of secrecy, but were the subject of conversation among the medical men of the place; and the writer frequently made the remark, that we were partakers of an inferior degree of the epidemic influence which existed on the continent. But certainly at the time he did not (nor does he yet) ascribe them to imported contagion; nor did he then conceive that we had, properly speaking, the epidemic among us. Whatever view others may now feel disposed to take of these cases, it would be difficult for them to suppose that the case we have mentioned, as having occurred in the interior in the beginning of July, was attributable to foreign importation.

Under either view, as it appears, whether we conceive that a current of contagion flows towards a district, or suppose the disease to be engendered there by indigenous causes, (not customary ones certainly, any more than those which existed in the Delta of the Ganges in 1817), and then to be invested with some contagious property, which observation of the disease will induce most candid persons to admit it possesses, it requires the operation of two principles to explain all the facts of the case; for even on the first supposition we are compelled to imagine this double operation to be in progress,—a current of contagion to be flowing from one point, and a *nidus* for its reception to be preparing in another.

We have been led to the conclusion that the disease possesses a contagious property, from having observed that a considerable proportion of attacks have taken place in individuals shortly after communication with the sick, or exposure to emanations from the dead bodies, and, in part, from a few examples having occurred of the disease appearing in parts of the town or neighbourhood where it did not previously exist, on the sickening there of persons who had communicated with the infected districts; but at the same time we beg to remark that there are circumstances which tend to show that this property is abstractedly feeble in degree, and to render it more than questionable whether it can be the sole agent in diffusing the disease.

This opinion is founded on the singular anomalies observed in the course of the disease, and which still mark its progress, and on the following considerations:—

1. Members of that class of society which has manifested the strongest predisposition to the disease have been very long exposed to the emanations from the sick under circumstances the most favourable to the propagation of the disease, without being infected.

2. No death, and scarcely an attack of serious indisposition, has occurred among the medical men, though they have spent hours in the pa-

tients' chambers, assisting in frictions and other offices usually performed by nurses, and from the fatigue they were undergoing might be supposed to be peculiarly obnoxious to contagion.

3. Medical practitioners have not in any ascertained case conveyed the infection in their clothes to patients whom they were attending for other diseases, or to their families. Certain of them have mingled unreservedly with their own families after long attendance on cholera patients, without any indisposition, however slight, occurring in consequence. It is proper, however, to remark that two cases have occurred, one of them a fatal one, which might be attributed to the intercourse of medical men with their families.

4. When the disease has appeared in a private family in a situation in life above the labouring class, it has been confined, so far as the writer's knowledge extends, and he is of opinion that he is acquainted with the circumstances of all the cases of the kind which have occurred, to the individual first attacked, and has not in any instance spread to the other members of the family; nor have in these instances nurses or other casual attendants on the sick suffered, though belonging to a class more obnoxious to the disease.

5. The *agricultural* villages in the immediate neighbourhood of Sunderland, which had throughout the whole progress of the epidemic the most unreserved intercourse with us, remained and still remain exempt from the disease. The populous village of Deptford, situated near the river, at the distance of half a mile from Ayre's Quay, where the disease was very prevalent and fatal, and having the most constant communication with it, partakes of this exemption.* The town of South Shields, containing nearly 14,000 inhabitants, and distant from Sunderland but seven miles, remained exempt from the disease (with the exception of two cases, stated to be very slight, and not traceable to any communication with this place,) during the whole of its epidemic prevalence here, though calculations have shown that eleven hundred persons pass weekly between the two places. Explanations have been offered of this exemption; but they appear inadequate if we suppose this disease transmissible to every locality by human intercourse, since typhus, scarlatina, and other infectious diseases frequently prevail there to a great extent. Even to the present moment, (Feb. 2, 1832,) though its intercourse with Newcastle and other infected places has been incessant, but seven cases have occurred, and, as our intelligent correspondent there remarks, "We have not as yet got the disease as an epidemic, the cases have been so few and far between."

6. Though the disease has appeared, in certain cases, to be transferred to previously uninfected districts by spreading from persons who had sickened there after arriving from places where the disease prevailed, yet facts have occurred which tend to show that the sickening of such persons and the diffusion of the disease have, at least in some instances, been mere coincidences.

* There were two slight cases in this crowded village inhabited by the class most susceptible of the disease, but it did not spread from them to the rest of the population.

A woman of the name of Liddle, who lived in Sunderland, sickened at the town of Houghton-le-Spring, six miles from this place, and died on the 5th of December. The next case occurred on the 8th of the same month, in the person of a female named Cockburn, who lived a considerable distance from the house where Liddle died, and in a different street, and had had no communication with her, direct or indirect; the family of the house in which the death occurred, and the persons who surrounded Liddle in her illness, escaping all infection. In many other instances in which the disease has appeared in a mining district or village, (and it has spread extensively in such situations,) the first cases could not be traced to communication with infected places. In certain cases, however, and we shall mention that of Hetton, the persons first seized had been in communication with infected districts.

7. On the first appearance of the epidemic in certain places, several have been simultaneously attacked; at Earsden Colliery, for example, thirty-two. On its first breaking out here, it manifested itself in three distinct points, between which no communication could be discovered; and the attacks in two of these points were simultaneous. It could not be traced from any source of infection to the individuals first attacked. In many instances, likewise, instead of residents in the same house being successively attacked, its invasion of several has been simultaneous.

8. There were feelings experienced by various persons, either otherwise in perfect health, or labouring under complaints distinct from the epidemic during its prevalence here, such as spasms, thrilling sensations of the extremities, and various affections of the nervous system, which appeared to betoken the influence of some cause more generally diffused than contagion; since many persons thus affected had not been exposed to any source of infection. The writer was at first disposed to attribute these occurrences to the influence of imagination; but they occurred in too many instances, and in persons too little sensitive and imaginative, to allow him to adhere to this explanation.

After assigning these reasons for questioning the exclusive operation of contagion, we think it right to remark that epidemic choleric fever has committed fearful ravages in some families, especially in those of which the circumstances were calculated at once to give intensity to the causes of the disease, and to render the individuals composing them more obnoxious to the action of such causes. Of one family seven were attacked with the disease, of whom five perished. The case of the first individual of the series constituted one of the sporadic cases, and it is incredible that the next in succession should have received infection from him, four months having elapsed between the dates of the respective attacks; but it is probable that contagion was transmitted from the second and subsequent cases, the diseases having commenced on the following successive dates, the 11th, 12th, 13th, 16th, 17th, and 20th of December. The case which occurred on the 20th was that of an infant, aged thirteen months, taken from the breast of the fifth patient in the order of succession.

Many other examples of transmission through families have occurred, but few so striking as this. We are disposed to attribute to contagion its full share in the production of such cases, aided by the circumstances of night-watching, neglect of order and cleanliness, &c., which are accompaniments of sickness in the dwellings of the poor; but we must remark that cases have fallen under our observation and come to our knowledge, which show a proneness to the disease in certain families, independent of reception from a contagious source. The following is an example of this kind. A respectable female, living in the village of Jesmond Vale, where the disease did not exist, and who had had no intercourse with the sick, received a letter announcing that a sister, whom she had not visited during her illness, and who resided at Hartley a distance of nine miles, had died of the complaint. She sickened in an hour from the receipt of the intelligence, and died in thirteen hours from the commencement of the attack.*

The following propositions appear to be reasonable corollaries from the facts presented by this extensive and intricate subject.

1. Epidemic choleric fever originated in a certain district under peculiar atmospheric circumstances; but these circumstances having previously occurred in the same district without the production of a disease identically the same, we must regard its terrestrial or atmospheric cause unascertained.

2. On many subsequent occasions there have been marks of its commencement and gradual rise in other districts, which show that, in their soil or atmosphere, there has been a tendency to the production of the disease from causes equally unascertained as those which first originated it, and in such districts it has ultimately displayed itself.

3. It has thus appeared to arise in various districts not by any means always continuous with those previously contaminated, but often situated in some general direction with regard to them, declining in one district as it arises in another, and thus appearing to move in a succession of local epidemic visitations.

4. Within the district which it occupies it possesses a contagious property, or, in other words, those individuals who have intercourse with the sick, especially in a locally impure atmosphere, are attacked in a greater proportion than other members of the community; and it is probable that this same contagious property may be the means of diffusing it through a district disposed to the production of the disease, earlier than it might have arisen spontaneously there, or of exciting it in a district in which, notwithstanding a degree of predisposition, epidemic choleric fever might not have arisen spontaneously; but facts which we have mentioned tend to render it questionable whether it can be thus transferred to districts unprepared to receive or engender it.

5. Within the district where it prevails, ordinary endemic causes mingle their agency with that of the general cause of the disease, and the malady is found to vary in prevalence and intensity in different portions of the same district: thus the disorder is found to assail more individuals,

and to be more destructive in parts which are dirty, and in those placed low or near the banks of a river, than in portions of the district differently situated. The effect of these endemic influences is illustrated by the progress of the disease in the town of Sunderland, and by the ravages it has committed in the village of Newburn. The latter place is built along the margin of the river Tyne, and between it and the river there intervenes only a bank, formed of a mixture of mud and sand, partially covered at high-water; whilst a shallow stream of water flows through the village. Here, although the disease has not ceased, three hundred and twenty persons have been attacked, and fifty-five have perished, out of a population of five hundred and fifty.

6. The character of the disease varies considerably in the different districts which it invades. Thus we had occasion to observe that in a mining population dispersed over an extensive tract of country, the township of Hetton, the disease was attended with less collapse than in the lanes and alleys of a populous commercial town, and the mortality was consequently much less; for we cannot too strongly repeat what we have already remarked, that the collapse is the measure of the danger. These observations are made with no view of depreciating the medical practice adopted in that district, which was extremely skilful and prompt, and even, with due allowance for the difference of the character of the disease, very successful. It should be remarked, moreover, that extremely collapsed were intermingled with the milder cases, but in proportions the very reverse of those we had observed elsewhere. In certain districts in Northumberland, we have reason to know the disease resembled, in its general character, that which prevailed at Hetton; but among some other mining communities the extremely collapsed has been the common form of disease. We have remarked, too, that whilst in some situations the cases have, almost without exception, commenced with diarrhoea, in others the proportion of instances in which this has constituted the initiatory symptom has been smaller.

This difference in the form of choleric fever in different local epidemic visitations, the cases occurring in any given district possessing a general correspondence in character, and being distinguished from those which occurred elsewhere, was observed in India by Mr. Scott; and it appears to us that this circumstance, coupled with the transmutation of the disease more and more into a febrile form as it has approached more northern climes, displays a deviation from that sameness of character observed in diseases engendered exclusively by human contagion.

It will hardly be expected that we should leave entirely untouched the question, whether the disease originated spontaneously in Sunderland, or was introduced from abroad; but the extent to which we have already pursued this intricate portion of our subject forbids our discussing it at any considerable length. Those who reason from the postulate that the disease is diffused only by human contagion will of course decide for importation; but others will very reasonably expect that before this be admitted, it should be proved by the same positive evidence that would be required to

* Related to the writer by Mr. Greenhow, surgeon, of Newcastle, who attended the case.

substantiate any other fact of importance. Any thing approaching to this, or even any considerable probability of such an occurrence, we have been unable to discover; and we cannot but agree with Dr. Ogden, that, whatever were the facilities for the importation of cholera here, they were much greater in other places; and that if it has been imported, so far from following the great routes of human intercourse, it has chosen one of the least frequented paths, (See Medical Gazette for January 21, 1832.) [See on all this subject the writer's *Practice of Medicine*, 2d edit. p. 138.]

The predisposing causes of the disease, and the means to be adopted for preventing its diffusion, have been published to the world in such multitudinous documents, that we consider it unnecessary to occupy our pages with remarks on subjects now so familiar.

[After the prevalence of cholera in England, Dr. Prout (*Bridgewater Treatise*, Amer. edit., p. 197: Philad. 1834,) observed an absence of the common lateritious sediments in the urine; and about the time the disease first made its appearance, he noticed a positive increase in the weight of the air, similar to what might be supposed to be produced by the diffusion of a heavy gaseous principle through the lower regions of the atmosphere. Hence he concluded, that the cause of cholera and of the urinary peculiarity was a poisonous body analogous to malaria, whose high specific gravity, and feeble diffusive powers, kept it near the earth's surface, along which it insensibly crept, especially in low and damp situations. He very properly, however, does not lay much stress on this conclusion. During the prevalence of the above-mentioned state of the urine, he likewise noticed, in almost every individual, an unusually acid state of the saliva, and of the cutaneous exhalations; and about the time the cholera prevailed, and a little afterwards, he saw more cases of oxalate of lime renal calculi, and of formidable hemorrhage from the kidneys, &c., than he had ever previously seen during the long period that urinary diseases had occupied his attention. As the cholera disappeared, these phenomena gradually subsided.

The epidemic at Naples was complicated by a verminous constitution of the most singular kind that has ever been recorded. This verminous epidemic was not, however, confined to those who died of cholera, or who were affected with symptoms of it, but occurred in all the inhabitants of the country; and it is asserted that the most constant morbid appearances, observed in cholera, such as injection of the digestive mucous membrane, development of the mucous follicles, the presence of an unusual kind of mucus, and of tricocephalous worms, with change in the character of the blood, were equally met with in those who died, during the epidemic, of other diseases than the cholera. (M. Thibault, cited in *Amer. Med. Intelligencer*, Feb. 15, 1838.)

Treatment.—Previously to entering on this very important subject, we think it advisable to endeavour to correct the misconception which appears to prevail very generally among members of the profession, who have not as yet witnessed the disease, that some one specific remedy, or, at

least, plan of treatment, must be sought for, and when discovered invariably adopted. The importance very properly attached by all writers to collapse as a feature of the malady, and their candid avowal of the difficulty they have encountered in combating it, is the explanation of the fact that medical men who are practically unacquainted with epidemic choleric fever, have taken a view of its treatment which in the case of almost any other disease they would have repudiated as unscientific. We know no condition more hopeless than that of extreme collapse in the disease:—so hopeless, indeed, is it, that often have we questioned, in watching a patient in this state, whether our art at present possesses or is likely to possess any resources against it, or, in seeing him emerge from it, and he has sometimes done so most unexpectedly, whether the remedies employed, or some hidden power of the constitution, had been instrumental in effecting re-action. But it should be remarked that only in a proportion of cases—a proportion varying, as we have already observed, in different localities, and in the same locality at different periods of the epidemic—does this extreme collapse occur; and that even in cases of which the natural tendency is to pass into this deplorable condition, much may be done by early treatment for its prevention. These considerations should teach physicians and patients that safety is to be found only in the early administration of remedies; and the former, when brought into contact with the disease, will soon discover that success in its treatment must result, as in the treatment of other fevers, from adapting his remedies to the varying circumstances of individual cases and of the different stages of the same case, rather than from the trial of specifics for one portion only of an extensive series of changes:—that his practice, in short, to be successful, must be rational, not empirical.

In the observations we have to make on the treatment, we shall follow the natural subdivisions adopted in describing the disease.

1. Treatment of the Incipient Stage.—

We have adverted to two forms which this stage assumes. In the one, there is some general uneasiness, nausea, and vertigo: in the other these affections may coexist with diarrhoea, but the latter is frequently present without the former being discernible. The first of these forms, in which it may be remarked that medical aid is rarely requested, requires that the stomach should be unloaded by an emetic, and a table-spoonful of good mustard constitutes a very efficient one; a few ounces of blood should be drawn from a vein; a laxative of calomel and rhubarb administered; and the patient restricted to a diluent diet, and kept within doors and warm. The treatment of the diarrhoeal form, to which circumstances witnessed by us lead us to attach considerable importance, must be noticed more at length.

It was mentioned that, in this diarrhoeal form of the incipient stage, the evacuations are at first found to be fecal and bilious; but at the time medical aid is summoned, they have generally assumed the serous character which they bear in the choleric stage. A state of the system resembling, in some degree, collapse, it was observed, coincided with this condition of the alvine dis-

charges. In this state it was found very advantageous to give a dose of calomel, conjoined with a proportion of opium and some aromatic,* and in twelve or fourteen hours afterwards a dose of castor oil. On first visiting such a patient, a large blister was generally applied to the abdomen, in the cases under our care; warmth was enjoined,—indeed where compliance with our wishes could be enforced, the patient was confined to bed,—and it was directed that the diet should be diluent. The subsequent treatment consisted in the employment of smaller doses of calomel and opium for one or two successive nights, and a second dose of oleum ricini was sometimes administered.

In certain localities the writer has found the constitutional state accompanying this stage of the disease to be one of marked excitement rather than of febleness and collapse, and some points of the abdomen have been painful on pressure. In such cases one general bleeding, or the very liberal application of leeches to the abdomen, has preceded the employment of other remedies. In other respects the same treatment has been found successful as that adopted in the preceding form, excepting that no stimulating ingredient was mixed with the calomel and opium.†

Under these plans of treatment we have the satisfaction to state that, in every case which has fallen under our immediate observation, the discharges have resumed their natural bilious appearance, and the diarrhœa has been finally arrested without the supervention of a cold stage, and, consequently, of fever, though the disease had occurred in various instances in persons who had been in incessant attendance on those ill of the feverish stage, and though in all cases it bore the characteristic marks of what we may term choleric diarrhœa. It should be remarked, however, that the choleric stage has supervened, as we have been informed, on diarrhœa which had been skilfully treated; but our inquiries have uniformly convinced us that in such cases medical aid had not been summoned till the diarrhœa had existed some time, and the subsequent stage was closely impending.

2. Treatment of the Cold or Choleric Stage.—In order that we may be distinctly understood in our observations on the mode of conducting this very important stage, it is necessary that we should adhere to its subdivision into two periods.‡

* The following is the formula we have usually employed.

R Hydrargyri chlorid. mit. gr. viii. vel. x.
Opis, gr. ii.
Pulveris capsici, gr. i. ss.
Confectionis rosæ, q. ss. ut fiat bolus, statim sumendus.

† We think it proper to remark, as probably the reader will perceive the discrepancy, that this excited state of the system was not enumerated among the symptoms of the incipient stage of the disease in our description of epidemic choleric fever. In extension of this omission, and, perhaps, of certain deviations from strict order that may be discernible, it should be mentioned that the composition of this article and our acquaintance with the disease, in various localities, have been simultaneously in progress, and we have deemed it better to sacrifice some degree of regularity than to withhold from the reader information which may speedily prove valuable.

‡ The credit of this subdivision belongs originally to Mr. Kennedy. Experience in the disease having convinced us of its practical importance, we have adopted it in this article.

The first period is certainly that in which alone our most powerful means of arresting morbid actions can be employed with a considerable prospect of success. It may be considered an axiom in medicine, that fevers, to be successfully, must be early treated, and the rule has a powerful application to a fever so rapid in its course as that under consideration. But there are many obstacles to its being generally acted upon amid a town population; and one considerable obstacle, we apprehend, will every where be found in that self-deception which seems to be quite a feature of the disease. We have met with persons to whom, from their peculiar situation, all the symptoms of this fever were as familiarly known as to medical men, yet when they were attacked with it, they did not or would not recognise it; and one such individual actually walked out with the disease upon him, and failed to send for assistance till eight hours after its invasion, though it was so severe as to destroy him in twelve. So strong is this tendency to self-deception regarding the nature of the disease when the choleric stage actually occurs, that wherever choleric fever prevails, strong appeals should be made to the public on the necessity of early treatment of this stage, as well as of due care of that which generally precedes it.

The first remedy to be considered is *bloodletting*, and we shall endeavour to point out the circumstances which, so far as our observations extend, indicate, and those which forbid its employment. Its safe administration should be early, not according to mere time only, but with respect likewise to the rapidity of the disease, for one case will have made as considerable a progress towards actual collapse in two hours as another will have done in ten; and we should regard a considerable degree of collapse, indicated by febleness or arrest of the circulation, and perceptible in the intervals of pain and spasm, (for when these occur, the pulse often sinks instantly, though only a second before it had been beating with considerable vigour,§) as an imperative reason for abstaining from drawing blood. But if we find the temperature not below or but little below the healthy standard, a pulse of tolerable force, and strong spasms recurring at short intervals, *provided collapse have not preceded this favourable condition*, we should at once open a vein, and not lose an opportunity, which will never be restored, of probably preventing extreme collapse, and either its immediate fatality, or its more remote but scarcely less fearful evils. But should this condition, with respect to circulation and temperature, have succeeded to collapse, either spontaneously or by the administration of remedies, our experience would dictate that bloodletting should be carefully abstained from, as we have seen great injury produced under such circumstances by its employment; cases having fallen under our notice in which the loss of three or four ounces of blood has destroyed the fruits of two or three hours' assiduous labour. The difference in the effect of bloodletting on conditions apparently very analogous, but differing in the periods from the commencement of the attack at which they manifest them-

§ Query—Does this sudden and momentary arrest of the circulation arise from spasm of the heart?

selves, cannot be too strongly impressed on the reader's attention. Perhaps the only difference in external character which can be discovered between the two states will be the existence of spasms of considerable strength in the early period, whilst in that more advanced they have nearly, if not altogether, ceased; but in the one case bloodletting breaks the morbid concatenations, and prevents collapse and congestion; in the other it lowers the vital energies which are freeing themselves from a state of oppression. But again, in a more advanced stage, when the constitution is no longer balancing between collapse and fever, and the latter may be considered as established, bleeding is a suitable remedy, if the state of the circulation and the general condition of the patient render it admissible. Thus, then, there are three periods of the disease at which, according to our experience, bloodletting may be employed: occasionally in the incipient stage, as has already been stated; in the early part of the first period of the cold stage; and at the commencement of the feverish stage, under circumstances to be subsequently mentioned.

We have been explicit on this head perhaps to prolixity, because we found great discrepancy in the testimony of various Indian and continental authorities regarding it; and in the early part of our experience of the disease, the selection of the appropriate time for bleeding, and the circumstances which indicated or forbade it, constituted the greatest difficulty we had to encounter.

The measure to be adopted next in succession to bloodletting will depend on the condition of the patient. If in a short time after bleeding we find a circulation of tolerable force, without much tendency to general or partial deficiency of heat, and if at the same time there be pain in the epigastrium increased on pressure, a very common accompaniment of cases in which the tendency to collapse is least conspicuous, a large blister or sinapism to the abdomen, and a dose of calomel and opium, in the proportion of from eight to twelve grains of the former to one and a-half or two of the latter, will be suitable remedies.—Should the circulation, on the other hand, be feeble, with general or partial deficiency of warmth, we should endeavour to rouse the system by full vomiting, and powdered mustard is a very proper means of accomplishing the object. Half an ounce of this substance, suspended in half an ordinary tumbler of warm water, may be considered a medium dose, and one which, in a great majority of instances, will act promptly and powerfully; but in a more advanced stage of the disease, when the collapse has been extreme, a whole ounce has been required to produce the full effect.* After full vomiting, sinapisms may be applied to the abdomen and along the spine; whilst the warmth of the patient is supported by bottles of hot water wrapped in flannel, bags of hot oats, and other familiar methods of applying dry heat, directed to the extremities or other points of which the temperature seems deficient. Frictions of the parts

affected with spasm will at the same time be probably required, and should be performed under the bed-clothes. We have not found any beneficial effect, in relieving the spasms, from oil of turpentine or other stimulating embrocations; the coldness produced by their evaporation probably more than compensating for any benefit they are in other respects calculated to effect. A bolus of calomel, capsicum, and opium, the latter not in a proportion exceeding a grain and a-half or two grains, may be administered as soon as the vomiting from the mustard has totally ceased. The quality of the liquid given at this period ought to depend on the condition of the patient: if, for instance, the tendency to collapse be considerable, a little weak brandy and water should be given at short intervals; but, should the circulation be tolerably vigorous, and the temperature good, simple diluents, such as toast and water, constitute the most suitable beverage.

Should the patient be in a state of considerable collapse, whether consequent on neglect of the earlier stage, or occurring, which will occasionally prove to be the case, in spite of the most diligent attention to it, bloodletting should not form part of the remedial agents selected. If the temperature be in any considerable degree below the healthy standard, with the hands cooling rapidly on exposure to the air; the pulse at the wrist either very feeble or totally suspended; the breath and tongue cool; the surface shrunk and pallid, or in certain parts livid; the vomiting and spasms diminishing in their intensity, or totally ceased;—at whatever period from the commencement of the disease this state of things may exist, bleeding should be abstained from. It will be advisable to endeavour to rouse the system by full vomiting; and half an ounce of mustard, or, if the attendant prefer another mode of accomplishing the object, two table-spoonfuls of common salt, a scruple of sulphate of zinc, or half a drachm of ipecacuanha with a small proportion of brandy may be administered. Should the emetic selected fail to produce its effect in a quarter of an hour, it ought to be repeated; or should the circumstances of the case lead the attendant to suppose that the sensibility of the stomach is very low, a larger dose of the emetic drug may be administered: we recollect having produced full vomiting by an ounce of mustard in a case of extreme collapse, in which two smaller doses had been administered successively without effect. Simultaneously with the exhibition of the emetic, dry heat should be applied by some of the methods already mentioned, or by that very convenient and simple apparatus, the hot air-bath.

Various internal medicines of the stimulating class have been recommended for this state. Those of which we have been led to form the most favourable opinion are mustard, carbonate of ammonia, and oil of turpentine. The first named substance we have not unfrequently administered in doses of a drachm, (a tea-spoonful unheaped,) at intervals of an hour or an hour and a half, apparently with the effect of giving additional vigour to the pulse, which had perhaps been restored by the vomiting; of producing bilious discharges from the bowels; of restoring the urinary secretion, and aiding the system in the transition

* It may save the reader some trouble to inform him, that an ordinary table-spoon, unheaped, contains half an ounce of mustard; and that the mustard sold in the shops under the name of Durham mustard, which is of a uniform bright yellow colour, is the most pungent and efficacious.

into the febrile stage. If the carbonate of ammonia be the stimulant employed, a convenient mode of giving it is in doses of five grains every hour, with carbonate of magnesia, which makes it more easily retained should the stomach still retain its irritability. Should oleum terebinthinae be selected, doses of two drachms may be given every second hour. Whatever stimulant medicine be employed, we should advise that calomel in doses of five or six grains, repeated at intervals of three or four hours, should be given at the same time, with the view of aiding the restoration of secretion; and, with the intention of at once rousing the system and lessening the irritability of the stomach, that a large sinapism should be applied to the abdomen, and another along the course of the spine.

Various stimulating nostrums, if applicable to any, certainly only to this period of the fever, have been bruited forth to the world as specifics for the disease. In many of these we are of course inexperienced, and of all we are convinced the powers have been overrated, in some instances from partial and mistaken views of the malady, and in others from less pardonable reasons. It will not be deemed necessary that we should pass them all in review; but of certain remedies which have been proposed for collapse, the professional reader will require some notice.

The inhalation of oxygen gas has been suggested from many quarters; and in some cases in which it has been tried here an instantaneous amelioration has been manifest, the pulse having become more vigorous, the lips florid, and the patient having experienced relief from precordial oppression and other distressful feelings, to an extent and with a promptitude not afforded by any other measure. But the experience of medical observers in general has led them to conclude that this effect is very transitory; and some are of opinion that they have witnessed an increase of the collapse after the temporary excitement, as if the vital power, instead of being permanently increased by the measure, had been expended in a momentary flash. Of some gentlemen, however, the opinion regarding it is more favourable. Our own opinion is, that inspired for a few seconds in single bladders, no great benefit is likely to accrue from it; but we should speak less positively of the effect of an atmosphere of diluted oxygen breathed for a considerable period.

The tobacco enema has been suggested by Mr. Baird of Newcastle, and, as he assures us, employed with considerable success. We acknowledge that *à priori* reasoning would rather have led us from this remedy than suggested it to us; but knowing the fallacy of such reasoning in medicine, we are not disposed to treat with neglect, still less with contempt, a measure of the beneficial effect of which a gentleman of talent and character adduces several examples. It was proposed after the disappearance of the epidemic from Sunderland, and we have no experience of it; but we would recommend that it should be tried in a case to the successful treatment of which other measures seemed inadequate, the practitioner being governed, as to its subsequent employment or rejection, by its effect.

Two remedies have also been mentioned to us

by an individual of talent, and of great experience in the epidemic, Mr. John Fyfe, of Newcastle: we shall, with his permission, make the reader acquainted with them. One is the employment, in the period of extreme collapse, of an enema, consisting of two pints of warm water, from four to eight ounces of brandy, and from one drachm to two drachms of laudanum or Battley's sedative liquor. This, he assures us, has the happiest effect, in abridging that stage of the disease on the intensity and duration of which so much of the danger depends. The other is an enema containing a drachm of powdered mustard, which he has found to be very speedily instrumental in restoring the urinary secretion. This accords with our experience, as already stated, of the efficacy of this substance given by the mouth, in accomplishing the same object and the restoration of the secretions generally.

Weak brandy and water may be given occasionally during the collapse; and we have observed no injurious effect in this or any stage of the disease from the ordinary diluents taken in moderate quantities.

3. Treatment of the Exeited or Febrile Stage.—The treatment to be now pursued will not require such lengthened discussion as that of the preceding stages, which may be considered as more exclusively belonging to this disease; for recognised principles, applicable to the treatment of pyrexia in general, must be our guides in conducting this fever.

The fever constituting this stage, be it in essence what it may, has inflammation accompanying it, of which the principal sites are the brain and the lining of the digestive canal, and to the subduing of these, by such measures as the state of the system admits, our attention should be carefully directed.

A form of fever has been described as supervening on an extreme and long-continued collapse in the cold stage, and in which fever it was mentioned that the vascular action was low and feeble, the temperature of the surface under the healthy standard, and the distribution of warmth very partial. In this low form of disease we have not ventured on general bloodletting; local bleeding from the temples has been freely performed, and occasionally too from the integuments of the abdomen, when there were any indications of inflammatory affection of the digestive canal; but the great degree of intellectual torpor and insensibility which attends these extreme cases renders the discovery of such an affection extremely difficult. Blistering the nape of the neck, and shaving the head so as to permit the application of cold, will be found very suitable measures. A degree of irritability of stomach, with occasional vomiting, is a very frequent accompaniment of such a case for the first two or three days; and under such circumstances leeches and subsequently a blister to the epigastrium have been resorted to with benefit.

Of internal remedies, that on which most reliance is to be placed is calomel, from its effects on the secretions, particularly of the intestinal canal, and from its facilitating the action of the laxatives which the state of the brain renders it advisable to administer. If two grains of calomel

are given at intervals of three or four hours, an occasional gentle laxative, such as castor oil or calcined magnesia, will generally produce two or three bilious discharges from the bowels. Simultaneously with the administration of these remedies, the imperfect development of heat and its partial distribution require attention. The patient should be placed near a stove or in some warm situation, and bottles of hot water, or hot flannels, should be applied to the feet, or other parts which are chilled. Even whilst endeavouring, by local depletion, to relieve partial determinations of blood, the general state of the system has been such as to require a little stimulus, and wine and water has been given, especially at an advanced stage of the disease, and occasionally medicinal stimulants, such as carbonate of ammonia, camphor, and sometimes, as a tonic, sulphate of quinine; but we cannot say that much benefit has resulted from the latter class of agents.

Such is the treatment we have generally adopted in that form of the febrile stage which is distinguishable from any fever we have been in the habit of observing here or elsewhere. The more excited form admits of one general bleeding with advantage, the amount of blood drawn being regulated by the degree of vascular action, of headach, of injection of the eyes, and various circumstances which would influence our proceeding in any ordinary fever. Should the head, as it generally does, continue affected after the blood-letting, the application of leeches and cold should be resorted to, the former being repeated, if necessary, to such extent and at such intervals, as the degree of headach, intellectual torpor, and vascular excitement may seem to require. Laxative medicine should be administered; and the purpose is exceedingly well answered by calomel in doses of four or five grains nightly, and six drachms or an ounce of castor oil every morning. The diet under such circumstances should consist of the mildest and simplest diluents, such as would be demanded in any case of inflammatory fever: after the case has subsisted some days, a little wine and water may be given if exhaustion be manifest, but it should not be continued beyond the necessities of the case. Though we have seen few or no cases without a degree of cerebral affection, examples are met with in which the disorder of the intestinal canal is more considerable than that of the brain. Diarrhœa, the discharges being deeply bilious; a red, glazed, and very dry tongue; some degree of fulness and tension of the abdomen, and of pain on pressure there; and scanty high-coloured urine, generally attend such cases. The general treatment of cases in which such an affection exists, must depend on the state of the system; but the intestinal disorder demands the free application of leeches to the parietes of the abdomen, repeated according to circumstances, and the internal exhibition of mild mercurials, such as hydrargyrum cum cretâ, or blue pill, with a small quantity of opium. That kind of permanent fomentation which is afforded by hot poultices to the abdomen, after the application of leeches, has been found beneficial. The diet throughout a case in which this inflammation of the mucous lining of the intestines exists, should be mild and demulcent. In cases of this descrip-

tion—indeed in the most excited as well as in the lowest forms of the disease in which the collapse of the cold seems prolonged through the febrile stage—it is advisable to counteract, by warmth to the extremities and other points, that tendency to irregular distribution of blood which forms so striking a feature of the disease. Cases are occasionally met with, so mild in all their stages, that the fever requires no medical treatment but a few leeches to the head, a little laxative medicine, and abstemious diet for a few days.

[The intense thirst of cholera must be satisfied by a liberal allowance of ice or of ice-cold water. They are most grateful, and tend to allay the irritability of the stomach.

To arrest the diarrhœa in all stages, the acetate of lead was much employed in this country, and was highly extolled by many practitioners, as well as by Dr. Graves, of Dublin. In the writer's own observation it was not attended with any strikingly salutary effects. Strychnia was used externally, and, it was affirmed, with advantage. It was, also, given internally to allay vomiting, and Dr. Ryan, somewhat hyperbolically we fear, states, that a twelfth of a grain, given in pill, and repeated a few times, has been frequently known to check a profuse diarrhœa with rice-water evacuations, and even when the extremities were blue, in cholera, (Ryan's *Universal Pharmacopœia*, 3d edit., p. 336 : Lond. 1839.)

The extensive loss of serum, and, consequently, of the watery and saline parts of the blood, led to the administration of solutions of common salt and of the carbonate of soda internally, both by the mouth and in enema; but owing to the suspension of absorption, these substances rarely or never got into the blood-vessels. It was then proposed to inject them into the blood-vessels; yet although they became mixed with the blood, they could not remove the pathological cause that gave occasion to the profuse separation of its watery and saline portions. Hence, they were not found to answer preconceived expectations.]

Convalescence is in many cases tedious, the strength being slowly restored, and slight irregularities of diet sufficing to disorder the system, and even to produce relapse. For weeks after the fever we have found the patient still languid, and exceedingly prone to irregular distribution of blood, especially to undue determination to the head, inducing headach (requiring the application of leeches) on any considerable exertion. To prevent such occurrences, we have found it advisable that the diet should consist, in the early period of convalescence, of a moderate quantity of vegetable matter only, and that the transition to more abundant and substantial food should be very gradual; in short, that convalescence from this disease should be conducted in the same manner as that from other fevers.

We have stated that relapse may be produced by dietetic irregularities; and it is important to observe that even the best directed treatment of the incipient or diarrhœal stage may fail in its object, that of cutting short the disease, if such irregularities are indulged in. The relapses, properly so called, have occurred at an early period of convalescence; but we have witnessed one example, and that a very severe one, of the recurrence

epidemic choleric fever after an interval of two months from the preceding attack. This we were disposed to consider rather as an example of second invasion than one of relapse, though it is proper to remark that the patient had remained feeble from the period of the previous disease. No assignable cause existed for the second attack.

[During the prevalence of cholera, municipal regulations were made in many of the cities in regard to the articles of diet that might be allowed with safety, during the epidemic constitution.—Some of these were of the most whimsical kind, dependent probably, at times, on individual likes or dislikes, caprices or prejudices. Ripe fruits, and succulent vegetables, were generally proscribed: yet the fact, that in charitable institutions, where no such articles were permitted, cholera was most fatal; that the disease prevailed most fatally at Moscow, St. Petersburg and elsewhere, at seasons when ripe fruits and vegetables could not be procured; and that where ripe fruits were freely allowed, as in London, at a later period of the epidemic, no inconvenience was found to result from them, ought to have created well-founded doubts, whether the proscription were founded on accurate observation. (See the writer's *Elements of Hygiene*, p. 302: Philad. 1835; and his *Prælice of Medicine*, edit. cit. i. 147.)]

JOSEPH BROWN.

[III. CHOLERA INFANTUM.—This form of cholera, commonly known under the name of *summer complaint*, has been generally regarded as peculiar to the United States. As elsewhere remarked, however, (*Prælice of Medicine*, edit. cit. i. 147,) it strikingly resembles the affection vulgarly called "*watery gripes*," in England. It does not appear to be known in Paris: (Barthez and Rilliet, *Traité Clinique et Pratique des Maladies des Enfants*, i. 552: Paris, 1843.) It is one of the most fatal affections to which children are liable. In Philadelphia, during a period of fifteen years, from 1825 to 1839 inclusive, 3352 infants died of it—being almost 10 per cent. of the whole number of infants under five years of age who died during that period; and 4.5 per cent. of the entire mortality of the city. (Condie, *Practical Treatise on the Diseases of Children*, p. 217: Philad. 1844.)

Diagnosis.—Cholera infantum commonly begins with diarrhœa, more or less profuse; but at other times both vomiting and purging come on at first, without any premonitions; or the infant may have suffered for a time under gastric or intestinal derangement. The pulse is usually frequent and somewhat tense; and there are almost always manifest signs of febrile irritation. The discharges are, at first, extremely fluid and often frothy, sometimes tinging the cloth green, and at others leaving mucus upon them. In very severe cases the system becomes rapidly prostrated, and the child may die in the course of twenty-four hours; but more commonly the disease continues for a few days before either the tendency to convalescence or to death is manifest. As in the cholera morbus of the adult, there is often severe intestinal pain, which may be increased by pressure; and, at times, the muscles of the abdomen and extremities contract spasmodically. The thirst

is excessive, and the appetite gone or singularly capricious. If the disease be about to terminate unfavourably, emaciation makes frightful progress; the febrile irritation is constant and manifest; the child becomes restless and comatose, and gradually sinks—the fatal termination being, at times, preceded by convulsions. Frequently, the evacuations exhibit the existence of great irritability of the digestive tube, the food passing rapidly through it without undergoing any change, and being squirted out with great force. At other times, they have a putrid or cadaverous odour. In the more protracted cases, these appearances are more frequently met with, along with aphthæ of the mouth, meteorism of the abdomen, and other signs of follicular inflammation. At times, before death, a vesicular eruption appears extensively on the chest, which Dr. Dewees (*Treatise on the Physical and Medical Treatment of Children*), considered to be invariably a fatal symptom; but Dr. Condie (*op. cit.* p. 219,) states, that he has in many instances known the patient to recover even when this eruption has been the most extensive and distinct.

The great indication of recovery is the appearance of feculent matter, and of the ordinary secretions in the evacuations.

Causes.—Excessive heat is unquestionably concerned in the causation. It is, indeed, in the summer months that the disease prevails so fearfully and so fatally in our cities; yet something more than heat is required to induce it extensively; for, in country situations, it is comparatively rare. Atmospheric vitiation must be combined with atmospheric heat, and hence it prevails in the most crowded alleys of cities. In cleanly and well-ventilated districts, and in large, airy apartments, deaths from it are uncommon; so that at times when the bills of mortality indicate the greatest amount of deaths, physicians who practise extensively in the better portions of cities may see but little of it. (*Prælice of Medicine*, i. 148.) Dr. Condie (*op. cit.* p. 221,) states, that when it occurs in the country, it is almost exclusively in low, damp, and otherwise unhealthy situations; but such has not been the result of the author's experience. Age affords a predisposition. The common idea is, that children are more liable to it in the second summer than in the first; but this does not seem to be confirmed by statistical observations. From the official reports of deaths in Philadelphia and New York, it would appear that, in the former city, of 229 deaths assigned to summer complaint, 142 occurred in children under one year of age; 75 in those from one to two years; and 12 in those from two to five years. It rarely occurs in infants under three months of age.

Under the predisposition induced by great atmospheric heat and vitiation, it is clear that improper aliment may be an exciting cause; hence, children brought up on spoon-meat suffer in greater numbers than those that are nourished at the breast.

In like manner, dentition may contribute to its production.

Pathological Characters.—The mucous membrane of the bowels generally exhibits evidences of inflammation, especially of the follicles which by some have been regarded as the primary

seat of the disease. When it has existed for any time, increased redness, in points and patches, has been observed in different parts of the stomach and intestines; but attention has not generally been paid to distinguish whether these consist in simple hyperæmia or in inflammation of the lining membrane. The follicles are very generally enlarged, inflamed, and occasionally ulcerated; the enlargement, according to Dr. Horner, (*Pathological Anatomy*, Philad. 1829,) often resembling a sprinkling of white sand upon the surface of the mucous membrane. Occasionally, considerable portions of the digestive tube are so much contracted as scarcely to admit a small-sized quill; at other times, portions of the mucous membrane of the stomach and intestines are greatly softened. The liver is almost always enlarged. This has likewise been regarded as the primary affection; but it is more probably secondary. The œncephalon, in nearly all cases, has been found in a state of hyperæmia, and in long protracted cases serous effusions have been met with in the ventricles, and at the surface of that viscus.

Treatment.—The general principles of management do not differ materially from those laid down under enteritis of the mucous coat, and diarrhoea. The cases that occur in the airy parts of a town are usually managed with facility, and carried to a fortunate issue; whilst those in the narrow alleys of the worst parts too often resist every effort of the practitioner. It is all-important to remove the little sufferer from the air that has generated the disease, to another situation. This of itself is often enough to arrest the affection; but it may be necessary to combine with it a gentle laxative — as a small dose of calomel or of rhubarb and magnesia. Should the febrile action be considerable, it may be advisable to apply a few leeches to the epigastrium, more on account of the revulsion, than of benefit to be derived from loss of blood,—covering the abdomen after the leech-bites have ceased to bleed, with an emollient poultice. In other cases, especially where there is great irritability of stomach, stimulating cataplasms or fomentations may be applied, and in protracted cases a blister. Should the disease not yield to the above treatment, small doses of the mild chloride of mercury may be given frequently, to produce a new action, if the child be under two years of age, which, as has been seen, is usually the case. After this age, there is greater danger of inducing severe mercurial stomatitis.—Should signs of acidity exist, magnesia in the early period, and prepared chalk subsequently, may be useful adjuncts. Hence, the hydrargyrum cum cretâ of the pharmacopœias is a convenient preparation. Where irritability of the stomach is present, which is not relieved by external revulents, injections of salt and water may be used in the way of revulsion; or gentle excitants may be given internally, as a drop or two of oil of aniseed in sugared water, or five or six drops of sulphuric ether in the same vehicle.

It need scarcely be said, that should irritation from teething exist, the gums should be freely divided, and should even the tooth not be set at liberty, the revulsion, thus induced, may prove salutary. The warm bath is beneficial in all periods of the disease. In the more protracted cases, astringents

become necessary. The acetate of lead has been highly extolled by many. (Dr. H. Lindsly, *Amer. Journ. of the Med. Sciences*, xxiv. 311.) The oil of turpentine has been advised when there is flatulent distension of the stomach and bowels; and with the same view, a few drops of any of the essential oils may be administered. Great caution must, however, be had in the use of both excitants and astringents. During the convalescence any of the milder tonic infusions may be prescribed.

Throughout the disease, care must be taken in regard to the diet; and, where practicable, the child should be mainly restricted to the mother's milk. Where this cannot be done, boiled milk and water, with any of the farinaceous preparations, as sago or arrowroot, may be used. By many, the infusion of benne-leaves or gum-water is given freely; but it may be questioned whether these mucilaginous substances are of much benefit;—they may tend to shield and soothe the part with which they come in contact, but they are difficult of digestion. The appetite is apt to be very capricious—a great desire being occasionally shown for salted meat, salt fish, butter, &c.; and it has been esteemed proper to gratify it occasionally to a certain extent. Doubtless, in many cases, no evil has resulted from such indulgence, but it must necessarily be hazardous. To allay the intense thirst, iced water may be allowed; or the infant may be permitted to suck ice contained in a piece of gauze.

At all periods of the disease, one of the most important curative agencies is change of air. If the child be removed into the country, this is the best course; but where this cannot be accomplished, riding or carrying the child about in the open air is of essential service.

In the way of prevention, removal during the summer heats to the country; or, if compelled to remain in town, sleeping on a mattress, with the door and windows of the chamber open; the daily use of the tepid or cold bath; exercise in the open air, and, if the child be weaned, well-regulated diet, with especial abstinence from unripe fruits and the succulent vegetable. The constant use of a flannel bandage, even through the heat of summer, has appeared to the writer an important prophylactic.

ROBLEY DUNGLISON.]

CHOREA.—The word *chorea*, as used by the ancients, signified a dance of many people to music, being derived from χορός, a band of singers and dancers. The origin of its application to nosology is involved in some obscurity. Sydenham and other writers have treated of the disease under the name of *chorea Sancti Viti*, a designation which has been very properly curtailed by Cullen and most subsequent authors. This latter appellation, we are told by Horstius, was acquired in consequence of some women of disordered minds and affected with a peculiar restlessness of their bodies, repairing, once a year, to the chapel of St. Vitus, near Ulm, and continuing there, night and day, leaping and dancing, until they were completely exhausted. By this means they were said to be cured for a time; but at the expiration of a year the disease returned, and was again removed in the same manner. The malady,

however, which is commonly known by the name of chorea, is very different in its symptoms from the original disease so called, although they have been classed together, and sometimes supposed to arise from the same causes.

In this, as in many other instances, it is difficult to determine by what name the disease was known to ancient authors. Probably it was for the most part confounded with other convulsive diseases. Even Cullen, in the first edition of his *Nosology*, included it in the general term convulsio, from which, however, he afterwards saw reason to separate it. Galen appears to describe it with tolerable accuracy under the name of scelotyrbē, which means "an agitation of the leg." "It is a species of atony or paralysis," says he, "in which a man is incapable of walking straight on, and is turned round to the left when the right leg is put forward, and to the right when the left is put forward alternately. Sometimes he is incapable of raising the foot, and hence drags it awkwardly, as those who are climbing up steep cliffs." It is also placed as a species of scelotyrbē in the nosological systems of Sauvages and Sagar. Dr. Mason Good, in his arrangement, ranks it as a species of synclonus, the term by which he expresses "a multiplied, conjunctive, or compound agitation of the muscles."

Cullen defines chorea in the following manner: "Convulsive motions, partly voluntary, and for the most part of one side, attacking either sex before puberty, generally between the tenth and fourteenth year; the motions of the hands and arms resembling the gesticulations of players; one foot being rather dragged than lifted in walking." Sydenham has described it in a very graphic and accurate manner, as being "a species of convulsion which for the most part attacks boys or girls, from the tenth year to puberty. It first announces itself by a kind of halting, or rather instability, of one leg, which the patient drags after him, as idiots do. Afterwards it shows itself in the hand of the same side, which, when applied to the chest, or any other part of his body, cannot be retained in the same situation by the patient even for a moment, but is twisted about from one place to another, however much he strive to prevent it. If a full vessel be given him to drink from, before he can bring it to his mouth he exhibits a thousand gesticulations, like a mountebank; for as he cannot carry the cup in a straight line to his lips, the hand being diverted by the spasm, he tips it from side to side for some time, until at length, by good fortune, approaching it nearer to his lips, he jerks the liquor suddenly into his mouth and drinks it with eagerness, as if the poor creature were merely performing a feat to excite the laughter of by-standers." (Sydenham's *Opera*, p. 463; Lipsiæ, 1827.) Dr. Hamilton, in his *Treatise on Purgative Medicines*,—after stating that the disease chiefly occurs from the eighth to the fourteenth year, in those who are of a weak constitution, natural or acquired; that it is generally preceded by a variable appetite, loss of vivacity, a tumid belly, and constipated bowels; and that the convulsive motions are ushered in by slight, irregular, involuntary twitchings, particularly of the muscles of the face,—presents us with the following description of the

disease in its more aggravated shape: "These convulsive motions vary. The muscles of the extremities and of the face, those moving the lower jaw, the head, and the trunk of the body, are at different times and in different instances affected by it. In this state the patient does not walk steadily; his gait resembles a jumping or starting; he sometimes cannot walk at all, and seems palsied; he cannot perform the common and necessary motions with the affected arms. This convulsive motion is more or less violent, and is constant, except during sleep, when, in most instances, it ceases altogether. Although different muscles are sometimes successively convulsed, yet in general the muscles affected in the early part of the disease remain so during the course of it. Articulation is now impeded, and is frequently completely suspended. Deglutition is also occasionally performed with difficulty. The eye loses its lustre and intelligence; the countenance is pale and expressive of vacancy and languor. These circumstances give the patient a fatuous appearance. Indeed, there is every reason to believe, that, when the complaint has subsisted for some time, fatuity to a certain extent interrupts the exercise of the mental faculties. Fever, such as arises in marasmus, is not a necessary attendant on chorea; nevertheless in the advanced period of the disease, flaccidity and wasting of the muscular flesh take place, the consequence of constant irritation, of abating appetite, and impaired digestion, the common attendants of protracted chorea." (*Observations on the Utility of Purgative Medicines*, chap. iii. p. 69, et seq.) The sensations are little, if at all, disturbed; but in extreme cases there are hardly any of the voluntary muscles exempted from the spasmodic affection. The tongue is occasionally protruded, the mouth drivels, and the eye itself is twisted in various directions. Not unfrequently there is some pain of the head, for the most part in the occipital region; vertigo; and imperfect vision. The patient is often fretful, and liable to the same varied, desultory, and causeless motions which occur in hysteria. The disease is apt to recur more than once in the same individual. Occasionally it has passed into hemiplegia or epilepsy, and instances are recorded of its proving fatal in that manner, or by exhaustion. Dr. Elliotson mentions, that when a student, he saw a young woman, labouring under the disease, die apoplectic. (*Med. Chir. Trans.* vol. xiii. p. 252.) In most cases, however, it terminates favourably, after a duration of variable length. In eighty-four cases occurring at the Norwich Hospital, Dr. Reeves states that the shortest period of medical treatment, was two weeks; the longest, eight months; and the common average, seven weeks. (*Edinb. Med. and Surg. Journ.* vol. viii. p. 314.) Although the disease commonly occurs between the ages of eight and fifteen, it is met with as early as the fifth or sixth, and, on the other hand, even in mature years. Dr. Powell mentions an instance of it in a lady of seventy, (*Med. Trans.* vol. v.); and Dr. Bouteille relates one which occurred in a lady eighty years old, after hemiplegia. (*New Med. and Phys. Journ.* vol. iii. p. 175; London, 1812.) It oftener attacks girls than boys. Heberden found it to do so in the propor-

tion of three to one, and Dr. Elliotson states that his experience presents nearly the same result. (Med. Gazette, vol. vii. p. 652.) Of the eighty-four cases reported by Dr. Reeves, fifty-seven were females, and twenty-seven males. Of seventy-two occurring in Dr. Manson's practice, at Nottingham, fifty-three were females, nineteen males. (Medical Researches on the Effects of Iodine, p. 230.) Of eighteen cases in the Hampshire County Hospital, during the last ten years, six were boys and the rest girls.

Occasionally, chorea is complicated with hysteria or other disorders, and thus a confusion of symptoms occurs. In some cases the disease is of so partial a description as to continue through life without any injurious effects to the general health, or even any serious inconvenience. Dr. Mason Good mentions the case of a barrister of great reputation, in whom the only symptom was an occasional awkward snatching of the arms and neck; and another of a person who, though a distinguished vocal and instrumental musician, had extraordinary gesticulations of the face and curvettings of the neck and head. Most practitioners have doubtless witnessed similar instances.

The characteristic signs of the ordinary disease are the permanency, the irregularity, and the partly voluntary nature of the motions. There are other diseases of clonic spasm, in which the motions are perhaps as unintermitting as in this, but they present a regular and unvarying appearance. On the other hand, spasms of an irregular description, but not continuing, are daily met with. In both these cases, however, the affection should be classed under the general term convulsion. The partial influence of the will over the muscular contractions is, for the most part, a circumstance which of itself distinguishes the ordinary chorea from every other spasmodic affection. It has, however, been customary to include under the same name some more rare diseases not always possessed of these characters; and the term seems to be somewhat loosely assigned to many abnormal affections of a spasmodic nature. We admit, indeed, that the very malady to which the name was originally given does not present the characteristic signs we have mentioned; and it might seem arbitrary to separate it entirely from that which has received the appellation, solely from somewhat resembling it in appearance. When it is considered, however, that there are no sufficient reasons for concluding that they are of similar origin, and that the disease to which the above characteristics do apply is of infinitely more frequent occurrence, and is at the same time universally known by the name of chorea, we think it right, for the sake of avoiding confusion and error, to confine our attention at present to the latter. Afterwards we will subjoin some account of the original disease, and other affections which resemble it or have received the same appellation. Some of the German writers have distinguished the two diseases by calling one the German, or great St. Vitus's dance, the other the minor St. Vitus's dance, or chorea of England. If they are still to be included under the same genus, the difference of their character might be better expressed by styling the one *intermittens*, or *periodica*; the other *continua*; the former *methodica*, the latter

abnormis; according as the circumstances above-mentioned shall, one or other of them, be considered the most characteristic of the chorea commonly met with in this country.

Causes.—The ordinary chorea has been attributed to various causes. Sydenham ascribed it to a humour thrown upon the nerves. By very many authors it has been considered as a disease of general weakness of the constitution. And others there are who conceive it to arise from a partial and slow inflammation of the brain. With regard to Sydenham's hypothesis, it has followed the rest of the humoral theories, and does not now require notice. That the disease is always simply one of general debility, is a notion opposed by the benefit sometimes obtained from bleeding, the very uniform advantage arising from purgatives, and the occasional failure of tonic medicines, when uncombined with other remedies, in the treatment of the disease. Many circumstances, however, concur in showing that, though debility may not be the original cause of the disease, yet it is often the principal reason of its continuance when once established. On the other hand, the idea that it is in general an inflammatory affection of the brain, as Dr. Clutterbuck and others have supposed, is contravened by the experience of Sauvages, Cullen, and many other practitioners, who have found bleeding very prejudicial in a great many cases. And although this was one of Sydenham's remedies at the beginning of the disease, he does not advise it to be repeated frequently; recommending, however, the purgatives and tonics with which he accompanied it to be continued through the whole course of the complaint. (Op. cit. 470.) Whether, as Professor Gregory supposed, (Edin. Med. and Surg. Journ. vol. i. p. 33), the success of Sydenham's practice was entirely owing to the tonics, or whether it was attributable to the purgatives, or to both together, may possibly be a matter of dispute; but we think there is not much reason to attribute it, in general or chiefly, to the venesection. Dr. Armstrong, who mentions a case in which the free use of the lancet was nearly fatal, states that he considers chorea to arise from irritation of the mucous membrane of the stomach and smaller intestines, accompanied with a torpor of the skin, liver, and colon. (Lancet, vol. viii. p. 70.) Dr. Hamilton, sen. from extensive experience of the benefit derived from purgative medicines, and the general appearance of the alvine evacuations, considers the disease to arise from disordered bowels. It has, however, been suggested by Dr. Coxe, (Med. and Phys. Journ. vol. xviii. p. 223), Dr. Uwins, (Edin. Med. and Surg. Journ. vol. viii. p. 411), Dr. Manson, (Medical Researches, &c. p. 192), and others, that such torpor and derangement may be merely an effect of the disorder, or at most a simultaneous expression of disease. Cullen thought that the malady depended upon "a state of mobility" in the system, (Materia Medica, vol. ii. p. 112); and we are so far of opinion with him as to believe that chorea may be induced by any irritating cause operating upon a sufficiently excitable habit of body. The greater number of diseases arising before puberty are perhaps connected or complicated with intestinal irritation; and chorea, among others, doubtless frequently proceeds from disordered alvine secretions, from

worms, from accumulated feces, improper diet, &c. But it has also been occasioned by affections of the mind, such as fright.* Dr. Reeves states that in the majority of cases the disease is attributed by the parents to this cause, (Edin. Med. and Surg. Journ. vol. viii. p. 315); and Mr. Bedingfield tells us, that of upwards of forty cases which occurred at the Bristol Infirmary, by far the greater number were induced by fright. (Compend. of Medical Practice, p. 52. London, 1816). It has also sometimes arisen from irritation.† It has been occasioned by a wound of the brain through the orbit, (Philosoph. Transact. vol. liii. 1763), and other injuries about the head. (Edin. Med. and Surg. Journ. vol. viii. p. 406; vol. ix. p. 123. Med. and Phys. Journ. vol. xv. p. 127). A case, in which it was induced in a man twenty-three years of age by injury to the scapula, is related in the Medico-Chirurgical Review. (Vol. ii. p. 569. 1827). It has also been occasioned by teething, (Edin. Med. and Surg. Journ. vol. i. p. 32); by the deleterious influence of certain metals and their compounds; preparations of lead, for example, or of mercury, (*De Haen*, Rat. Med. part iii. p. 202. New York Med. and Surg. Register. 1818. Med. and Phys. Journ. vol. xlii. p. 160); by suppressing eruptions of the skin, (Darwin's Zoonomia, vol. iv. p. 290. *Wendt*, Nachricht von dem Krankeninstitut zu Erlangen. 1783); and frequently by retarded or difficult menstruation. (Bedingfield's Compendium, &c. p. 52).

[Age occasions a marked predisposition. The disease is one of childhood. Of 32,976 children, admitted into the Hôpital des Enfants of Paris, during 10 years, only 189, according to M. Ruz, (*Archives Générales de Médecine*, iv. 239: Paris, 1834), were affected with chorea; so that it is not very common. In the composition of their chapter on this subject, MM. Barthez and Rilliet, (*Traité Clinique et Pratique des Maladies des Enfants*, ii. 294: Paris, 1843), state that they had analyzed only nineteen cases, and some of these were communicated to them by other observers. In a recent clinical lecture on chorea, (*Medical Examiner*, Jan. 27, 1841), the writer stated that he had not seen, altogether, more perhaps than thirty well-marked cases. The ages, at which the disease prevails most, are from 6 to 14.

Sex, also, affords a predisposition, according to all observers. Of 240 cases, recorded by M. Dufossé, 79 were in boys, 161 in girls, (H. Bell, *Art. Chorée*, in *Dict. des Études Médicales*, Paris, 1839); and of the 189 cases referred to above, 51 were males, and 138 females. From the cases that have been recorded by different practitioners, it has been calculated, that the proportion of females to males is nearly 3 to 1. (*Practice of Medicine*, 2d edit., ii. 240: Philad. 1844.)

In regard to constitution, great difference of sentiment has existed. Some—as the Franks—affirm, that it occurs chiefly in the serofulous

and the rickety; while others, as Dr. Elliotson, (*Principles and Practice of Med.*, Amer. edit. by Dr. Stewardson, p. 624: Philad. 1844), M. Ruz, and MM. Barthez and Rilliet, state, that no constitutional difference is perceptible between those who are affected with chorea and those who are not. A like discrepancy exists in regard to the colour of the hair. MM. H. Bell, Ruz and Dufossé say that the subjects are chiefly light-haired; whilst Dr. Watson (*Lectures on the Principles and Practice of Physic*, Amer. edit. p. 360: Philad. 1844) remarks, that the disease occurs much more frequently in children having dark hair and eyes. It would appear, also, that a predisposition to chorea may be transmitted from parent to child. (Elliotson, *op. cit.*)

The disease may unquestionably be boarded by imitation, and hence the necessity in boarding-schools of keeping the patients separated. (Andral, *Pathologie interne.*) It is proper, however, to remark, that M. Blache states, that in the large Hôpital des Enfants, of Paris, he never saw it produced in this manner.

Dr. Bright has drawn attention to the connection of chorea, in certain cases, with affections of the heart and pericardium; and Dr. Addison has noticed mitral *bruit* or other signs of morbid action of the mitral valves to be pretty uniformly present in chorea,—which he is rather inclined to consider an effect of the disease than a cause. (The author's *Practice of Medicine*, ii. 241.)]

It is extremely probable that the convulsive motions may be continued, merely from habit, a considerable time after the original cause is removed.‡ Mr. Hunter, of Glasgow, conceives that, although the motions are not at first dependent on any derangement of the brain or spinal cord, yet the irritation, which acts at first locally on the nerves of the affected muscles, may spread till it affect the root of the nervous system itself; and in this way he would explain the continuance of the convulsive motions after the removal of the original cause, (Edin. Med. and Surg. Journ. vol. xxiii. p. 270.) May the morbid appearances, such as the following, which have been observed in some cases of chorea after death, be accounted for in this manner?

In two instances Dr. Willan found some ounces of serum in the ventricles of the brain, (Reports on the Diseases of London, p. 245.) Dr. Coxe, of Philadelphia, who conceives that chorea uniformly arises either from hydrocephalus or its forerunner, inflammation and turgescence of the blood-vessels, found, in a fatal case, the vessels turgid, and twelve ounces of serum in the ventricles, (Med. and Phys. Journ. vol. xiii. p. 405; vol. xviii. p. 221.) Dr. Patterson, of Londonderry, (who, in opposition to Dr. Coxe's Views, and in accordance with Dr. Percival, of Manchester,—see *Medical Tracts*, vol. i. p. 125, 1791,—considers that in chorea, as in other convulsive diseases, hydrocephalus is for the most part rather a result than the cause,§) has related a case in which he found the blood-vessels

‡ "Sæpe tamen malum consuetudine ingravescens levioribus causis excitatur, parum cognitiss, neque facile observandis." *Gregory*, Conspectus Medicinæ. Theoret. vol. i. p. 212.

§ This question is ably argued between Drs. Coxe and Patterson, in the 13th, 15th, and 18th vols. of the Med. and Phys. Journal.

turgid, and traces of inflammation in the brain, a kind of serous diffusion over the convolutions, and three ounces of serum in the ventricles.* He also mentions a case in which the patient, after being cured of chorea, very soon fell a victim to hydrocephalus, (Med. and Phys. Journ. vol. xv. p. 127.) M. Serres states that in one case he found a fatty tumour resting on the tubercula quadrigenina; in another, marks of considerable excitement, with bloody effusion at the base of these bodies; and in two others the whole of their substance was inflamed, and the inflammation extended to the roof of the fourth ventricle, (Lancet, vol. xiii. p. 133.) It appears also that he has, by experiments on living animals, found that injury of these parts is followed by motions similar to those of chorea. We are not aware that these experiments have been published in detail, and are therefore unable to estimate their accuracy or conclusiveness. We would, however, express a doubt whether M. Serres's cases of chorea were of the ordinary species; and we think that the simple fact of their proving fatal, in some measure justifies us in this hesitation, especially when the vagueness with which the term has been often used is taken into consideration. We shall presently remark on the probable origin of those more rare diseases which have been denominated chorea. In the mean time, we shall only mention that M. Serres admits that he has seen cases of chorea in which no injury in the brain could be discovered after death. In a fatal case of a somewhat anomalous character, published by Dr. Hawkins, there was no morbid appearance discovered within the cranium, but earthy concretions were found in the pancreas, omentum, and mesentery; tubercles in the lungs; and the uterus was large and vascular, with its lining membrane highly injected, (Med and Phys. Journ. vol. lvii. p. 240.)

[The fact, that the disease generally terminates in perfect health, shows that the affection of the neurine is not serious, and classes the disease amongst the neuroses. They who believe that the cerebellum is the regulator of the movements would necessarily place chorea in that part of the encephalon. Dr. Marshall Hall refers it, with convulsive movements in general, to his reflex system;—in other words, to the true spinal marrow. The disease belongs, however, rather to a badly regulated volition, like that which exists in stammering, which has, indeed, been called—not inappropriately—a “Saint Vitus’s dance of the voice,” and is, consequently, cephalic rather than spinal. The disease is essentially a functional affection of the nervous centres, in the large majority of cases, but of what precise nature we know not,—except that, generally, signs of great nervous mobility and debility are present, and have to be energetically combated.]

Treatment.—If proof were wanting of the varied origin of chorea, it might perhaps be found in the numerous and sometimes conflicting remedies, which have from time to time been extolled as successful in its treatment. From this circumstance, indeed, it has been concluded by some that the disease in general subsides spontaneously, and

is but little under the control of medicine; a belief which receives some degree of countenance from the general tediousness of the complaint, under any mode of treatment. It is, doubtless, quite as difficult in this disease as in many others to distinguish between mere *sequence* and *consequence*. As we have, however, a perfect conviction of the efficacy of certain remedies, almost opposite in their nature to others which have been sanctioned by high authority, we must either admit a difference in the exciting causes, or explain the seeming inconsistency by supposing that one remedy cures the disease by removing the apparent cause, and another by correcting some state of the system which may either render it susceptible of its influence, or be itself an immediate and essential link between that cause and the symptoms of the disorder: for example, that of the two most approved methods of treatment in the present day, purgative medicines may be beneficial by removing causes of irritation from the intestinal canal; while metallic tonics may cure the malady by correcting a weak, mobile, or irritable state of the body, without which such irritating causes would not have produced the disease, and in consequence of which, indeed, it may often be prolonged after such causes are removed.

Since the publication of Dr. Hamilton's work, “On the Utility of Purgative Medicines,” the administration of cathartics has almost uniformly entered into, if it has not constituted, the sole treatment in chorea. Though it formed perhaps, the principal part of Sydenham's practice in this disease, it had become in a great measure discontinued; and Dr. Hamilton undoubtedly produced by his treatise a most important and useful change in this respect; and proved, in a vast many cases, not only the safety, but the extraordinary efficacy of very powerful cathartics. When the disease is yet in an early stage and scarcely established, gentle aperients may be sufficient, or indeed all that it is proper to administer. But he tells us that in the confirmed stage, when the intestines have in a great degree lost their sensibility, and the accumulation of faeces is great, whoever undertakes the cure of chorea by purgatives, must be decided and firm to his purpose. Powerful medicines must be given, in successive doses, in such manner that the latter doses may support the effect of the former, till the expulsion of the accumulated matter is completely effected. When worms are known to have been passed by the bowels, or are suspected to be the cause of the complaint, the most successful, if not a specific remedy, is the oil of turpentine, in a full dose of from three to six drachms, or more, according to the age of the patient and other circumstances.

[The oil of turpentine is a valuable remedy in chorea, whether produced by worms or not. When the bowels have been torpid, and the girl is of an age at which the first occurrence of menstruation may be looked forward to, its advent has appeared to have been hastened, and great relief to be produced by turpentine.]

Although purgatives, however, are in many cases the most efficacious remedies, and perhaps necessary in the greater number, both in commencing the treatment, and at intervals afterwards, we believe most practitioners will admit

* Med. and Phys. Journ. vol. xv. p. 119, et seq.; vol. xviii. p. 234; or “Letters concerning the Internal Dropsy of the Brain.” 1794.

that they have often failed in removing the disease, and that medicines of another kind have succeeded without their assistance; while Cullen and other high authorities state that they have found repeated evacuations, of any kind, in many cases injurious.

In most instances, more especially after the exhibition of purgatives, we conceive that of all remedies tonics are the most successful. Sydenham used only the vegetable tonics; and Cullen preferred cinchona to the metallic preparations, as being of safer administration. We think there is no doubt, however, that the latter possess considerably more efficacy, and many of them are now found to be perfectly safe, in infinitely larger doses than were formerly considered prudent. The preparations of iron, zinc, copper, silver, and arsenic, are those which have principally been exhibited.

Dr. Elliotson has contributed much to establish the efficacy of the subcarbonate of iron in chorea. In the thirteenth volume of the *Medico-Chirurgical Transactions*, he published an account of eight cases cured by it, and proved that it might, and required to be given in much larger doses than had before been usual. Even the presence of headach, giddiness, and symptoms of paralysis, do not always, he says, forbid its use, but frequently disappear under its exhibition. In four of these cases no purgatives were administered, and in some of the others they could have aided but little in the cure. In his lectures, published in the *Medical Gazette*, he tells us that he has since cured many dozen cases by the same medicine, and has scarcely failed in a single instance; and adds that he thinks it will prove effectual in more cases than any other remedy. Occasionally it has been necessary to continue it for three months. (*Medical Gazette*, vol. viii. p. 653.) The dose of the medicine may at first be from half a drachm to a drachm, increased by degrees to three or four drachms, and taken every six hours, in gruel, mucilage, or treacle; which latter may obviate any constipating effect from it. The sulphate of iron has also been found of some efficacy in chorea, and may be administered in doses of from one to four grains.

[The ferro-cyanuret of iron has been administered with success,—three grains being given in the form of pill three times a day.]

The sulphate of zinc has great power over the disease, and may be given in considerable doses, when they are increased in a gradual manner. The oxyd of that metal, however, is a more manageable preparation, and we have found it of the most uniform efficacy. It may at first be given in doses of five grains, and gradually increased. We have given it, in one case, in doses of twenty-five grains. Mr. Bedingfield states that this remedy was so speedily and decidedly successful in the Bristol Infirmary, that he cannot help regarding it as a specific. Upwards of forty cases, occurring there, were, with one exception, cured by it; and he attributes its failure in other hands to its not having been administered with sufficient regularity, or in sufficient doses to excite nausea. Some of the cases, however, were cured without the nauseating effect. (*Compendium of*

Medical Practice, p. 51.) [The cyanuret of zinc has likewise been efficacious.]

The preparations of copper having been sometimes efficacious in other convulsive diseases, such as epilepsy and hysteria, have been given in chorea. The sulphate may be administered in doses of a quarter of a grain, or half a grain, twice a day, and the quantity increased if the stomach will bear it. The ammoniuret, or the cuprum ammoniatum, introduced into practice by Cullen, is of safer exhibition, though it should also be begun in very small doses. Cullen states that he had in some cases increased the dose by degrees to five grains and upwards, and that he had often found it to cure epilepsy. In chorea its virtues do not appear to have been by any means so striking as those of iron and zinc. Dr. Uwins relates a case which got well under its use, combined with digitalis and myrrh. (*Edin. Med. and Surg. Journ.* vol. viii. p. 408.)

The nitrate of silver, likewise a successful remedy in epilepsy, has been occasionally administered in chorea. In our own practice it has almost uniformly disappointed our expectations. By others, however, it has sometimes been found successful, as in a case related by Dr. Uwins, in the *Edinburgh Medical and Surgical Journal*, (vol. viii. p. 407;) in two, by M. Priou, in the *Medical and Physical Journal*, (vol. lii. p. 262;) in another, by Mr. Franklin, in the same work, (vol. xxxiii. p. 273;) and in another, by Dr. Crampton, in the *Transactions of the King and Queen's College of Physicians*, (vol. iv. p. 114.)

The liquor arsenicalis has been used as a tonic, in this as in some other diseases, with considerable success. Several cases of its efficacy are published in the fourth, tenth, and eleventh volumes of the *Medico-Chirurgical Transactions*. In two of these arsenic was the only remedy used, (vol. x. pp. 227, 229;) in the others it had been preceded by purgatives. The dose of the solution should at first be three drops thrice a day, and it may be increased to ten drops or more, according to its effects.

Of the vegetable tonics, Peruvian bark will be found the most powerful. Cullen says that he found it remarkably useful in this disease. Gentian, likewise, and other bitters, have occasionally been of service. De Haen used the leaves of the Seville orange-tree as a stimulant and tonic in spasmodic diseases, with considerable success.

Iodine is a medicine which has lately been used with some success in chorea, probably from possessing a tonic and stimulating power. Dr. Manson has published a number of cases which were successfully treated by it, in combination with mild cathartics. (*Medical Researches*, &c. p. 187 et seq.) Dr. Gibney, of Cheltenham, has also published two cases in which it was used with success along with other medicines, (*Medical Gazette*, vol. i. p. 54;) and Dr. Peltz relates a similar case in the *Philadelphia Journal*. (See *Med. and Phys. Journ.* vol. lix. p. 454.) It may be given in the form of tincture or the solution of the hydriodate of potass. The former, Dr. Manson directs to be made by dissolving twenty-four grains of iodine in an ounce of rectified spirit; and the dose may be from five to ten or fifteen drops three

times a day, in some distilled water. He makes the solution by dissolving twenty-four grains of the hydrate of potass in an ounce of distilled water; the dose is ten drops to twenty. As the preparations of iodine, however, have been made of various strength by its various advocates, and will probably continue so until admitted into our pharmacopœia, they ought to be administered with due consideration; very mischievous effects, and in some cases an affection not unlike chorea itself, having been occasioned by its incautious exhibition. (See BRONCHOCELE.)

Of the remedies used for the purpose of giving tone or strength to the system, cold bathing and cold affusion are not to be overlooked. [The Russian bath and sulphurous baths have, likewise, been found serviceable. (*Practice of Medicine*, 2d edit. ii. 244 : Philad. 1844.)] Electricity and galvanism, also, have been recommended, and the former employed in some instances [especially of late, by Drs. Addison and Golding Bird] with advantage.

Narcotic medicines have been frequently used with benefit, though they have occasionally been useless if not injurious. Stoll used the extract of belladonna, in doses of one sixth or one fourth of a grain every six hours, with great advantage; and Cullen says that he found opium very generally useful in chorea. (*Materia Medica*, vol. ii. p. 246.) Dr. Patterson mentions that an unusually severe case in the Bristol Infirmary was cured by opium and camphor; and Mr. Bedingfield tells us that the only case under his observation there which resisted the oxyd of zinc, was cured by laudanum and tartarized antimony. Digitalis has by some been occasionally found of service; and in the twenty-eighth volume of the Edinburgh Medical and Surgical Journal two cases are related in which the convulsive motions ceased under the use of hydrocyanic acid, preceded by purgatives. Some cases are related in the Medical and Physical Journal, in which a speedy cure was effected by colchicum, without its producing a cathartic, or any other sensible operation. (Vol. xxxi. p. 181, 292.)

[Testimony has been afforded in favour of cimicifuga, which, in large doses, is an acro-narcotic. The dried root may be given in powder in the dose of a teaspoonful three times a day; or it may be given in decoction. (*New Remedies*, 4th edit. p. 164 : Philad. 1843.)]

Musk, valerian, camphor, and other antispasmodics have occasionally been given, but in general without any benefit. Two cases however, are related in the fifth volume of the Medical Transactions, in which Drs. Powell and Maton found the first of these successful. The cardamine pratensis, also, had at one time a reputation in this disease. Sir George Baker published some cases of spasmodic affection, two of them chorea, in which it appeared to him to be of decided benefit; but there is little confidence now placed in it.

Although we conceive that in the great majority of cases chorea will be most successfully treated by means of purgatives and tonics, more especially the latter, it cannot be denied that instances have occurred in which there has been such affection of the head as to indicate the propriety of local, or even general bleeding, and other antiphlogistic

means of cure. Bleeding, as we have seen, was one of Sydenham's remedies; and Cullen admits that he had in some instances found it useful, though frequently very hurtful. In one case, Dr. Robert Watt found that it had an almost immediate effect in allaying the convulsive movements. (Cases and Observations, &c. Paisley, 1808.) Dr. Clutterbuck has in a number of instances prescribed it, at intervals of a few days, ten or a dozen times, and even oftener, without any other active remedies, and without failing of success. (See his Lectures. *Lancet*, vol. xii. p. 421.) Dr. Armstrong, who trusted principally to cathartics, aided by diet, exercise, air, and the tepid bath, to restore the functions of the skin, cautions us against the free use of the lancet, and mentions a case, as we stated above, in which it nearly proved fatal. (Lectures. *Lancet*, vol. viii. p. 70.)

The use of external counter-irritants has often been of much service, especially when there has been any considerable affection of the head. Blistering the scalp, or rubbing it with tartar-emetic ointment, has been adopted with this indication. The same remedies have been applied in the course of the vertebral column, a mode of treatment which accords with the conclusion drawn by Magendie, from the experiments presently to be recounted, that the direct cause of motion is in the spinal chord; and which would therefore promise, as it has afforded, in cases of a more permanent description, especial advantage. For such purpose, also, a seton in the neck, the moxa, &c. have been recommended. As the disease often arises about the period of puberty, from impeded menstruation, the application of a blister to the sacrum promises to be useful. Dr. Chisholm states that he found it successful after purgatives and antispasmodics had failed. (On the Climate and Diseases of Tropical Countries, p. 97, Svo. 1822.) Mr. Swan, of Lincoln, found it to have an immediate effect in allaying the convulsive motions. (*Edinburgh Med. and Surg. Journal*, vol. xxii. p. 94.)

When chorea arises from the coming of the second set of teeth, lancing the gums, or the removal of some of the first set, will be proper. Instances in which the disease was speedily removed in this manner by Drs. Monro and Gregory, are referred to in the first volume of the Edinburgh Medical and Surgical Journal, p. 32.

Darwin, as he conceived the disorder to arise sometimes from the itch being hastily repelled, begins his directions for the cure by telling us to "give the patient the itch again." (*Zoonomia*, vol. iv. p. 291.) He also furnishes us with an ingenious suggestion, that perpetual and repeated efforts should be made to move each limb in the designed direction, in expectation of the same good effects that follow from such efforts in stammering. Independently of any other benefit from such an exercise, one evident advantage would be, the abstraction of the patient's attention from his complaint—a matter of no slight importance in this and many other convulsive diseases. M. Louvet Lamarre found the exercise of the skipping-rope of much use in one instance. (*Med. and Phys. Journ.* Vol. ix. p. 89.) On this subject Dr. Mason Good remarks that a long and punctual discipline of the affected limbs to regular

and measured movements, might, where the disease is not very severe, recal them to their wonted order and firmness; and adds that with this view the exercise of dancing, by which the original chorea Sancti Viti is said to have been cured so singularly, may be well worthy of attention. (Study of Medicine. Vol. iv. p. 485.) The influence also of music alone, independent of the measured efforts in dancing, ought not to be overlooked. In some of the diseases resembling the original St. Vitus's dance, as we shall presently see, an extraordinary passion for music has been among the most prominent symptoms; and Dr. Armstrong relates a case in which music had the effect of procuring sleep, and of ultimately curing the disease altogether, after it had resisted purgatives, sulphate of zinc, the arsenical solution, and various other means. (Lectures. Lancet. Vol. viii. p. 70.) When the will retains any power over muscular action, as it does in the ordinary form of the malady, it might be expected that such power, in a person susceptible to music, would be irresistibly or unconsciously exerted, to reduce the erratic movements as much as possible into harmony with its measured cadences. Nor will this appear fanciful to any one, who, being endowed with a musical ear, may have experienced how difficult it is, while music is sounding, even to obey the will in movements which do not accord with its measures.

[Under the head of chronic chorea, Dr. Watson (*Lectures on the Principles, &c. of Physic*, Amer. edit., p. 364: Philad. 1844.) has placed *partial choreas, tics, spasmodic tics, or nervous tics*, which consist in the most irregular and fantastic movements of certain muscles,—at first dependent upon bad habits, badly regulated volition, but subsequently executed independently of all volition. At times, they arise in consequence of some morbid condition of the nerves, and in spite of every effort of the individual. There is no plan of treatment which can be serviceable in such cases. Mental attention, with appropriate revulsion, may be sufficient; but if not, every other agency must fail. There is no danger, however, in these affections.]

We shall now advert to those singular affections which seem to have been erroneously classed with the foregoing disease, as well as to some others which appear to have been equally entitled to the appellation of chorea.

There is the following curious account of the original chorea Sancti Viti, in Burton's *Anatomy of Melancholy*. "Chorus Sancti Viti, or St. Vitus's dance; the lascivious dance Paracelsus calls it, because they that are taken with it can do nothing but dance till they be dead or cured. It is so called, for that the parties so troubled were wont to go to St. Vitus for help; and after they had danced there a while, they were certainly freed. 'Tis strange to hear how long they will dance, and in what manner, over stools, forms, tables; even great bellied women sometimes, (and yet never hurt their children,) will dance so long that they can stir neither hand nor foot, but seem to be quite dead. One in red clothes they cannot abide. Music above all things they love; and therefore magistrates in Germany will hire musicians to play to them, and some lusty sturdy com-

panions to dance with them. This disease has been very common in Germany, as appears by those relations of Selenkius, and Paracelsus in his *Book of Madness*, who brags how many several persons he hath cured of it. Felix Platerus (*de Mentis Alienat. cap. iii.*) reports of a woman in Basil, whom he saw, that danced a whole month together," (Vol. i. p. 15. 8vo. edition. London, 1826.) This malady appears to have been generally considered as a disease of the mind, and we learn from Horstius and others, that it was liable to recur every year at the same period. The movements do not seem to have been actually spasmodic, but rather to have arisen from an irresistible propensity to muscular action, increased to a sort of phrenzy by the sound of music and the force of imitation. The frequency of the disease, as reported, however, gives rise to suspicions of imposture.

Baglivi, who has given us an account of somewhat similar symptoms arising from the bite of the tarantula, or venomous spider, in Apulia, and cured exactly in the same manner, states that the disease was very often counterfeited by the women, who in that country lived solitary lives, for the purpose of enjoying the agreeable diversion of music and dancing, which was only allowed to those afflicted with the malady. "In fine," says he, "the musical entertainment of this country" (in allusion to the mode of curing the disease) "is so very agreeable to the women, that 'tis a proverb with us, '*Il carnevalletto delle donne.*'" He informs us, however, that there really was an unfeigned disease arising from the bite of the tarantula; Sauvages has named it *tarantismus*; and says that "those who are stung die in a little time without the present assistance of music, all other remedies giving no relief." His description of the symptoms and the mode of cure are very singular. "A few hours after the bite," says he, "the patient is seized with a great difficulty of breathing, a heavy anguish of heart, and a prodigious sadness," &c. The malady, "after the sharp fit of the violent symptoms, which appear for the first days, is over, ends at last in a peculiar kind of melancholy, which continually hangs upon the sick person, till by dancing, or singing, or change of air, those violent impressions are quite extirpated."—"Many of these persons are never well but among graves and in solitary places; and they'll lay themselves along on a bier, as if they were really dead; they'll throw themselves into a pit as if they were in despair. Maids and women, otherwise chaste enough, without any regard to modesty, fall a sighing, howling, and into very indecent motions, discovering their nakedness; they love to be tossed to and again in the air; and the like. There are some that will roll themselves in the dirt like swine, and are mightily pleased with the exercise. Others, again, you cannot please, unless they be soundly drubbed on the breech, heels, feet, back, &c. And there are some that take a great pleasure in running. There are also curious observations made about colours; some of which are very agreeable to those persons, as others are offensive to them." In describing the manner in which they are worked upon by music, he says, "When any are stung, shortly after it they fall down upon the ground,

half dead, their strength and senses going quite from them. Sometimes they breathe with a great deal of difficulty, and sometimes they sigh piteously; but frequently they lie without any manner of motion, as if they were quite dead. Upon the first sounding of the music the forementioned symptoms begin slowly to abate; the patient begins to move his fingers, hands, feet, and successively all the parts of the body; and as the music increases, their motion is accelerated; and, if he was lying on the ground, up he gets, (as in a fury,) falls a dancing, sighing, and into a thousand mimic gestures. These first and violent motions continue for several hours, commonly for two or three. After a little breathing in bed, where he is laid to carry off the sweat, and that he may pick up a little strength, to work he goes again, with as much eagerness as he did before, and every day spends almost twelve hours by the clock in repeated dancing; and, which is truly wonderful, so far is he from being wearied or spent by this vehement exercise, that (as they say) it makes him more sprightly and strong. There are, however, some stops made; not from any weariness, but because they observe the musical instruments to be out of tune; upon the discovery of which, one would not believe what vehement sighings and anguish at heart they are seized with; and in this case they continue till the instrument is got into tune again, and the dance renewed. This way of dancing commonly holds four days, it seldom reaches to the sixth. Every patient has not only his particular tune, but also his particular instrument; some a pastoral pipe, others a little drum, cittern, harp, timbrel, violins, and pipes of several sorts. Here 'tis remarkable that sometimes the musicians will tune three or four different sorts of sounds without having the least effect upon the patient. But when they fall into a tune that 's accommodated to the poison, they presently receive the benefit of it. However, this must be taken for a truth, that how much soever they vary in their particular tunes, yet they all agree in this—to have the notes run over with the greatest quickness imaginable, (which quickness of sound is commonly called *tarantella*.) And therefore the players that have not their lesson to learn in these matters, easily discover the cheat of the women; for if they find that they presently take any motions, and jog on indifferently, without any regard to the swiftness, slowness, or other difference of sounds, they give to understand that the honest woman is but in jest, and afterwards experience puts the matter out of doubt." (Baglivi's Practice of Physic, p. 363 to 382, *passim*. London, 1704.) He states that the disease, like the German chorea Sancti Viti, generally returned about the same time of the year that the patient was stung; and seems much at a loss to understand either how it was produced, or in what manner it was cured. He appears inclined, indeed, to account for the latter, by the profuse sweatings induced by the violent exercise; but he admits that the physicians could not cure it by artificial sweatings. A cony which was stung by a tarantula and died on the fifth day after, was not at all influenced by music. On opening it after death, he tells us that "the veins and arteries of the brain were swelled up, and the brain

itself a little inflamed, and set about with blackish spots here and there. The lungs and other entrails were distended with clotted and black blood. In the ventricles of the heart were observed greater clots of blood, and small branches of a polypous concretion. There was abundance of serum lying about the outward parts of the brain. The other parts were sound and untainted." (Page 386.) There is a case related in the New York Repository, (Hex. ii., vol. i., p. 1-11. Med. and Phys. Journ. vol. xv.), of a convulsive disease, ascribed to the bite of a spider, which, like that from the tarantula, was most effectually counteracted by music. In the latter malady, as in the original St. Vitus's dance, the principal peculiarities were the excessive love for music, and desire of muscular motion, especially in regulated measures. In both there was a liking or dislike of certain colours; and in both, the imagination at least, if not the intellect, was from the commencement disordered. Such, however, it is almost needless to observe, are far from being the characteristics of the ordinary chorea.

Mr. Kinder Wood has related a singular case in the Medico-Chirurgical Transactions, which he names chorea Sancti Viti; and it certainly had much in common with the original disease of that name. The patient, a married woman, aged twenty-two, after complaining of severe pains in the right side of the face, succeeded by heaviness and wildness of the eyes, became affected with extraordinary involuntary motions, commencing in the eyelids, which were opened and shut with excessive rapidity. They then affected the muscles of the extremities. The palms of the hands were beat rapidly on the thighs, and the feet on the floor, the arms being at times extended, the palms turned outwards and inwards, and the backs of the wrists struck violently on each other, or the middle fingers on the palms of the hands with great quickness. The motions soon extended to the trunk of the body and the pelvis; and the patient was half raised from the chair, and instantly reseated in rapid succession. Sometimes she was forcibly thrown on her feet, when she jumped and stamped violently, and she had often a propensity to spring or leap upwards, and strike the top of the room with the palm of the hand. Frequently she would dance on one leg, holding the other with the hand. These attacks were accompanied with headach, sickness, and vomiting, which generally succeeded the affection of the eyelids. On the third day she began to strike the furniture and doors violently with her hand, and was greatly pleased with the sound. At length the bystanders observed that the strokes assumed a regular tune and measure, and the motions were changed into a step about the room, regulated by an air, or series of strokes upon the furniture as she passed. Though, previous to her illness, she could not even dance a country dance, she would now move about in all the elegance of a minuet. When she looked around, she had an irresistible propensity to spring up and touch little spots or holes in the ceiling; and she would dart the forefinger with amazing rapidity and precision through a hole in a wooden screen. A person, thinking he recognised the tune which she beat on the furniture, began to sing it, and she

danced directly up to him, and continued dancing till she was out of breath. A drum and fife were now procured, and she immediately danced up to the drum, and as close to it as possible, till she missed the step, when the motions instantly ceased, and this was always found to be the case. The motions were always found to cease, also, when the measure was changed, or increased in rapidity beyond her power to keep pace with it. When a continued roll was kept up on the drum, it had likewise the effect of stopping the motions. Their approach was therefore watched, and by uniformly rolling the drum when it was observed, the chain of associations which constituted the disease was at length broken. Mr. Wood states that the alvine excretions were unnatural during the complaint, and that the menstrual discharge appeared on the evening of the day on which it ceased; together with an eruption on the skin, in diffused patches, of a bright red colour. Whether these were essential circumstances in the history of the case is a question worthy of consideration. Mr. Wood thinks that the case establishes the connection of such instances of inordinate muscular action with some peculiar state of the mind. He tells us, however, that the patient's spirits were good, her perception and judgment accurate and just; that during the absence of the paroxysms she went about many household affairs; and that she had a correct knowledge of her situation, and of the advantages she derived from the agency of the drum, with an anxious desire to continue its use. A subsequent less severe attack of the complaint disappeared under the use of aperients and tonics; and the third and last, which terminated in spasmodic affections of the abdomen, chest, neck, and face, seems to have been chiefly benefited by bleeding. It is curious that, after the nature of the motions was changed in this last attack, the drum had no effect upon them. (*Medico-Chirurg. Trans.* vol. vii.)

[In another work, (*Practice of Medicine*, edit. cit. ii. 295,) the author has given, on the authority of a young medical friend, an account of a singular affection said to be somewhat common in the southeastern portion of the state of New York, and known among the common people as the *magrums*. It is said to consist essentially in a spasmodic action of all, or nearly all, the voluntary muscles. In the involuntary movements, the upper part of the air-passages occasionally participate, as witnessed by a clucking sound in the neighbourhood of the glottis, and a manifest impediment in the powers of speech. The movements of the face, neck, extremities and body, wholly cease during sleep. The disease very rarely makes its appearance before adult life, and attacks after forty-five years of age are very rare. It rarely or never ceases whilst life lasts, and appears to be hereditary.]

Of the disease which has been at times prevalent in some parts of Scotland, and known by the name of "the leaping ague," the following is a concise description:—"Those affected first complain of a pain in the head or lower part of the back, to which succeed convulsive fits or fits of dancing at certain periods. During the paroxysm they have all the appearance of madness, distorting their bodies in various ways, and leaping and

springing in a surprising manner, whence the disease has derived its vulgar name. Sometimes they run with astonishing velocity, and often over dangerous passes, to some place out of doors, which they have fixed on in their own minds, or perhaps even mentioned to those in company with them, and then drop down quite exhausted. At other times, especially when confined to the house, they climb in the most singular manner. In cottages, for example, they leap from the floor to what are called the baulks, or those beams by which the rafters are joined together, springing from one to another with the agility of a cat, or whirling round one of them with a motion resembling the fly of a jack." (*Edin. Med. and Surg. Journal*, vol. iii. p. 835, or the *Statistical Account of Scotland*, by Sir J. Sinclair, *passim*.)

The most recent published case of this disease, so far as we are aware, will be found in the 31st volume of the *Edinburgh Medical and Surgical Journal*. Mr. Crichton states that the patient was a girl fifteen years old, and that the affection was announced by frequent shakings, with foaming at the mouth, followed by coma. In addition to many of the symptoms mentioned in the foregoing passage, such as dancing, jumping upon the furniture of the room, running round a table, springing on the top of a door to swing backwards and forwards, leaping over a staircase at one bound, and desiring to spring out of a window; she had likewise the following singular affection: "she would occasionally converse with those in the room, but in a language that no stranger, and hardly even those of the family who were constantly beside her, could understand. This arose from her commencing the sentence with the last word, and very frequently pronouncing the words themselves with the last letter foremost. At times, when by no possibility she could make herself be understood by her parents or sisters, she became irritated, and would write down what she wished to convey; but her manner of writing was equally singular, beginning at the right edge of the paper, and writing backwards towards the left, the last word of the sentence first, and often the last letter of the word first; and this she performed with great rapidity, and seemingly without consideration." (*Vol. xxxi. p. 300.*) She had a propensity to secrete things; and so irresistible were the impulses to motion, that the strength of several people was insufficient to constrain her. Purgatives afforded her little benefit. Opium before the paroxysm sometimes prevented it; and the shower-bath cured the disease, though it produced locked jaw for eight days. The "leaping ague" may be said to consist, generally, of a morbid propensity to running, leaping, dancing, or tumbling, which the patient is unable to resist. The muscular motions, though in a great degree involuntary, are performed with more agility and exactness than usual; for the person affected can run with greater velocity, leap with greater vigour, and do feats which even professed tumblers could not equal, balancing the body with correctness, and dexterously avoiding dangers. It is scarcely necessary to point out how widely the disease differs in all these respects from the ordinary chorea.

M. Piedagnel has related the case of a man,

who, after some symptoms of cerebral affection, was seized with an irresistible propensity to move forwards, only stopping when exhausted. Finding his apartment too confined for the gratification of his propensity, he would sally into the streets, and continue walking straight forward until he dropped down, and was obliged to be brought home in a litter. On opening the head, several tubercles were found, involving in a particular manner the anterior part of the hemisphere. (Magendie's Physiologie, tom. iii. or Magendie's Physiology, translated by Dr. Milligen, 3d edit. p. 189.) In direct opposition to this case, Dr. Laurent, of Versailles, exhibited a young girl to the Academy of Medicine, who, in the attacks of a nervous disease, was irresistibly propelled backwards, and with some rapidity, being unable to avoid obstacles or hollows, and, consequently, receiving many bruises and falls in her course. (Magendie's Physiology, p. 191.)

An account of a very remarkable case, in which a young girl, in Renfrewshire, was affected with violent fits of leaping, dancing, running, crying, fainting, &c., was published at Edinburgh, in 1698. It was entitled "A True Narrative of the sufferings of a Young Girl, who was strangely molested by Evil Spirits, and their Instruments, &c." The disease being ascribed to witchcraft, a commission was appointed by the king to inquire into the matter, and seven unfortunate beings in consequence were condemned to the flames!

One of the most extraordinary cases of convulsive disease on record has been related by Dr. Robert Watt, of Glasgow, in the 5th volume of the Medico-Chirurgical Transactions, under the title of Chorea, or "Periodical Jactitation." The patient was a lively, but rather delicate girl, ten years old, from Ayrshire. She was first seized with excruciating headach, and almost incessant vomiting, increased by the slightest inclination of the body either backwards or forwards. These symptoms continued for a month, during which time she lost the power of speech and of walking. At the end of that time she was seized with a propensity to turn round on her feet, like a top, with great velocity, always in one direction, and was gratified when the attendants assisted her in increasing the rapidity of her movements. After continuing nearly a month these motions ceased, the headach returned with increased severity, and was succeeded by a total loss of power over the muscles of the neck. In a short time after, she was seized with a new kind of motion. She would lay herself across the bed, and, turning round like a roller, moved rapidly from one end of it to the other. The fits continued at first for about two hours; but they gradually increased to six or seven hours daily. On being carried into the garden, she rolled rapidly from one end of a walk to the other; and, even when laid in the shallow part of a river, though at the point of being drowned, she began to turn round as usual. Nor did the sudden dashing of cold water over her interrupt her movements. Her rotations were about sixty in a minute. In a month or six weeks, the movements became of an entirely new kind. The patient now lay upon her back, and, by drawing her head and heels together, bent herself like a bow, and then allowing her head and heels

to separate, her buttocks fell with considerable force upon the bed. She repeated these movements ten or twelve times in a minute; at first for six hours daily, and at length for fourteen. After this had continued for about five weeks, she was seized with a propensity to stand upon her head with her feet perpendicularly upwards. As soon as the feet were elevated in this manner, all muscular exertion seemed to be withdrawn, and the body fell down as if dead; her knees first striking the bed, and her buttocks striking her heels. This was no sooner done than she instantly mounted as before, and continued to do so, from twelve to fifteen times in a minute, for fifteen hours a day. The disease left her after a spontaneous diarrhœa, having previously resisted cathartics, an emetic, local bleeding, blistering, a seton in the neck, &c. Dr. Watt states that another instance, similar to this, had occurred some years before in Ayrshire, and that he had been informed of a third in the same county: in both of these, also, the patients were young women. There is a case mentioned in the 3d volume of the Edinburgh Medical and Surgical Journal, page 437, in which a young girl was affected with a species of motion similar to the first which Dr. Watt's patient presented. "Her complaint began with convulsions of the diaphragm and abdominal muscles, producing an action like retching, or something between hiccough and retching. Convulsions of the extremities supervened, and in the paroxysms, which lasted several hours, she performed the most singular motions; at one time bounding upon her bed, then turning round and round, as upon an axis; then running round the outside of the ropes by which her hammock was suspended." She had several paroxysms a day, coming on at stated intervals, and she had constant pain, which she referred to the region of the uterus. Nothing was discovered on dissection after death, which could at all explain the nature of the disease: some time before she was affected, she had rather a severe fall upon her head.

Mr. Hunter, of Glasgow, relates a case in which the principal symptom was a convulsive rotation of the head and trunk; he entitles it, therefore, "*rotatio*," or chorea. The patient was a female, twenty-three years old, and unmarried. While lying on her back, the head was rolling from side to side, with a quick, regular, and continued movement. When a fit came on, "she sprang with a strong convulsive movement from her back, and sat up in the bed. The rotatory motions of the head now became furious and alarming. They were executed with such immense rapidity, that it was difficult even for eye to follow them. She appeared absolutely to be looking backwards and forwards, and in every direction, at the same instant. The movements, while in the sitting posture, were not confined to the head; for the whole trunk likewise partook of the rotatory motions, the breech being the pivot upon which the whole turned. These convulsive motions continued about a minute, when they took a new but equally strange direction. The flexor and extensor muscles of the head and trunk were alternately called into action, and without the breech of the patient moving from its first position, her head was rapidly carried forwards to her knees, and

backwards to her pillow, for about half a minute, when the paroxysm ceased, and left the patient greatly exhausted." (Edinb. Med. and Surg. Journal, vol. xxiii. p. 261.) She was perfectly rational, but the external senses were blunted and torpid. She sometimes had fifty paroxysms in a day. The disease appeared to commence in the uterine region, where there was pain on pressure; and it was cured by rubbing tartar emetic ointment on the scalp, and along the course of the vertebrae. A case in some respects similar to this has occurred in our own practice, in the person of a young woman, who was affected for a long time with rotation of the head, without pain, but accompanied by intolerance of light. The motions, however, were far more gentle and slow than in Mr. Hunter's case, and they were unintermitting.

A patient attended by Dr. Conolly became subject, about the period of the cessation of the catamenia, and when menstruation had become irregularly performed, to violent paroxysms of rotation: they occurred many times in a day, and were always preceded by an inordinate disposition to talk. When the fits came on, the head was forcibly rotated from side to side about eight times in a second, and the paroxysm commonly lasted three or four minutes. In this case, the affection yielded to cupping behind the neck, application of leeches to the head, and the persevering use of aloetic purgatives.

Another singular form of disease, which has at times been ranked with chorea, is that affection, by some authors called *malleatio*, and consisting, principally, of a striking of the knees with one or both hands, as with a hammer. The hands are generally open, but sometimes they are clenched. Morgagni mentions a case of this description, in which one hand was convulsed; on extending any of its fingers the other hand became affected also; and if attempts were made to arrest the motions by force, they became both more violent and more general. We ourselves recollect the case of a man, in the Hampshire County Hospital, in whom there was a constant and uniform striking of the palm of one hand upon the side of the thigh, to such a degree, as speedily to wear out the part of his dress on which it fell.

In the preceding cases of anomalous convulsions, it will be observed that there was for the most part a periodical return and intermission of the spasms, as well as some method or regularity in the movements themselves. In both these respects they differ from the common chorea of this country. Other cases have been met with, occurring in paroxysms, but in which the motions were obedient to no rule or method. Dr. White, of York, describes a case of this kind in the fourth volume of the Edinburgh Medical Commentaries, p. 326, in which the muscles of various parts were, not simultaneously, but in succession, painfully convulsed, producing appearances so grotesque as to defy description. Three cases, occurring in one family in the county of Rutland, are related by Dr. Armstrong, in the ninth volume of the same work, p. 317, in which the patients were affected periodically, and suddenly, with fits of shrieking, jumping, writhing, &c. The disease

first occurred after hooping-cough, and Dr. Armstrong considered it as epileptic.

There are some singular instances recorded of affections like the last being propagated by sympathy or imitation. These have generally been attended, and in the first instance, excited by religious or some other species of enthusiasm. This was strikingly the case in that extraordinary epidemic, as it has been called, which prevailed in 1742 in the parish of Cambuslang, in Lanarkshire, during the ministry of Mr. Macculloch, and produced by his preaching and exhortations on the subject of regeneration. (Edinb. Med. and Surg. Journ., the Inquirer, No. 11), vol. iii. p. 441). A similar epidemic occurred in the western districts of America, in consequence of the electrical spread of religious enthusiasm throughout the states of Tennessee and Kentucky, about the year 1800. Dr. Robertson, who published an account of it, states that the converts indulged in alternate fits of coughing, laughing, singing, shouting, and extravagant gesticulations, until, at length "to their own astonishment, and the diversion of many of the spectators, they continued to act from *necessity* the curious character which they had commenced from *choice*."* He informs us that the convulsions were generally in the muscles of the neck, trunk, and superior extremities; and that they were sometimes so violent as to throw the patient on the ground, "where, for some time, his motions resembled those of a live fish when thrown on land, more than anything else."

M. Magendie relates a case of the most extraordinary nature, in which the power of the will over the muscular motions was, at intervals, entirely lost; but instead of the muscles being paralysed or remaining at rest, they were abandoned to the most irregular and indescribable movements for hours together. After stating that the disease was preceded by great mental anxiety, followed by melancholy, the understanding remaining however entire in all other respects, M. Magendie describes the peculiar symptoms of the case in the following words: "It is impossible to paint, by language, the variety and oddity of his motions and positions. Had he lived in the times of ignorance, he would, beyond all doubt, have passed for one possessed; for his contortions were so far removed from the motions proper to mankind, that they might easily have passed for diabolical. It was worthy of remark that, in the midst of these contortions, in which his slender and pliant body was sometimes carried forward, sometimes thrown back, or to one side, like certain tumblers, he never lost his equilibrium; and that in the multiplicity of attitudes and singular motions which he exhibited for several months, he never once happened to fall. At certain times his motions would pass into the train of ordinary actions. Thus, without the least participation of his will, he was seen to rise and walk with rapidity, until he met with a solid body that opposed his passage. Sometimes he walked backwards with the same readiness, and was only stopped by a similar

* Edin. Med. and Surg. Journ. vol. iii. p. 446; or an Inaugural Essay on Chorea Sancti Viti, by Felix Robertson, of Tennessee. 8vo. Philadelphia, 1805.

cause. He has often been observed to re-assume the power over certain motions without being in any way capable of directing others. Thus his arms and hands frequently obeyed his will, and more frequently still, the muscles of his countenance and speech. It was sometimes possible for him to retrograde in an instant, where progression forwards was anyhow prevented; and he then employed that retrograde motion to direct himself towards objects to which he wished to attain. Finally, these movements, which might be called automatic, never lasted an entire day. He enjoyed pretty long quiet intervals between the accessions; his nights were always tranquil. Although his muscular contractions were extremely violent, even to the extent of producing abundant sweats, when they had ceased, he perceived no sensation of fatigue in proportion to the efforts which he had made; as if the intellectual action which we exert to excite our motions were that which in the healthy suffers most exhaustion." (Compendium of Physiology, pp. 201 and 202).

The causes of such anomalous cases of convulsion, and the manner in which they operate, are exceedingly obscure. Modern physiologists, however, have afforded us some light on the subject. Thus, Magendie has, by experiments on some of the lower animals, shown great reason to believe that the *will* has more particularly its seat in the cerebral hemispheres, while the direct cause of motion is in the spinal marrow. We can easily conceive, therefore, says he, "why, in certain cases, these motions are not produced, though commanded by the will; and why, in certain circumstances of a contrary nature, very extensive and energetic motions are developed without any participation of the will." (Op. cit. p. 202.) In some of the following experiments confirmatory of this view, it will be observed that many of the anomalous symptoms in the cases we have just related, were produced by artificial means.

M. Magendie found that the cerebral hemispheres might be deeply cut into, or even entirely removed, provided the corpora striata were not injured, without any marked alteration of motion taking place. In a number of cases he has seen birds, reptiles, and fishes, run, leap, and swim, after the hemispheres were removed. Neither does the longitudinal section of the corpus callosum, or its entire removal, produce any additional effect upon the motions. But if the corpora striata be removed, the animal immediately darts forward, and runs rapidly, as if impelled by a power within which it cannot resist. This effect arises from the destruction of the white and striated portion of these bodies, for the removal of the brown matter does not produce any change in the movements of the animal. In unison with these facts, M. Magendie has opened several *immoveable* horses, or horses that cannot go backwards, though they can move forward with rapidity; and he has in all of them found a collection of water in the lateral ventricles, which must have compressed the corpora striata, and had even disorganized their surface. He considers it extremely probable, therefore, that there exists in man and the mammalia a force or impulse which tends to carry them forward, and which in a state of health is directed by the will. Again, both he

and others have found that lesions of the cerebellum cause animals to move backwards contrary to their will. He found also that injuries of the medulla oblongata produce the same effect. Pigeons, into which he forced a pin through that part, constantly receded, for more than a month, and even *flew* backwards. The energies of the cerebellum and medulla oblongata appear, therefore, to be directly opposed to those of the corpora striata; those of the one counterbalancing the other in the sound state, and being rendered preponderant, or otherwise, by disease or injuries of the respective parts. A still different effect was produced upon the movements of the animals when the peduncles of the cerebellum were divided. In that case the creature rolled laterally upon itself, as if impelled by a great force; the rotation being made upon the side on which the peduncle was cut; the animal making sometimes more than sixty revolutions in a minute, and the motions continuing frequently for eight days without a moment's interval. The same effect was produced by vertical and entire sections of the cerebellum; the motions being more rapid according as the section was nearer to the origin of the peduncles. When the cerebellum was cut vertically into two perfectly equal parts, the animal first rolled once or twice to one side, and then as often to the other, as if for relief. Similar effects to these were obtained by sections of the pons varolii, which, together with the peduncles of the cerebellum, forms a circle round the medulla oblongata. Sections to the left of the median line produced rotation to the left, and sections on the right side of the line, rotations to the right. A movement in a circle, resembling that of the *manège*, was occasioned by a section of the medulla oblongata, where it approaches the exterior of the anterior pyramid. If cut on the right side, the animal turned to the right; and when cut on the left, it turned to the left. Lastly, when the spinal marrow was separated from the brain by a section made behind the occipital bone, the influence of the will appeared to be entirely cut off from the movements; which, however, did not cease, but became very irregular in extent, rapidity, duration, direction, &c. (Compendium of Physiology, p. 187 to 193—200 and 201.)

These experiments, as well as those of Rolando and of Flourens, are strongly in favour of the opinion, that individual parts of the brain answer individual purposes, so far, at least, as regards the power of regulating our movements. Such singular and anomalous instances of muscular action, therefore, as those we have related, may arise from causes which produce an excitement or oppression of certain parts of the encephalon, without affecting the other parts. Certainly in many, or most of the cases, marks of cerebral affliction were observed. In M. Piedagnel's case, as we have already mentioned, several tubercles were found pressing upon the brain; in the immoveable horses, water was uniformly discovered in the ventricles; in the rabbit that died from the bite of the tarantula there were marks of inflammation, congestion, and effusion of serum on the brain. In the leaping ague, one of the first symptoms is pain in the head. Dr Watts's case was preceded by excruciating headache and incessant vomiting; Mr. Kinder Wood's

was attended with the same symptoms; and the patient whose case is referred to in the third volume of the *Edinburgh Medical and Surgical Journal*, had had a severe fall on the head some time previous to the convulsive affection. Although the existence, therefore, of partial pressure or other affections of the brain may not in all cases have been discovered, or even discoverable, — since, unless it arise from a permanent cause, it may be impossible to detect it after death, — yet it must be admitted that there are strong grounds for attributing these cases to such an origin, and for directing our remedial attentions accordingly. Whether the strange mental or monomaniacal symptoms which have sometimes accompanied the convulsive motions, may, as well as the latter, be attributed to an affection of certain individual parts of the brain, is more problematical. The disciples of Gall and Spurzheim, however, would doubtless advert with complacency in Mr. Wood's case to the prominent symptoms of excitement in the vicinity of their organs of *time* and *tune*, as confirmatory of their doctrines. [See *Watson, Op. cit.*, p. 367.]

(CIRRHOSIS. (See LIVER, DISEASES OF THE.)
CIRRHOSIS OF THE LIVER. (See LIVER,
DISEASES OF THE.)

CIRRHOSIS OF THE LUNG. Under this name, Dr. Corrigan, of Dublin, has described a pathological condition, the general character of which is a tendency to consolidation or contraction of the pulmonary cellular tissue with dilatation of the bronchial tubes. The diminution of the lung is regarded by him as the first step of the disease, and the dilatation of the bronchia the consequence of this. The primary seat of the disease he considers to be—the web of cellular tissue, constituting the matrix of the lung, which has a tendency to contract, so as to produce, when the disease is advanced, a very considerable obliteration of the air-cells. (*Dublin Med. Journal*, May, 1842, and the writer's *Practice of Medicine*, 2d edit., i. 201 : Philad. 1844.)]

ROBLEY DUNGLISON.

CLIMACTERIC DISEASE. (See AGE.)

CLIMATE. The general import of the word climate (from *κλίμα*, regio,) is sufficiently understood, although it is not easy to give an accurate definition of it. In medicine the term is used to designate those habitual conditions of the atmosphere, in connection with the state of the surface, soil, exposure, &c. of particular countries or districts, which are capable of influencing the health of persons inhabiting them.

The subject of climate may be treated under two distinct divisions, physical and medical. The consideration of the former, or physical climate, we must leave to the natural historian, as not coming properly within the scope of this work, although affording matter of the greatest interest to the medical philosopher. The latter or medical climate, may also be considered under two separate heads—as it affects the body either in causing or curing disease. The latter part of the subject, or the consideration of climate as an agent in the prevention and cure of disease, is that which we propose to treat in the present article; availing

ourselves, however, of the physical characters of climate and the geography of disease, as far as a knowledge of these departments of the subject tends to illustrate the medical application of climate.

We shall first give a brief account of the climate of the principal places in our own Island, in the South of Europe, and in the Northern Atlantic, which have been most frequented by invalids; and endeavour, at the same time, to determine their respective characters and their relative merits. We shall then point out the diseases which are most decidedly benefited by change of climate, and the particular situations most suitable to each.

The influence of climate on the animal economy is now so well known and appreciated by the more observant part of the profession, that it would be a waste of time, in a work of this nature, to enlarge upon the advantages which may be derived from a well-timed and judicious change of it in the treatment of disease. The removal, for example, from a cold, humid, and variable climate, to one which is warm, dry, and more equable, is well known to be productive of the most beneficial effects on a large class of invalids, when other therapeutical agents are of little avail; while, on the other hand, a contrary change is as certainly attended by a deterioration of the health, and often by the supervention of fatal diseases, even in persons previously in the enjoyment of good health.

If our limits permitted, it would not be difficult to account for many of the effects of climate, whether favourable to health or the reverse. For instance, when we reflect on the powerful influence of a warm dry air on almost all the functions of the animal economy, but more especially its obvious agency in promoting an equable distribution of the circulating fluids over the whole system, and particularly its effect in augmenting the activity of the circulation in the capillaries of the surface, and in diminishing in the same proportion the congestion of the internal vessels, (a state which very generally obtains in chronic ailments,)—we have a satisfactory explanation of much of the benefit which invalids experience by a removal from a cold to a warm climate. If we take into account also the effect of the continual action of a bland atmosphere on the extensive surface of the respiratory organs, both as abating irritation of the lungs, and enabling them more effectually to produce those changes in the blood that are essential to health, we have another very obvious explanation of the results observed. And if to these we add the influence produced on the nervous system generally, on the external senses, and through them on the mind, and, reversely, the re-action of the mind on the bodily functions — we need have little difficulty in accounting for the beneficial influence of the change of climate which we are now considering.

The contrary state of the functions and of the circulation, and the diminished energy of the nervous system induced by a change from a genial to a cold and humid climate, will with equal readiness account for most of the evil consequences so frequently observed under such circumstances.

Independently, however, of these effects, more directly attributable to climate, properly so called,

there are many incidental circumstances attending a change of this kind, which have often no small share in improving the condition of the invalid. The hopes inspired by the measure itself, the influence of the journey or voyage, the change of scene, of occupation, and often, also, the escape from business and other sources of discomfort and care, all claim a part in the benefit produced.

While all these circumstances will, therefore, have their due weight with the physician, when deciding upon such a change of climate as we are now contemplating, he must not omit, at the same time, to take into account the inconveniences and even disadvantages, which in many cases are inseparable from the removal of the delicate invalid from his own home and country. These latter considerations will rise in importance in his mind according to the advanced state of his patient's disease, and consequently the diminished prospect of permanent advantage from the measure. So many circumstances of a conflicting nature often present themselves for our consideration in such cases, that it is only by a comprehensive and dispassionate view of all the bearings of the case that we can come to a right decision, and then often not without difficulty. It is perhaps the rarer case, that we have merely to consider the nature of the patient's disease, and the probability of its being benefited or cured by any particular climate.

Among the numerous circumstances which require attention in recommending a change of climate, one of much importance is often entirely lost sight of, both by the physician and his patient:—we mean the necessity of perseverance in the regimen and mode of life which the peculiar nature of the disease demands. This must be urged upon the invalid as the condition on which alone he can expect to derive benefit from the prescribed measure.

We would press upon the minds of our professional brethren the importance of giving a full consideration to all the circumstances which have been just noticed; as we are satisfied, from ample observation, that change of climate has not hitherto been productive of all the benefit which it is calculated to effect,—nay, that it has often done positive mischief, chiefly on account of the inconsiderate and injudicious manner in which it has too generally been prescribed and carried into effect.

We shall now proceed to give some account of the individual places in this and other countries which have been chiefly resorted to by invalids, on account of the mildness or other peculiarities of their climates.

ENGLISH CLIMATES.—The great desideratum in this country is to find a mild climate and sheltered residence for our pulmonary and other delicate invalids during the winter and spring: we shall therefore direct our attention principally to this point.

Our warmest winter residences in England are mostly found on the southern and south-western shores; indeed it is their vicinity to the sea which in a great degree renders them warmer than the inland parts in their respective vicinities.

The mild region of England admits of a natural division into four districts or groups, each

having some peculiar features in its climate which characterise it and distinguish it from the others, both as regards its physical and medical qualities. These are—

1. The *south coast*, comprehending the tract of coast between Hastings and Portland Island, including the Isle of Wight; 2. the *south-west coast*, from the latter point to Cornwall; 3. the district of the *Land's End*; and 4. the *western group*, comprehending the places along the borders of the Bristol Channel and estuary of the Severn.

South Coast.—The superiority of the climate of this district exists chiefly during the months of December, January, and February. In March the temperature of this coast, and that of the interior, (e. g. the vicinity of London, which we select as a convenient point of comparison,) is nearly the same. In April and May, the temperature of the interior rises above that of the coast and continues higher, though in a less ratio, through the summer months. In October the mean temperatures are again equal, and in November, that of the coast begins to exceed the interior. The only places on the south coast which we consider deserving of particular notice, are, Undercliff in the Isle of Wight, and Hastings and Brighton on the coast of Sussex.

Undercliff is decidedly the most sheltered and warmest of these places, and it has moreover this convenience over most of our other winter residences, that it also affords a good summer climate, a circumstance of considerable importance to many invalids. Unfortunately, at present, few can avail themselves of the advantages of this sheltered district, from the want of the necessary accommodations. [Of late, the accommodations for invalids have been greatly increased. (Sir James Clark, *The Sanative Influence of Climate*, p. 134. Lond. 1841.) The Isle of Wight presents a great variety of healthy and beautiful sites for different classes of valetudinarians, both as winter and summer residences.]

Hastings follows *Undercliff* in point of shelter and warmth during the winter and spring months. Its situation at the base of a range of steep hills, which protect it in a considerable degree from the north and north-east winds, render it a milder and more sheltered residence during this season than the other parts of the coast of Sussex.

[*St. Leonard's* is about a mile to the westward of *Hastings*. The climate of the two places is almost identical;—but the accommodations are much better at the former. (Sir James Clark, *op. cit.* p. 126.)]

Brighton differs materially in the character of its climate from both these places. It is more exposed to northerly winds, but the atmosphere is drier and more bracing. While inferior to *Undercliff* and *Hastings* as a residence in diseases of the respiratory organs accompanied with much irritation, it offers advantages over both to invalids of a relaxed and nervous habit who are not very excitable. Autumn is the season during which the climate of this place possesses the greatest advantages; and even to the end of December it is one of the mildest climates in our island, and most favourable for a large class of invalids; more espe-

cially for cases in which a relaxed state of the system is a leading feature.

Invalids who select the coast of Sussex as their winter residence, might find it advantageous to pass the autumn at Brighton and the winter at Hastings.

South-west Coast.—The winter climate of the south coast of Devon has long been noted for its mildness. The temperature of its more sheltered spots during the months of November, December, and January, (when the difference is greatest,) is, in the average, about five degrees higher than that of London during the same period: whereas, on the south coast, the difference scarcely exceeds two degrees. This superiority of temperature over London at both places, occurs chiefly during the night; though the days are proportionably warmer, and the temperature more steady on the south-west than on the south coast. In making this comparison, however, between these two districts, it is right to observe that Undercliff is not taken into the account for want of sufficient data.

Various places on the coast of Devonshire are held in repute on account of the beneficial effects of their climate, more especially in pulmonary diseases. The principal of these are *Torquay*, *Dawlish*, *Sidmouth*, and *Exmouth*. *Salcombe*, the Montpelier of Huxham, is unquestionably one of the warmest spots in our island during the winter; but it possesses few accommodations, and its sheltered climate is confined to too small a space to admit of its ever acquiring importance as a residence for invalids. Indeed, this limited character of the climate is the great defect of all the places on this coast, with the exception of *Torquay*. Here the invalid has the advantage of a considerable tract of sheltered country, some part or other of which will afford a protected ride or walk, in whatever direction the wind blows. *Torquay* is superior in this respect to every place in our island. Its position, also, on the southern declivity of a range of pretty steep hills, composed chiefly of calcareous rocks, renders it comparatively dry. Hence, while *Torquay* possesses all the advantages of the climate of this coast, its chief disadvantage (humidity) is felt in a less degree than elsewhere.

Land's End.—The only place in this district deserving particular notice is *Penzance*, which has long been frequented by invalids on account of the mildness of its winters. *Penzance* has a very peculiar climate, which depends on its almost peninsular situation at the south-western extremity of the island. A remarkable equality in the distribution of the temperature throughout the year, and throughout the day and night, is a striking character of this place. In this respect, indeed, the climate of *Penzance* is superior to that of the south of Europe, and the only climate which we have examined that excels it is that of *Madeira*. This peculiarity of the climate of *Penzance* will be shown at once by comparing it with that of London, where the difference between the warmest and coldest months is 26° , while at *Penzance* it is only 18° . In winter, *Penzance* is, on an average, nearly six degrees and a half warmer than London during the night, and but little more than three degrees during the day.

In other respects the climate of the *Land's-End* does not stand so high in a medical point of view. It is very humid; the quantity of rain which falls annually at *Penzance* being nearly double that which falls in London, and the number of rainy days much greater. This district is also proverbial for the frequency and violence of its gales; and *Penzance*, owing to its total want of shelter from the northerly and easterly winds, is colder during the spring than either *Torquay* or *Undercliff*. Hence it is that although *Penzance* possesses a decided superiority over all the other situations in our island in the mildness and equability of its winter climate, its humidity, exposed situation, and liability to winds, render it inferior to several other places as a residence for invalids.

In giving the above as the character of the climate of the *Land's-End*, we are fully borne out by the experience of *Dr. Forbes* of *Chichester*, who resided there for some years, and to whose excellent *Medical Topography* of this district we are chiefly indebted for our information respecting its climate, and the influence of this on disease.

Flushing, a small village in the vicinity of *Falmouth*, is the only other place in this district deserving notice. The position of *Flushing* differs from that of *Penzance* only in being somewhat protected from the north and east winds by a low range of hills which rises immediately behind it. But the place is extremely confined, and deficient in accommodations for invalids.

Before quitting the south-west coast and *Land's-End*, it is proper to remark, that, though varying somewhat in degree at different places, the predominant character of the climate is that of softness and humidity; on the system generally, it has a soothing but relaxing influence.

From this character of the climate of the whole south-western coast of our island, it will be at once understood that it is most suitable for the irritable and inflammatory habit, and least so for the relaxed nervous constitution; that in the dry, irritated conditions of the mucous membranes, with a parched state of the skin, it will prove beneficial; while in the morbid states of the same membranes, accompanied with copious secretion, or when there exists a disposition to profuse discharges of any kind, it will prove injurious. Even many of those cases which are benefited by a temporary sojourn, would be injured by a permanent residence in this district. The climate, indeed, possesses qualities of so marked a kind, that when it ceases to do good, it generally begins to do harm; hence it will seldom be prudent, much less advantageous, for the invalid who has passed the winter and spring on this coast, to prolong his residence through the summer; he will in general do well to betake himself to a drier and more bracing air, especially if he intends to return the succeeding winter.

Unless the circumstances which we have just pointed out respecting the character and effects of this climate, and the nature of the constitution and diseases of the invalid, are kept in view, little benefit will be derived from a residence in *Devonshire*.

West of England.—*Clifton*, the only place in the western district which we deem it necessary to notice, has several local advantages, and pos-

sesses the best climate in the part of the country where it is situated. Compared with that of the south-west coast, it is more exciting, more bracing, and drier, but not so mild. It is therefore less suited for pulmonary and other diseases, accompanied with much irritation, and with a tendency to inflammation. On the other hand, it is better adapted to invalids of a relaxed, languid habit; and is also very beneficial in many cases of dyspepsia, in affections of the mucous membranes with much secretion, and in the scrofulous affections of young persons.

In making a selection among these, which we consider the best winter climates in our island, in any particular case, we must consider well the character of the patient's disease and the nature of his constitution, before we venture to decide upon the situation best suited to him. But by attention to these points, and to the qualities of the different climates, which we have endeavoured to state as clearly as the nature of the subject and the extent of our knowledge would admit, the medical practitioner will not err greatly. In order, however, to illustrate the subject further, we shall add a few more particular observations on the practical application of English climates to disease.

The climate of the south coasts of Devon and Cornwall will be found very efficacious in soothing an irritated and irritable state of the respiratory organs, and of the mucous surfaces generally; as in chronic inflammation of the fauces, and of the laryngeal, tracheal, and bronchial membrane, of a dry irritable character, or at least accompanied with little secretion, and highly susceptible of increased irritation from sharp, dry winds. In dyspepsia depending chiefly on an inflammatory condition of the mucous membrane of the digestive organs; in disorders of the uterine system, arising from a similar condition of the parts, giving rise to dysmenorrhœa; also in the numerous nervous affections originating in the disorders of these two influential classes of organs, this climate may be confidently recommended, and will generally be found beneficial. To these may be added cutaneous diseases of a dry, irritable character. On the other hand, in disorders of the same organs and parts attended with passive congestion, or very copious secretion; in dyspepsia from an atonic state of the stomach, and in disorder of the uterine system, accompanied with an excessive flow of the catamenia, or leucorrhœa; and, in short, in all diseases attended with a relaxed state of the system generally, benefit is not to be expected from the climate of the south-west coast; more especially if the invalid prolongs his residence beyond a few months. The climate of Clifton, as has been already remarked, will prove more favourable in the cases last referred to. Brighton also presents an excellent autumnal climate for such invalids, and to persons of little constitutional sensibility offers a good residence throughout the winter, provided the more sheltered situations be selected. Hastings is a residence better adapted to invalids suffering from pulmonary irritation. During the spring months, that is, after March, any dry sheltered situation in the milder districts of the interior we believe to be superior to the south coast, with the exception of Undercliff.

After this survey of the best winter climates in England, it may be expected that we should take some notice of our more salubrious summer residences. On this subject, however, it is not necessary to go into detail, as there is no lack of healthy situations to which our invalids may repair with advantage during this season. In the selection of a summer, as of a winter residence, the same circumstances require attention, both as regards the character of the climate and the nature of the invalid's disease. The milder and more sheltered situations must be chosen, even during this season, for delicate and very sensitive invalids; while for the relaxed and enervated, and those possessing less sensibility, the bracing air of the higher and drier localities will prove more suitable. To a large class of invalids our sea-side watering places offer a variety of excellent situations; and for those cases in which sea-bathing promises benefit, they deserve a preference over the interior, especially during the latter part of the summer and autumn. Several of our inland watering places, independently of the advantages to be obtained in many cases from the use of their mineral waters, afford good summer climates; and, indeed, some of them, more on this account than any other, have become places of fashionable resort. Among these we may mention *Malvern, Cheltenham, Leamington, Tunbridge Wells, Matlock, Buxton, &c.* When the intention is to use the mineral water, the climate must of course be made subservient to this object; but when a choice of waters is admissible, it is of importance to many invalids that the climate selected also be suitable to them. In general it will be advantageous to invalids who have taken a course of mineral waters at any of those places, to pass the autumn by the sea-side, as at some of the driest places on the south, or south-east coast. In the greater number of cases in which travelling is borne without inconvenience, several changes, or a succession of short journeys, will be more beneficial than a residence at any one place during the whole season. It is remarkable how such repeated changes, with frequent gentle exercise, especially on horseback, renovate the constitution enfeebled by disease, enable it to overcome many chronic affections, and contribute to the restoration of permanent health. But we shall have occasion to recur to this subject.

[The *Island of Bute*, which lies in the Frith of Clyde, about 18 miles below Greenock, resembles, in the character of its climate, the south-west of England and France, and the Channel Islands, although its temperature is considerably lower than any of these. As a winter residence for invalids, it is considered by Sir James Clark, (*op. cit.* p. 170,) to hold out considerable advantages to that class for whom a soft, equable, but rather humid atmosphere is indicated.

Cove, on the island of the same name in Cork harbour, has one of the mildest climates in Great Britain, corresponding in general characters, and its influence on diseases, with the south-west of England, and other similar climates. In equability of temperature, Cove is surpassed by few places. Recent observations have shown, that the mean difference of temperature of the days and nights rarely exceeds four or five degrees, and often, in

the winter months, does not exceed one degree. The town is completely sheltered from the north wind, and, from its southern exposure, receives the full influence of the sun and the southern breeze. (Stokes on *Diseases of the Chest*, 2d Amer. edit. p. 427; Philad. 1844.)

Before commencing our review of foreign climates, the islands of *Guernsey* and *Jersey* require some notice, as they are occasionally resorted to by invalids from this country. The climate of these islands resembles in its general characters that of the coast of Devonshire; it is somewhat warmer but not more steady, and is more exposed to high winds. Those from the south-west prevail during the autumn and winter, while those from the north-east often continue for weeks together during the spring, producing the same unpleasant effects on invalids which arise from them in this country. The climate is found by experience to be beneficial in the same diseases, and in constitutions of a similar character, as that of our south-west coast; the observations therefore formerly made relative to the class of invalids that may expect to derive advantage from the latter, apply equally to persons who may be sent to Jersey, which, of the two islands, is in all respects the best suited for invalids. The summer climate of these islands is delightful.

FOREIGN CLIMATES.—The climate of the *South of France* has long been held in repute, out all the southern provinces of that country are far from possessing the same climate; those situated on the eastern frontier being very different in this respect from those on the western. It is highly important, as we shall presently show, to attend to this distinction in recommending the south of France as a place of residence for invalids.

South-west of France.—We comprehend under this division the tract of country which extends from Bordeaux and Bayonne to Toulouse.

The transition from the climate of the south-western shores of our own island to that of the south-west of France is easy and natural, inasmuch as they exhibit a striking similarity in their general characters. Taking the south-west of France generally, the mean annual temperature is only about 4° higher than that of the south-west of England. Both climates are soft and rather humid, and agree, and disagree, generally speaking, with diseases of the same character.

Pau is the only place in this district of France which we deem it necessary to notice particularly. This little town, which has been a good deal frequented of late years by invalids from this country, is pleasantly situated at the base of the Pyrenees; and when its close vicinity to that range of lofty mountains is considered, it certainly possesses a far milder winter and spring climate, and is much less subject to high winds and extensive transitions of temperature than might be expected. One remarkable circumstance in the character of its climate is the mildness of the spring, and its comparative exemption from sharp cold winds during that season. In this respect it bears a very favourable comparison with the climates of the south of Italy. While *Pau* is 6° colder than Rome during the winter, it is only 2½°

colder in the spring. Compared with the warmest parts of England, the same superiority of its spring climate holds good. Penzance during the winter months is 3° higher than *Pau*, but 5° lower in the spring. This mild character of the spring constitutes the great advantage of the climate. *Pau* is also very free from fogs, and possesses a dry soil. Its chief fault is the unsteadiness of its temperature. It may however be considered, upon the whole, the most favourable residence for invalids in the south-west of France, as far as we have had the means of judging. The difference between the climate of *Pau* and that of the best situations in England is not great. It is drier and warmer in the spring, and the northerly winds are much less trying to invalids than in this country. One advantage possessed by it is its vicinity to the delightful watering places among the higher Pyrenees, which offer to the invalid who has passed the winter at *Pau* a healthy summer climate without the inconvenience of a long journey.

South-east of France.—Under this division we include that extensive tract of country which stretches along the shores of the Mediterranean, from Montpellier to the banks of the Var, the boundary stream between France and Piedmont. The climate of this district is warmer and drier, but more irritating and exciting than that of the south-west. It is also subject to sudden vicissitudes of temperature, and to frequent harsh, cold winds. This great liability to cold piercing winds, more especially the north-west, (*mistral*), which often continues to blow with considerable force for many days together, renders the whole of this country an improper residence for patients suffering under, or peculiarly disposed to inflammation or irritation of the respiratory organs. We consider the custom, therefore, which has long prevailed, of sending consumptive patients to the south of France, a grievous error; an error which the obvious character of the climate, and the result of ample experience of its effects, should have long since corrected. There may be constitutions having a tendency to tuberculous disease, which might even derive some benefit from a temporary residence in this climate; but when tubercles already exist in the lungs, it will certainly prove injurious.

After this account of the climate and its effects on phthisical patients, (the cases which have been chiefly sent thither,) it will be unnecessary to say much of the different places in this district which have been most frequented by invalids. We shall, however, notice the principal of these briefly.

Montpellier.—This place has now so completely lost the character which it once possessed as a mild climate, that it may suffice to remark here, that a more improper residence could scarcely be selected for a person disposed to pulmonary disease. Its high, exposed situation renders it liable to all the evils of this climate in a remarkable degree; and it is, moreover, well ascertained that pulmonary inflammation and phthisis are among the most prevailing diseases of the place.

Marseilles.—Although less exposed than Montpellier, this is an equally improper residence for consumptive invalids. From the manner in which

the environs of Marseilles are divided into small properties, surrounded with high walls, the invalid has no means of taking proper exercise, or of breathing country air; and without these, consumptive invalids can derive little advantage from any climate. For cases likely to benefit by a dry sharp air, Marseilles forms a good winter residence. It is said to prove particularly favourable to persons who have suffered from intermittent fever.

Hyères possesses the mildest climate in the whole of this district, and this advantage it owes chiefly to its sheltered situation at the base of a range of hills which protect it, in a considerable degree, from northerly winds. The country also around this little town differs in its character from that of Provence generally (which comprehends the larger portion of the district now under consideration). The hills here present the appearance of verdure, being covered with shrubs, many of them evergreens, affording a pleasing contrast to the bare and rugged mountain masses which form so striking a feature, and compose so large a portion of Provence; a country which very generally disappoints the expectations of the traveller, and especially of the invalid, whose hopes have been raised high respecting the beauty of the south of France. The extensive orange gardens which flourish under the immediate shelter of *Hyères*, and the verdure of its hills, afford evident proofs of the amenity of its climate, while by experience it is known to be one of the most favourable residences for invalids in this part of France,—certainly the best with which we are acquainted.

Nice.—This place has long been celebrated for the mildness of its climate, and continues to form the favourite resort of a numerous class of invalids, both from this and other northern countries. Although situated in the same line of coast as Provence, *Nice* is superior to it in several respects. In the general qualities of its climate it certainly resembles that of the south-east of France; but it has some important local advantages over the best parts of that country. By its steep and lofty range of mountains it is protected from the northerly winds, and especially from the mistral, which we have stated to be so prevalent, and which experience proves to be so injurious to delicate invalids, in Provence. This circumstance gives a comparative degree of softness to the climate: but it is still rather exciting. *Nice* is not exempt from cold winds, especially during the spring; indeed, the prevalence of these constitutes one of the principal objections to the climate of this place in pulmonary diseases generally. For consumption, even in its earlier stages, we consider *Nice* an unfavourable situation, in a very large proportion of cases. In bronchial diseases of the dry irritable character, it is also prejudicial; and in dyspepsia, depending on an irritated or inflammatory condition of the mucous membrane of the stomach, it is equally so. So decidedly, indeed, is this the case, that when such a state of the digestive organs exists, the invalid will derive little benefit from a residence at *Nice*, whatever may be his disease. Though warm and dry, the climate is ill suited to irritable habits. With languid, torpid constitutions, on the other hand, it agrees well. In the scrofulous affections of young persons pos-

sessing this character of constitution, it produces the best effects; as it does in chronic bronchial disease accompanied with copious expectoration, and in what has been termed humoral asthma. In chronic rheumatism it is found very beneficial; and in deranged health from various causes, in which a dry, warm, and rather exciting climate is indicated, advantage will be derived from a winter spent at *Nice*; provided always that the state of the digestive organs which we have adverted to does not exist. In consequence of the tendency of the climate to aggravate and even excite gastric irritation, a more abstemious diet is requisite for invalids than in England. The summer at *Nice* is too hot for any class of invalids.

[*Villa Franca*, situate on the southern base, or rather declivity of a steep and lofty range of mountains, and having a beautiful bay extended before it, is immediately to the eastward of *Montalbano*. It corresponds in its general character of climate with *Nice*; than which, however, it is said to be drier and somewhat warmer. *Menton* is described as a very retired spot, about 14 miles from *Nice*, on the *Genoa* road; and *San Remo*, still farther, is even more protected from easterly winds; but the accommodations at those places are not good. (Sir James Clark, *Op. cit.* p. 214).]

ITALY.—The climate of the south of Italy differs little in actual temperature from that of Provence and *Nice*, but it is softer, more humid, and less exciting. On the other hand the sirocco, which is scarcely felt at the latter places, forms an objection to the Italian climate, though this objection is not of much weight during the winter.

The only places which we consider deserving of notice as winter climates in Italy, are *Pisa*, *Rome*, and *Naples*.

The climates of *Pisa* and *Rome* resemble each other in their general qualities. *Rome* is somewhat warmer in the winter. It is also drier than *Pisa*, though more humid than *Nice* and the parching climate of Provence. About one-third more rain falls at *Rome* than in the latter country, and the number of rainy days is considerably greater. Taking into account all the qualities of the climate of *Rome*, we consider it one of the best of Italy: to the invalid capable of taking exercise in the open air, it affords advantages over both *Naples* and *Pisa*. Patients, on the other hand, who can bear little exposure to the air, and who must therefore confine themselves to the most sheltered situations, will find in the *Lung'Arno* in *Pisa*, a residence possessing advantages, perhaps, over every other place in Italy.

Naples differs somewhat in the character of its climate from both the last-named places. Independently of the effect which its immediate vicinity to the sea may have in modifying the climate, it is more subject to winds, and the air is more exciting than that of *Pisa* or *Rome*. As a residence for invalids labouring under pulmonary irritation, or chronic rheumatism, it is inferior to both; nor are we aware of any cases in which it ought to be considered a more favourable climate. The beauty of the scenery around *Naples*, however, and the gaiety and excitement of the place and climate altogether, prove very attractive to strangers generally, and render it a very agreeable winter residence for persons who visit Italy rather

as a recreation than for the removal of actual disease.

The diseases in which the climate of Italy proves most beneficial, are chronic bronchitis and rheumatism. We have, in particular, observed many decided examples of the beneficial effects of a residence at Rome in both these diseases. But it is still more in the numerous cases of deranged health which scarcely admit of being defined, though well known to the medical practitioner, that a tour and winter spent in Italy will prove beneficial. Such persons need not be limited to any particular situation, but may, with proper caution, visit the different places frequented by strangers in the south of Italy, and that even with greater advantage to their health than if they had remained stationary at any one of them.

These observations have reference to the climate of Italy during the winter and spring, that is, from October till May or June. To such as are under the necessity of remaining in that country through the summer, the baths of Lucca, Siena, and the vicinity of Naples afford the coolest residences.

There may be several situations on the shores of the Mediterranean which have climates equal, and perhaps superior to those which have been mentioned. Malaga has been particularly mentioned to us as possessing a very mild winter climate; but our information respecting the south of Spain is too imperfect to enable us to speak positively on this subject. And even were the climate of that country superior to that of the south of Italy, the want of proper accommodations and the various comforts which are as necessary to the invalid as climate, forms an insuperable objection to them as places of residence for delicate English invalids.

THE MEDITERRANEAN ISLANDS do not merit much notice. Some parts of the coast of Sicily afford a pretty good winter climate; but here again the difficulty of obtaining the necessary comforts, and even conveniences of life, renders them almost useless to English invalids.

This objection, however, cannot be made to *Malta*, the only island in the Mediterranean belonging to this country. All the wants of the invalid may be supplied here, and the packets which are established between this place and England afford the means of reaching it conveniently. But, unfortunately, the climate of Malta has little to recommend it to any class of invalids, and least of all to such as suffer from pulmonary affections. The arid nature of the soil, the quantity of impalpable dust which is suspended in the atmosphere whenever the weather is dry, the currents of cold air to which the capital (the residence of invalids) is subject during the winter, and the frequent and heavy rains which prevail during the same season, render it an unsuitable residence for patients of this class. It may not be irrelevant to mention also that phthisis carries off a large proportion of the inhabitants of Malta, constituting nearly one-tenth of the whole mortality, according to Dr. Hennen. Indeed, the full and satisfactory information respecting the medical topography of Malta, supplied by this gentleman, affords more than sufficient grounds for excluding it from the list of climates which promise any advantage to

phthisical patients. We are not, indeed, aware of any class of invalids likely to derive much advantage from the winter climate of Malta, and we are not acquainted with any to whom its summer climate would not prove injurious.*

ATLANTIC CLIMATE.—The climate of the Northern Atlantic in the temperate latitudes is more steady than that of the Mediterranean, and imparts a similar character to the climate of its islands. Various groups of islands scattered over this ocean, between the 28th and 38th degrees of latitude, having been praised for the excellence of their climate, and occasionally frequented by invalids in consequence, deserve some notice in this place. The Azores, the Madairs, and the Canary Islands in the Eastern, and the Bermudas and the Bahamas in the Western Atlantic, have all been recommended as suitable residences for persons requiring a mild and equable climate, and more especially for consumptive invalids.

As our information respecting the climate of Madeira is the most complete, we shall notice it first, with the view of making it a standard of comparison in estimating that of the other islands.

MADEIRA.—The minute and careful observations of the late Dr. Heineken and of Dr. Renton, for a series of years, have afforded us sufficient data to form an accurate estimate of the climate of this island; and although our materials for enabling us to judge of the other Atlantic islands are much less complete, they leave little doubt in our minds that Madeira is superior to any of them; while it affords conveniences in other respects as a residence for invalids possessed by none of them. The height of the central ridge of mountains which compose the greater part of this island, although it may detract somewhat from its warmth during the winter, contributes greatly to temper the heat of its summer. It gives Madeira the advantage of a cool land-breeze during the night, which, alternating with a refreshing sea-breeze in the day, moderates the summer heat in a very material degree; while the trade winds which prevail at this season in the latitude of Madeira, contribute also to its coolness and salubrity. The invalid, moreover, by choosing for his summer residence an elevated situation in the interior, finds a climate considerably cooler than that of Funchal which is situated on the sea-shore and affords the best winter residence.

Comparing Madeira with the south-east of France and Italy, we find that, although its mean annual temperature is only about six degrees higher than that of these places, this temperature is very differently distributed throughout the year, the range being far less at Madeira than in the most favoured spots in the south of Europe. Thus, while the winter is twelve degrees warmer than in Italy and France, the summer is five degrees cooler; and while the mean annual range at Madeira is only fourteen degrees, it is nearly double this at Pisa, Rome, Naples, and Nice. In the equable distribution of heat throughout the year, it possesses a similar superiority over the same places; for example, while the mean difference of

* We refer those who desire to examine the facts upon which the above character of the climate of Malta rests, to Dr. Hennen's *Sketches of the Medical Topography of the Mediterranean, &c.* [See, also, Sir James Clarke, *op. cit.* p. 241.]

temperature of successive months at Madeira is only two degrees, at Rome and Nice it is four, and at Pisa and Naples five degrees.

In the progression of temperature during the day, it maintains the same superiority; the mean range for twenty-four hours being ten degrees by the register thermometer, while at Nice it is nine degrees, at Rome ten degrees, and at Naples thirteen degrees by the common thermometer. In steadiness of temperature from day to day, (a very important quality in a climate,) Madeira excels all those places greatly. There is also a considerable difference in respect to the dryness of the two climates. Nearly the same quantity of rain falls at Madeira as at Rome; but there are only seventy-three days on which any rain falls, while at Rome there are one hundred and seventeen days. The rain at Madeira also falls at more regular seasons, chiefly in the autumn, the atmosphere being generally dry and clear for the remainder of the year.

The annual range of atmospheric pressure is very small, which is the case also at Rome and Naples.

From this comparison, the superiority of the climate of Madeira over that of the south of Europe will be at once seen. We shall have occasion hereafter to notice their comparative influence on disease.

Canary Islands.—These rank next to Madeira in point of climate. They are somewhat warmer; the mean annual temperature of Funchal, the capital of Madeira, being 65°, while that of Santa Cruz, the capital of Teneriffe, is nearly 71°. This excess of temperature, however, is not equally distributed over the whole year, the difference between the winter temperatures at these two places being considerably less than between their summer temperatures; while Santa Cruz is 7° warmer than Funchal in summer, it is only 5° warmer in winter. The temperature is also more equable throughout the year at Madeira than at Teneriffe; the difference between the mean temperature of summer and winter being 9° at the former place, while it is 12° at the latter. The want of sufficient materials prevents us from comparing the climate of Teneriffe more minutely with that of Madeira. It seems probable, however, that when we are better acquainted with the climate and topography of Teneriffe, we may find it a favourable winter residence. But whatever may be the merits of its climate, it is at present very deficient in the other requisites necessary to render it a suitable abode for delicate invalids.

The **Azores**, or **WESTERN ISLANDS**, as they are sometimes called, lie about 5° north of Madeira, and considerably more to the westward. In their external characters these islands resemble Madeira and the Canaries. We have not had the means of making ourselves sufficiently acquainted with the temperature of the Azores to speak very positively on the subject. The climate appears to be mild but somewhat humid; less warm than Madeira during the winter, and more oppressive during the summer. They certainly possess no advantages in point of climate over Madeira, while they afford few of the conveniences which that island offers to invalids.

[The mean in-door temperature of a room without fire, carpet, or curtains, in Villa Franca, on

the southern coast of St. Michael's, during the period from Dec. 1838 to April 1839, was 60°.9, with a mean range of 3°.6. The mean out-door temperature, during the same time, was 60°.10, and the mean daily range 7°.6. The highest point to which the thermometer rose in the shade, between eight o'clock in the morning and ten at night, was 76°; and the lowest point to which it sank was 51°. The average out of doors was not, however, taken with the register thermometer; but it approximates the truth. Sir James Clark (*op. cit.*, p. 288,) is of opinion that a change from the Azores to Madeira, and from thence to Teneriffe, would prove, in many cases, more beneficial than a residence during the whole winter in any one of those islands.]

Bermudas.—This numerous cluster of small islands is in the same latitude as Madeira, and differs little from it in the mildness of its winter climate. From the stormy character of the Western Atlantic, however, these islands are much more liable to high winds in the winter than Madeira, while their low character and arid rocky soil render them extremely hot during the summer, and quite improper at this season for the residence of such invalids as are likely to be sent from this country.

Bahamas.—This is another and much more extensive group of low islands, further south than any of those which have been mentioned, being only just beyond the limit of the tropics. The climate of the Bahamas has not much to recommend it. The winter and spring are considerably cooler than the same seasons in the West Indies, while the temperature of the summer and autumn is nearly the same as in those islands. During the winter the temperature is subject to rapid and considerable vicissitudes, and cold, harsh, northerly winds are not unfrequent. The close vicinity of the Bahamas to the North American continent no doubt has the effect of rendering the climate less equable than it otherwise would be, judging from what we know of insular climates generally in the same latitudes.

We may safely dismiss these two western groups with this brief notice; as from the character of their climates, their great distance from England, and the few local advantages which they possess, they are never likely to prove beneficial as a residence for invalids from this country. They are better suited, in point of climate, and more conveniently situated, particularly the Bahamas, as a temporary retreat for the inhabitants of the islands which we are now to notice.

WEST INDIES.—Although these islands are not often resorted to by real invalids, yet there seems to exist, even among the profession, a vague idea that they afford a preferable climate to that of any of the places which we have noticed. That this opinion has been formed from an imperfect knowledge of the nature and effects of a tropical climate, we shall endeavour to show.

The mean annual temperature of the West-India Islands, near the level of the sea, is about 80°, and during the six months which include the winter season the temperature is only 2° lower. Now it will be readily admitted that few invalids are likely to be benefited by so high a temperature, more particularly when continued,

almost without sensible variation, night and day. The extreme annual range in the West Indies does not exceed 20°, while the mean daily range throughout the year is only 6°. But it is not so much the actual degree of temperature of a tropical climate, as its unceasing and unvarying character, which oppresses and exhausts the invalid, more especially in cases where there exists a disposition to symptomatic fever.

[Moreover, it appears from the British Army Reports, that nearly twice as many cases of consumption originated among the British troops in the West Indies as at home: twelve per thousand of the aggregate strength of the troops serving in the West Indies being attacked annually, whilst of the Dragon Guards, serving in Great Britain, the ratio is only 6½ per thousand. The disease, according to the same reports, is even of more frequent occurrence among the black than the white troops. (Sir James Clark, *op. cit.*, p. 303.)]

From this brief account of the climate of the West Indies, it is evidently an improper one, generally speaking, for consumptive invalids, who, nevertheless, are frequently sent thither. The uniformly high temperature, and almost cloudless skies which afford no shelter from the direct rays of a tropical sun, preclude invalids from taking exercise in the open air, the principal object for which they are generally sent abroad. There is no twilight to compensate for the heat and glare of the day, and the nights are too hot to admit of refreshing repose. When we add to the foregoing evils of climate the many privations, discomforts, and annoyances which are almost inseparable from a temporary residence in these islands, and the still more weighty objection derived from the experience of medical men who have resided there, we may consider the question of the propriety of sending patients labouring under consumption to the West Indies as finally set at rest. The concurrent testimony of all the medical men whom we have consulted on the subject, and whose opportunities of judging were ample, establishes the fact that consumptive cases sent thither from this country proceed much more rapidly to a fatal termination than in temperate climates.

Notwithstanding what has just been stated respecting the climate of the West Indies and its influence on consumption, we are not prepared to say that some, nay, many cases of deranged health, of a different nature, might not be benefited by passing a few of the less sultry months (from November to February) in that climate; more especially if the invalid possesses the means of enabling him to spend the greater part of his time on the water, merely visiting some of the more healthy islands occasionally. The remarkable revolution effected in the distribution of the circulating fluids, and the immense increase in the secretion from the cutaneous exhalents, excited and steadily maintained by a high atmospheric temperature, and this continued without intermission for many months, or even years, is unquestionably capable of producing material and very important changes in the animal economy, and may therefore be made a powerful agent in the cure of chronic diseases.

Calculous disorders are extremely rare in the West Indies, a circumstance which probably depends, in a great degree, on the abundance of the cutaneous secretion, by which the largest proportion of fluid is discharged from the system, and along with it some of those saline principles which constitute the chief ingredients of which urinary calculi are composed. A well known case has been recorded of an officer who was about to undergo the operation of lithotomy in this country: he was suddenly ordered to Jamaica, and after some time no calculus could be discovered in the bladder, nor were there any symptoms of the existence of one. Aneurisms and diseases of the heart and large vessels are also rare, and the osseous deposits, which are so generally found in the coats of the larger arteries in persons who die at an advanced age in cold climates, are said to be rarely met with in those who die at a similar age in the West Indies. Gout is not common, and rheumatism neither frequent nor severe.

Reasoning on the above facts, we should expect that the climate of the West Indies would prove serviceable to persons labouring under what has been denominated the calculous diathesis, in which there is a constant disposition to renal irritation, and the formation of gravel, upon any material change of the weather, or any trifling derangement of the digestive organs. The functions of the skin in such persons are generally imperfectly performed, and it is not unreasonable to believe that the powerful action excited, and unremittently kept up for some months, in the cutaneous exhalents might effect a permanent change in the constitution, and if followed up by warm clothing, daily friction, and a proper diet, might entirely destroy the disposition to the formation of gravel. Upon the same principle this climate also promises benefit to persons in whom we have either positive, or strong presumptive evidence that ossific deposits are forming in the arterial system, and laying the foundation of aneurism or diseased heart. Reflecting on the powerful effect of a high temperature on the various secretions, we think it not improbable that the further progress of such a morbid process might be checked by a timely removal to the West Indies, or any similar climate, and a residence for a longer or shorter period there, according to the circumstances of the case. What has been already stated respecting the rare occurrence of calculous disorders and diseases of the arteries in this climate, affords some grounds for such a conjecture; and it may be adduced in further support of it, that *gout*, a disease intimately related in its nature and causes to both the preceding affections, is greatly relieved, and even entirely cured in many cases, by a change from a cold to a hot climate. This effect of climate has long been known. Van Swieten mentions the case of a gentleman who had almost entirely lost the use of his hands and feet from gout, and who, after a residence of nearly three years in the East Indies, returned perfectly free from disease, and continued so; and Haller relates the case of Lord de Poiney, who, when an old man, went to the warm American islands, and got rid of his gout and other infirmities. And such instances

must have come under the observation of almost every physician.

Scrofula is a very rare disease in the West-India islands, and there are many cases of scrofula in this country which we have little doubt would be greatly benefited, if not cured, by a temporary residence in that climate. The cases in which we should expect the greatest benefit are those in which the disease exists chiefly in the lymphatic glands in torpid constitutions.

[UNITED STATES.—For those of delicate lungs, it would appear, that *St. Augustine, Tampa Bay, Pensacola, Mobile*, and certain situations on the *Peninsula of Florida*, are the best situations, judging merely from meteorological registers: but, in all such cases, the extent of accommodation for the valetudinarian must be taken into account. The places on the eastern seaboard, especially, are exposed to frequent north-east storms, during which, however, the invalid must remain at home; yet there are few days during the winter when he cannot have the salutary revulsion which exercise in the open air is capable of effecting. Hence, any of these situations has a decided advantage over those of the northern and middle states. In the interior of *Georgia, Florida, Alabama, or Louisiana*, the same objections do not apply; and accordingly, they are often visited by the invalid during the winter, and with great advantage.

During the summer, the wide extent of this country affords great choice of residence. The *sulphur springs of Virginia*, especially the red sulphur; and the warm, the hot, and the sweet springs, are often frequented. These are situate high above the level of the sea, and afford as great a change as difference of climate can easily effect. During the summer, a tour may be made to any interesting region that is capable of exciting new impressions upon the mind; and, of late, favourable attention has been directed to the northern lakes as a summer residence for invalids of the south; and a tour to them may be of great advantage to those from every part of the country. (Prof. Drake, *The Northern Lakes, a Summer Residence for Invalids*. See also the writer's *Elements of Hygiene*, 2d edit. Philad. 1844.)

SOUTHERN HEMISPHERE.—The climates of the southern hemisphere are calculated to exert the same sanative agency on the frame as those of the northern. From their situation south of the equator, their seasons are the reverse of ours. August, September, and October, constitute the *spring* months; November, December, and January, *summer*; February, March, and April, *autumn*, and May, June, and July, *winter*.

Of the climate of certain portions of *South America*, we know something from the observations of the navy surgeons more especially. It rarely happens, however, that invalids are sent thither for change of climate. Dr. Burrough resided four years in *Lima*, and did not meet with a single unequivocal case of phthisis, which originated there during that period; although scrofula was not uncommon,—a fact which confirms the view of the distinctness of scrofulosis and tuberculosus. He stated to Dr. Morton, (*Illustrations of Pulmonary Consumption*, p. 159: Philad. 1834.) that he knew many foreigners in consumption to be much benefited by a residence in Lima;

but that in every instance where they had been tempted to go farther south into *Chili*, the effect on their constitutions was fatal.

The *Cape of Good Hope* is occasionally resorted to by invalids from India and England.—From the Army Medical Reports it appears, that the climate is at least as favourable to health as that of Great Britain. The troops are less subject to diseases of the lungs at *Cape Town*, than in the other British colonies; and there is a smaller proportion of deaths from consumption than has been observed in our foreign stations, except the East Indies. Rheumatism is, however, very common. The places chiefly resorted to by invalids from India and England at the Cape of Good Hope, are *Rondebosch*, about five, and *Wynberg*, about eight miles from Cape Town; at both of which places there are good accommodations.

The climate of *Australia* is said to be remarkably healthy. Europeans, enervated by a residence in India, are very much invigorated by a short residence there. (Sir James Clark, *op. cit.* p. 336.)

We have now noticed the principal climates, both in our own and foreign countries, which have acquired the greatest reputation as places of residence for invalids, and regarding which our information is sufficiently accurate to enable us to speak with much certainty. From a residence at one or other of these places, or at several of them in succession, all that climate can effect may, we believe, be obtained by the invalid whose disease admits of benefit from a change of this kind; provided always that the climate which is best suited to his disease and constitution be selected. In making this selection we must, in the present state of our knowledge, be guided chiefly by experience; for although an acquaintance with the physical characters of a climate is highly useful in enabling us to form a tolerably correct opinion respecting the diseases in which it will prove beneficial; still, until we have had some experience of its effects, we can never be sure that our conclusions are correct; so complex is the subject of climate, and so many are the circumstances, some having reference to the agent and others to the subject, which require to be taken into account.

We shall now state briefly the effects of climate on those diseases on which it has been found to exert the greatest influence.

Pulmonary Consumption is the disease in which, from its supposed dependence on climate, and its being found to resist all other modes of treatment, this remedy has been more particularly had recourse to, and almost as the only remaining hope. This is not the place to enter into a full detail of the circumstances under which climate promises benefit in that disease. (See the article **PULMONARY CONSUMPTION**.) We may, however, remark here, that climate, to be productive of real benefit, must be tried at a much earlier period in the progress of tubercular disease than it generally is. Such is the insidious manner in which consumption, in many cases, steals upon its victims, that it has too often stamped its indelible impression on the vital organs ere the alarm is sounded, or climate or any other effectual means of treatment, have been seriously thought of. Before we can reasonably hope to cure phthisis, we must take a much more comprehensive view of

the pathology of that disease than we have hitherto done: in place of fixing our attention solely on the diseased state of the lungs, we must direct it to the morbid condition of the system,—to the tubercular cachexia in which phthisis has its origin. As regards the application of climate to the disease, it is not, we believe, saying too much, when we state that consumptive patients are, for the most part, sent abroad one year at least, often several years, too late to derive any essential benefit from change of climate.

During that peculiar state of deranged health which may often be observed to precede tubercular cachexia,* and during the existence of this morbid state of the constitution, before the disease has manifested itself in the actual development of tubercles in the lungs, change of climate forms a powerful adjunct to the other means best calculated for removing such a state of the system. When tubercles already exist in the lungs, the chances of cure are immeasurably lessened; but even then climate affords one of our most valuable resources, and one which promotes the salutary action of all our other remedies; and although our hopes of benefit under such a discouraging state of things must in general be faint, we believe the further progress of the disease may, in some cases, be thereby arrested. But such instances of success are no doubt very few, compared to the many which proceed unchecked in their course to a fatal termination, in despite of climate and every other means which we can oppose to their progress. We would therefore beg to impress upon the minds of our professional brethren the urgent necessity of directing their attention to the earliest indications of this disease, seeing how utterly inefficient all our efforts are even to stay its fatal career, when so far advanced as to manifest itself to the common observer. Until the tubercular affection of the lungs, which constitutes the essential character of what is commonly termed phthisis, is considered in its true character, as the last stage of a disease,—as the result of a morbid state of the system, which in its progress might often be cured, but which in this its termination is scarcely to be remedied,—we must still continue as heretofore, little better than idle spectators of the ravages of a disease which destroys one-fourth of our population, and numbers among its victims a large proportion of the best and fairest of our youth.

In proof of the correctness of our opinions respecting the influence of climate on phthisis in its early and late stages, we shall give the experience of Dr. Renton, an intelligent and observing physician, who has long practised at Madeira, and has had ample opportunities of watching the effects of that climate on phthisical invalids sent thither from this country.

This gentleman has favoured us with notes of the cases which came under his own particular observation. From these we find that between the years 1827 and 1830, *nineteen* patients labouring under confirmed phthisis arrived in Madeira, the whole of whom died; the greater number on the island, the remainder after returning to

England. Of *thirty-three* cases of incipient phthisis, which arrived during the same period, *twenty-three* are now at home, (June, 1830,) apparently in good health; two remain in the island, one apparently well, the other considerably better since his arrival, but still in a doubtful state; two died, one in the island, and another after leaving it: the fate of the remaining six is not known. We consider this statement as a satisfactory reply to those who doubt and cavil respecting the influence of climate; their opinions being formed in general from a few cases sent abroad at a period of the disease when no hope of benefit could be reasonably entertained. It is only by such numerical records as the above, that we can expect to arrive at accurate conclusions respecting the influence of any means of cure in a disease, which will prove fatal in a very large proportion of cases, under any circumstances. The result in the first series of cases is nothing more than every one would expect who is acquainted with the nature of phthisis, and knows the state of the lungs in what generally passes under the name of confirmed consumption. But while Dr. Renton's experience of the effects of the climate of Madeira shows the inutility of change of climate in the advanced period of phthisis, it holds out considerable hopes from the adoption of this measure in its early stages: of *thirty-three* cases of incipient consumptions, *twenty-four* were apparently cured. Such a ratio of success, we have reason to believe, has never before been observed among consumptive invalids sent to Madeira, and for this plain reason—that they were rarely sent till the disease was too far advanced to admit of recovery. Dr. Renton remarks in his communication to us, "With respect to the invalids sent out, they have been very different for the last two or three years from those sent out formerly." We have the satisfaction of thinking that we have contributed, in some degree, to this favourable result, by our appeal to British physicians in the work already referred to; and we shall be happy to find that the striking proof of the truth of our former remarks, now recorded, induces our professional brethren to pay still more attention to this subject.

Of the Atlantic Islands, Madeira; in Italy, Rome and Pisa; and in England, Torquay and Undercliff, afford the best climates for consumptive cases. [Sir George Lefevre (*Thermal Comfort*, Amer. edit. p. 39: New York, 1844) recommends Valencia, in Spain. In the United States, St. Augustine, Savannah, Mobile and Pensacola, on the sea-board, are often visited; and occasionally the interior of the peninsula of Florida, Alabama or Louisiana.]

In stating these places to be the most favourable residences, we beg to be understood as referring to the winter chiefly. Italy, during the summer, is decidedly injurious to the phthisical invalid; and those who have passed the winter in the milder climates of England should in general seek a more bracing air in summer, such as that of Malvern, or even some of the more elevated and drier districts of our island; or, what would be still better, they might in the course of this season change from one place to another, taking care always that no place was visited possessing a

* For an account of this affection see a work by the writer of this article, entitled "*The Influence of Climate*," &c., p. 315, &c. 2d edit. Lond. 1830. 3d [edit. Lond. 1841.]

climate decidedly hostile to their particular state of health. Such frequent changes of residence, when judiciously conducted, and combined with exercise on horseback, and a regimen suited to the particular state of the patient, are among the most effectual means which we possess for preventing consumption in persons predisposed to it, more especially in early life.

Chronic Bronchitis.—The morbid conditions of the mucous lining of the larynx, trachea, and bronchi are greatly influenced by climate, and the change from a cold and moist to a mild and dry air seldom fails to relieve, and occasionally removes them. The situations which have been mentioned as most favourable in phthisis are best suited also to bronchial diseases generally. Of the continental climates, those of Rome and Pisa are the most beneficial in cases attended with an irritable state of the affected parts without much secretion; and that of Nice in cases attended with less sensibility, a more copious expectoration, and a relaxed state of the system generally. Madeira, as far as our experience goes, has proved more beneficial in the former class of cases than in the latter. In England, Torquay and Undercliff afford the best climates in the first class of cases, and Clifton in the latter, in which Brighton also is a very favourable residence during the autumn.

Asthma is often greatly relieved and occasionally ceases under the influence of a mild climate, more especially when complicated with disease of the bronchial membrane, as it almost always is when of some duration. In what has been termed humoral asthma, Nice is the best residence; but Rome is preferable when this disease is accompanied with an irritated state of the digestive organs, a complication which is exceedingly common.

Chronic Rheumatism.—Climate produces the most decidedly beneficial effects in this disease, and that often with surprising rapidity, even in cases of long standing, which have resisted the best-directed medical treatment. We would particularize Rome and Nice as the best residences for invalids suffering from this complaint. The preference to be accorded to the one or the other place will depend upon the character of the patient's constitution and the state of his digestive organs. When there exists an irritable state of these, we have already remarked that the climate of Nice will generally disagree, whatever may be the more prominent disease. [Signal benefit is often derived, during the summer, from the Warm Spring and Hot Spring baths of Virginia.]

Gout is remarkably alleviated by a warm climate. In the selection of a residence for the gouty invalid, we must be guided by the particular state of his constitution, and the effects of the different climates which have been already pointed out. Genoa is rather remarkable for the rare occurrence of the disease among its inhabitants. But a warmer climate than any part of Italy would, in many cases, we have no doubt, prove still more effectual in removing gout. We have already remarked the effects of the West-Indian climate in this disease.

Serofula.—Strumous affections, especially when seated in the skin and lymphatic glands, are frequently cured, and the general health is

greatly improved, by a mild climate. In such cases Nice and Rome have appeared to us the most favourable residences; but in giving a preference to either, in this and all other complaints in which a residence in these places is useful, the practitioner must always keep in view the characteristic peculiarities of these climates formerly pointed out. There are cases of this disease in which the climate of the West Indies, as already remarked, would prove more effectual than any European climate; those, namely, of an indolent character with little disposition to febrile excitement.

Dyspepsia.—Different forms of dyspepsia, hypochondriasis, and other nervous affections, intimately connected with a disordered state of the digestive organs, all of which are aggravated by a cold and humid atmosphere, are much mitigated by a winter's residence in the south of Europe, if aided by proper regimen. Attention to the diet is particularly necessary in changing from a cold to a warm climate, and in no class of cases is this more requisite than in those of which we are now treating. (See **DYSPEPSIA**.)

The dyspeptic invalid from the north will require to be still more on his guard in the south of Europe than in his own country, particularly as regards the use of stimulants; but in nervous and hypochondriacal cases the state of the mind must always be taken into consideration in our selection of a climate and residence for the invalid. Unless we can produce an impression on the mind as well as the body, we shall make little progress in the cure of these affections. A change from one place to another will, generally speaking, be better than a long residence at any one; as much of the benefit obtained in such cases arises from a constant succession of new and agreeable impressions made upon the mind. A judicious and timely change of climate, combined with a considerable extent of travelling through a country and scenery which excite a lively interest, produces the best effects on the health of persons whose minds have been overstrained and exhausted by long-continued application to the same subjects, or whose general health has been destroyed by chronic dyspepsia, and the abuse of medicines, to which it too generally leads.

A single season properly spent in the south, more especially in Italy, is often productive of the most salutary effects in restoring the energy both of the mind and body; and if due attention is paid to regimen, especially as regards diet, the benefit derived will be both greater and more permanent than can be obtained, perhaps, from any other mode of treatment.

The morbid states of the mucous membranes generally are greatly benefited by a mild climate. We have already remarked its beneficial effects in the diseased conditions of the bronchial membrane, and that of the stomach, in dyspeptic affections. In similar states of the intestinal membrane, accompanied with chronic diarrhoea, a mild climate will contribute powerfully to restore the parts to a healthy state. Dysmenorrhœa, which is frequently dependent on irritation of the mucous membrane of the uterus, is often quite removed, and the healthy state of the whole uterine functions restored.

Irritable cutaneous diseases are also much alleviated by a residence in a warm climate.

It would be impossible, without extending this article to an undue length, to particularise all the disordered conditions of the system in which the change to a mild climate proves useful; but we must not omit to notice several distinct periods of life at which the beneficial effects of such a measure have appeared to us most striking, when from any cause the health has become deranged. The first is during childhood. From what has been said, in the early part of this article, of the operation of a mild climate on the various functions, it will be easily understood how beneficially this influence must be exerted at this early period of life, in favouring the growth and development of the system; and accordingly we have had abundant opportunities of observing the excellent effects produced on the health of delicate children by a residence of one or two winters in Italy.

When the health of children is naturally delicate, or when it has been rendered so by some of the diseases of childhood, such as measles, whooping-cough, scarlet fever, &c., no measure with which we are acquainted will prove so effectual in restoring the health as a change to a dry and warm climate.

Again, about the period of puberty, or a little before this time, a change to a southern climate for one or two winters is a measure which, if judiciously advised and carefully executed, will seldom fail to improve the general health of delicate persons, and favour the full development of the system which takes place at this period of life; and when there exists a disposition to tubercular disease, it will tend materially to obviate it. We beg however, to observe, that we speak of the effects of climate in those cases, not so much as a single remedial measure, as a measure which, while it contributes powerfully of itself to improve the health, favours the operation of a proper regimen, and such other remedies as the circumstances of the particular case may require.

The third period of human life at which we have remarked the powerful influence of a mild climate in ameliorating the health, occurs at a more advanced age. The two first occur while the body is yet in progress to maturity, the third when it has passed the zenith of its power. In the first instance, a mild climate enables a delicate frame to attain more certainly its full maturity; in the latter it prevents it from sinking prematurely into decrepitude, and enables it to prolong its existence until the period marked for its natural decay.

From about the age of fifty to that of sixty, though not unfrequently at a much earlier period, either when the system is naturally weak, or the causes of disease have been powerfully applied, the impaired condition of health now alluded to usually supervenes. This state is marked rather by anomalous disorder of various functions, indicative of a premature decay of the powers of life, than by any formal disease acknowledged in our systems of nosology. The activity of the mind and the bodily vigour have sunk many degrees, without any evident cause, and the individual, both in appearance and feeling, seems rapidly

lapsing into premature old age and its accompanying infirmities. This disordered state of the health has been termed the *Climacteric Disease*; but, as we have already remarked, it occasionally occurs long before the period of life at which this change of the constitution is stated to occur naturally. (See AGE.)

The causes which lead to this condition of the health are various; as, for instance, an anxious and sedentary life, long-continued and close mental application, or irregular and intemperate habits of living; and oftener still it is the consequence of the combined influence of several of these causes. From whatever cause it originates, a change for one or two years to a milder climate will prove of the greatest benefit in restoring the invalid to his wonted health.

Before closing this brief survey of climate, and of the various diseases benefited by it, there remains one circumstance to be noticed, and it is one of some importance to the invalid: we allude to the proper period for his returning to this country from the milder regions where he has been sojourning. Invalids finding a very sensible improvement in the state of their health, are too apt to consider themselves well, and become impatient to return home on the least feeling of inconvenience from the heat of the spring. Influenced by this or other causes, they frequently err by leaving a southern climate too early. A relapse of the disease, for the cure or relief of which they were sent abroad, is not unfrequently the consequence; and thus it often happens that by a little impatience, or imprudence, and occasionally from ignorance of the consequences, the advantages obtained by passing a whole winter in a mild climate are speedily destroyed. It should be the care of the medical adviser to warn his patient, before he leaves his own country, of the risk he runs by returning home too early. If his winter residence has been Italy, the invalid should avoid recrossing the Alps till the summer is fairly established in Switzerland. He may commence his journey northwards from his winter quarters in May, but should linger in the north of Italy, or among the Italian lakes, till he finds the heat inconvenient. This will seldom happen before the first or second week of June; and whatever may be his feelings in Italy, the period we have just mentioned will be sufficiently early to arrive in Switzerland. Independently of the risk of exposure to cold while crossing the Alps, which may, indeed, be avoided by proper clothing and arranging the day's journey so as to complete it before sun-set, the invalid will find a remarkable difference between the atmosphere of Switzerland and that of Italy. He will be particularly sensible of the keenness of the evenings and nights in Switzerland. Indeed, the scenery of these two countries does not differ more remarkably to the eye than does their climate to the feelings.

When the winter has been passed in Madeira, or any of the other Atlantic islands, and more particularly the West Indies, the invalid should be still more careful not to leave his quarters too early in the season. By a little care to avoid exposure to the sun, he may escape injury from the heat; but it will be difficult for him to guard

against the pernicious effects of our cold north-east wind as he enters the Channel, or arrives on our shores.

A delicate invalid who has passed the winter in any southern climate, should endeavour to arrange his journey or voyage so as not to reach England before the middle or rather the end of June; and his warm clothing, which he may have laid aside, should be resumed the moment his feelings tell him that he is entering a colder and more variable climate.

[Invalids who have passed the winter in the West Indies, or in the southern part of the United States, should be especially careful not to return too early to their homes. The spring months are markedly those of great vicissitudes, and trying to the delicate. Dr. Jackson, of Boston, who sends his patients chiefly to Cuba, directs them to remain there until the last of April; then to go to Georgia or South Carolina, and to return to Boston very slowly, so as not to reach New England until the end of June; and the course is precautionary and wise. (Sir James Clark, *op. cit.* p. 306.) Should the invalid be unable to pursue this course, he ought to remain in his winter retreat until the end of May, if practicable.]

It is of the greatest consequence to invalids to maintain an active state of the circulation in the surface and extremities, which cannot be done in this country without the assistance of warm clothing. The increased circulation in the extreme vessels is one of the effects of a warm climate, from which the invalid derives the greatest advantage; and it should be his especial care to preserve it while in progress to and after his arrival in a colder, as to the steady maintenance of this for a considerable length of time he must mainly look for the preservation of his new stock of health.

In leaving his own country, therefore, in the early autumn, on his way to a warm climate, and in returning home in the succeeding spring, he should avoid exposure to great vicissitudes of temperature, and thus endeavour to secure the advantages, as it were, of several successive summers.

JAMES CLARK.

COLD.—It is designed under this head to treat of the morbid effects of excessive cold applied to the human body, and of the means of removing them; and also of the application of cold as a remedy in diseases.

The term *cold* is relative, and, perhaps, strictly speaking, ought to be restricted to that sensation which is produced in the animal body by the abstraction of caloric from it, in consequence of the application of any solid, fluid, or gas, of a lower temperature than itself. In common language, however, cold is spoken of as a positive agent, and by some men of science it has been supposed to have as distinct an existence as caloric, or the matter of heat. The result of some experiments instituted to demonstrate that cold may be radiated in the same way as caloric, appears to have confirmed this opinion in some minds; but the effects produced by those experiments are explicable on the supposition that caloric is radiated, and not an agent of an opposite character.

The sensation of cold is not always produced

by the same degree of temperature, for it depends very much on the state of the body previous to its application; indeed, what may be considered a low temperature under some circumstances will cause the sensation of warmth, and a comparatively high temperature will produce that of cold. If the right hand be immersed in water at the temperature of 80° of Fah., and the left in an equal quantity of water at 40°, the former will receive the sensation of heat, and the latter that of cold; but if the two quantities of water be then mixed, and both hands dipped into the mixture at the same time, the feeling of cold will be produced in the right, and the feeling of warmth in the left; so that no fixed temperature can be called either hot or cold. The generation of animal heat, or, in other words, the internal development of caloric, is accomplished by a process continually going on in the body, more actively perhaps at some times than at others.

The abstraction of caloric from the body within given bounds may be regarded as a salutary process; on this circumstance the degree of vigour observable in the human frame, in temperate climates, so much greater than in either what are called the torrid or frozen regions, may in no small measure depend; the degree of abstraction being neither so great as to leave the system torpid, nor so slight as to render it oppressed. Instinct and reason have led to attempts to regulate, by various artificial means, this cooling effect of the surrounding atmosphere in cold climates and seasons, as well as by contrivances for cooling the air in hot regions, to protect the system against the effects of excessive heat; and it is a remarkable fact, that a provision in nature seems in some degree to be made to accomplish the same object in the animal kingdom; for in very cold climates wool and hair grow abundantly long and thick on the brutes, so as to protect them against cold, while in the hotter climates their skin is scarcely covered; and the same animal on being removed from a cold to a warm country, or from a warm to a cold one, is found to change the length of his coat. Thus dogs taken from England to India will often lose all their hair; and in our own climate the horse is well known to have the length of the hair covering his skin regulated by the clothing in the stable.

Perhaps the temperature of the atmosphere which is most congenial to the human body is a range between 55° and 70° of Fah.; but habit has much to do with this, as with almost every thing connected with the actions of the animal economy. An extreme degree of heat may be often endured without much inconvenience by those who have been long habituated to it; and the same may be said of cold. But when the system has been making an effort, if the expression may be used, to resist the bad effects of either a very low or high temperature, a great and sudden change in the surrounding atmosphere is always productive of inconvenience. This remark refers not to a change of climate only, but to the vicissitudes which may occur in the temperature of the atmosphere in the same climate. Persons who are strong and robust, however, feel less inconvenience from these sudden changes than those who are weakly; hence the importance of regu-

lating the quantity of clothing according to the powers of the system, and especially according to the vigour with which the circulation of the blood is carried on. A very frequent exposure to changes of temperature will often enable the body to resist the ill effects of these changes, and affords another instance of the power of habit. The fact just mentioned is illustrated by the good health often enjoyed by those persons who attend large furnaces, glass-blowers, smelters, &c. The wonderful power of the body to accommodate itself to the circumstances under which it is placed, is, in this particular, exemplified in a very striking way. Hence, undoubtedly have originated the various modes of attempting to harden the system, and thus to prepare it to resist the morbid agency of cold. It is undoubtedly true that such means will often give tone to weakly persons, and prepare them for the vicissitudes of climate; but with such persons much care is requisite that the plan be not carried too hastily into effect. Indeed, it will be found that many cannot by any care be brought to bear it, and in such instances warm clothing must be mainly depended on as a defence from the sedative action of cold.

This leads to the more special consideration of the morbid effects produced on the human body by the undue degree of the abstraction of heat from it.

Caloric, or heat, as it is commonly termed, acts as a *stimulant* when applied to the animal body, its effects being local or general according to the extent and degree of its application: it increases, like most other stimulants, the action of the heart and blood-vessels; but (as is also the case generally with stimulants) a secondary effect occurs, which consists in a collapse, (or in an action lower than that which is natural,) after the excitement has subsided. Effects exactly the reverse of these take place from the abstraction of caloric, or, to use the common phrase, from the application of cold. Heat is therefore a stimulant, and cold a sedative, although the exact mode in which heat or cold acts on the body will probably never be determined.

The well-known immediate effects of a considerable abstraction of heat are—the sensation which is called *cold*, pallor of the skin—from the absence of blood in the capillary vessels; or a reddish blue colour especially of the hands, ears, nose, lips, from a delay of blood within the capillaries, so that it becomes venous;—a shrunken state of the skin, and a contraction of it around the small glands which are imbedded in it, and around the hairs, causing it to become rough, and to resemble the surface of a plucked goose; hence the technical term *cutis anserina*. The same state of the skin of the scalp often causes the hair to rise in some degree from the head, with a feeling of tightness; this is called *horripilatio*. The extremities of the body suffer first, as the fingers, toes, ears, nose, &c., *i. e.* the parts farthest from the heart. The fingers and toes become sensibly smaller, so that rings which fitted before fall from the fingers, and shoes drop from the feet for which they were not previously too large. The action of the heart becomes diminished in force, and sometimes also in frequency—the latter being most commonly the result of exposure to a

very intense degree of cold; and not unfrequently the pulsations, although weak, become more frequent than natural. These symptoms, which may be considered the moderate effects of cold, will vary greatly as to their degree in different persons exposed to the same low temperature: indeed, to some persons the abstraction of heat by the cold air of a frosty day affords a grateful feeling, and to such it may be really salutary: this will be referred to when speaking of the therapeutic effects of cold. In all persons, however, a very intense degree of cold will produce unpleasant sedative effects; and in those who have been previously debilitated, the powers of the system are depressed to an alarming, and even sometimes to a fatal extent: indeed there are very few individuals who have such vigour as to be enabled to resist the consequences of exposure, without sufficient clothing, to the severity of the winter months in the frozen regions, or to the intense cold which is met with in passing over very high mountains. The vascular system is not alone affected by the agency of cold on the body, as is proved by the symptoms which occur in the more severe cases of exposure; the brain and nervous system generally being soon brought under its influence. Perhaps it may be with propriety supposed that the nervous system primarily receives every impression from external agents; and that cold, therefore, first acts on this system, the vascular system being only secondarily affected: this question need not be here discussed.

Numbness, or a want of the ordinary acuteness in the sense of touch, is a consequence of exposure to cold: this numbness is experienced by most persons in their fingers and toes on a very cold day, or after having been long immersed in cold water. It is worthy of remark, here, that in these individuals there appears to be something very peculiar as it respects the action of cold on their extremities; the blood appears to cease to flow altogether into the vessels of the fingers and toes, which look exactly (as the common expression implies) like those of a dead person; and so torpid do they become under these circumstances, that a pin can scarcely be felt when placed between the ends of two of the fingers, and the motions of the hand are regulated, not by the touch, as is usual, but entirely by the sight. This singular idiosyncrasy has never received a satisfactory explanation: it does not appear to arise from debility of the vascular system alone, for it is found in some who have no sign of such debility: probably it may depend, as all idiosyncrasies appear to do, on an original peculiarity of structure: it is found to prevail in individuals of the same family. The very great diminution (almost suspension) of sensibility in such cases may arise in some measure from a want of the necessary supply of blood to the extremities of the nerves; as it is an undoubted fact that their sensibility is greatly regulated in its degree by the quantity of blood circulating through the capillaries. It may also in part depend on the direct effect of the cold on the nerves themselves; but that this action on the nerves is not the only cause of the torpor is rendered probable, if not proved, by the fact, that if artificial warmth be applied so as to bring the fingers to their natural tempera-

ture, the sensibility will not return until the circulation is restored.

The whole surface of the body becomes less sensible to the touch under the influence of a great degree of cold; and the sense of taste is sometimes blunted. But further, when a still greater effect is produced, the brain loses its energy, and an irresistible desire to sleep ensues. Here we may again observe that it is hardly possible to determine whether this is the direct result of the action of the cold as a sedative on the brain, or whether it depends on a want of the due supply of blood to that organ, on account of the diminished action of the heart. When this overpowering tendency to sleep has commenced, much danger is to be apprehended; for it has generally been found, when indulged, to be the precursor of death. The interesting account given by Captain Cook of the excursion of Dr. Solander and Sir Joseph Banks, with nine other individuals, over the hills of Terra del Fuego, affords a very strong illustration of this effect of cold. Dr. Solander, who had witnessed the torpor and death produced by severe cold while crossing over some of the mountainous districts of the north of Europe, thought it necessary to put his companions on their guard, and requested them to resist determinately the strong tendency to sleep which he expected some of them would feel; his words, quoted by Captain Cook, were, "Whoever sits down will sleep, and whoever sleeps will wake no more." The doctor was the first who began to experience the anticipated effect of the cold; and so irresistible was the inclination to sleep, even in him, that in spite of his judgment and fears he entreated his companions to allow him to lie down; they acted upon the knowledge he had afforded them for their own safety, and partly by entreaty and partly by force kept him for some time from indulging his destructive inclination; but at last, becoming themselves almost exhausted, they were obliged to leave him behind together with two black servants who had also become drowsy. Dr. Solander was, however, roused, although with the greatest difficulty, after having slept about five minutes only, and carried to a fire which some of the party had succeeded in kindling, and thus narrowly escaped death, although for a time he almost lost the power of his limbs. The two poor blacks perished.

Many examples of this extreme effect of cold will be found on record in the writings of travellers and historians. [See Copland, art. Cold, *Diet. of Practical Medicine*; Dunglison's *Elements of Hygiène*, 2d edit.: Philad. 1844; Guérard, art. *Froid*, *Diet. de Méd.*, xiii. 522: Paris, 1836; and Veiter & Michaelis, art. *Kälte*, in *Encyc. Wörterb. der Medicinisch. Wissenschaft*, xix. 271: Berlin, 1839.] The same effect is produced, to a certain extent, in this country in very severe winters. The celebrated traveller Dr. Edward Daniel Clarke, the late eloquent Professor of Mineralogy in the University of Cambridge, was on one occasion nearly losing his life by cold. Having performed divine service at a church near Cambridge in the afternoon of a very severely cold snowy Sunday, in the year 1818 or 1819, he mounted his horse for the purpose of returning home. Soon finding himself becoming very cold and sleepy,

and knowing well the danger of giving way to sleep, he put the horse into a fast trot, hoping by that means to arouse himself from the alarming torpor which was coming over him: this means was unavailing; and then fearing that he should soon fall from his seat, he dismounted and determining to use every effort to resist sleep, put the bridle under his arm and walked as rapidly as he could. This, however, did not long succeed: the bridle dropped from his arm, his legs began to falter, and he was just sinking down upon the snow, to rise, probably, no more, when a gentleman who knew him came up to him in a gig, and rescued him from his perilous situation. This account was given to the writer of this article by Dr. Clarke himself the succeeding morning; he then felt languid and feverish, after having had a good deal of re-action during the night, but the effect soon passed off entirely.

The action of cold is probably, as has been already remarked, greater on those persons who have naturally a weak circulation, or who have become weak from any debilitating cause; and this last is the reason why those are very soon affected by it who have undergone much fatigue. A moist state of the skin from perspiration or damp clothing will also accelerate the effect of cold, by superadding to the direct effect of the cold air the further abstraction of caloric by evaporation. It is a curious but well-established fact, that when the mind is deeply engaged, the body is less affected by cold; and it is perhaps on this account that maniacs will often bear exposure to extreme cold without complaining.

When the body is warm, and the circulation vigorous, provided there be no perspiration on the skin, the bad effects of exposure to cold are less likely to be experienced. The common practice, therefore, of persons cooling themselves gradually before they pass from a warm room into the open air has originated in error: the greatest protection from the bad consequences of such a change is found in a vigorous circulation, a warm dry skin, and thick clothing.

Long-continued immersion of the body in cold water seems to be productive of nearly the same symptoms as those which arise from exposure to a very cold atmosphere. It has been asserted, on the ground of recorded facts, that less danger is likely to ensue from immersion in sea-water than in fresh water; and it has been alleged that this minor degree of effect is referrible to the stimulating quality afforded to the sea-water by the salts which are dissolved by it. This solution of the facts is probably in part correct; but it must be remembered that the water of the sea is rarely so cold in winter as that of rivers, the immense mass of the ocean requiring a much longer period than that of a winter to cool it down to the lower degrees of temperature of the winter atmosphere: there must besides, by means of the tides, be a continual admixture of the warm water from the southern seas with the colder water of the northern. A doubt, however, cannot be entertained of the advantage which persons who are exposed to the misfortune of shipwreck during severe cold will derive from keeping themselves immersed in the sea-water; and not only because the water is warmer than the atmosphere, but also because it

will prevent the effects of evaporation. Many interesting accounts of shipwrecks have been published which show that this is not mere theory.

The complete and speedy destruction of life from exposure to intense cold may result from the general sedative effect which has been already described; but when life is not totally lost, the extremities may lose their vitality, and mortification to a greater or less extent ensue. Limbs are frequently in this way mutilated in cold seasons in northern latitudes, and in very high situations; when the surface of the nose and the ears suffers in this way, they are said to be frost-nipped or frost-bitten.

But the injury sustained from exposure to cold is not always dependent on its direct sedative action, for it may produce disease, and even cause death, by that secondary effect which is denominated *re-action*. This re-action after depression consists in the return of the action of the vascular system; if moderate, it may go little beyond the natural degree: the pulse becomes rather more frequent and full, and the heat of the surface greater than natural, and a glow is experienced over the whole body: this soon passes off, and leaves no evil consequences. But when the re-action is great, the vascular excitement is so increased beyond its due bounds as to constitute *fever*; and perhaps there may be in reality no difference between this state of the body and fever from other causes. The symptoms are often the same, and sometimes last as long; but the feverish state in a day or two will give way, in many cases, on using very mild remedies, or even without any remedies at all: such cases are called *ephemeral fever*.

Fever is not the only consequence to be feared from re-action after exposure to cold; local inflammation may follow this general re-action, and any of the internal membranes or organs may become the seat of the inflammation; but the particular organ affected in each case may be determined by some local predisposition: thus one person will have catarrh, another cynanche tonsillar, a third pneumonia, as a consequence of exposure to cold.

It appears from what has been said, that it is to the excess of the re-action that such effects, both local and general, are to be attributed; and hence the importance of guarding against every circumstance which may have a tendency to stimulate the system immoderately after exposure to cold, and of employing measures calculated to subdue the action of the heart and blood-vessels when there is a threatening of sanguineous excitement. The danger of applying heat too rapidly is now generally known, as well as that of administering internally any strong stimulants. A person who has become seriously affected by cold should be placed in warm air about 65° or 70°, and should be well covered over with flannel to prevent the heat, as it becomes generated in the body, from passing off. Friction of the surface by means of the warm hands of two or three attendants, or with warm flannels, may be employed: in extreme cases the body may be wrapped in hot blankets until re-action commences; large hot poultices or fomentations may be applied with advantage to the abdomen; the warm air,

vapour, or water bath, about the temperature of 98°, may be employed in those instances where the vital spark appears almost extinguished. The means already recommended must be combined with the employment of internal stimulants, alcohol, spices, ammonia, &c.: but it must be borne in mind that it is desirable to avoid the employment of internal stimulants to any great extent: indeed, to avoid them altogether if possible, as, after re-action has commenced, they, by their action on the system, may cause the injurious consequences of excessive excitement. If asphyxia (or a suspension of the action of the heart and lungs) succeed to the application of cold, artificial respiration, and the other means recommended in the treatment of asphyxia, may be required. When the heat and action of the system begin to return, care is especially necessary lest the excitement rise to an immoderate degree. The same principle must be our guide in attempting to prevent injurious consequences after the local effects of cold. Chilblains, which are a common consequence of the local application of cold, may be prevented by warming the parts affected very gradually, and by cooling them, as soon as re-action takes place, to the extent of producing the sensation called the *hot-ach*.

Large draughts of cold fluids, taken when the body is fatigued and perspiring, are often productive of serious or even fatal consequences: the effects are a faltering of the pulse, laborious breathing, dimness of sight, giddiness, and then general torpor and death. The proper mode of treating these cases has never been well pointed out; it appears, however, a rational practice to give, as soon as possible, some warm fluid, to apply hot fomentations or poultices to the epigastrium, and to resort to the means indicated by the principles already laid down.

The abstraction of caloric from the body may and is frequently made to conduce to the recovery of persons labouring under disease.

As a therapeutical agent, cold is employed to accomplish one of the three following purposes:—1st, to depress inordinate action of the vascular system; 2d, to relax the muscles; 3d, to give vigour to the body.

The sedative effect produced by cold has been already sufficiently dwelt upon to show how it may be employed beneficially to subdue high vascular action. In inflammation, therefore, and in fevers, cold may very often be considered as one of our most valuable remedies. It may be supposed by some persons, that the beneficial effect resulting from the employment of cold in inflammation and fever, arises from the simple diminution of the heat: indeed it is most probable that it was on account of the augmented heat in those diseases that it was at first resorted to; but our present improved pathological views enable us to form a more correct judgment of the action of remedies; and there cannot now exist a doubt that the advantage arising from the use of cold in fever and inflammation is to be ascribed to its allaying vascular action.

When inflammation is situated in the external parts of the trunk of the body, or in the extremities, one of the means most commonly employed to subdue it is the application of an evaporating

lotion. The lotion may be used cold, and then the heat is in some degree abstracted directly by the cold fluid; but the principal advantage (unless the lotion is constantly applied) is derived from the evaporation of the fluid. It is not, therefore, absolutely necessary that the lotion should be colder than the body of the patient, as evaporation will take place more speedily when it is tepid; and in some cases it is preferable to use it warm, on account of its being more agreeable to the feelings of the patient.

Although there cannot be a doubt entertained of the advantage of employing cold applications in cases of common inflammation of the surface and of the extremities of the body, yet by many it is held to be problematical whether they are properly employed in cases of internal inflammations, as of the membranes and organs included within the skull, the thorax, and the abdomen; as by such means the blood may be so thrown upon the internal parts as to aggravate the inflammation. As it respects the brain and its membranes, this reasoning, although at first sight plausible, is evidently fallacious. The object in cases of inflammation being to lessen the flow of blood to the part affected, any means which will control the action of the carotid arteries must be useful in inflammation within the head, as it is by those arteries that the greater part of the blood is conveyed thither. Cold applied to the scalp will be found to act as a sedative, not only upon the vessels of the integuments, but (by a sympathy which is well known to exist between the larger and the smaller vessels) upon the carotids also. It must be clear, therefore, even from theory, that cold applied to the integuments of the head will be of service in inflammatory diseases of the brain: but experience has long decided the point, and no practitioner omits this powerful remedy when he has to combat with such affections.

The immediate effect produced by a sudden dash of cold water, or by a stream of the same poured upon the face and head, is found useful in many states of the brain. This mode of using the remedy is sometimes adopted with advantage in phrenitis, in hysteria, in syncope, and in cases where narcotic poisons have been taken in large quantities, especially opium. The advantage may be owing in some degree, as in inflammation, to the sedative effect of the cold upon the blood-vessels; but this cannot account for the benefit produced in syncope, and the sudden impression made on the nerves by the cold must be also taken into the account.

It seems to remain doubtful whether or not cold may with advantage, or even with safety, be applied to the chest or abdomen when there exists inflammation of the membranes or viscera within those cavities. This practice has, however, of late been recommended by some physicians whose opinions ought to have weight, and especially so as the recommendation seems to be grounded on the result of experience: the limits of this article will not allow of a full examination of this interesting subject; the author, however, may be allowed to say, that in some cases of phthisis pulmonalis, where the pleura has become inflamed, an evaporating lotion, applied over the

part in pain, has often appeared to be of considerable service.

Cold applied to the body has become a very common remedy in fever, when the system is in a state of very high excitement; and it is undoubtedly a remedy of almost unequalled efficacy in such cases. It may be employed by means of cold fluids received into the stomach, or by means of water or air applied to the surface. From the time of Hippocrates the powerful effects of cold have been appreciated in controlling febrile action; and it has from that period to the present time been occasionally lauded as an important therapeutical agent: but it was not until of late years that its applicability in cases of fever became fully understood. We are more especially indebted to the late Dr. Currie of Liverpool for our knowledge of the value of this refrigerant, and of the mode of employing it, (on the Effects of Water, &c. in Fever, London, 1805;) although very valuable information may be found scattered through other medical works. It is not in all cases of fever that this remedy can be employed with advantage, or even with safety: it is only calculated to subdue excessive action when that action is accompanied by a temperature of the body above 98°: even among such cases there may be a few in which some other peculiarity may forbid its use,—for example, when the skin is moist. At least, if it be employed under such circumstances, it will require the greatest caution, even although the temperature of the body be high, which, however, is very unusual when the skin perspires. In measles, cold is in no case to be applied to the skin, nor are cold fluids to be drunk. Nevertheless, in scarlet fever cold is of the greatest service in moderating the action of the system. It is probable, although not clearly proved, that where fever is accompanied by some visceral disease, this remedy may act injuriously, by determining a large quantity of blood to the internal parts of the body.

The circumstances which, when combined, may justify the employment of cold as a sedative in common fever, are an increase of the animal heat above 98° of Fahrenheit, a uniform increase of temperature over the *whole* body, and a dry state of the skin over the whole surface. If there be a tendency to perspiration, it will show itself first in a damp state of the palms of the hands, or of the axillæ. Should a sense of chilliness be felt by the patient, that also will render the employment of cold of doubtful propriety.

Several different modes of bringing the body under the influence of cold are resorted to by medical men.

First, immersion of the body in a cold or tepid bath.

Secondly, affusion of cold or tepid water over the body.

Thirdly, sponging the body with a cold or tepid fluid.

In some few cases, and in the very early stage of re-action, fever has been arrested in its progress by the cold bath or by cold affusion; but where fever is fairly established, it can rarely be suddenly put a stop to by these or by any other means: we can then only mitigate the severity of the symptoms, and thus give a better chance of the occur

rence of a favourable crisis. But the practice of immersing the patient in a bath, or of throwing water over the body, has of late been very rarely adopted; and its disuse has not been without reason, for considerable inconvenience both to the patients and to the attendants is given, especially in private practice, by the employment of both these modes. But the principal objection to them arises from the impossibility of determining the precise extent to which we ought to carry the sedative effects of cold, while the body is immersed in the water, or while it is passing over it in the way of affusion. The patient may be kept too long or too short a time in the bath, or too little or too much water may be affused; so that the action of the system may be too much depressed, or not sufficiently overcome. These objections cannot be made to sponging the surface of the body with cold water: by this means the cooling process can be carried to the exact extent which is required; the criterion for judging of the effect being the feelings of the patient—a slight chilliness will mark the time to desist. Two or three attendants should be employed at the same time, with large wet sponges, passing them over the different parts of the naked body in succession, until the chill comes over the patient, who is then to be placed in a dry bed and moderately covered.

The temperature of the water when used with the sponges may not be a matter of much moment, as it is by means of the evaporation that the heat is principally abstracted from the body: tepid water (from 70° to 90°) will in general be found most agreeable to the feelings of the patient, and it will be equally, if not more speedily efficacious in reducing the morbid heat. It seems also probable, for reasons already assigned, that re-action will not so quickly occur after tepid as after cold sponging. When the desired effect is produced by this mode of refrigeration, the pulse becomes softer and slower, the skin cool and perspirable; headach, if before existing, is relieved, and frequently delirium is suspended, and the general feelings of the patient are so improved that sleep will follow. The remedy will, however, require repetition to derive from it its full advantage, and this should be as soon as re-action takes place to any extent; indeed the sponges may be used partially or generally many times in the day and night; but should the pulse rise very speedily, and the heat return very soon after it has been reduced by this remedy, other means must be combined with it, as bleeding, purging, &c.: but in by far the majority of cases of fever, dependence may be placed on refrigeration alone to keep down inordinate action. Vinegar, spirit, ether, &c., are sometimes used to increase the evaporation, but these are seldom required.

Cold air admitted into the patient's room, or a current of air passing over his body, will often tend to allay vascular excitement: hence poor patients, in fever, who have been lying in their own confined apartments, are often speedily benefited by removal to an hospital through the open air. It is very questionable if any medicine admitted into the stomach is worthy, strictly speaking, to be called a refrigerant, at least to be called so on account of any quality which it possesses, except-

ing its low degree of temperature, although many articles of the *Materia Medica* are reputed to have this effect; but on this point the reader is referred to the article REFRIGERANTS.

When hemorrhage occurs from increased action of the circulation, or is accompanied by such increased action, it may very frequently be restrained by the sedative effect of cold. The local application of cold to the bleeding vessels, or cold so applied as to act upon the large vessels which supply those which are bleeding, will be often found of very great service; for example, in hemorrhage from the nose (epistaxis), cold water used to the face and head will often of itself stop the flow of blood; but in cases of bleeding from the internal organs, cold, made to act upon the system generally, will often be found of great use in helping to restrain the action of the heart. A patient labouring under hemorrhage from the lungs (hæmoptysis), may with great advantage be kept uncomfortably cold: of course when the hemorrhage is not active, but of the passive character, injury rather than benefit might result from the employment of this means.

The depressing effect of cold upon the energies of the animal body is remarkably exemplified in the debility which is felt in the muscles of a person who has been long exposed to a very low temperature; indeed it is very probable that the sedative action of cold on the circulating system is to be ascribed to a diminution of the irritability of the muscular fibres of the heart and blood-vessels. When, therefore, an inordinate contraction of the muscles occurs, as in spasmodic diseases, the sedative quality of cold may cause them to relax when that remedy is applied to the body to a great extent. The cold bath and cold affusion have for this purpose been frequently employed in tetanus; the relaxation, however, which often occurs immediately after the application, is generally of very short duration, and it ought to be remarked that the sudden shock experienced on the first impression of the cold water will often excite an exacerbation of the spasm, and that immediate death has ensued in a few instances. This mode of treating the disease is certainly, in general, far from being effectual; and it cannot be deemed altogether a safe one. The sedative effect of cold on the muscles has been said to show itself in alleviating the irregular actions in chorea, hysteria, and other convulsive diseases; in these cases the cold bath or shower bath has been recommended. As an instance of the effect of cold in producing muscular relaxation, it may be stated that surgeons are sometimes able to reduce with great ease a dislocated limb during the temporary debility, which is induced in the muscles after long immersion in a cold bath. There are, however, other remedies capable of producing relaxation of the muscles, which must be considered much more certain than cold. (See the article ANTI-SPASMODICS.)

The last therapeutical agency of cold which remains to be considered, is its invigorating quality when employed in cases of debility, or, in other words, its *tonic* property.

It has already been remarked that the direct effect of a moderately cold atmosphere is grateful and refreshing to the feelings of some persons;

those who have naturally a very vigorous and too rapid a circulation, those who suffer from the production of too much animal heat, and those who are liable in warm weather to have an inordinate secretion from the skin, are generally benefited by the cold season of winter: by such persons, from their feelings, a cold frosty day will be called bracing and invigorating. To those individuals, however, who have a languid circulation, either naturally or as the effect of disease, cold weather is far from being either agreeable or beneficial. It has been found on inquiry that a severe winter is in this country, and especially in the metropolis, productive of more disease than a milder season; the old and the infirm being the chief sufferers, (*Bateman, on the Diseases of London.*)

An especial reference must here be made to the beneficial effects of that moderate degree of the re-action in weakly persons which follows the application of cold to the surface. The glow which pervades the body, arising from the increase of the circulation, is often at the moment accompanied by a sensible increase of vigour and activity. The benefit appears to depend very much on the blood being thrown in greater quantity into the capillary vessels, and on a consequent increase of their action in preserving the well-being of every part of the system. Cold, therefore, in this respect, seems to act indirectly as one of the diffusible stimulants. (See the article *BATHING.*)

Some kinds of diseases of the skin are benefited by cold or tepid bathing. When there is much inflammatory action of the cuticular vessels, it is desirable to avoid re-action, and this is best accomplished by the use of tepid water, (about 70°,) keeping the body a long time immersed, and afterwards preventing the skin from getting hot: in other cases, where an eruption seems to depend on a torpor of the cuticular vessels, it is desirable to favour the occurrence of re-action.

On the whole, the action of cold on the human body may be regarded as very important in a therapeutic point of view; it requires, however, as all remedies do, much judicious management; but with such management it is every day made the means of alleviating sufferings and of prolonging life.

JOHN WHITING.

COLIC, (colica.) This term, derived from *κῶλον, colon*, the name given to the large intestine, is in its medical application restricted to cases in which there is pain in the bowels, obstinate constipation, and generally vomiting, but without symptoms of pyrexia. The pain which accompanies enteritis and diarrhoea is denominated *tormina*, or griping.

Symptoms.—In cases of colic, although there be no tenderness at first, the attention of the patient is soon attracted by pain which is generally felt near the umbilicus and in the lower part of the abdomen, though sometimes over the whole belly. In most cases it is relieved by pressure, so that the patient endeavours to get relief by leaning upon his folded arms, or upon the edge of a bed, table, or chair; sometimes by lying with his weight upon the abdomen. The pain, however, may be increased on pressure. Dr. Abercrombie states that an intestine which has become rapidly distended is painful on pressure, though by atten-

tion the kind of pain can generally be distinguished from the acute tenderness of peritonitis. The pain, although constant, comes on in paroxysms, accompanied by a sense of twisting or wringing, especially about the navel. The abdomen is sometimes retracted, or drawn inwards; and occasionally the partial spasmodic action of the abdominal muscles gives an idea of the formation of balls or knots in the belly. In other instances the abdomen feels tense, elastic, and sonorous on percussion, from accumulation of flatus, which, after passing through the intestines with a rumbling noise, is expelled, temporary relief generally following its expulsion. These symptoms are usually from the first attended with vomiting, which is often so incessant, that whatever is taken into the stomach is sooner or later rejected; and in severe cases, from an inverted peristaltic action of the duodenum, the vomiting assumes a bilious character.

A variety of this disease, called *flatulent colic*, is very common in dyspeptic persons, more particularly in those who are ill nourished, or who are addicted to the use of spirits; and in children who are improperly fed, or whose bowels are disordered. In this form there is little sickness, and seldom constipation, but painful retention of flatus in the bowels, the colic depending principally upon debility of the muscular fibres of the intestines. Another very painful affection of a similar nature, which is not unfrequently mistakenaken for the effects of gall-stones, appears to depend on flatulent distention of the upper part of the intestinal canal—the duodenum and jejunum. In cases of this description, the pain is felt chiefly in the right hypochondrium, often extending to the back; and in consequence of the pressure on the ductus communis choledochus, where it perforates the duodenum, the flow of bile is interrupted: hence these attacks are often accompanied or succeeded by symptoms of jaundice. In such cases, on the subsidence of the pain, there is usually a perceptible movement of air in some part of the intestines, accompanied by a gurgling noise and discharge of flatus. The pain occasionally ceases entirely, but recurs at irregular intervals, varying from an hour to a day or two. This distention of the duodenum and jejunum is occasionally observed in dyspepsia, and in these cases bilious vomiting generally takes place.

When inverted action takes place throughout the greater part of the alimentary canal, not only the contents of the stomach and small intestines are discharged by vomiting, but those also of the large intestines. The vomiting is then termed *stercoraceous*, and such cases are denominated *ileus*, or the *ileac passion*.

The bowels, both in colic and ileus, are obstinately constipated; so that ordinary doses of aperients do not act.

At the commencement of the attack, the tongue is white, clammy, but soon acquires a thick coating or fur. The pulse is often natural, sometimes rather slow; but when the pain is excessive, or when the symptoms do not yield to the remedies adopted, it becomes quick, and the skin hot, indicating the threatening or supervention of inflammation of the bowels: hence the occurrence of febrile symptoms in colic should never be overlooked

Several divisions of colic, founded on the supposed causes of the disease, have been proposed by systematic writers. Thus Cullen has enumerated no fewer than seven varieties. 1. *Colica spasmodica*, characterized by retraction of the umbilicus and spasm of the abdominal muscles. 2. *Colica stercorea*, arising from accumulation of the contents of the bowels. This form occurs in costive habits, and is speedily removed by active cathartics, which often expel an incredible quantity of feces. 3. *Colica meconialis* is applied to the spasmodic pain of the bowels which infants suffer from retention of the meconium: it is evidently a modification of the last variety (*stercorea*). 4. *Colica accidentalis* implies the origin of the disease from acrid ingesta, and is frequently induced in individuals by particular articles of diet. 5. *Colica callosa*, in which there is a feeling of constriction ascribed to some fixed part of the intestines. 6. The *colica calculeosa* arises from the formation and retention of intestinal calculi. And, 7. *Colica pictonum*, produced by the poisonous effect of lead on the system, which will be afterwards particularly considered.

All writers appear to agree in the opinion, that during the continuance of colic there is some cause which impedes or obstructs the passage of the alimentary contents. It is with reference to this obstructing cause that disputes among practical writers have arisen. The solution, however, of these discrepancies will be found in the fact that the symptoms of colic originate in a variety of causes. Cullen was of opinion that spasm was the essential cause of colic, and founded his varieties of the disease on the supposition that the spasm is the result of the operation of different agents on the muscular fibres of the alimentary canal. Dr. Abercrombie, on the other hand, attributes the symptoms of colic to a certain loss of the muscular power in a portion of the intestine, in consequence of which it does not act in concert with the other parts, but becomes distended by the impulse from the parts above, which in the healthy state would have excited it to contraction. He therefore infers that in colic the distended part is the real seat of the disease, and that the contracted part is not contracted by spasm, but merely collapsed, because it is empty, its muscular action being unimpaired.

It appears to us that the symptoms of colic may be referred to one of the following causes; spasm, obstruction, over-distension, inverted action. Although Dr. Abercrombie calls in question the possibility of spasm occurring in the muscular fibre of the intestines, he cannot be said to have proved this point; he has, however, made it clear that, in many instances where colic has been supposed to arise from spasmodic contraction of some part of the bowels, it ought to have been referred to another cause. It would require numerous facts to show that all muscular fibres are not occasionally liable to a state of spastic contraction; and it cannot be fairly doubted that, when irritating matters are passing through the bowels, such matters may cause an undue degree of contraction, so as to obstruct the passage of the contents of a portion of the tube which is above the point of contraction. We can in no other way explain the occasional production of colic from acrid ingesta. We

know, however, that obstruction giving rise to colic, often arises from organic diseases, such as stricture in some portion of the intestine; various morbid growths in the intestinal canal diminishing its calibre; from hernial protrusion or internal hernia; intussusception or invagination; twisting of the bowels, or a long band of organized lymph encircling them, forming a ligature. Colic also sometimes originates in adhesion between the adjoining portions of intestine, between the intestines and other viscera, or between the intestines and the parietes of the abdomen. Moreover, obstruction and a consequent attack of colic may arise from mechanical causes, such as collections of hardened feces, calculous concretions formed in the intestines, large gall-stones, or hard substances which have been swallowed and become impacted in some part of the alimentary canal. Many of these latter causes may act in conjunction with spasm; indeed it is probable that spasm will, as Dr. Cullen supposes, often be induced by their presence, and that thus hard substances may be arrested in their progress downward by exciting a spasmodic action of the muscular fibres around them.

It is also plain, when any of the causes of obstruction just mentioned occur, that by the detention of the gaseous fluid, or solid contents of the bowels above the point of obstruction, over-distension of the intestines must ensue, the peristaltic action become inverted, or their muscular power altogether lost, as happens in an over-distended urinary bladder. It is an interesting subject of inquiry, whether, independently of any obstruction, the muscular power of any part of the intestines may sometimes become so paralyzed as to be incapable of propelling its contents onwards; and whether from this cause over-distension can take place to such a degree as to cause colic. Dr. Abercrombie, we have seen, has pronounced it to be his belief that the muscular action is entirely destroyed, the part which has been distended falling flat when it is emptied, and presenting a broad surface like an empty bag, without any tendency to contraction. He gives a case in which the patient lived for eighteen hours, with a free external opening directly communicating with the distended intestine, but without any discharge taking place, though the part contained only air and fluid feces, and in which, notwithstanding the intestine for a considerable space above the opening must have been entirely deprived of its muscular action: on examination after death the part presented only a uniform distension, without any remarkable change either in colour or texture. Dr. Abercrombie therefore concludes that such want of power is the common, if not the constant cause of this disease. He gives also an interesting case, accompanied with painful local distension, in which, after resisting the most active purgatives, galvanism succeeded in procuring copious evacuations. Cases of colic are, no doubt, daily observed, which appear to arise from this cause; and it is probable that this debility of the muscular fibre produces, in many cases, the painful gaseous distension which often succeeds to enteritis or violent diarrhoea. Is it not probable that colic from the effects of lead is produced in this manner? Lead when applied externally does unquestionably destroy the tone of

the muscular fibres of the limbs; and it would be a very remarkable circumstance, if the same agent caused paralysis in one part of the body and spasm in another. This species of colic, therefore, (*colica pictorum*.) may be adduced as a presumptive proof of the accuracy of Dr. Abercrombie's opinion, viz. that the symptoms of colic may require for their production nothing more than the loss of tone of the muscular fibres of some portion of the intestinal canal. In these cases the part of the intestinal tube which is affected will, from want of power, be incapable of propelling its contents onward; and thus by continuing to receive without being able to transmit them, the portion of intestine becomes more and more distended, and at length the whole tract above the point of the accumulation assumes an inverted action. Dr. Abercrombie thinks that this loss of tone in the muscular fibre may be caused by rheumatism; and as it is well known that colic often succeeds to exposure to cold, this theory is plausible.

In colic arising from spasm of some of the fibres of the muscular coat of the bowels, or by mechanical obstruction, the same distension and inverted action may take place; only in such cases they are the result of the obstruction, and not of the debility. It has been asserted by some writers, that an inverted action of the whole or of part of the alimentary canal, may be produced independently of either debility, spasm, or obstruction: they adduce, in proof of this opinion, the speedy discharge by the mouth of fluids which have been thrown into the bowels by clyster. These last are called cases of simple ileus, and perhaps the evidence adduced to prove the existence of such a state is still open to controversy.

Morbid Anatomy.—In the preceding account of the history of colic, it has been shown that the symptoms are dependent on a variety of causes, many of which are removable; but those cases in which the colic or ileus is merely symptomatic of uncontrollable organic disease in the alimentary canal, are beyond the possibility of removal. Dr. Abercrombie, to whom the profession is so largely indebted for the record of many valuable cases and pathological deductions, states that ileus may be fatal without inflammation, and gives two cases in which a large part of the small intestine was found in a state of great and uniform distension, without any appearance of inflammation. In other instances, besides distension, lividity or incipient gangrene has been found, but without any appreciable change of texture: in some cases the usual inflammatory exudation was not observed; in others there was vivid redness, and in more advanced cases gangrene, with and without exudation of false membrane. Hence the usual progress of the disease in the fatal cases is into inflammation and its consequences—the inflammation varying from a recent tinge of redness to extensive gangrene; and it should be kept in view that these changes may be going on in a latent form with every variety of symptoms. Indeed we meet with cases in which inflammatory exudation has gone on to a considerable extent before death, yet in which there was neither frequency of pulse nor tenderness of abdomen.

Various kinds of mechanical obstruction have been found in fatal cases of ileus. The obstruc-

tion is occasionally connected with disease of the intestine, with hernial protrusions, with adhesions between two contiguous portions of intestine; so that, as in a case recorded by Dr. Abercrombie, a turn of intestine insinuates itself between the two adherent portions. Various forms of internal hernia, twisting of a portion of the bowel upon itself, intus-susception or invagination and calculous concretions (intestinal calculi), have also been discovered in fatal cases of ileus.

The symptoms of colic have been traced to various organic changes of structure, which diminish the caliber of the intestine. Under these are comprehended contraction or stricture of the bowel, which are situated less frequently in the small than in the large intestines; various morbid growths or tumours having their origin in the internal surface of the bowel, and which in their progress gradually diminish its diameter, till at length even liquids do not pass through the diseased or contracted portion.

The following observations of Dr. Abercrombie are valuable from the practical inferences to which they give rise. "From a review of the whole subject, it appears that there is a remarkable variety in the morbid appearances in those cases which are usually included under the term ileus. We have seen simple distension without any change of structure, and we have seen even extensive inflammation and gangrene. We have seen in several instances the distension apparently taking place at an early period, and gradually increasing through a protracted case, and then fatal, with little or no change in the texture of the part; and in others, we have seen at a very early period, and with much less distension, extensive inflammation, and gangrene. It would therefore appear probable, that in the cases which assume the character of ileus, there is great diversity in the primary state of the affected parts; that in some it consists of simple loss of muscular power, though it may pass into inflammation at an advanced period; while in others it is at an early period connected with inflammation as a part of the primary disease. These cases seem to differ from enteritis in their symptoms chiefly by the absence of fever; and in the morbid appearances, by being fatal with simple gangrene, uncombined with the flocculent or pseudo-membranous deposition, which is so prominent a character of enteritis. Now gangrene in the intestinal canal appears to be chiefly a disease of the muscular coat. A state resembling it is indeed observed occasionally in the mucous membrane; but the cases in which this occurs are accurately distinguished by their own peculiar symptoms, and they do not affect this part of the inquiry. When, in the cases now under consideration, therefore, we find gangrene uncombined with any other morbid appearance, we are perhaps warranted to conjecture that the muscular coat has been the principal seat of the inflammation. It seems to constitute a modification of disease of much practical importance, quite distinct from enteritis, and assuming simply the characters of ileus; but a modification of ileus of the most formidable kind, and very rapidly fatal. We shall afterwards see reason to believe that inflammation may be seated in the peritoneal coat alone, producing a disease which may be fatal

without any interruption of the action of the canal, or that it may affect the peritoneal and muscular coat at once, giving rise to the disease which we commonly call enteritis." (Pathological and Practical Researches on Diseases of the Stomach and Intestinal Canal, p. 140.)

Diagnosis.—It is necessary to distinguish colic—1. from enteritis; 2. from hernia; 3. from obstinate vomiting, sympathetic of disease in some distant part.

The absence of fever, the pain being generally relieved by pressure, the aspect of the countenance, and the quiet soft pulse, will generally distinguish colic from enteritis. It is however never to be lost sight of, that enteritis may not only exist, but may be proceeding to a fatal termination without frequency of the pulse or abdominal tenderness. On the other hand, there may be abdominal tenderness from simple distension of a portion of the intestine, but without inflammation. The stage of the disease must also be taken into consideration; though in the primary there may be no inflammation, in the more advanced stage it may supervene, and thus prove fatal.

When the symptoms of colic arise from a hernia, the protrusion will generally lead to its detection; besides, there is no pain in the beginning at least, and when it does occur, it is more circumscribed, and the tenderness does not extend over the abdomen until the hernia has existed some time, and has become strangulated.

There are many diseases accompanied by sympathetic vomiting, which may, without sufficient care, be confounded with colic. The sympathetic vomiting may arise from renal or biliary calculi, but in these cases there are some local signs of the origin of the affection; in the former case, pain of the back, and along the groins to the testicle and thigh, and disorder of the urinary functions; and in the latter, a greater disturbance of the functions of the liver, together with pain chiefly felt in the situation of the gall-ducts; besides, in neither of these diseases is there the same obstinate constipation of the bowels as in colic.

[In the form of colic, generally termed 'bilious,' a vitiated condition of the bile has commonly been considered the cause; but in the mass of cases this is certainly a secondary result. The disease consists, essentially, in great impressibility of the nerves of the digestive tube, under which a neuropathic condition is induced; this extends to the liver, which, under the erethism, increases its secretion; and, in like manner, an increase, and a morbid condition of the different intestinal secretions are occasioned. In this form of colic, prior to the appearance of the characteristic symptoms, the patient usually suffers under symptoms of disordered stomach and intestines, bitter taste, yellow fur on the tongue, nausea, vomiting, &c. When the colic occurs, the pain is excessively severe, cutting and screwing. The thirst is great, and anxiety and restlessness are attendants. After a while, bilious vomiting supervenes, and the bowels, which had been previously confined, or with scanty discharges, are evacuated freely—the fæces being largely mixed with bile. The symptoms then gradually abate, and terminate in entire restoration to health. Very frequently, the disease is attended with fever, and the severest forms are

apt to end in inflammation of the intestines and death. (*Practice of Medicine*, 2d edit. i. 163: Philad. 1844.)]

Prognosis.—The prognosis in this disease must depend principally on the nature of the exciting cause. When it arises from acrid ingesta, such offensive matters will generally pass spontaneously or by proper treatment, and thus the symptoms will cease. When, however, hernia, intus-susceptio, stricture, or organic disease, produce an obstruction, of course the danger is in proportion to the hazard arising from the disease on which the colic depends; the symptoms of colic, in such instances, being entirely symptomatic of the primary affection. But, as we have seen, it is by no means an easy task, nay, often impossible, to distinguish the cases originating in such obstructions from those which are less dangerous; and the prognosis should therefore not be formed hastily in any case.

It has been observed by Dr. Abercrombie, that ileus has been fatal while the contents of the bowels were of a natural appearance; and when obstruction has existed, its entire removal has not been followed by corresponding relief of the symptoms.

Treatment.—We have seen that colic may depend on causes which are capable of removal, as well as on incurable organic disease: and the symptoms in both classes of cases being nearly similar, it is impossible to ascertain whether or not the colic depend on causes capable of being removed: we must proceed on the supposition that the disease is still capable of being controlled. It is always, however, a necessary precaution to ascertain that the symptoms do not arise from hernial protrusion, as it has not unfrequently happened that hernia, which has been the cause of the symptoms, has been overlooked, and the life of the patient thus exposed to danger. When the practitioner is satisfied that there is no hernial protrusion, or that there is no evident external cause to account for the symptoms, it will be a safe practical rule in all cases of obstinate colic, more particularly if the pulse rise and there be tenderness of the belly, and the powers of the patient do not forbid it, to abstract blood, both with the view of anticipating inflammation, or subduing that which is to be apprehended, and as a powerful means of procuring the evacuation of the bowels; the syncope, which generally follows bloodletting, especially if performed when the patient is placed in the upright posture, being often accompanied with this effect. The bloodletting may therefore be carried to this extent in all cases where the patient is vigorous, and even repeated if the state of the pulse and other symptoms require it.

In persons who are weak, and in elderly people, however, due consideration must be given as to the expediency of bloodletting. In such cases the topical abstraction of blood may be more advisable.

It is a matter of nice practical inquiry, how far the intestines should be stimulated by purgatives: on this point Dr. Abercrombie truly observes that the adaptation of the remedies to the individual cases demands the utmost discretion: it is impossible to lay down any general rules. There

are some cases which yield at first to a powerful purgative, and there are others in which an active purgative is decidedly injurious. [Dunglison's *Practice of Medicine*, 2d edit. i. 163: Philad. 1844.] With these sentiments our individual experience leads us to concur, as well as with the plan of administering, at short intervals, moderate doses of mild aperients. Sometimes large doses of calomel, eight, ten, or even twenty grains, will remain on the stomach, and in the course of a short time move the bowels; in other instances very small doses of purgatives in combination, and frequently repeated, answer this purpose. Purgatives will often operate best when combined with sedatives, and this is explained by the effect of the sedative taking off resistance by allaying undue contraction in the muscular fibres of the intestines, while the purgative excites the general peristaltic action, and increases the secretions from the mucous membrane. Calomel combined with opium may be given with advantage every second hour for three, or four times, and then a full dose of castor oil. If the oil be rejected by vomiting, it may be repeated with the addition of twenty or thirty drops of laudanum, and an enema, containing castor oil and laudanum, be administered to assist the operation of the aperient. In some cases attended with most obstinate vomiting, we have seen a drop of croton oil rubbed on the tongue, and repeated six, eight, or ten times, at intervals of half an hour, procure solution of the bowels when every other purgative had been rejected as soon as it had reached the stomach.

While we endeavour to act on the bowels by aperient medicines given by the mouth, and also in cases in which they are at once rejected, it is expedient to stimulate the colon by injections: these may consist of a combination of various purgatives in common use—infusion of senna, to which may be added neutral salts, cathartic extract, croton oil, turpentine, &c. The forcible injection of a large quantity (five or six pints) of warm water, in which soap has been dissolved, has proved successful. The tobacco glyster has been administered when the ordinary remedies have failed. It should be exhibited with much caution. Dr. Abercrombie recommends that the enema should be made by *infusing* fifteen grains of tobacco in six ounces of boiling water for ten minutes. If no effect has been produced by this injection after the lapse of an hour, it may be repeated in the strength of one scruple to the same quantity of water; and so on, until such effects are produced (slight giddiness, muscular relaxation, &c.) as show that its peculiar action on the system is taking place. It may then be repeated at intervals of one or two hours, if the case do not speedily yield. With these precautions he states that he has seldom seen any unpleasant effect from the free use of this powerful remedy. He adds, if while the tobacco injection is used in this manner, mild purgatives, such as aloes and hyoscyamus, are repeated in full doses every hour or two, the treatment is perhaps that which is most generally adapted to the ordinary cases of ileus, with the assistance of one or two bleedings if the symptoms require it, and especially if the patient be of a full habit. Opiates

are very often useful in colic to allay pain. After a full bleeding, when there is tenderness, the administration of a full dose of opium, combined with an aperient, or thrown into the rectum by glyster, is often followed by relief of the pain, and evacuation of the bowels. Still, however, from the tendency of opium to diminish secretion and to suspend the peristaltic motion of the intestines, it should not be indiscriminately prescribed, but only when there are paroxysms of severe tormina. In these cases it should either be combined with a purgative, or, if given alone, it should be followed by some aperients.

There are other measures which should be put in force: the warm bath; hot fomentations, to which laudanum may be added: large blisters or oil of turpentine may also be applied to the abdomen.

When the means recommended have failed, some physicians have advised the administration of crude quicksilver in doses of one or two pounds. Sometimes the sudden dashing of cold water on the extremities, and the application of cold to the belly, have afforded relief by procuring evacuation of the bowels. These are severe measures, and are only to be adopted when the disease has resisted every other plan of treatment.

In cases in which the colic depends on incurable organic disease, all measures are alike unsuccessful. The patient is generally, under such circumstances, speedily relieved of his sufferings by death; though in some instances life is protracted for an uncertain period, during which the unhappy victim endures the greatest agony. The only resource left is palliation by narcotics, and other means calculated to soothe the sufferings.

[In bilious colic, the great indications of treatment are, *first*, to remove the spasmodic condition of the canal; *secondly*, to evacuate morbid secretions; and *thirdly*, to prevent the occurrence of inflammation. In plethoric and active habits, bleeding may be prescribed, with frictions and stimulating cataplasms to the abdomen; glysters of soap and water with laudanum or spirit of turpentine may be thrown into the colon; and should these remedies not be effective, full doses of opiates may be given by the mouth or rectum, until relief is obtained. Should there be danger of the supervention of inflammation, blood may be taken from the arm, or leeches may be applied to the abdomen, followed by the application of a warm cataplasm; with mild cathartics, as castor oil and laudanum, aided, if necessary, by emollient or anodyne enemata.]

JOHN WHITING.—A. TWEEDIE.

COLICA PICTONUM.—This form of colic is generally traceable to the action of lead upon the body, and is so called from its occurrence as an epidemic at Poitou. It has also received the names *Devonshire colic*, *painters' colic*, *plumbers' colic*. It seems probable, from both fact and analogy, that this metal produces a specific disturbance of the animal economy, of which disturbance the symptoms of colic are only a manifestation, so far as the alimentary canal partakes of the disorder. This agent, however, may produce a local disease, the effect of its morbid agency showing itself more strongly in the part

to which it is immediately applied. Persons who are employed in lead manufactories, or in smelting ores which contain lead, painters, who use much white lead, and plumbers are more particularly the subjects of this disease; but it occasionally happens to patients who are employing some of the preparations of this metal for the cure of disease. Moreover this form of colic has occurred epidemically, and has been (as in the case at Poictou) supposed to arise from the employment of the acetate of lead in clarifying wine, cider, and other liquors. (See the papers of Sir George Baker in the Transactions of the College of Physicians of London.)

[The principal marks of lead cachexia are said to be—a peculiar bluish or bluish-grey tinge of the gums, which sometimes extends over the mucous membrane of the mouth generally, and which has been regarded by Dr. Burton (Watson's *Lectures on the Principles and Practice of Physic*, Amer. edit. p. 712: Philad. 1844) as an infallible proof of the presence of lead oxide in the system; the teeth at the same time become discoloured, and affected with caries: there is a sweetish, styptic, astringent taste in the mouth, with a peculiar factor of the breath; sallowness of the skin, and dull yellow tinge of the conjunctiva, general emaciation, soft, small, compressible pulse, and in rare cases, a considerable reduction in the number of its beats. Of these symptoms, the discoloration of the gums and teeth is most frequent, and most characteristic, and it is considered to be owing to the deposition of a very minute film of sulphuret of lead on the mucous surface, and on the enamel of the teeth. It is important to attend to these premonitions, for of 1217 cases of lead colic observed by M. Tanquerel des Planches, (*Traité des Maladies de Plomb*: Paris, 1839,) 1195 were previously affected with one or more of them; and in many instances, by attending to these premonitions, with temporary cessation from work, the threatened attack of lead colic was prevented.]

This affection has more largely fallen under the observation of those physicians on the continent residing where it prevails endemically. M. Ranque, Physician to the Hôtel Dieu at Orleans, has given a clear account of it, as it occurred between the years 1820 and 1826, among the persons who are employed in the white-lead manufactories at Orleans; and from this physician's account the author is induced to lay before his readers the symptoms of the disease. At first the patient loses his appetite; he feels sick, with increased discharge of saliva from the mouth; there is disturbance in the nervous system, and his nights are restless. He then vomits and discharges every thing he has swallowed, mixed with bile and morbid secretions: to this succeeds pain in the abdomen, which is at first not constant, but returns at intervals, these intervals being longest at the commencement of the disease. The pain is severe about the navel, the epigastrium, the hypochondrium, the loins, and above the crest of the ileum. As the disease advances, the pain is almost constant, but is usually most severe at night, and is not increased by pressure. The abdomen is generally flat, but sometimes feels as if knotted, in other cases more or less distended.

The disease is now attended with headach, pain of the limbs, especially of the inside of the thighs, knees, calves of the legs, ancles, and soles of the feet. There is no fever; the pulse, indeed, is often below 60 in a minute. Constipation of the bowels is an invariable symptom, although it does not always occur at the very commencement; the bowels are excessively obstinate, and when feces are discharged, they are dry and lumpy. The appearance of the urine is generally natural. The expression of the patient's countenance indicates distress, and there is great prostration. Symptoms of inflammation of the peritoneum occur now and then at an advanced stage of the disease, indicated by tenderness of the abdomen, frequent hard pulse, and other febrile symptoms; and in some rare instances the cerebral functions are disturbed.

The pain of the limbs is sometimes very speedily succeeded by paralysis, but it is more frequently after the severer symptoms have passed away that the extremities become so affected.

[The disease, in the large mass of cases, terminates favourably. Of 500 cases, treated at La Charité, in Paris, only 5 had a fatal issue; and in 3569 collected cases, there were only 95 deaths, or about 1 in 30.]

The appearances presented by dissection after death throw but little light on the nature of colica pictonum. Inflammation of any of the textures appears to be only accidental, and is probably the effect, when it occurs, of the strong purges which are often used, or of the distension of the bowels, which is usually, if not invariably discovered. It is particularly mentioned by those who have had opportunities of inspecting the bodies of persons who have died from the effects of lead, that the bowels appear remarkably pale, as if the quantity of the blood in the vessels was less than usual. As has just been remarked, the intestines are often greatly distended in some parts, but in others they are contracted. Whether this contraction is the consequence of spasm, or (as Dr. Abercrombie would say) only the natural state of the tube when empty, it is not easy to determine; and this uncertainty about the cause of the contraction renders it very doubtful whether the distension is the consequence of spasmodic obstruction, or the effect of debility or paralysis; but as we know that the action of lead on other muscular fibres of the body is to destroy their tone, it is the most probable conjecture that those of the intestinal canal, when affected by this poison, cease to be able to propel their contents forward, and that in this way distension takes place.

The foregoing history renders it clear that the action of lead upon the system is very general; and it also seems calculated to lead to the opinion that the symptoms arise from changes in the intestines, analogous to those which are produced in other parts of the body. The primary impression made by this metallic poison is probably upon the nervous system, which secondarily causes a change in the blood-vessels and the muscular fibres. Upon the muscular and vascular system it seems to act as a powerful sedative. It is probable that it is on account of its sedative action on the capillary system that lead is found useful in some cases of hemorrhage and inflammation—

may it not be from this same action upon the capillaries that the muscles become paralysed? It is a well-known fact that without a due supply of blood to their texture, the muscles lose their tone. The shrunk wasted state, and the blanched appearance of the muscles of persons who have died after having been paralytic from lead, seem to favour this opinion. In explanation of the primary action of lead upon the nervous system, it is difficult to form a reasonable conjecture. The acute pains which are felt at the commencement of the disease in different parts of the body, forbid the supposition that it acts as a sedative upon the nerves; and the fact that the sentient nerves of the limbs, when the muscles are paralysed by lead, remain as sensitive as in health, favours the same conclusion.

It may here with propriety be observed, that after the first severe symptoms of colica pictonum have been removed by free evacuations from the bowels, there remains usually great torpor of the alimentary canal, and that it is probable that this torpor is the result of a paralytic condition, more or less complete, of the muscular fibres which produce the peristaltic action of the canal.

Treatment.—The remarks on the nature of the disease tend to show that the treatment of colic arising from the poisonous effects of lead must be regulated by nearly the same indications as those which have been recommended for the treatment of colic from other causes. The object is, first, to procure a full discharge of the alvine contents, and afterwards to restore the bowels to their healthy condition. Purgatives, combined with sedatives, seem well calculated to fulfil the first intention; and no combination is better adapted than that of calomel and opium in the proportions already recommended. After a few doses, a large dose of castor oil, or a drop or two of croton oil may be given; enemata also will be found valuable auxiliaries; they should be administered about the time the purgatives may be expected to begin to act. The warm bath, the tobacco enema, and the other measures suggested as useful occasionally in the cure of colic, may here also be employed; and should there occur tenderness of the abdomen, or any of the signs of inflammation, bleeding from the arm or by leeches will be required. Emetics are employed largely on the continent. At the Hospital La Charité, at Paris, a very complicated plan of cure is adopted, but which, when analyzed, seems to be analogous to that which has been recommended in this article, although strangely pursued: it consists of emetics, cathartics, enemata, diluents, and anodynes. (See M. Andral on Abdominal Diseases.) M. Ranque, in the memoir already alluded to, recommends, on the ground of extensive evidence of its efficacy, the employment of strong counter-irritation to the abdomen and back by means of a plaster which contains cantharides and tartar emetic; and he also prescribes a liniment, made with some convenient vehicle, containing the extract of belladonna, to be rubbed on every part where pain is felt; he uses also belladonna in clysters; and the same sedative by the stomach, in the form of an ethereal tincture, (ʒi. of the powdered leaves to fʒiii. of sulph. ether, of which twenty drops is the dose.) The only peculiarity

in this method of cure is the counter-irritation, which may probably with advantage be added to the list of curative means.

If the opinion be correct that lead acts as a powerful sedative upon the blood-vessels, no measure can appear better calculated to meet this morbid effect than powerful irritants. It is a fact well established that the paralysis which results from lead is most effectually treated by the use of blisters or other stimulating applications to the parts affected; and may we not, on the same principle, (through the medium of the sympathy which is so obviously maintained between the surface and the parts contained within the abdomen,) hope to rouse the activity of the circulation of the intestinal canal by strong irritants applied to the skin? When the first urgent symptoms are overcome, and the bowels have been made to act, great attention will be required to restore completely the tone of the digestive powers. Besides those means which have been enumerated as applicable during convalescence from common colic, astringents and stimulants seem particularly serviceable when a patient is recovering from colica pictonum. Alum in doses of ʒi. with a few grains of ginger or capsicum, may be taken with decided advantage two or three times a-day, with an occasional aloetic purge. The desideratum in this stage of the ailment is to restore the tone of the weakened bowel; and this will be most probably obtained by the combined effects of external and internal stimulants and astringents, wholesome and nutritious food, and a free state of the alimentary canal.

[Of late years, alum (gr. xv. to ʒij. every four or five hours) has been highly extolled, as well as sulphuric acid lemonade. M. Gendrin (Vidécocq, art. *Colique*, in *Dict. des Études Médicales*, Paris, 1830) affirms, that he has cured more than 300 cases, by administering daily from a drachm to a drachm and a half of sulphuric acid, diluted in three or four pints of water. The cure was effected in three or four days. The experience of Gendrin has been corroborated by other observers; but others, again, have not been so fortunate. (See the writer's *Practice of Medicine*, edit. cit. i. 169.)

It has been elsewhere shown (ART. ARTISANS, DISEASES OF, p. 175.) that sulphuric acid is largely used in many lead works and laboratories, and with great success, as a prophylactic.]

The *dry belly-ach* of the West Indies is a disease of nearly the same description as the colica pictonum, and so is the *colic of Madrid*, mentioned by Dr. Pascal. (Mém. de Méd. et Chirurg. Milit. 1826.) Dr. Musgrave, of Antigua, has, in the Medical Repository, 1825, given a very good account of the former of these two diseases which is so very common among the negroes of the West India islands. He attributes the complaint to a morbid condition of the liver; but, in the estimation of the writer of this article, without sufficient evidence. The condition of the alimentary canal, which has already been pointed out, and especially that portion of it, the duodenum, which receives the gall-ducts, seems sufficient to explain the disturbance of the biliary function which he describes. In the West Indies the disease is attributed to the new rum which is drunk

by the slaves. Dr. Musgrave depends principally on mercury for the cure of this complaint, and carries it to salivation, assisted by bleeding and purgatives. It is evident that this gentleman is influenced in his plan of treatment by the pathological views he entertains of the disorder; and it is a question which no one is better qualified, by talent and opportunities, than himself to decide, whether the cure may not be accomplished by mercury more sparingly administered.

JOHN WHITING.

[COLITIS. (See DYSENTERY.)

COLON, DISEASES OF THE. (See CONSTIPATION AND ENTERITIS.)

COLON, TORPOR OF THE. This disease is the source of anomalous symptoms, and, although generally the result of other morbid conditions, is worthy of a distinct mention. Many pathological phenomena, commonly referred to the heart and stomach, unquestionably acknowledge for their cause this affection.

Diagnosis.—Torpor of the colon is thus defined by Dr. Copland, (*Dictionary of Practical Medicine*, Art. Colon, Torpor of the)—“General debility, with indigestion; slow or irregular state of the bowels; distension, borborygmi, or stridulous noises in the course of the colon; frequently pain or uneasiness, sometimes with tumours in some part of this viscus.”

Causes.—Torpor of the intestine may be owing, at times, to defective action of the system generally, and of the colon in particular; but not unfrequently it appears to be dependent upon narrowness of the canal, which occasions a dilatation of the intestine above the narrow portion, in which feces or air may accumulate, and give rise to all the phenomena of ileus; or by pressure interfere with the functions of neighbouring organs. Occasionally, hard tumours, painful on pressure, exist in the colon, especially in the ascending portion. The writer has attended many cases in which various evidences of indigestion were present, with irregularity in the alvine evacuations; generally, constipation alternating with diarrhoea; great irregularity of the heart's action; often intermission of the pulse; giddiness, apparently from modified circulation in the encephalon; and undefinable uneasiness referable to the stomach and bowels, which is often relieved by a moderate dinner, so that the after part of the day may be passed in comparative comfort.

Treatment.—This must vary with the cause, where it is appreciable. When the condition indicates general or local debility, the preparations of iron, as the subcarbonate or the citrate, or the sulphate of zinc, may be prescribed, with the Russian belt, and a diet easy of digestion. This course must be persevered in for weeks. Change of air should be recommended, and the bowels be kept open by enemata rather than by cathartics. Violent purgatives have always appeared to be positively injurious. Where narrowness of the canal exists, it must be treated as noticed under CONSTIPATION; and when attacks of enteralgia supervene, they must be met as inculcated elsewhere. (See COLIC.)

In almost all cases of torpor of the colon, the writer has found decided advantage from a gener-

ous diet, restricted, however, in quantity, and from the use of a glass or two of dry wine, as sherry, at dinner. (Holland, *Medical Notes and Reflections*, Amer. edit. p. 108: Philad. 1839; and the writer's *Practice of Medicine*, 2d edit. i. 155: Philad. 1844.)

ROBLEY DUNGLISON.]

COMA, (from *κῶ*, or *κίω*, to lie down,) a propensity to sleep; in pathology, a suppression, more or less complete, of the powers of sensation, thought, and voluntary motion. This may occur in various degrees, from a state of slight temporary drowsiness and torpor to one of profound and permanent stupor with general paralysis both of feeling and motion. The mental powers alone may be affected, whilst sensation and voluntary motion remain unimpaired. There may be suspension only of some of the intellectual faculties, as occurs in somnambulism and several forms of lethargy; or thought, sensation, and voluntary motion may be alike completely abolished, and life only sustained by a partial supply of nervous influence to the involuntary organs. These modifications of disease are easily accounted for by the natural divisions of the nervous system into parts having distinct functions.

Coma is a symptom not characteristic of any one condition of the brain, but may exist in connexion with morbid actions very different and even opposite in their nature. Nosologists have on this account been greatly embarrassed how to dispose of comatose affections in their classifications of disease, so as to bring them under one head. By attempting this they have introduced a degree of confusion calculated to lead to dangerous mistakes in practice; for comatose affections, decidedly connected with an inflammatory condition of the brain, have been erroneously ranged under the class *neuroses* or *adynamix*, to which classes some other of these affections, originating in debility, legitimately belong. Coma may either be a primary affection, or supervene, in the course of other diseases, as a symptom. In Cullen's system, comatose affections constitute the first order of the class *neuroses*, under the title *Comata*, which order is divided into two genera, *apoplexy* and *paralysis*. Those affections which are more especially comatose, such as apoplexy, carus, cataphora, catalepsy, ecstacy, and all the varieties of lethargy, are included under the first genus. Dr. Mason Good, in his *Nosology*, classes all the affections characterized by torpor, either mental or corporeal, under the genus *carus*, having six species—*asphyxia*, *ecstasis*, *catalepsia*, *lethargus*, *apoplexia*, *paralysis*. The strong sympathy which the different parts of the brain and nervous system have with each other, establishes a close connexion between several of these forms of coma, and they not unfrequently pass into one another. In the present article we intend to confine ourselves to a brief description of the characteristic features of each of these affections; a more detailed history of some of them will be given under separate heads.

By *lethargy* is meant a torpor both mental and corporeal, with deep quiet sleep; it has a close affinity to natural sleep, differing chiefly in being more prolonged, and depending on a morbid con-

dition of the brain. This is the slightest form of coma, and has been termed also, by some writers, *cataphoru*.

Catalepsy, or trance, is a total suspension of sensibility and voluntary motion, mostly also of mental power: the pulse and breathing continue natural, the muscles are flexible, the body yielding to and retaining any given position. (See *CATALEPSY*.)

Ecstasy is a total suspension of sensibility and voluntary motion, mostly also of mental power; the pulse and breathing remain natural, the muscles are rigid, the body erect and inflexible. It is persons of a nervous temperament and ardent imagination, much given to reverie and deep abstraction, who are most subject to this affection. The power of attention appears wholly concentrated on one train of thought engaging only a few of the intellectual faculties, whilst the others remain in a state of complete torpor. The patient seems to experience, for the time, a high degree of intellectual enjoyment. This is the description of ecstasy given by ancient writers, by some of whom it has also been termed *catochus* and *catoche*.

There is a complete abeyance of the mental faculties, of the external senses, of feeling, and voluntary motion, in the most perfect and aggravated forms of coma. The pulse is generally very slow, either full and soft, or small and hard; sometimes intermittent, at others, however, rapid, feeble, and irregular. The breathing is slow, laboured, and stertorous, the stertor arising from the relaxation and paralysis of the muscles of the internal fauces. There is sometimes dropping of the lower jaw and distension of the cheeks at each expiration, with difficulty of deglutition. The pupils are dilated and insensible to the strongest light: in some cases, however, they are either contracted or insensible, or one pupil is contracted and the other dilated. The surface of the body and the extremities are cold and clammy; the patient lies supine, and there are several other distressing symptoms indicating the rapid approach of death. This is the form of coma that generally attends diseases affecting the structure of the brain,—apoplexy, paralysis, meningitis, cerebritis, hydrocephalus, &c. It has been named by some nosologists *carus*. Others have described coma as a degree of torpor more profound than lethargy, but less than *carus*. Coma is sometimes attended with low muttering delirium, and has then been called *coma vigil*; and when resembling more a profound sleep, *coma somnolentum*.

The attack of coma is sometimes sudden, without any premonitory symptoms, and it may assume at once its most aggravated character, terminating speedily in dissolution. In other cases the loss of sense and motion is less complete, and consciousness returns in a few minutes or hours. There may be a recurrence of the attack in either regular or irregular paroxysms, as occurs in epilepsy. The invasion and progress of the complaint are, however, sometimes very slow. It commences by a tendency to drowsiness, which gradually increases until it reaches the state of complete coma. It frequently succeeds or alternates with convulsions and high delirium, and in

such cases is to be considered a symptom of worse omen than delirium.

The most frequent and obvious cause of coma is pressure on the brain. A state of perfect coma can be produced artificially by applying pressure to the brain of an animal, and the coma is relieved the moment the pressure is taken off. The brain is exposed to pressure from a variety of causes. The principal of these are, congestion, inflammation, effusions of blood, pus, or serous fluid, organic tumours seated in the brain, in its membranes, or on the parietes of the skull, fractures of the skull, with depression, &c. Coma is perhaps too frequently attributed to serous effusion in the brain, which may exist in a considerable degree without any coma, more especially when it takes place very slowly. Sudden attacks of temporary coma sometimes occur in consequence of the distended state of the stomach and bowels, compressing the large vessels in the neighbourhood of the heart, and causing an accumulation of blood in the head.

Another very important and not uncommon cause of coma is a deficiency of nervous energy of the brain. There are various ways in which this may happen. It may take place suddenly, as the consequence of a violent shock or commotion given to the brain by a fall or a blow, causing some temporary derangement of the contents of the head, and suspending the operation of the nervous principle; this is termed concussion. The same effect may be produced without any physical cause, by violent impressions made on the nervous centres, and suddenly paralyzing, as it were, the action of the nervous principle, as sometimes happens after strong mental emotions, or the intense pain of severe operations. In such cases the patient sinks into a state of profound coma, from which there are instances of his never recovering; nature appearing, as is remarked by some writers, suddenly to relinquish the struggle. Intense cold acts on the brain and nervous system by producing a state of numbness and torpor which speedily passes into coma, and terminates in death.

This loss of power in the functions of the brain, or in the nervous principle of the brain, may however have occurred very gradually; and the fact of this being a cause of coma is a highly important one, which, until lately, had been too much overlooked. The profession is much indebted to the late Dr. Good and to Dr. Marshall Hall for having directed their attention to this principle in pathology. After protracted attacks of inflammatory diseases, when the patient, although considerably weakened, is considered nearly convalescent, he sometimes falls into a state of coma, preceded occasionally by acute cerebral symptoms. Children are particularly subject to this variety of coma from exhaustion; they lie in a state of insensibility, the pupils dilated, the eyes open and insensible, the face pale, the skin cold, and the pulse feeble; they may continue for a day or two in this kind of stupor, and then recover. We apprehend, however, that these symptoms have often been mistaken for those of hydrocephalus, and that death has been hastened by the active treatment employed. There are in other cases symp

toms of considerable nervous irritation, headach, delirium, great frequency and irregularity of pulse, general restlessness, which are sooner or later succeeded by fatal coma. This affection has been observed in persons who had long suffered from great mental distress. Dr. Kellie and Dr. Abercrombie have attempted to give an explanation of these phenomena, which appears not unreasonable; they suppose that when the general volume of the blood is much diminished, that balance of the circulation in the brain which seems necessary for the healthy condition of its functions is destroyed; that the arteries of the brain become contracted in their caliber, in consequence of receiving a less quantity of blood; but that, as the whole quantity of blood in the head must always continue nearly the same, a proportionate accumulation takes place in the veins and their sinuses, producing venous congestion. The considerable venous congestion observed in the heads of animals which have been bled to death, whilst the other parts of the body are blanched, and drained of their blood, favours this explanation. Some of the old writers mention a form of apoplexy analogous to this affection, to which they have given the name of *apoplexia ex inanitione*. A state of high mental excitement is in some cases followed by collapse and coma. This happens in individuals endowed with a highly sensitive and irritable nervous system, possessing more imagination than judgment, and subject to alternations of great exhilaration and a proportionate depression of spirits. It is persons of this temperament who are generally exposed to attacks of lethargy, catalepsy, somnambulism, &c. The coma of hysteria belongs to the same class of cases.

The use of certain medicinal and other substances may be followed by coma, in consequence of their specific action on the brain and nervous system. This is the case with narcotics and spirituous liquors. The effects of spirituous liquors and of some stimulating narcotics, may partly be accounted for by their causing an increased flow of blood to the head, and a temporary congestion; but, independent of this, they have a direct and specific action on the nervous energy, which they first highly stimulate and disturb, and next appear to prostrate and paralyse. This is what occurs in intoxication from alcoholic liquors and opium. There are other powerful narcotics, the effect of which seems to be that of at once paralyzing and extinguishing the nervous energy without previous excitement, causing thus almost instantaneous death. This is the mode of operation of the opus, tobacco, belladonna, &c. Some narcotics stimulate in small doses, and cause direct stupor in large doses.

Amongst the causes of comatose affections are to be mentioned, retrocedent gout, the suppression of exanthems or old sores, of the hemorrhoidal and menstrual flux, &c. In cases of coma, strict inquiry into these points should never be omitted.

The great practical importance of being able to distinguish accurately between the different varieties of coma must appear obvious, when we consider how widely the causes which have just been enumerated differ from each other in their nature, and that the most opposite remedies will be required for their removal. The diagnosis,

however, in these affections is sometimes involved in great obscurity; and when the attack of coma is sudden, as the physician is required to act immediately, he may find himself placed in a delicate and perplexing situation, for the life of the patient may depend on his selecting the right course of treatment.

The important question he will have to determine is, the exact condition of the brain to which the symptoms of coma owe their existence; whether they are to be ascribed to any of the causes of cerebral pressure, such as congestion, effusions of blood, pus, or serous fluid, fractures of the skull, with depression, &c.; whether simply to the weak and torpid state of the nervous energy of the brain, or whether finally to both these causes, and in what degree they are combined. Much correct information respecting these points, and the degree of danger with which the case is attended, will be obtained by inquiring carefully into the state of the circulation and respiration, and into that likewise of the temperature and sensibility of the surface of the body and of the extremities: an accurate account of the patient's state of health previous to the attack will sometimes throw considerable light on its nature.

In the milder forms of coma, the structure of the brain is not affected; there is only a slight degree either of vascular congestion or of nervous torpor, or else a combination of both these conditions. The patient lies in a quiet sleep, out of which he can sometimes be momentarily roused by calling aloud or shaking him. The breathing is tranquil and free; the pulse soft and regular; the temperature of the body natural, and the feeling but little impaired; the pupils may be a little dilated, but retain some degree of motion. This is the usual condition of the patient in attacks of lethargy, catalepsy, ecstasy, and in the coma which follows moral emotions. When coma supervenes on gradual exhaustion, the antecedent circumstances of the case, the pallidness of the countenance, febleness of the pulse, and coldness of the surface, will sufficiently point out its true nature.

The characteristic features of the most aggravated form of coma have already been described; they are generally to be ascribed to some disease seriously affecting the structure of the brain, or else to a formidable prostration of its nervous power. Stertorous breathing has been insisted on as a sure sign of danger; its absence is not, however, to be taken as a proof of the reverse. But we may lay down as a general rule, that the danger is always in proportion to the degree in which the respiration, the circulation, and the temperature of the body are affected.

The distinction between the coma which follows simple concussion of the brain, and that arising from compression in consequence of fracture and depression of the cranium, or else effusion of blood on its inner surface without fracture, has been a point of interesting inquiry with surgical writers; having principally for its object to determine under what circumstances operations are to be performed in injuries of the head. A great deal of valuable information on this subject is to be collected from the works of Pott, Abernethy, and Dessault. Cases of slight concussion

are easily distinguished from compression, the patient still retaining some degree of consciousness and feeling, and the stupor being soon relieved. But in cases of very violent concussion, where the prostration of the sensorial power is extreme, the coma is so complete, and the symptoms so closely resemble those of compression, that the most experienced observers acknowledge the difficulty of drawing any exact line of distinction between them. The chief source of apprehension in simple concussion is the period of stupor being followed by one of inflammatory reaction.

Abernethy gives the following very graphic account of concussion, which he thinks may be divided into three stages. The first stage is that of insensibility and derangement of the bodily powers, which immediately succeeds the accident. Whilst it lasts, the patient scarcely feels any injury that may be inflicted on him. His breathing is difficult, but in general without stertor; his pulse intermitting, and his extremities are cold. But such a state cannot last long; it goes off gradually, and is succeeded by another, which he considers the *second* stage of concussion. In this, the pulse and respiration become better, and though not regularly performed, are sufficient to maintain life and to diffuse warmth over the extreme parts of the body; the feeling of the patient is now so far restored that he is sensible if his skin be pinched; but he is stupid and inattentive to slight external impressions. As the effects of concussion diminish, he becomes capable of replying to questions put to him in a loud tone of voice, especially when they refer to his chief suffering at the time, as pain in the head, &c.: otherwise he answers incoherently, and as if his attention was occupied by something else. As long as the stupor remains, the inflammation of the brain seems to be moderate; but as the former abates, the latter seldom fails to increase, and this constitutes the *third* stage, which is the most important of the series of effects proceeding from concussion. These several stages vary considerably in degree and duration. Mr. Abernethy proceeds to observe that the treatment must be different in each of them, and to caution against the very free use of stimulants in the first stage, which is too often prescribed, and particularly against their continued exhibition in the third stage, when a plan of treatment directly the reverse is required.

The coma produced by excessive intoxication has some similarity to that of apoplexy, and we have known this lead to ludicrous mistakes, not very creditable to the practitioners' discernment. The smell of the breath will in most cases supply a sure means of avoiding such errors; in some extreme, though rare instances, actual coma has, however, supervened. It is deserving of notice that impostors, who feign epilepsy, with a view to extort charity, can always be detected by examining their eyes, when the pupils will be found in their natural state as to size and sensibility. In epilepsy they are almost always contracted and insensible. In coma they are generally, though not always, dilated, and their sensibility is more or less diminished.

Syncope and asphyxia bear a close resemblance

to coma in many of their symptoms; they are characterized in common with coma, by the absence of sensation and motion, by dilatation and insensibility of the pupils, &c. They differ chiefly, however, in the state of the respiration and general circulation. The *primary* cause of syncope is a diminution or temporary cessation of the action of the heart; the brain being thus deprived of the usual supply of its natural stimulus, the flow of nervous influence from the sensorium, which is indispensable for the maintenance of all the actions of life, is suspended, and a general torpor with other symptoms of apparent death is the necessary consequence. In asphyxia the circulation is also stopped, through the interruption of the functions of the lungs. The primary symptoms therefore in both these diseases are a great feebleness or complete suspension of the action of the heart and lungs, and the occurrence of coma is but secondary; while, when the same symptoms occur in coma, it is only secondarily and in its advanced stages. It is not unimportant to attend to these distinctions, for we have seen a protracted fit of syncope in a fat corpulent person mistaken for apoplectic coma, and the adoption of active remedies nearly followed by fatal consequences.

As the treatment of the various kinds of comatose affections will be described under their respective heads, we intend in the present article to confine ourselves to some general observations on bloodletting in this class of diseases. When a person is suddenly deprived of sense and motion, the practitioner sent for is expected by the alarmed friends to employ instantly some active and efficient means of relief, and it is a very general rule with the profession to have recourse at once to the lancet. Should there even be any doubt in the mind of the practitioner respecting the propriety of such a course, he may still be driven to adopt it, in deference to the opinions of the public, who ignorantly conclude that, because bloodletting affords relief in some sudden fits, it is equally essential in all. If the patient recovers, the cure is attributed to the venesection; and if he dies, it is hastily inferred that nothing would have saved him. If we turn, however, to a calm consideration of the various and very opposite causes of comatose affections, it will appear a most obvious truth that nothing can be more contrary to the legitimate deductions of science, and more dangerous in practice, than this indiscriminate and empirical use of the lancet. It has been seen that among the causes of coma, some are connected with morbid conditions of the substance of the brain, for the removal of which bloodletting is the only, if not a sovereign, remedy; but that on the other hand coma is frequently to be ascribed to a deficiency or prostration of the nervous energy of the brain, in which case it is evident that the subtraction of any large quantity of the vital fluid can only have the effect of preventing the powers of the constitution from rallying, and of thus turning the scale against the patient's recovery. We have little doubt that some of the recoveries from coma after bloodletting ought to be considered as lucky escapes from death, rather than cures.

There are, as just stated, well-marked cases in

which there cannot be a shadow of doubt as to the propriety of venesection; as, for instance, when the coma is very profound, with a flushed face, hot skin, full and strong pulse, stertorous breathing, &c. But when in the young, the aged, or the infirm, there are evident symptoms of great debility; when the face is pale, the skin and extremities cold, the pulse feeble, the breathing not much embarrassed, &c., the propriety of general depletion to remove symptoms of coma is more than questionable; all the relief that bloodletting is capable of affording can be obtained from cupping or leeches, should even local depletion be thought necessary; and we have seen coma depending on cerebral pressure very quickly relieved by the abstraction of only three or four ounces of blood from the head; an apparently trifling cause being sometimes sufficient to destroy the balance of the circulation in the brain.

We are aware that there may be cases in which the indications both for and against general bloodletting are so nicely balanced, that it is difficult to determine which course to pursue. Under such circumstances we must proceed with great caution,—and a small bleeding may be tried for the purpose of exploring the nature of the case; we should watch the effects produced, as the blood flows; and in all doubtful cases it is preferable to take a small quantity only at first, as the operation can easily be repeated if judged advisable. In coma as well as in asphyxia, when the powers of life are sunk very low and appear to be fast ebbing, a favourable re-action is sometimes prevented from taking place by the circumstance of either the brain or the heart being completely overpowered by an excessive accumulation of blood. The timely abstraction of a very few ounces of blood has sometimes appeared to be of essential service in such cases, by relieving the mechanical oppression of the organ, and enabling it to recover a slight degree of action, sufficient perhaps to lead gradually to a favourable re-action in the other vital functions; whilst copious bleeding under similar circumstances would most probably have completely extinguished the remaining sparks of life.

The temperature of the surface of the body may be considered one of the safest guides with respect to the propriety of bloodletting, together with the state of the pulse and the action of the heart. We have never, indeed, seen beneficial effects follow venesection, when the animal heat has been very low, even although the strength of the pulse might appear to justify its being prescribed. The temperature of the body is, perhaps, a safer general criterion of the exact condition of the powers of life than even the pulse; for do we not see the arteries pulsating and throbbing with great force and frequency in cases where there is an undoubted tendency to debility and sinking? Whilst, however, a low state of the animal temperature is sufficient of itself to counter-indicate copious depletion, the opposite condition must not always be conceived to justify the use of the lancet; for a morbid pungent heat is a frequent attendant on a state of great irritability of the nervous system, characterized also by a quick throbbing irregular pulse, but indicative of a general and dangerous deficiency of the powers

of life. This important point of pathology will be more fully examined in the article INFLAMMATION. We shall conclude therefore by repeating, that the practice of bleeding rashly and indiscriminately to a large amount in all cases of sudden loss of sense and motion, cannot be too strongly deprecated. A good paper on this interesting subject, by Dr. Latham, will be found in the 6th volume of the Transactions of the London College of Physicians.

ADAIR CRAWFORD.

[COMBUSTIBILITY, PRETERNATURAL. (See COMBUSTION, SPONTANEOUS.)]

COMBUSTION, SPONTANEOUS HUMAN. When we reflect upon the difficulty with which the proximate principles of the animal kingdom are made to undergo combustion, even when exposed under the most favourable circumstances to an elevated heat, it is not to be wondered at that relations of this process having spontaneously occurred should have been received with suspicion and ascribed for a length of time to credulity or imposture. That cases, however, of this kind have really taken place seems now established by indisputable evidence; but while the fact is very generally admitted, we are still, as in the instance of meteoric stones, at a loss for an adequate explanation of it. Before entering upon an analysis of the different conjectures which have been hazarded upon so obscure a subject, we shall first quote, for the purpose of illustration, a few well-authenticated instances of individuals who have fallen victims to this most mysterious of all human affections.

Cornelia Bandi, Countess of Cesina, an Italian lady, sixty-two years of age, having felt drowsy one evening, retired earlier than usual to bed, and was attended by her maid until she fell asleep. When the girl on the following morning entered her mistress's apartment for the purpose of awakening her, a dreadful spectacle presented itself. At the distance of four feet from the bed there was a heap of ashes, in which the head, legs, and arms of the countess alone could be traced. The head lay between the legs, but the half of its posterior part, together with the brain and chin, were entirely consumed. The legs and arms were uninjured. The ashes, which alone remained of the rest of the body, when touched, left upon the fingers a greasy fetid moisture; and a sooty matter was deposited upon the furniture and tapestry, and had even penetrated into some drawers and soiled the linen which they contained. There was no unusual derangement of the bed, the bed-clothes being merely thrown aside, as is the case when a person gets up. The wax of two candles placed upon a table near the bed was melted, but the wicks remained unconsumed. It is deserving of remark that it was a constant practice of this lady to bathe her body with camphorated spirit of wine. This case was first published by Bianchini, but is chiefly known to the British public in a paper communicated to the Royal Society by Dr. Cromwell Mortimer, and which may be found in the Philosophical Transactions for the year 1745.

Don G. Maria Bertholi, a friar, who lived in Mount Volere, went to the fair of Filetto, and

having walked about all day, retired in the evening to the house of a relation at Fenile, to spend the night. Upon his arrival, he went direct to his bed-room, and had a handkerchief placed between his shoulders beneath his shirt. In a few minutes after, having been left alone, a singular noise, mingled with cries, was heard from his room; and when the people of the house rushed in, they found him on the floor, surrounded by a lambent flame, which retired as they approached. When visited next morning by Joseph Battaglia, a surgeon of Ponte Basio, the integuments of the right arm were found loosened from the muscles, and hanging down, and those of the back, between the shoulders and the thighs, were in the same state. The part of the right arm which had sustained most injury appeared in a state of incipient putrefaction, and next day was quite gangrenous. On the third day there were thirst, fever, violent convulsions, fetid stools, vomiting, and delirium; and the gangrene had extended to all the injured parts. On the fourth day he fell into a comatose state, which lasted two hours, and then died. Battaglia observed, during his last visit, that putrefaction had commenced, and indeed had already made considerable progress. The nails had loosened and were ready to fall off. The stench was insupportable, and maggots crawled from the body at every point. The account which the patient gave of his singular attack was, that he felt a blow upon the right arm as if inflicted by a club, and then saw a spark hanging to his shirt-sleeve, which immediately reduced it to ashes. The handkerchief already spoken of, as also his drawers, were uninjured; but his nightcap was consumed, although his hair was not touched. There was no empyreumatic smell, and not a trace of fire or smoke in the room. It should also be observed that the night was calm, cool, and clear.

A detailed account of this case appeared in the *Allgemeine Literatur Zeitung*, for 1786. It has been transcribed by most writers on juridical medicine, partly in consequence of its singularity, but chiefly because it is conceived to illustrate and support the electrical theory of the origin of what is denominated spontaneous combustion. It is also remarkable as being the only well-established instance of an individual who suffered from such a calamity having lived sufficiently long to give an account of the manner in which he was attacked.

Anne Nelis, wife to a wine and porter merchant, living in South Frederick street, Dublin, let in her husband, who had been out at a party, between twelve and one o'clock on a Saturday night. After some altercation had taken place between them, both being in a state of intoxication, Mr. Nelis went up stairs to bed, but in a few minutes came down to request his wife to accompany him, an invitation which she positively declined; upon which he took with him her candle, observing that if she was determined to sit up, she should do so in the dark. Next morning the maid-servant having opened the windows of the back parlour, observed something in the arm-chair in which Mrs. Nelis usually sat, which she at first sight imagined to have been put there by young Nelis, who at the instant entered the room,

for the purpose of frightening her. Upon examination, however, it turned out to be the remains of her mistress, who was found in the following state. She was seated in the chair, at a distance from the fire, which appeared to have burned out, with her head leaning upon her right hand, and bearing behind against the wall. The trunk of the body was burned to a cinder, as also the clothes which invested it; but the pelvic region, the lower and upper extremities, and such portions of her dress as covered these parts, sustained no injury. Her face had a scorched appearance; but her hair, and the papers she had put in it, had entirely escaped. The back and seat of the chair had not suffered, but its arms were charred on the inner side where in contact with the body. With the exception of the arms of the chair, the combustion had not extended to surrounding bodies. The room was filled with a penetrating and offensive odour, which was still perceptible after the lapse of several days. This woman was about forty-five years of age, of low stature, had rather a tendency to corpulence, and was a confirmed drunkard. The preceding facts may, we believe, be depended on, though we have experienced very considerable difficulty in collecting them. Strange to say, there was no inquest; and such was the anxiety of the family to hush up every thing connected with the occurrence, that a request made by Dr. Tuomy, late Professor of Physic in the School of Medicine, to be permitted to examine the body, was refused.

The following case is extracted from the *Methodist Magazine* for 1809, as related by a Mr. Wood, a Wesleyan minister, then residing in Limerick. "Mr. O'Neil, keeper of the Five Pounds Alms-House in the city of Limerick, was awakened about two o'clock at night by a person knocking at his room door, upon which he arose, and having inquired who knocked, he opened the door, and going with the person who had called him into his apartment, which lay under Mrs. Peacocke's room, he found a dead body lying on the ground burning with fire, and red as copper, having dropt down from the loft, which was on fire. Examining the loft, he saw a large hole, the size of the dead body, burned through the boards and ceiling. He instantly ran up stairs, and having burst open Mrs. Peacocke's room-door, saw in the middle of the room the burnt hole through which the body had fallen. Having with assistance quenched the fire about the hole, he examined by what means the body had taken fire, and could find no cause. There was no candle or candlestick near the place, no fire in the grate but what was raked in the ashes, as is the manner of preserving fire by night; the room was examined, and nothing had taken fire but that part of the floor through which she had fallen. Even a small basket made of twigs, and a small trunk of dry wood which lay near the hole, escaped, and were not so much as touched by the fire.

"This phenomenon was the next day examined by the mayor, clergymen, and several gentlemen of the city. The impossibility of ascertaining the cause of the fire, the extraordinary circumstance of no part of the room being burnt but the centre of it, through which she had fallen, added to the well-authenticated circumstance of her re-

cent diabolical imprecations and lies, obliged every observer to resolve so awful an event into 'the visitation of God's judgment in the punishment of a daring and persevering sinner.' — It is proper to add here, that for the leading facts of this case we do not rely solely upon the Methodist Magazine. They have been detailed to us in a letter received from Mr. Wood himself, and confirmed by an intelligent lady residing in Limerick, who personally inspected the floor through which the hole was burned; the repairs undergone by which still point out the spot at which the perforation took place. We should not omit to mention that Mrs. Peacocke was about sixty years of age, and that she indulged immoderately in intoxicating liquors.

Mrs. Stout, widow of a watchmaker, and married a second time to a man of the name of Hanna, went to bed one evening in apparent health, and was found next morning burnt to a cinder on the floor of her bed-room. When discovered, a vapour was still issuing from her mouth and nostrils, and those parts of the body the form of which had not been altered, immediately crumbled down upon being handled. Her chemise and nightcap escaped uninjured. This case occurred in 1808, at a place called Coote Hill, in the county of Cavan. The subject of it was about sixty years of age, and an inveterate dram-drinker. An inquest was held, and from the impossibility of accounting for the occurrence upon any known principle, the verdict was — "death by the visitation of God."

A. B., a woman of about sixty years of age, who lived with her brother, in the county of Down, retired one evening to bed with her daughter, both being, as was their constant habit, in a state of intoxication. A little before day some members of the family were awakened by an extremely offensive smoke which pervaded their apartment, and on going into the chamber where the old woman and her daughter slept, they found the smoke to proceed from the body of the former, which appeared to be burning with an internal fire. It was as black as a coal, and the smoke issued from every part of it. The combustion having been arrested, which was effected with difficulty, although there was no flame, life was found completely extinct. While the body was being removed into the coffin, which was done as soon as possible, it was dropping in pieces. Her daughter, who slept in the same bed, sustained no injury; nor did the combustion extend to the bed or bed-clothes, which exhibited no other traces of fire than the stains produced by the smoke. According to the testimony of one of the relations, who is represented as a woman of the strictest veracity, there was no fire whatever in the room. The subject of this case had been grossly intemperate for several days before her decease, having drunk at this period much more ardent spirit than usual.

For the preceding facts we are indebted to the Rev. Mr. Ferguson, of Camden-street, Dublin. They are given almost exactly in his own words. He had professional opportunities of acquaintance with the family, and he states that shortly after the occurrence, he examined the room in which the old woman had been burned, and satisfied

himself that the fire had not extended to the bed, bed-clothes, or furniture.

From the cases just related, and several others which might be quoted from the writings of Vie D'Azyr, Lecat, Lair, Kopp, Dupuytren, and Marc, it would appear fully proved that the human body is capable of being reduced to such a state as to undergo spontaneously, [?] or upon the contact of flame, rapid changes analogous to those which may be effected by the agency of fire. A careful examination, also, of the histories of the several instances upon record, has enabled us to collect, at least with some probability, the circumstances which precede, accompany, and characterize this malady; for such it obviously must be considered. These we shall now enumerate, as they will serve as a guide to our inquiries respecting the immediate or proximate cause of the phenomenon.

1. Spontaneous combustion would appear to be a calamity almost peculiar to the old and feeble; for it has seldom occurred to persons of a robust constitution, or under sixty years of age.

2. Women seem particularly prone to it. Thus, of the seventeen cases collected by Kopp, sixteen occurred to females, while the subjects of the eight cases mentioned by Lair are all of the same sex.

3. Individuals who have thus suffered have, generally speaking, been remarkable for the inactivity of their habits, for corpulency, or the opposite state, great emaciation, and for their inordinate use of spirituous liquors.

Of the circumstances which distinguish spontaneous from ordinary combustion, the following seem most deserving of notice:—

1. The combustion spreads with extraordinary rapidity; the decomposition of the entire body being usually effected in an extremely short period of time.

2. The flame is of a lambent and flickering nature, of a blue colour, very difficult to extinguish by water, and not readily communicable to inflammable bodies placed in its vicinity.

3. A strong empyreumatic odour is usually exhaled, and there is found upon adjacent objects a fetid and moist fuliginous deposit, of a greasy nature.

4. The trunk is generally entirely consumed, but portions of the head and extremities are occasionally left uninjured.

Before examining the theories which have been advanced in explanation of spontaneous human combustion, it will be convenient to define in what *ordinary* combustion consists, and the conditions indispensable to its production. We shall thus be the better prepared to pronounce upon received hypotheses a correct and impartial judgment.

When any two forms of matter, whether they be simple or compound, combine chemically with the evolution of heat and light, combustion is said to have taken place. In order, therefore, to the production of these phenomena, the contact of at least two dissimilar principles, having for each other a strong affinity, is essential. Combustion may thus obviously result from the chemical action of a variety of principles; but, in all ordinary cases, one of the substances concerned is oxygen,

and the other carbon, or hydrogen, or some compound of both these elements. If to these we add sulphur and phosphorus, which are associated with the preceding as component parts of animal bodies, we shall have enumerated all the elements with which we can have any thing to do in our present discussion.

But the mere contact of oxygen with a combustible is seldom, of itself, sufficient to determine union, much less union with the development of heat and light. Carbon and sulphur may be encompassed by oxygen, and hydrogen mixed with it, without the occurrence of any chemical action; and though this is not true of phosphorus, the union of which with oxygen takes place at the usual temperature of the atmosphere, yet the process is slow, and visible flame is altogether wanting. These observations are equally applicable to the compounds which the combustibles form with each other, with a single exception. All of these but phosphuretted hydrogen, which inflames upon mere contact with oxygen gas, require, in order to accension, the application of a somewhat elevated heat. Neglecting, therefore, for a moment, this particular compound, it may be laid down that the conditions of ordinary combustion are two-fold:

1. That the combustible be in contact with oxygen.

2. That its temperature be considerably raised.

Now the human body is a combustible compound, and is constantly surrounded by an elastic medium, one-fifth of whose volume is pure oxygen gas. One of the conditions, therefore, necessary to combustion, is here fulfilled; and experience tells us that the co-existence of the other, that is, of a sufficient heat, will actually determine accension. But the human body, at least in a state of health, does not spontaneously take fire; and we also know that when heat is applied to any particular part of it, the mischief done is local, and does not extend to remote organs. In reference, therefore, to the subject of this article, two questions present themselves for solution.

First, whence arises that extreme degree of inflammability of the human body, in virtue of which its combustion is so readily produced, and occurring at any one point, is propagated with rapidity to distant parts? And, secondly, how does the combustion commence—what is the origin of the first spark?

As to the cause of the preternatural combustibility of the human body, the opinion generally entertained is, that it is to be found in the alcoholic impregnation, which, as is alleged, invariably accompanies such a state. In support of this doctrine, it is affirmed that individuals who die of intoxication emit at every point a strong smell of spirits; that the colour of the flame afforded by the latter is precisely the same as that which has been observed in cases of spontaneous combustion; and, lastly, that all who have fallen victims to this calamity have been remarkable for the immoderate use of intoxicating liquors.

That the bodies of drunkards may become, as it were, soaked with alcohol, seems fully established by observation. Thus, Breschet found the different tissues of the bodies of criminals, opened shortly after their execution, to evolve a

strong smell of eau-de-vie; and a similar observation has been made by Dumeril and Cuvier upon the body of a labourer, at the Garden of Plants, who had died from the effects of a large quantity of wine, which he had drunk for a wager. Dr. Marc also mentions the case of a shepherd of Laliowitz, addicted to excessive drinking, who during his last illness was constantly affected with eructations of an inflammable nature, and which emitted a strong alcoholic odour. Some, indeed, adopting an ancient physiological dogma, that, however the ingesta may vary, the chyle is always the same, deny the possibility of alcohol entering the circulation unaltered. It should, however, be recollected that many substances, such as the colouring matters of madder and rhubarb, and the odoriferous parts of musk, camphor, and garlic, do certainly resist the assimilating powers of the digestive apparatus, and re-appear unchanged in the secretions. Nor are such facts even opposed to the opinion to which allusion has just been made. These substances may enter the blood directly by the veins, which are now known to exercise the function of absorption, instead of reaching it through the circuitous route of the lacteals and thoracic duct.

But the theory of alcoholic impregnation is, *per se*, quite insufficient. When a healthy individual dies of intoxication, his body is found but little, if at all, more inflammable than if he had perished from any other cause; and if the flame of a candle be applied to an anatomical preparation just removed from the spirits in which it has been preserved, after the combustion of the alcohol has ceased, the surface of the preparation alone will be found burned.

From these considerations it appears pretty certain, that though the human body may to a certain extent become impregnated with alcoholic vapours, its combustibility will not, by this alone, be materially augmented; and that, therefore, when a great tendency to combustion exists, it must be the result of some peculiar pathological state. In what this state consists, it is probably impossible, with any accuracy, to assert in the present state of our knowledge; but every thing which we know upon the subject justifies us in inferring that the causes which produce it are such as have most influence in reducing the powers of life and enervating the system. Thus it occurs, as we have seen, almost exclusively to people advanced in years, and of constitutions broken down or enfeebled by intemperate habits.

A theory of preternatural human combustibility has been more recently advanced by Dr. Marc, which appears better sustained by facts than that of alcoholic impregnation. This learned physician, who has apparently studied his subject with great attention, contends that the combustion is owing to inflammable gases which are, in such cases, developed throughout the system.

That inflammable gaseous products are usually present in the stomach and intestines, in health as well as in disease, is a fact well known to the physiologist; but it seems difficult to admit that these can be evolved in the different tissues during life; for such an opinion would appear to involve the possibility of the occurrence of some degree of spontaneous decomposition antecedent

to death. There is, however, sufficient evidence that this has occasionally occurred. Besides the case of Father Bertholi already detailed, several others to this effect might be quoted. We shall, however, confine ourselves to the following, which is of recent date, and quite to the purpose.

A man ill for fourteen days with headache and colic pains, followed by an attack of diarrhoea, which lasted three days, was taken by M. Bally into the Hôtel-Dieu. Upon entering the hospital, his left thigh and scrotum were swollen, and his respiration was short and impeded; but he complained of nothing but weakness of the lower limbs. During a fit of delirium, which lasted a few minutes, he spoke of having been bitten by a dog in the leg; but upon examination no mark of any such injury could be found. He died on the night of the day on which he had been admitted into the hospital, and on examination eight hours after, exhibited the following appearances:—Blood had transuded from the thighs and trunk, and was also found, in a gelatinous state, in the nasal cavities. The whole of the surface of the body was emphysematous, of a violet colour, and studded with a vesicular eruption in detached spots, the vesicles being filled, some with a reddish serum and gas, others with gas alone, the latter being of a white colour. The left leg and thigh were most swollen and puffy, and evidently contained fluid. The abdomen and scrotum were also much distended, the gas in the former occurring not within the intestines, but in the cavity of the peritonæum. The brain and spinal marrow were healthy, but the vessels of the pia mater contained air. Upon cutting into any emphysematous part, a gas escaped, which was set on fire by the flame of a candle; and from a perforation made in the abdomen a gas issued, which was ignited in a similar manner, and burned with a bluish flame.

This case, which was communicated to the Académie Nationale de Médecine, excited a good deal of discussion. M. Bally considered it as illustrating Dr. Marc's theory of spontaneous combustion, while others looked upon it as proving that the putrefactive process, from which alone they conceived the gases could be derived, may set in before death. This latter opinion may appear paradoxical, but it does not seem at all improbable, much less impossible, that a spontaneous though limited decomposition may in certain states of the system take place in the living body. The elements of organized matter are, we know, combined, under the influence of vitality, into compounds very different from those which they would form if submitted to the sole agency of their mutual affinities. When released from the controlling influence of the vital powers, they enter into new arrangements; and it is but reasonable to expect that effects similar, at least in kind, may attend the diminution of those powers which is the consequence of disease, to those which are known to follow upon their extinction by death.

It is not, however, necessary, in order to account for the development of the gases, to resort to the hypothesis of putrefaction. They may be the products of depraved secretion; and this opinion seems even established by the many cases

upon record of the cellular substance having become emphysematous without the occurrence of any external injury. In fact, spontaneous emphysema is at present recognized by all nosologists. (See the article ΕΜΦΥΣΗΜΑ; also *Frank de Retentionibus*, and the articles *Emphysemè* and *Pneumatose*, in the Dictionnaire des Sciences Médicales.)

But though we admit with Marc, that inflammable gases may be developed during life throughout the different textures, yet this will not explain the completeness of the incineration which has been observed to occur, nor the rapidity with which the combustion spreads over the whole body. If a taper be applied to carburetted hydrogen, it will burn merely at its point of contact with the oxygen of the atmosphere; and to determine the instantaneous inflammation of a given volume of such gas, it must, previously to the application of the taper, be mixed with a certain quantity of oxygen. These facts, so familiar to the chemist, suggest a necessary modification of the hypothesis of Marc. The gases evolved cannot be all of an inflammable nature, but must include a proportion of oxygen, to act the part of a supporter. On this supposition they will constitute a species of explosive mixture, and we shall be enabled perfectly to comprehend the rapidity and the extent of the destruction which must ensue from their accension.

It must, however, be admitted that, though oxygen may proceed from secretion, it is a gas not likely to be liberated by any process of spontaneous change, for it does not occur amongst the products of putrefaction. The views, therefore, which have been here advanced must, until confirmed or refuted by chemical analysis, be considered as chiefly recommended by their adequacy to explain phenomena.

Having attempted to account for the preternatural inflammability of the human body, we shall now direct our attention to the manner in which the combustion commences. In most of the recorded cases some ignited body, as a candle, fire, or lighted pipe, has been found in the immediate vicinity of those who have suffered. The consequence of this has been that some have attributed the origin of the combustion in every instance to an external cause. Such was the doctrine first taught by Vic D'Azyr, and since sanctioned by Lair, Breschet, Dupuytren, and others. Should it prove well founded, the epithet *spontaneous* will obviously cease to be applicable to human combustion.

Others, however, amongst whom may be mentioned Maffei, Lecat, Kopp, and Marc, conceived this theory inadequate to the explanation of all the cases with which they were acquainted, and to supply its deficiency, called in the calorific powers of the electric fluid.

That electricity, in the form of a spark, is attended with the disengagement of heat, and is capable of setting inflammable substances on fire, are facts which cannot be contested. But the source of the electric accumulation, in the cases under consideration, remains to be satisfactorily pointed out. And, indeed, it may be added, that the statements that have hitherto been made upon the subject rest upon mere conjecture. Some

conceive that certain persons possess the power of generating within themselves a state of electric tension, and quote relations of individuals who emitted sparks at the suggestion of the will. Dr. Marc has adopted this improbable hypothesis, and coupled with it one of his own, which appears equally destitute of foundation. The gases with which the body abounds in its combustible state sometimes become, according to him, ideo-electric, from an elevation of their temperature, whether produced by exercise, exposure to a fire, or any other cause; and hence proceeds the spark which determines the accension. Lastly, others conceive the spark when it occurs to be purely accidental, and to result from the electric fluid selecting the human body as a conductor in its passage to or from the earth. This latter supposition being the only one which in modern science is admissible, we arrive at the conclusion that electricity can scarcely ever have any thing to do in producing human combustion.

It is believed by some that cases of genuine spontaneous combustion have taken place, or that the human body has sometimes taken fire, as it were, of its own accord, without the application of external heat, or the agency of electricity. Assuming such to be the fact, can any rational explanation of it be assigned? This is almost the only question of a theoretical nature connected with the subject of this article which remains to be discussed.

Of the elementary principles which enter into the composition of the human body, phosphorus must be reckoned as one of the most abundant. It exists, in very considerable quantity, as a constituent of bones, and, in many of the secretions, in the form of phosphoric acid, united to some base; and is also to be found, in a peculiar state of combination, in the cerebral mass, and in the fat which is deposited throughout the cellular tissue. When putrefaction occurs in the dead body, experience proves that phosphorus is evolved amongst the gaseous products in union with hydrogen; and there seems little reason to doubt that this is one of the gases which are occasionally generated throughout the different textures of the living system. Now, if this be admitted, as phosphuretted hydrogen inflames upon contact with the atmosphere, we shall have a perfect and simple solution of the difficulty of *spontaneous* combustion. This theory was very early advanced, and has been particularly insisted upon by Morelli and Fanzago, and more recently by Grabner Maraschin: (*Journal Complémentaire de Dictionnaire de Médecine.*) It is, however, passed over in silence by the majority of writers.

There is another mode of accounting for the spontaneous combustion of the human body, which is entitled to a brief notice here. The chemical actions which give rise to the inflammable gases of which we have so often spoken, are attended by the development of heat; and when this rises beyond a certain point, combustion, it is alleged, must ensue.

In support of these views, the spontaneous firing of pyritic coal, heaps of charcoal, oat-meal, cotton, and black wax soaked with oil, are appealed to. Whatever may be thought of this hypothesis, the records of medicine prove that the pro-

duction of inordinate heat may be classed amongst the well-established consequences of disease. In the Essay of Maraschin already quoted, three cases are detailed which will illustrate this position. We shall merely mention one which occurred, in 1822, to Balbani, an Italian physician, and which was communicated by him to Morelli, Chemical Professor at Pisa.

A farmer, twenty-six years of age, was seized, in the beginning of January, with an intermittent fever connected with gastric irritation. On the seventh day he felt in the throat a burning heat, ascending from the region of the stomach, so intense as to resemble the effects of the application to the body of red-hot coals. His breath, which smoked, could not be borne by the hand at the distance of two feet. He incessantly drank cold water, but with only temporary relief. The thirst was succeeded by a most voracious and insatiable appetite, the internal heat continuing unabated. He was treated by repeated immersion in the cold bath, conjoined with the exhibition of draughts of iced water; and was finally cured perfectly.

From the preceding facts and arguments the following conclusions may be deduced:—1. The human body admits of being reduced to a highly inflammable state. 2. This condition is chiefly owing to the development, by perverted secretion or incipient putrefaction, of gases constituting a more or less explosive mixture, but is probably often promoted by the dispersion throughout the system of alcoholic vapours. 3. In most instances of human combustion the process has commenced in consequence of the contact with the body of external fire, or of an electric spark. 4. Cases truly spontaneous, if any such have occurred, must be referred to the disengagement of phosphuretted hydrogen, or to the caloric developed by those internal actions which determine a highly combustible state of the body.

Before concluding this article, it will be proper briefly to advert to its medico-legal bearings. The human body, in a state of perfect health, may be consumed by accident or design, and it is obviously a matter of the first moment, with a view to the protection of innocence and the punishment of guilt, that we should be enabled to distinguish such cases from those in the consideration of which we have now been engaged. The importance of the study of spontaneous combustion under this point of view is usually illustrated, in works upon medical jurisprudence, by the celebrated case which occurred at Rheims in 1725. The wife of a man of the name of Millet, who was much addicted to the use of spirituous drinks, left her husband's bed one night, and was found next morning, at a short distance from the kitchen fire, reduced to a heap of cinders. Millet, who was suspected of intriguing with a handsome servant-girl in the house, was accused of the murder of his wife, and being sentenced to death, was saved from execution by the report of a commission of medical men, who, after having investigated all the facts, declared it to be a case of spontaneous combustion.

By attending to the circumstances already enumerated as characterizing spontaneous combustion, we shall be in no danger of confounding it with that which may be produced by the ordinary

artificial means. Thus, when the subject of the calamity is a female, advanced in years, and of intemperate habits; when the destruction has been very rapidly effected, and nothing remains unconsumed but portions of the head and extremities; when the room is filled with an offensive empyreumatic odour, and a moist and fetid sooty matter is deposited upon the ashes which remain and upon the walls and furniture;—these circumstances, or the greater number of them concurring, remove all doubt respecting the spontaneous origin of the fire. On the other hand, when the combustion is of the ordinary kind, and has been the result of accident, it will generally be but partial, and not directed in preference to any particular part of the body. In such cases, also, it will almost invariably be found to have extended to adjacent combustible substances. Lastly, when designedly produced, there will be evidence of the consumption of a large quantity of fuel.

As to the appropriate treatment of individuals who manifest a tendency to spontaneous combustion, nothing certain can be laid down: nor is our ignorance on this head much to be lamented, at least in a practical point of view; for such an affection is seldom announced by any precursory symptoms. Should, however, such a case as that which occurred to Balbiani be encountered, nothing appears more judicious than the treatment to which he resorted, namely, immersions in the cold bath, and copious draughts of cold water. Dr. Swediaur, indeed, states that spontaneous combustion is very prevalent in the north of Europe, from the excessive use of *eau-de-vie*, and that the tendency to it, when detected, is with certainty removed by the administration of recently voided human urine. Upon this statement Fodéré observes, "*credat Judæus*," and we do not hesitate to avow that we participate fully in his scepticism.

JAMES APJOHN.

CONGESTION OF BLOOD. [HYPEREMIA.]

—Though this term is familiar in medical writings, and in daily use among practitioners, it appears to be employed as expressing simply an acknowledged fact, rather than as referring to any pathological exposition of the phenomenon to which it relates. [It is often employed in a strangely imprecise manner, and, too frequently, it is to be feared, to shroud the ignorance of the practitioner as regards the precise pathological condition.]

Congestion of blood and determination are terms not unfrequently used to denote the same state; yet they do not signify the same thing. By congestion is implied simple engorgement of blood-vessels, without reference to any continued increase of vascular action; while determination includes the idea of the increased impetus with which the blood is propelled into the affected part. Local inflammation is perhaps the acme of this state, combining the whole three conditions; though each of the preceding may exist independently of it, and without passing into it. [Hyperæmia is, however, a precursor of inflammation in almost all, if not in all, cases.]

The subject, though undergoing much discussion in various works on pathological anatomy, is not yet sufficiently matured for the several facts

and reasonings to be embodied in a special essay. The several local congestions will of course be noticed under the heads of the diseases in which they respectively occur. The general principles, so far as any are deducible from such facts as are ascertained, will, perhaps, be best understood when presented in connection with general pathology of the circulation. Simple congestion evinces over-distension of vessels, and clearly implies debility of their coats. In several tissues it seems the result rather of irritation than of pure inflammatory action. When it passes into inflammation, this seems more dependent on the general state of constitution, on the plethoric condition of the blood-vessels, with the tendency towards febrile and inflammatory excitement which this induces, than on the primary irritation, or the congestion occasioned by it. Hence congestion might be considered as passive or active; the former term applying to the simple state, the latter to that in which inflammatory action is either concomitant or superinduced.

Facts, however, are still wanted for establishing a clear and consistent theory of congestive ailments. These facts the researches of pathological anatomy, so zealously and minutely pursued at the present day, cannot fail to supply; and when sufficiently accumulated, it will not be difficult to arrange them so as, with the aid of correct physiology and sound pathology, to deduce the principles of their occurrence, and establish on a rational basis the curative treatment of the morbid condition to which they relate. The presence of internal congestions must, for practical purposes, be of course inferred from the symptoms which indicate them; and to connect the symptoms with the structural lesions which they denote, so as to furnish practical guidance in their treatment, is the proper object of medical research. This can be accomplished only by multiplied observations of phenomena, generalised by a cautious induction. An essential part of this inquiry, however, consists of a scrutiny of those modifications or changes of structure which the morbid actions occasion, and by which the effects of these can be traced on necroscopic examination. The correctness of all theory must depend on the accuracy of the facts from which it is deduced; and as no complete theory of internal congestions can be established without the aid of numerous facts derived from actual inspection of the diseased parts after death, it is of importance that inquirers should be aware of the fallacies by which they are liable to be misled in the inspection of the structures and tissues supposed to be diseased. These fallacies are displayed by M. Andral, in his elaborate and valuable work on pathological anatomy, with a minuteness and accuracy which merit the highest praise. To render any account of his laborious researches would exceed the bounds of the present article, without sufficing for that completeness which a perfect essay on congestion would require.

It may be noticed that the different degrees of colouring observed in internal parts after death, which are so often attributed to increased vascularity, and supposed to denote the pre-existence of congestion or inflammation, may result from various causes independently of disease. Of these

M. Andral specifies several; the passive hyperæmia, which has always a tendency to take place in the last moments of life in parts abounding in capillaries;—mechanical obstacles to the venous circulation, formed a longer or shorter period before death;—the hypostatic accumulation of blood in depending parts;—the transudation of blood through its vessels;—other peculiar transudations;—various gases, &c. He also remarks that differences are presented according to the part examined, the age, the period of the digestive process going on at the time of death; with other circumstances.

Unless due allowance be made for all such sources of deception in noting the effects of morbid actions, as displayed in structural lesions, the evidences afforded by pathological anatomy, though generally regarded as the most certain which medical science possesses, must be as fallacious as medical facts derived from the observation of mere symptoms and of outward phenomena are so often alleged to be. From the industry and precision, however, with which this branch of science is now cultivated, there is every reason to hope that pathological anatomy will in no long time rest on a sure and stable foundation, furnishing in the truth and extent of its facts a basis on which a firm and abiding superstructure of pathology may be ultimately reared.

The treatment of local congestions must depend partly on the nature of their site, but principally on the cause which occasions them; whether general plethora exciting increased arterial actions and determination of blood to particular parts; simple irritation inducing an increased afflux of blood by the local excitement occasioned; or mechanical obstruction causing a retardation of blood in extreme vessels, with over-distention of their coats, and preventing its free return by the refluxing veins.

Each of these states must require an appropriate adaptation of remedies; for if a just discrimination be not practised in this respect, no consistency can be preserved, nor any uniformity of success be realised. If congestions result from a plethoric habit, mere local treatment can never give effectual or permanent relief; the affection recurring so soon as the local means are discontinued. With these means depletion and abstemious diet must be combined, else disappointment and further decline of health must ensue. On the contrary, if there be no plethora, and the congestion be owing to irritation only, then general depletion is not only unnecessary but injurious, enfeebling the system, and weakening those efforts by which the congestion would be naturally relieved. In both respects are errors committed. Many congestions originating in plethora are treated as local diseases until structure becomes permanently and irremediably altered; while congestions arising from irritation are occasionally confounded with inflammation, from a delusive resemblance in some of their symptoms, and blood-letting is injuriously resorted to. In no class of diseases is the former error of more frequent occurrence than in affections of the stomach and bowels. Increasing plethora begets almost necessarily a congestive state of the gastro-intestinal mucous membrane, the constitution endeavouring to throw off its redundancies by this and other

outlets; secretions become increased and then vitiated; digestion is impaired; appetite declines; and a condition results to which the term *dyspepsia* is usually applied. Indigestion and loss of appetite are regarded as the disease; they are imputed to weakness of stomach, and tonics are employed; some amendment may be felt by the capillaries being excited, and the appetite may improve, but the disease is not thus arrested, nor a healthy condition restored. The capillaries may contract upon their contents, and thus abate the congestion so far as they are concerned; but it is only by repelling the blood into the vessels which led to them, and thus substituting another form of disease more mischievous and less remediable, because less within the reach of those curative processes by which the constitution so continually rectifies its own derangements. In this condition tonic treatment, subsidiary to depletory, may be and oftentimes is of service; when employed as the chief means of cure, or to the neglect of evacuants, it is invariably pernicious. The natural relief derivable from increase of secretions being arrested, the blood repelled, not only overloads the larger vessels which lead immediately to the capillaries, but becomes in time congested more distantly in several of the viscera, giving rise to diseases of various kinds.

With respect to the diseases which, arising from irritation, present appearances simulative of inflammatory action, and in which congestions often occur, much valuable information may be derived from the works of Dr. Gooch, Dr. Marshall Hall, Mr. Travers, and others, who have done much to introduce greater discrimination and accuracy into the treatment of such complaints.

[See, on the whole subject of Hyperæmia, Duglison's *Practice of Medicine*, 2d edit. i. 520: Philad. 1844; and Dr. C. J. B. Williams, *Principles of Medicine*, § 287: Philad. 1844.]

E. BARLOW.

CONSTIPATION. — The word constipation is derived from the Latin *constipō*, to crowd together, a compound of *con* and *stipō*, to fill up close. The corresponding term *obstipato*, under which costiveness is usually described by Latin authors, is from *ob* and *stipō*, to stop up, and the root of the Latin *stipō* seems to be the Greek *στυφω*, to bind as an astringent, to thicken. The true import of the word constipation, therefore, would appear to be the collecting and impacting of the excrementitious matters, the residuum of the various processes concerned in alimentation, in some part of the intestinal tube.

Constipation is not so much marked by the infrequency of the evacuations from the bowels as by their firmness of consistence, and by the occurrence of fulness and tension in various parts of the abdomen, and other symptoms indicative of impaired or impeded action in one or more of the various organs contributing towards the passage of the refuse of the alimentary process. The observations of Heberden afford so apposite an illustration of these views that we shall not hesitate to refer to them in this place: — "Homines frequentia alvum exonerandi plurimum inter se differunt. Alteri semel tantum singulis mensibus venter solutus est; alteri duodecims quotidie æ-

scendit per triginta annos, uti ipse mihi narravit, et dein septies quotidie per septem annos; neque vir hic intera macuerat, quin potius aliquanto habitior factus erat." It is obvious that with one of the persons here alluded to a daily evacuation would have been in fact an attack of diarrhoea, while with the other it might have been justly considered as indicative of constipation, and in either case much general disturbance of the system would probably have arisen. Similar instances, though not to so great an extent, frequently present themselves to our notice, especially amongst females, with whom the functions of the intestinal canal seem generally to be less regular than in the male sex.

Constipation has commonly been considered by writers on nosology as it occurs in persons of a lax and weak habit of body; in those of greater rigidity of temperament; and as arising from obstruction in some part of the intestinal tube. It will be sufficient for our present purpose, if we treat of it under the heads of simple constipation and constipation from obstruction, leaving the more refined divisions till we come to consider the variation produced in the symptoms by the immediate pathological state to which they may owe their origin.

Under simple constipation we mean to include those morbid affections which, without more prominent disease, are characterized by a confined state of the bowels arising from various causes so acting upon the mucous and muscular coats of the bowels as to impede the regular and efficient performance of the functions of these organs.

In accordance with these views the leading symptom of simple constipation is a costive or more consistent state than usual of the fecal excretions, with a less frequent call for evacuation than is customary with the individual when in a state of perfect health. Other symptoms usually attendant upon this state are, more or less pain in the frontal or occipital regions, some degree of fulness and tension of the abdomen, a foul tongue, with loss of appetite, and often an undefinable sense of oppression, accompanied with corporeal languor and listlessness of mind. These symptoms are, however, materially modified by the immediate cause giving rise to the attack; and since it is of the first importance, in respect of treatment, that the relation which the symptoms and causes bear to each other should be fully established, it will be desirable to consider the variations thus induced somewhat more at length when passing the causes under review.

Causes.—1. The first cause of constipation to which we shall allude, because the most simple in its nature, is laxity or debility of the fibre of the muscular coat of the intestines. Constipation from simple debility is not an unfrequent occurrence, and is apt to arise during the debility which attends convalescence from acute diseases. It is also observable in those who lead a sedentary life, and have a general pallid look and relaxed fibre. An opportunity of verifying, by *post-mortem* examination, the state of debility and wasting of the muscular fibres of the larger intestines, which occurs in this condition of the system, does not often arise; but the following example affords a good illustration of this lesion, and serves also to

show, that without care and circumspection, the diagnosis is not always easy to be attained. A bookseller, aged forty, who led a sedentary life, had from his youth experienced great difficulty in regulating his bowels, and had constantly been using bitters and cathartics under medical advice. Latterly vomiting had succeeded to the symptoms, and he had become pale and emaciated, which induced a suspicion in the minds of his medical attendants that he was labouring under diseased pylorus. Under this view of the case the use of active aperients was discontinued, and an attempt was made to regulate the action of the bowels by enemata, but without avail, as the attendant could never succeed in injecting any quantity of liquid into the rectum, and consequently small portions only of liquid fecal matter were ever brought away. The patient, finding himself grow weaker, and considering that he had no hope of relief, would not consent to any examination of the rectum; and as the vomiting and constipation continued, he gradually became exhausted, and died. On examination after death, the stomach was found to contain nearly three pints of a dark coffee-coloured fluid. The mucous membrane of the organ was not redder than natural, but it was generally thickened. The small intestines were nearly empty, and were not diseased. The colon throughout its whole extent was enlarged, and its muscular fibres were thin and pale; it also contained fecal matter and a great quantity of gas. In the descending colon and in the sigmoid flexure this was more particularly remarked, and the fecal matter was here very hard. The whole of the rectum was enormously distended with very hard feces. On pursuing the investigation downwards to the termination of the rectum at the anus, nothing like stricture was discovered; but the intestine was much dilated, and the muscular fibres, even near to the anus, were remarkably thin and pale. The intestinal mucous membrane did not seem to be at all diseased.

It is not often that we have an opportunity of witnessing so decided a case of debility of the muscular fibre producing constipation as this example affords; but analogous instances, in debilitating diseases, occasionally happen, where the feces will lie for a length of time in the extremity of the rectum, without the patient having the power of voiding the accumulated hard mass, and surgical aid is sometimes necessary for its removal.

This accumulation of the feces from debility of muscular fibre is by no means uncommon in old people; indeed we believe the existence of a weak propulsive power in the large intestines to be the most frequent cause of constipation in advanced age.

When any part of the intestinal canal has been inflamed, the care which is subsequently required in regulating the diet and in selecting the aperients necessary to keep up a due action of the bowels is familiar to every practitioner of medicine. In fact, the necessary consequence of inflammation having existed in any part is debility, and when this occurs in a hollow organ, such as the intestinal canal, we are naturally led to expect, after the acute symptoms have been subdued, a loss of power in the inflamed muscular fibre, and conse-

quently distension of the bowel and retention of its contents. "Inflammation," observes Dr. Abercrombie, (*Pathological and Practical Researches on Diseases of the Stomach, &c.* 2d edition, p. 7,) "seems also to destroy the action of muscular fibre. Thus, intestine which has been inflamed is generally found in a state of great distension, showing the complete loss of its healthy muscular action; and, if the disease has gone on until the intestine has either become ruptured, or has given way by ulceration, it is found to have fallen together like an empty bag, without any appearance of muscular contraction; whereas healthy intestine, when it is empty, contracts uniformly into a round cord." The constipation, then, which arises during convalescence from inflammation of different parts of the intestinal canal, and which is so readily induced by slight irregularities of diet, is the direct result of debility of the muscular fibre, and in cases where the inflammation has arisen from obstruction, may be altogether independent of the original cause of disease, though perhaps often attributed to its continued or renewed operation. Several cases illustrative of the preceding observations will be found in the work which has just been referred to. The following affords a similar example, and at the same time shows the tendency of previous debilitating causes to produce constipation. A female servant, aged twenty-four, had miscarried about the fifth month of pregnancy, and was much weakened by profuse hemorrhage. She then had diarrhœa, which was checked by appropriate measures. Subsequently the bowels became obstinately constipated, and there was tympanitic distension of the abdomen with some pain on pressure, especially in the right iliac region. The skin was jaundiced, and there was bilious vomiting, with much depression and sunk countenance. The vomiting was checked by the application to the epigastrium of a fold of linen soaked in laudanum; but the measures employed to procure an evacuation from the bowels were unsuccessful, and the enemata administered were returned without effect, though it was ascertained by examination that the rectum contained fecal matter. She gradually sunk, having had one copious evacuation a few hours before she died. On examination of the body, the capillary system in general was found injected with dark-coloured blood, the heart and larger blood-vessels being empty. In the abdomen, the omentum and peritoneal coat of the intestines were vascular in places, the colour of the vascular injection being more florid than in other parts of the body; and upon some portions of the small intestines circumscribed patches of lymph were found adhering to the surface of the serous membrane. Portions of the mucous membrane of the stomach, duodenum, and small intestines were also injected, and there was evident thinning of the coats of the ileum near its termination in the valve of the colon. A sac formed by the doubling of the peritonæum between the rectum and uterus was found filled with purulent matter, which was confined by recent adhesions in its vicinity. Pus was also found in the substance of the uterus near the cervix. This case was obviously one of inflamed uterus with subsequent peritonitis; but the constipation appears to

have resulted from the general debility, induced in the alimentary canal by the acute disease which had previously existed there, and the remains of which were found on examination.

2. The secretions concerned in the process of alimentation may be vitiated in quality or deficient in quantity. Under these circumstances there will be a want of stimulating power in the alimentary mass resulting from their combination with the food; the propulsive powers of the muscular coat of the bowels will not be so efficiently called into action, and constipation will necessarily result. Slight changes of this kind in the nature or quantity of the secretions are of very common occurrence, and are perhaps the most frequent cause of the more trivial and temporary irregularities in the excretive function, to which every one is more or less liable. When these causes are more permanent in their action, they become of greater importance. Thus the biliary secretion is frequently disordered without giving rise to any other inconvenience than the omission or retardation of a customary evacuation; but when the morbid change is more intense in degree, or prolonged in its duration, the constipation is more marked, and inspection of the evacuations commonly shows the impaired state of the function of the liver, by deviation from the healthy colour and consistence of the fecal matter. The evacuations will be found of firmer consistence, less homogeneous in their appearance, frequently containing portions of considerable hardness, and the colour will be pale and clayey, dirty or muddy, greenish or dark, accordingly as the bile is less copiously poured out from the biliary ducts, or so vitiated in its nature as not to preserve its usual characters. In such conditions of this secretion, in addition to the constipated and otherwise altered state of the alvine discharges, there is more or less uneasiness in the region of the liver, scarcely, however, amounting to pain; tension of the upper part of the abdomen; a moist brownish fur coating the tongue; a muddy colour of the conjunctiva, and pain of the head, usually referred to the occiput, with a sense of heaviness or oppression.

The existence of an altered state of the mucous secretions poured out from the surface of the inner membrane of the intestinal canal, and from its numerous glands and follicles, though probably of not infrequent occurrence, is much more obscure in its characters, and consequently less easily recognized. In the early stage of fever and of most inflammatory diseases there is a suppressed or diminished state of these as well as of most of the other secretions, which appears to contribute much to the confinement of the bowels occurring in such cases. And hence we have more or less of oppression at the epigastrium, with tension and fulness of the abdomen, constantly attendant upon febrile diseases. The oppression and tension of the abdomen have been referred to an inflamed condition of the stomach and small intestines; but we are inclined to question the correctness of ascribing those symptoms which are indicative merely of oppression, and are of such frequent occurrence in various febrile states, to inflammation, when the vascular fulness arising from suppressed secretions affords

so adequate an explanation of the attendant phenomena. Many cases of diarrhoea, and especially such as arise from exposure to cold and wet, if closely investigated, will be found to be preceded by costiveness of some duration. In such instances one of the first links in the chain of causation appears to be a suppression of the secretions from the intestinal mucous membrane, while the general progress of the symptoms affords a striking analogy with the effects produced by a similar exposure upon the corresponding membrane of the pulmonary system. The primary effect of the exposure is in either case the same, the capillary vessels of the membrane become distended by the blood thrown into them in an increased proportion, and a suspension of secretion, producing local oppression and constitutional disturbance, is the immediate result. Should this condition not be relieved, a degree of inflammatory action is induced, which is subsequently followed by the pouring out of the altered secretions, the products of that inflammation, constituting coryza, catarrh, or diarrhoea, according as the Schneiderian, the bronchial, or the intestinal mucous membrane may have been originally acted upon by the exciting cause.

Cases of disordered digestion not unfrequently occur in which much tenacious mucus is occasionally brought up from the stomach, and it will readily be allowed that, the surface of the mucous membrane being thus covered with its morbid secretions, the customary changes cannot take place in the food, and much distress must be the necessary consequence. Such a state of the follicular and mucous secretions existing in other portions of the intestinal tube will necessarily tend to lessen the susceptibility of its internal surface to the stimulating impression of its contents, and may thus prove a cause of constipation. We have witnessed cases in which such seemed to be the sole cause of the detention of the alimentary mass in various parts of the bowels; and in these examples we have found the evacuations to consist sometimes of a mucous or mucogelatinous substance, at others of fecal matter mixed, or, when formed, smeared with a mucous fluid, apparently of considerable tenacity. In Dr. Abercrombie's work upon Diseases of the Abdomen there is a case, (Op. citat. p. 314,) which, as far as the state of the bowels is concerned, affords a good illustration of these remarks; and the slowness of the bowels in the following case, related by the same author, probably admits of explanation upon the views here advanced. "A lady, aged about thirty, had been in bad health for four or five months, and when I saw her was wasted like a person in an advanced stage of phthisis. She had a small frequent pulse and bad appetite, but complained of nothing except some undefined uneasiness in the abdomen. The bowels were slow, requiring the constant use of medicine; the motions were consistent and formed, but always of the deep brown colour of dark mahogany or rosewood; and no treatment had any effect in correcting that colour. The abdomen was collapsed, and nothing could be discovered by examination. Some time after I saw her, she began to have uneasiness in her chest, with slight cough; she then became liable to fits

of coma, in which she lay with her eyes open, but unconscious of any thing; at length she had repeated paroxysms of convulsion, and she died in a state of the most extreme emaciation, after an illness of eight or nine months' duration. On inspection no disease could be discovered in the brain, and the lungs were quite healthy, except some very old adhesions of the pleura. The intestinal canal was throughout so thin as to be transparent like goldbeaters' leaf. On the mucous membrane there was in many places a tenacious mucus of a dark brown colour, but no disease could be discovered in the membrane itself, and no morbid appearance could be detected in any organ." (Op. cit. p. 336.)

3. Perhaps the most common cause of simple constipation of the bowels is to be found in the nature of the diet to which, in the present artificial state of existence, we are accustomed to resort. Food which is imperfectly soluble in the gastric secretions, unless of an irritating quality, must necessarily impede the process of digestion and assimilation throughout its several stages. It is unnecessary here to point out those articles of diet which come under this description; but it may be stated as a general principle, that according to the readiness and completeness with which this solution is accomplished within the stomach, except in cases where the product of the digestion is of a too stimulating or irritating nature, will be the perfection of the subsequent parts of the process, and the gradual and regular transmission of the mass through the whole course of the alimentary canal. There are, however, many substances used for food, which, after they have passed the stomach, are so little fitted for the purposes of alimentation, that they are not taken up by the absorbent vessels which open upon the intestinal mucous surface, and consequently form a part of the refuse to be propelled onwards, and ultimately rejected as excrementitious. When these substances are taken in considerable quantity, they give rise to constipation, and occasionally even to fatal obstruction from the firmness and intractability of the resulting mass. The seeds of various plants seem especially to have this tendency when taken in any quantity, and instances in which the kernels of the nut, walnut, or almond have been productive of injurious and even alarming effects, by inducing constipation and obstruction of the bowels, must have occurred to almost every practitioner extensively engaged in the duties of his profession. Two cases of fatal obstruction, the one resulting from almonds eaten in considerable number, the other from nuts, have arisen within the knowledge of the authors of this essay.

4. Increased tone of the muscular fibres of the middle coat of the intestines may not infrequently give rise to a remora in the passage of their contents, and the effect of many of that class of medicines called astringents appears to be owing to their tonic powers. It has been remarked by Dr. James Johnson, that the beneficial effects produced by travelling, on the general strength and health, are commonly accompanied by a confined state of the bowels. This is no doubt to be attributed partly to the increased activity of the absorbents, by which the alimentary mass is left in

a drier state than when the assimilating organs generally are in a more debilitated condition, but in part also to the increased tone of the muscular fibre, by which its contractions are rendered more equable, and consequently the resistance offered by one portion of the intestine to the propelling powers of another so adjusted as, by retaining the mass longer in its passage through the bowel, to co-operate with the increased tone and activity of the absorbents in extracting a greater quantity of nutriment than under other and less favourable circumstances could be obtained. Such a state is a frequent accompaniment of a healthy and effective performance of the functions of digestion, and may be considered rather as indicative of the excess of health than as requiring to be interfered with by having recourse to remedial measures.

5. Constipation is a symptom of very common occurrence in those morbid states of the encephalon in which more or less oppression is observed to exist; and in such a condition of the brain and nervous system it is probably owing to the deficiency of that influence exercised by these important parts of our frame over every organ, and in the performance of every function of the body. Usually the existence of this state of cerebral oppression is sufficiently evident from symptoms more especially characterizing it, in itself constituting the disease; but cases occasionally occur in practice in which the constipation will be found to be the prominent morbid condition, and the oppressed state of the brain not more marked than is usual; more or less headach, as we have before observed, commonly attending a confined state of the bowels. For instance, a child may have had no evacuation from the bowels for two or three days; there may be considerable fulness and uneasiness of the abdomen, with a white tongue and loss of appetite. There may also be some dulness of expression and headach. The symptoms are naturally considered to depend upon the confined state of the bowels, and appropriate purgatives are given. No action results, however, from these measures. There is oppression of the brain, and the impressions, which, under other circumstances, would have been sufficient to have excited the dormant powers, are here insufficient. If a few leeches be now applied to the head, the bowels will be almost immediately relieved. The constipation, then, in such a case will clearly have arisen from the interchange of communication between the brain and the organs of alimentation being suspended, or at least materially impeded. It is, in fact, symptomatic of a morbid condition of that organ, as in other cases it may be of a morbid condition of the liver, of the intestinal mucous membrane, or of the muscular coat; it is, however, the prominent symptom, and indeed the actual expression, of disease to be removed only by remedying the cause giving rise to it.

The obstinate constipation which occurs in connection with irritation of the spinal cord in some cases of irregular hysterical disorders, should here be noticed, since we have seen instances of young females in whom all the symptoms of obstruction of the bowels have apparently arisen from no other cause. The possibility of the

symptoms arising from this cause should always be borne in mind when the patient is of the age and temperament liable to hysterical paroxysms; and where such is the case, particular inquiry should be made into the state of the menstrual secretion, and the most careful examination of the medullary column instituted, both by pressure over the vertebrae, and by drawing a sponge, which has been immersed in water as warm as can be borne, down the spine. Not unfrequently some irregularity of the periodical discharge will be discovered to exist, and some portion of the spinal column will be found tender. When such is the case, by having recourse to the appropriate remedies for this class of diseases, an apparent obstruction, which had withstood the best-directed measures, and in which the most powerful cathartics had been of no avail, will rapidly give way.

6. Another cause of confined bowels is an increase of the secretions from other organs of the body. There is an adaptation of the several functions to each other, and a relation existing among them, which, if disturbed, gives rise to many very interesting morbid affections. If any one function be either diminished, increased, or otherwise altered, some one, or perhaps all the others, will also be disturbed. Thus, if the functions of the skin be interfered with, and the perspiration be checked, we have diarrhoea not unfrequently established as a compensation, or there is an increased flow of urine to obviate the injurious effects which would otherwise be induced by the suppression of the natural secretion. Again, in diabetes, where the urinary secretion is increased, the secretions both from the skin and the intestinal mucous membrane are considerably diminished; and we have the constipated bowels, the dry glazed tongue, and the harsh dry skin, which so commonly accompany that disease. Thus, also, in cases where the powers of life are breaking up, an alternation in the state of the impaired functions may not unfrequently be observed strikingly illustrative of these views.

We come now to consider the second class of cases; namely, those in which a constipated state of the bowels is produced by obstruction to the passage of the fecal mass through some part of the alimentary canal.

1. One of the most important causes productive of constipation by obstruction, both on account of the very precarious state in which the sufferer is often placed, and the nature of the remedies to be adopted, is the constriction of some part of the intestines in consequence of hernia. The consideration of this cause belongs more especially to surgery; but whenever obstruction of the bowels exists, careful examination of the usual seats of ruptured intestine should be made. But without producing actual obstruction, the existence of a hernia necessarily interferes with the regular performance of the functions of that portion of the intestines in which it is situated, both by inducing a tendency to lodgment of the fecal matter in the sac, and by disturbing the peristaltic action of the muscular coat. In the treatment of constipation it will be necessary, therefore, to keep this in view, since very different measures may be required when a portion of the intestine is in such a

state, from those which would be proper under other circumstances.

2. In enteritis, colic, and ileus, constipation forms a very prominent part of the disease, and one which, independently of the morbid state giving rise to it, frequently requires much and anxious attention. The subject is amply discussed under the articles COLIC and ENTERITIS. We should, however, observe, that it is doubtful how far those cases of colic which have been referred to obstruction arising from spasmodic constriction of a portion of the bowels are really owing to this cause. We are convinced that many of these are to be attributed to a paralysed state of portions of the muscular coat of the bowels rather than to spasm; that, in fact, the obstruction arises rather in that part of the bowels in which the faecal mass is retained from defect of propulsive power, than from spasmodic action of the muscular fibres of the portion immediately beyond it; and the *modus operandi* of opium in such cases seems to consist in moderating the action of the propelling fibres behind, and thus affording time for the over-distended bowel gradually to empty itself of its contents, rather than in resolving the supposed spasm of the portions beyond. This explanation is likewise more in accordance with many of the causes concerned in the production of these forms of colic: thus, in the colic produced by lead, it is more consonant with the known effects of that deleterious agent upon other parts of the body, to infer that partial and irregular paralysis of portions of the intestinal canal, rather than obstinate spasmodic contractions, should result from exposure to its influence. Dr. Abercrombie's observations upon this subject, with the cases of which they are illustrative, are well worthy of attentive study, and the conclusions at which he has arrived are in strict accordance with the preceding observations. The following considerations are adduced by him as confirmatory of the view which he is disposed to take:—1. that the collapsed state in which it assumes the form of a cord appears to be the natural state of healthy intestines, as indeed of other muscular organs when they are empty, as, for instance, the bladder;—2. that a state of uniform distension with lividity may occur as a primary disease of the intestinal canal without any appearance of obstruction, and without any part of it being in a contracted state;—3. that in ileus the collapsed parts are almost invariably found in a healthy condition, the morbid appearances being for the most part confined to the distended part;—4. that the suspended action has continued when the obstruction below has been entirely removed, and the parts above were apparently healthy;—5. that in a case where the application of galvanism was uniformly followed by copious evacuations from the bowels, the agent employed must have acted upon a part the functions of which were impaired, not upon one which was spasmodically contracted;—6. that cases occur in which the state of distension arises from causes entirely of a different nature, without the peculiar contraction referred to, at the same time that there are others in which, though the disease may be traced to a mechanical cause, this peculiar contraction existed below the seat of obstruction, but could not be considered as having any influ-

ence in producing the disease; as, for instance, where there is adhesion of a portion of intestine, the regular peristaltic action of the part is impeded, and this peculiar state of contraction is found to exist below the obstructed part, though in such a case it can scarcely be supposed to arise from spasm. (Pathological Researches, &c. p. 145.)

3. But of all the causes which occasion constipation of a very obstinate nature, none are more frequent and important than certain changes of structure which occur in the large intestines, the whole course of which, commencing with the cæcum and terminating at the extremity of the rectum, is liable to various, and some of them intractable morbid affections. It will be desirable, in enumerating some of these, to enter rather more into detail than might seem at first sight to be necessary, as it will be impossible to lay down any thing like correct rules, with respect to the management of a costive state of the bowels, unless an accurate view is taken of the more obvious deviations from health in the large intestines which are connected with this affection.

The diseases of the cæcum alone are of great importance, and until lately have attracted very little attention. Looking to the structure of this portion of the intestinal canal, and considering the complexity of its mechanism, it cannot be a matter of surprise that it frequently becomes the seat of disease, and that occasionally we find the contents of the alimentary canal lodged in large quantities in this pouch. Any one who reflects on the manner in which the fold of mucous membrane projects from the ileum, and is connected with the corresponding membrane of the cæcum to form the valvular mechanism, by which a barrier arises between those two portions of the alimentary canal, must be prepared to find in this part occasional obstruction, and cannot fail to wonder that from year to year, in many individuals, the functions of this admirable portion of the human machine are performed with the utmost regularity and integrity. If it be considered, further, that where the cæcum connects itself with the colon, and for some distance afterwards, the contents of this part of the alimentary canal are propelled forward in opposition to the laws of gravity, additional reasons will appear why it should frequently happen that when the larger bowels become overloaded, the cæcum should more especially suffer.

The natural construction, then, of this part of the alimentary canal is such as to render it probable that impediments might arise to the propulsion of its contents onwards. A state of costiveness is not unfrequently connected with intestinal concretions, and these are most commonly lodged in the cæcum; and instances are recorded, where, after having been retained there for a considerable length of time, they have been discharged by the rectum. A nucleus is often found imbedded in the centre of these concretions, as for instance, some extraneous substance, which may have been accidentally swallowed, and after having passed into the cæcum, have there gradually collected around it a considerable quantity of faecal matter; thus it is well known that pins, needles, pieces of

bone, and stones of fruit, may be detained, and become the centre of alvine concretions. Upon this point much valuable information will be found in Dr. Monro's work on Morbid Anatomy, where several interesting facts are described concerning these productions, and their influence is shown in interfering with the propulsive action of the bowels, and inducing constipation.

It is of great importance to bear in mind that these concretions, as well as scybala, collect in large masses in the cæcum and colon, as a want of accuracy in distinguishing this accumulation has often been the occasion of embarrassment to the practitioner, by leading him to suspect the existence of some more important lesion in the adjoining viscera. An accurate examination of the abdomen by compression will generally enable him to distinguish the tumour which is produced by distension of the cæcum, in the right iliac region; and where this is unconnected with inflammatory action in the investing peritoneum, but little tenderness is discovered in the part. The extent to which the cæcum, on some occasions, becomes enlarged, is very remarkable. It has been found sometimes nearly equal in size to the stomach, and the pressure produced under such circumstances by its accumulated contents, has occasionally been so great that rupture of the distended bowel has occurred.

We have now been considering the least formidable of those conditions of the cæcum, which are productive of constipation; and all that is necessary in such cases for the restoration of a more healthy state of this part is, that the accumulated load should be removed. This, however, in the case of concretions, is not always an easy matter; for they are often very firm in texture, and cannot be dissolved by any medicinal agent; and even when they are dislodged from the cæcum, and carried on into the rectum, they are sometimes productive of acute pain, and a constant and ineffectual effort to evacuate the bowel by stool, and may ultimately require surgical assistance for their removal. The following case, detailed by Dr. Walker, of Huddersfield, in a communication published in the *Midland Reporter*, (Vol. iii. p. 236,) is worthy of attention:

"Lydia Turner, aged forty-two, had for *twenty-three years* suffered from pain in the right iliac region, with considerable tumour, which varied in size, and was larger at the time of menstruation. She was subject to great irregularity in her bowels, had frequent diarrhœa, and could part with little at once, which was as frequently followed by constipation. On January 21st, 1827, whilst carrying a can of water, she felt, as she described, something break and fall down, which was followed by immediate desire to have a motion, but nothing passed. After having had a restless night, she sent for Mr. Jubb, of Halifax, and stated she had something to part with, and that she had had pains, as strong as labour pains, all night. On examination he found a hard substance in the rectum pressing against the sphincter ani, which appeared too large to pass. It was, however, with some difficulty, removed with a pair of lithotomy forceps, and proved to be a very large, hard, and tough scybalous mass. The woman lost the pain, and had never after-

wards a return of the tumour in the right iliac region."

The immediate cessation of all symptoms on the removal of the hard substance, necessarily implies that there was little or no disease in the texture of the cæcum in this case, and that the accumulation arose from want of proper propulsive action in the part. There are, unfortunately, cases where the accumulation in the cæcum is combined with considerable disease, either in the peritoneum investing this part of the alimentary canal, or in its mucous lining; either of which occurrences makes the constipation more formidable than if it arise solely from a want of proper muscular action. This is not the place to enter very fully into a description of this particular form of disease, but its frequent connection with constipation makes it necessary to place before the reader the more prominent characters which show the existence of this lesion. In addition to the tumour, which is felt in the right iliac region where the cæcum is simply distended by an accumulation of fecal matter, there is, when its peritoneal covering is inflamed, tenderness on pressure, usually confined to the part, though not unfrequently extending more generally over the abdomen. Sometimes the functions of the bladder are affected by the contiguity of the disease, and a morbid irritability of that organ results. The constitution, also, is generally more affected; the tongue becomes white and flabby, and occasional nausea arises. If the inflammatory action extend itself to the general peritoneal covering of the intestines, there are then present the more obvious symptoms of peritonitis, under which the patient usually sinks. The following case strongly illustrates the destructive effect of this diseased action, when it commences in the peritoneal investment of the cæcum, and extends over the abdomen:

A healthy boy, aged ten years, received some months before his death a blow on the lower part of the abdomen, after which he complained of a good deal of pain in the right iliac region, and his bowels became costive. As but little importance was attached to the accident, no advice was taken upon the subject, and being at school, he allowed his bowels to remain for a length of time inactive, occasionally complaining of a good deal of pain in the abdomen. At length, after continuing for some weeks in this state, without any medical assistance, he became so ill that prompt measures were demanded. The case then presented all the appearances of peritonitis; and, more especially, the tenderness on pressure was remarked in the region of the cæcum. The most active treatment, by bleeding, general and local, large doses of calomel, the warm bath, and blisters, was adopted, but without avail; and he died in a week after medical advice was resorted to. On examination of the body after death, the abdomen was found distended; and when a section was made so as to expose its contents, a sero-purulent effusion, amounting to about eight ounces, was discovered. The omentum adhered slightly to the peritoneum. The peritoneal covering of the intestines generally seemed inflamed, and towards the right iliac region the intestines were evidently united together by the deposition of lymph. The principal disease was in the peritoneum investing

the cæcum, the commencement of the colon, and the termination of the ileum. The colon and the ileum were united to each other and to the cæcum. In all of these parts the peritoneum was much thickened and injected with blood. Part of the peritoneal covering of the cæcum was ulcerated, and corresponded to an ulcerated portion of peritoneum lining the lower part of the abdominal muscles, just where the spermatic vessels enter the abdominal ring. There was a considerable accumulation of fecal matter in the cæcum, but the mucous membrane lining this part was free from disease.

Affections of the mucous membrane lining the cæcum are likewise not unfrequently the cause of constipation. Thickening of the membrane forming what is called the valve of the cæcum, occasionally occurs, and produces obstruction to the free passage of the contents of the bowels. The following case occurred in a young lady of delicate constitution, who had throughout life been of a costive habit of body. For many weeks previous to the acute attack which seemed to be the immediate cause of death, the bowels had been unusually inactive, never indeed being moved without the use of active aperients. She often complained also of uneasiness in the right iliac region; but on examination, no particular tenderness was produced by pressure, nor was there any remarkable tumour or fulness in that part. After having taken some active doses of cathartic medicine, without any effect being produced on the bowels by them, this young lady was seized with violent vomiting and general pains over the surface of the abdomen, with considerable tenderness on pressure. Very active remedies, as copious bleeding, large doses of calomel, blisters, warm baths, were used without any relief, and she died in thirty-six hours after the severe symptoms came on. On examination after death the peritoneal covering of the bowels was very slightly inflamed; but when the mucous membrane lining the bowels was exposed, it was found extensively diseased. A great portion of the ileum showed marks of inflammatory action, and as that part of it was approached which terminates in the cæcum, considerable thickening was observed, and when the cæcum itself was opened, the whole mucous membrane lining this bowel manifested great alteration of structure. The valve of the cæcum especially was much thickened, showing that chronic inflammatory action had for a length of time been going on in that part. The diseased action extended to the mucous membrane lining the commencement of the colon, but did not proceed further.

[Of late, great attention has been paid to the inflammatory affections of the cæcum, as well as of the appendix vermiformis cæci; and much valuable information has been obtained in regard to pathological conditions, which had been previously overlooked. (See ENTERITIS.)]

It sometimes happens that without any very acute pain or other severe symptoms, a considerable thickening takes place in the membranes which compose the cæcum, and, excepting constipation and emaciation, no other remarkable change arises in the state of health. For example, a young woman, who had for the most part

enjoyed very good health, became costive, and was not in her usual spirits; but not being otherwise unwell, no attention was paid to this state of things, although progressive emaciation was, after two months, added to the symptoms. She at length complained of pain in the right iliac region, and on examination, a tumour, which was tender on pressure, was discovered there. After this was known, remedies were promptly employed; leeches and blisters were repeatedly applied to the neighbourhood of the affected part; and a course of mercurial alteratives and saline aperients was combined with these remedies; but they proved unavailing, for the young woman gradually emaciated and died. On examination of the abdomen, the mesenteric glands were found to be enlarged. The stomach was healthy, and so were the small intestines. When the cæcum was examined, its coats appeared much thickened; indeed, in some parts the coats of this bowel were nearly half an inch in thickness. This was produced by a deposit of layers of lymph upon the mucous membrane. The commencement of the colon was also similarly, though not to the same degree, affected.

But thickening of a chronic nature in the mucous membrane of the cæcum is not the only pathological change of this portion of the intestinal canal which occurs in conjunction with a costive state of the bowels. The very reverse now and then happens, and this membrane becomes exceedingly attenuated, and in patches ulcerated, notwithstanding which the costive state continues, as the following observation testifies.

The subject of this case was a lady of a delicate constitution, who was about forty years of age. She through life had been a victim to the most obstinate constipation, and had suffered so much from this cause, that she had for years been in the habit of taking daily aperients; at the same time that the most drastic purgatives, which had often been given, had occasionally failed in producing the desired effect. Her last illness commenced with severe vomiting, accompanied by acute pain in the epigastric region, and complete inactivity of the intestinal canal. In despite of all remedies that could be applied, the vomiting and constipation continued. She lingered many weeks in this state, gradually emaciating, and rejecting every kind of nourishment. She continually referred to the epigastrium as the only seat of uneasiness; and as there was no tenderness on pressure of any part of the abdomen, the sense of sinking at the pit of the stomach and the continued vomiting led the medical attendants to suspect that there was disease either in the stomach or the duodenum. Not a suspicion was ever entertained that the cæcum or any part of the larger intestines was the seat of disease. On examination after death, the stomach and duodenum were found perfectly healthy. The small intestines were empty: the peritoneal covering of the ileum seemed redder than natural. The mucous membrane of the small intestines was healthy. In the cæcum the mucous membrane displayed a very curious alteration of structure: it was of a very dark colour, and had become very thin, so that the muscular coat of the bowel was readily exposed. In one part the membrane

was ulcerated for the size of a bean. At the commencement of the colon the mucous membrane was of a dark colour, and as thin as gold-beaters' skin. The least touch separated it from and exposed the muscular coat of the intestine. This condition extended for about a foot, when the mucous membrane was observed to be thickened, and appeared inflamed, and in patches ulcerated. The inflamed and thickened state of the mucous membrane with occasional ulceration continued until the colon terminated in the rectum, which latter throughout its course from thence to the anus seemed to be free from any disease. The large intestines throughout were loaded with hardened fæces. The liver was not quite healthy; it had a nutmeg appearance, and its texture was less firm than natural. The spleen and pancreas were healthy.

There is much reason to believe that affections of the cæcum producing constipation, have been frequently mistaken for diseases of other organs, and certainly for none more commonly than for diseases of the liver; an organ which, for a long period, was regarded as the fruitful source of all abdominal disorders, whilst the affections which arise in the course of the alimentary canal itself were much neglected. The functions of the cæcum are likewise liable to be interrupted by any deviations from health in the contiguous parts, whereby the propulsive force may be so deranged as not to transmit the fæculent mass from the small to the large intestines; for if the neighbouring viscera are only slightly altered in their structure, the passage of the contents of the bowels through the valve may be materially impeded, if not altogether obstructed. The part which is more especially liable by its derangement of function to impede the propulsive action of the cæcum is the colon, particularly the ascending portion, and the transverse arch.

Simple want of propulsive power in the colon is sufficient to cause accumulation in this bowel; and when the ascending portion and the transverse arch become thus distended with fæces, the pressure upon the liver occasionally so interferes with its functions, that the diseased condition may, without care, be mistaken for hepatitis itself. The pressure upon the *ductus communis choledochus* induces an icteric appearance, and there is even, at times, uneasiness and fulness in the right hypochondrium. Constipation is of course the result, and the cæcum suffers distension and consequent disease. We cannot, however, at all times, under these circumstances, discover any tumour in this part, as the enlargement must be considerable before it can be ascertained by external examination. An erroneous judgment, therefore, may readily be formed; and the affection, which is arising simply from the distension of the colon and cæcum, may be mistaken for enteritis or hepatitis, or even nephritis; for it is by no means uncommon for the urine to be scanty and very high coloured, and for pain to extend up the right side of the loins and to the region of the right kidney. But under such circumstances, the constipation continuing, and the fæces being pent up in the colon and cæcum, much irritation is of course excited, and long-continued disease of the mucous membrane of these parts may be thereby

induced; for the secretory glands of this part of the colon being necessarily obstructed, chronic inflammation may be produced in them, and thickening of the coats of the bowel to a prejudicial extent eventually ensue.

Other and more serious organic affections may also result from this disposition to constipation, and from the disease of the mucous membrane connected with it. Ulceration may arise, or, what is more common, a portion of this large intestine may become contracted, and thus oppose a permanent obstruction to the free passage of the contents of the alimentary canal. Examples are not unfrequent, and the following instance may be sufficient to adduce. A labouring man, aged forty, had been for many months liable to constipation. His bowels occasionally would not be moved for a week, and he had been subject to an appearance of icterus when the constipation was most urgent. During the paroxysms of pain, which often came on when the bowels had been some time confined, he writhed about in great agony, and the pain was generally accompanied with violent vomiting. When, at length, by the assistance of enemata and active aperients the bowels were acted upon, a very large quantity of fæcal matter usually passed away, and it was often of a pale colour. In this case there was not any tenderness in the right iliac region, nor was there any tumour to be discovered in that situation. The patient, however, was a corpulent man, and the examination was thus rendered more difficult than it would otherwise have been. After various paroxysms of the nature above described, and from which he had been recovered by enemata and aperients, he died in very great suffering, apparently exhausted by the frequent recurrence of vomiting and pain. On examining the abdomen there was not discovered any disease of the peritoneum; the liver, spleen, and pancreas were likewise healthy. The stomach also and the small intestines were not apparently diseased. The cæcum was enlarged, and contained a large quantity of fæcal matter. At about three inches from its commencement the colon became very much contracted, and for nearly an inch in length it had a scirrhus appearance, and when a longitudinal incision was made in this part, the coats of the bowels had a cartilaginous feel. The caliber of this part was so much narrowed that the little finger could scarcely pass through it. No other alteration of structure was discovered in any part of the larger intestines to the termination at the anus.

It is worthy of remark, that a stricture of any portion of the colon may exist for a series of years, and the only result observable from it shall be an habitual state of constipation, which, after the occurrence of paroxysms of severe pain resembling colic, may end by abundant and relaxed stools, into which state of softness it appears to be, under such circumstances, necessary that the alimentary mass should be reduced before it can pass freely from the bowels. After such a state has continued for years, and a costive condition of the bowels has been almost habitual, an opposite state occurs, and a tendency to diarrhoea constantly prevails. There is reason to believe that this change in the condition of the bowels, where

constipation has been long kept up by a stricture in any portion of the colon, sometimes arises from ulceration taking place in the constricted portion of the intestine, by which means a more easy transit is afforded to the contents, and a greater degree of irritation of the mucous membrane lining the bowels is produced. The following case strikingly exemplifies this circumstance. A gentleman, aged sixty, had for more than twenty years been troubled with habitual constipation and occasionally colicky pains. After a severe cold, which very much affected the bronchial membrane, and from which he with difficulty recovered, the condition of the intestinal evacuations became very much altered, and, instead of being costive as they formerly were, always of a liquid nature, two or three motions occurring daily. Under this increased evacuation from the bowels he became thinner and weaker. His tongue also continually showed a morbid incrustation, and the skin was dry and rough. The most careful examination of the abdomen could not discover any unnatural tenderness; and although he occasionally complained of griping pains, it was not very common for him to do so. The relaxation of the bowels continued for many months, and he sensibly declined in flesh and strength. At length, after an unusually severe attack of diarrhoea, which was also accompanied with hemorrhage from the bowels, his life fell a sacrifice to this prolonged disease. On examination of the abdomen, the peritoneum generally appeared free from disease, excepting at one part, where the arch of the colon was adherent to the edge of the liver. The stomach and small intestines were healthy; the mucous membrane lining the caecum as well as at the commencement of the colon was healthy; but near the transverse arch it bore marks of inflammatory action, and when the investigation was pursued to that part of the colon which was adherent to the liver, a large ulcer was discovered, surrounded by very hard edges. The ulcer extended nearly through the circumference of this part of the intestine, and the intestine itself was contracted for half an inch, as is customary in scirrhus. The mucous membrane of the colon, extending onwards to its sigmoid flexure, was a good deal inflamed. It may be inferred that the habitual constipation which marked the life of this gentleman for twenty years, was owing to the contraction of the colon, and which was only succeeded by some months' diarrhoea, when ulceration had so destroyed a portion of the contracted part as to render the passage of the contents more easy, and when in consequence a greater degree of irritability had been given to the whole course of the large intestines.

But it is not either in the ascending portion or in the transverse arch of the colon that alterations of structure, producing constipation, are most frequently brought under our notice. It is at its sigmoid flexure that this intestine seems more especially prone to fall into a state of disease. Spasmodic stricture, in this part, appears often to arise and to be the cause of constipation. On examining bodies after death, the tendency to contraction of this portion of the alimentary canal has been frequently observed, and where this tendency exists to any great extent during life, it must prove

an obstacle to the free transmission onwards of the faeces contained in the arch of the colon. But in addition to this very common state of contraction of the sigmoid flexure of the colon, it appears to be correctly ascertained that organic stricture of the intestines is more frequent in this part than either in the ascending portion or in the arch of the colon. If, indeed, we attend to the annals of medicine, and consider the many instances there are on record of this form of disorganization in this portion of the alimentary canal, we are compelled to admit that it is not an unfrequent cause of obstinate constipation. At the same time it should be observed, that in proportion as organic constriction approaches the exit of the bowels at the anus, so does it become more easily investigated by external means; and, consequently, as a cause of constipation, it is more frequently ascertained when it occurs in the sigmoid flexure of the colon than when it is produced in the ascending or transverse portion. For in addition to the signs depending upon the disturbance of the intestinal action which direct us in this as well as in other intestinal affections, we have it also in our power, in this instance, by passing bougies and flexible tubes, to become tolerably certain of the diseased state into which the intestinal tunics have degenerated, at least when the scirrhus condition is so far advanced as to produce any extraordinary obstruction to the transit of faecal matter. It is true that this investigation may not be very easily made by those who hastily come to a conclusion with respect to the state of their patient; yet the anxious inquirer after truth, although not always able to cure the affection, may have the satisfaction of discovering the cause of the constipation, and of laying down such a plan as may materially alleviate the suffering, and for a time at least arrest the fatal termination. There is nothing novel in cases of this kind, but still it is not amiss to impress the mind with striking facts which bear directly upon any subject under consideration, and the following example seems very much to the purpose. A gentleman, aged fifty-eight, who had for many years been in the East Indies, and was of a full habit, and what is commonly called a strong constitution, became, after his return from India, liable to constipation, for which, during the space of two or three years, he was in the habit of taking aperient medicines. At length the constipation assumed a more serious aspect, for it became very difficult to move the bowels excepting by the exhibition of very active cathartics; indeed, so obstinate did they become, that they resisted altogether ordinary measures, and in consequence vomiting and distension of the abdomen came on. He was treated as for enteritis, by bleeding, warm bath, calomel, and castor oil, and enemata were administered. He recovered under these measures, but it was only to suffer at the end of a short time a recurrence of the symptoms. The same remedies then failed to relieve him, and the common form of enemata returned without any quantity of faecal discharge. It was at this juncture that it was thought desirable to ascertain whether, by introducing a hollow tube into the colon, and by injecting warm fluids into it, any beneficial effect might result, and whether any obstruction might thereby be discovered

in the sigmoid flexure. No obstruction was experienced within ten inches of the anus; but at about twelve inches there seemed to be a difficulty in passing on the instrument. A considerable quantity of fluid, however, was injected into the intestines, and it was happily followed by a free evacuation of their contents. The patient from that time again recovered, and by the habitual use of gentle saline aperients, and the daily injection of warm fluids into the colon, he was for several months kept in a very comfortable state, and enjoyed very tolerable health; fatal obstruction, however, in the end took place, and he died about a year after the attack before-mentioned. On examination after death, all the viscera of the abdomen were quite healthy, excepting the cæcum and colon. The cæcum showed marks of much distension, and its coats were thickened, and the mucous membrane lining this part was inflamed and thickened. There was nothing worthy of notice in the ascending portion or transverse arch of the colon; but in the sigmoid flexure, not far from the rectum, there was a very remarkable narrowing of the intestine. For the space of half an inch the coats of the bowel had here become scirrhus and cartilaginous, and ulceration was commencing in the inner portion. The colon and cæcum were much loaded with fecal matter.

But without any particular contraction occurring in any one portion of the large intestines, it sometimes happens that habitual constipation is accompanied with a general thickening of the mucous membrane lining the cæcum and colon, and the sigmoid flexure of the colon is more especially the seat of this alteration of structure. The means of investigating this state of the large intestines do not often occur, as, unless some other disease be connected with it, fatal effects seldom result. A lady, aged forty-five, who died of cancer of the breast, had always been of a very costive habit of body, and had latterly never been moved without the aid of aperients or enemata. She had occasionally suffered very much from pains of the abdomen and griping, and when the bowels were much constipated had been subject to attacks of vomiting. Death took place apparently not so much from this state of the bowels as from the exhaustion induced by the cancerous affection. On examination of the body, the stomach and intestines as far as the sigmoid flexure of the colon were healthy, but from that part to the middle of the rectum there was considerable disease. The mucous membrane was thickened and highly vascular, and the inflammatory action had extended to the other coats of the bowels, and the peritoneum covering that part of the colon was found adhering to the contiguous parts. The thickening and adhesions seemed to be of long standing.

4. Numerous, however, as are the instances in which a costive state of the bowels is produced by disease in the cæcum and colon, they are not so frequent as those which arise from affections of the rectum. The structure and functions of this part of the intestinal canal, and its contiguity to important viscera in the pelvis, in some measure account for this. "The rectum," observes Mr. Chevalier, "commences from the colon, close to the last vertebræ of the loins, and passing down into the hollow of the sacrum, it takes the curva-

ture of that bone, in which it lies comparatively loose, invested anteriorly, but not posteriorly, by the peritoneum. When it reaches the os coccygis, it quits the peritoneum entirely, and is connected loosely by cellular membrane with the bladder, in the male, and the vagina in the female, with the muscles of the perineum, with the levatores ani, the sphincter ani, and the common integument. This lower portion of the rectum is easily distensible; but while it is in a natural state, the peculiar sensibility of its internal surface speedily excites it, when moderately distended, unless the feces are unnaturally hard, to expel its contents, and its muscular fibres are competent to enable it to do so, with a very moderate assistance from the action of the abdominal muscles. It is needless to say of how much consequence it is to the general health that the sensibilities of this important organ should remain unimpaired, and that strict attention should be paid to the regular performance of its functions; if this be long neglected, its natural sensibility becomes gradually diminished, it will remain overcharged for an undue time; the energy of its muscular fibres will become impaired; so that a more forcible exertion of the abdominal muscles will be required to expel the stools, and not unfrequently this will often be insufficient, without some medicine be taken to quicken the action of the bowels." (Medico-Chir. Transactions, vol. x. p. 402.)

The morbid affections we shall notice as occurring in the rectum, so as either to cause or increase the constipated condition of the bowels, are, relaxation of the rectum, stricture of the rectum, hæmorrhoids, and spasmodic contraction of the sphincter ani.

Relaxation of the rectum is not unfrequent in delicate children, in whom, when the bowels have been for some time in a very irregular state, the rectum is often found to become prolapsed, apparently from the want of a due degree of contractile power in the muscular parts of its lower portion. This form of relaxation of the rectum is very common; but there is another which is not so open to observation, and which has consequently often been passed without being noticed. It exists sometimes without any external protrusion of the bowel, for the whole of this portion of the intestinal canal becomes much distended, whilst the colon, and the rectum itself above the distended part, retaining their contractile power, the upper part of the rectum sometimes falls down within the lower, constituting what may be termed an internal prolapsus. The harmony of action between the upper and lower part of the rectum being thus destroyed, the stools are expelled with difficulty in small irregularly-shaped pieces. The difficulty thus occasioned becomes a source of considerable irritation to the lower part of the rectum, and tenesmus, with ineffectual straining, leads to distension of the hæmorrhoidal veins and increased secretion of mucus from the intestine. The parts adjacent do not fail to suffer from this disturbance: in men, the prostate gland and neck of the bladder become affected; and in women uterine irritation and frequent micturition are the result. In other instances the rectum becomes dilated to an almost incredible extent, and the whole pelvis filled with feces; whilst, at the same

time, little or no effort is made by the bowels to discharge this extraordinary accumulation. This state of the rectum is most commonly observed in females, and in those whose sedentary occupations lead to a neglect of those measures necessary to ensure regularity of the functions of the intestinal canal.

Stricture of the rectum is, doubtless, a much more frequent disease than, until within these few years, it was supposed to be. In all cases of constipation of long duration, the state of this part of the intestinal canal should be particularly examined, with a view to ascertain how far it is connected with stricture. Mr. Salmon, in his late Essay on Stricture of the Rectum, considers this bowel as composed of three portions; the first, or upper portion, extending from the termination of the sigmoid flexure of the colon half way to the anus, and having its concavity forwards; the second, or middle portion, extending to the prostate gland, and having its concavity upwards; the third comprehending the last two inches of its course, and having its concavity turned slightly backwards; and he is of opinion that stricture always occurs at the junctions of the upper and middle, or of the middle and lower of these component curves of the rectum with each other, or at the point where the upper curve unites with the sigmoid flexure of the colon. Its most frequent seat appears to be at the junction of the upper and middle curves, five or six inches from the anus, and consequently beyond the reach of the finger. The next most frequent seat is where the sigmoid flexure of the colon terminates at the rectum; and it is least frequently found in the immediate vicinity of the sphincter ani.

Many symptoms are written down in books as attending upon a contracted state of the rectum, but little dependence can be placed upon these as being always present; and with the exception of constipation, we cannot rely with confidence upon any. It cannot, therefore, be too often repeated, that when costiveness exists habitually, the state of the rectum should be closely examined. For it has been clearly proved by the labours of Sherwin, Mossman, Home, Copeland, White, Howship, and Salmon, not only that scirrhus-contracted rectum, — a disease, the carcinomatous malignity of which but too surely defeats the best-directed attempts of the practitioner to save the life of the sufferer, — is of not infrequent occurrence, but also that much more often stricture of the rectum may arise from other causes of a far less serious nature, which by skilful management admit of cure or alleviation. It seems now to be pretty generally conceded, that stricture of a spasmodic nature, not dissimilar to spasmodic stricture of the urethra, may arise in the rectum, and, if not judiciously managed, may lead on to thickening and induration between the muscular and villous coats. Even in this stage, however, the suffering may be considerably alleviated; and when the disease arises from causes of an accidental nature, as the irritation of drastic purgatives, it may be altogether removed. Should it originate even in some defect of structure, as from narrowness of the sigmoid flexure of the colon, or from unusual prominence of the superior part of the sacrum, still the practitioner may hope to afford some alleviation of the

costive state, by bearing in mind the cause upon which it depends.

Habitual costiveness, then, being the most constant effect produced by a strictured state of the rectum, we need not dwell here on the sense of fulness, which is said generally to be felt in the transverse arch of the colon, and especially towards the sigmoid flexure of that bowel; on the sense of pressure, and sometimes acute pain with violent spasmodic contractions near the same part; on the uneasiness felt on going to stool, attended with difficulty in voiding the fæces; on the sensation of tenesmus and uneasiness still continuing after the evacuations; or on the changes in quantity, size, and figure induced in the evacuations.

We must not allow ourselves to be lulled into a false security by the stools not having an irregular figure, and not being in small quantity at a time; for Mr. White very justly remarks, "if the stricture should happen to be so low in the rectum as not to allow room for the accumulation of the fæces, it must appear evident that they will be found uniformly small in diameter (in proportion to the degree of stricture,) while they continue to be discharged in a figured state. And also, when the stricture is high up in the rectum, so long as the gut below retains its natural expulsive power, an accumulation will be prevented, and the diminished size of the fæces will continue.

But as the disorder increases, the inferior portion of the intestine gradually loses that power; and when the contraction becomes considerable, a small quantity of fæces only passes at a time through the stricture, and being insufficient to stimulate the lower part of the rectum, which in a great measure is deprived of its natural action, an accumulation goes on from time to time, until at length it becomes difficult to remove; and on these occasions fæces of a natural size are oftentimes discharged."

In the costiveness which depends upon mechanical obstruction of the fæces in their passage through the rectum, we have before observed that pains of a spasmodic nature in the course of the colon occur; and there is also often a sensation as if a cord were tightly tied around the abdomen. The great distension to which the colon is occasionally subjected from the accumulation of fæces, owing to the costiveness produced by the strictured state of the rectum, may explain these distressing feelings. The enormous extent to which the colon becomes dilated, in some instances, in consequence of this mechanical obstacle to its passing forward its contents, is truly astonishing. Its circumference, under such circumstances, has been found, throughout its whole course, equal to that of a stomach of the full size, and the muscular fibres and longitudinal bands proportionably increased in size.

It is usually in cases where the costiveness has been in existence for a very long period that the colon is found so enormously distended, and when stricture of the rectum has proceeded gradually, and has at length arrived at so aggravated a state that scarcely any fæces can pass through the contracted part, that this dilated condition of the colon is most remarkably developed. The following case occurred some years ago at the Worcester Infirmary. The patient, Elizabeth Stockall,

was for three or four years the victim of stricture in the lower part of the rectum, which was sufficiently near the sphincter ani to admit of her being relieved from time to time by dividing the stricture with a bistoury; and for two years the accumulated fæces arising from the costiveness were, as it became necessary, removed either by a division of the stricture, or by the use of glysters. She never complained of much pain down at the strictured part of the rectum, but very often in the direction of the sigmoid flexure of the colon. There was in this case so little contractile power in the rectum below the stricture, that the fæces passed by little and little through the contracted part, and accumulated in large quantities in a pouch below the contraction, and it was necessary to wash this accumulation away by the repeated use of clysters. At length, the strictured part would no longer admit of the passage of any fæces, and stercoraceous vomiting took place, soon after which her existence terminated. On examination of the abdominal viscera, the first thing that claimed attention was the arch of the colon distended to the size of a large stomach, and completely concealing the small intestines. On further tracing the colon, the dilation of it was found to be equally great from the cæcum to its termination in the rectum. The sigmoid flexure of the colon was displaced from its usual situation, and lay across from the left to the right iliac region. The rectum also, from its commencement to the strictured part, near the anus, was equally distended. The fæcal matter contained in the cæcum was hardened, but that in the colon and rectum was soft and pulraceous.

Numerous, then, as are the instances in which costiveness depends upon stricture of the rectum, we must again revert to the importance of attentive examination of this part in habitual costiveness; for although additional symptoms often unequivocally point to this lesion when it exists, as in the above examples, in a very marked degree, yet there are instances in which, with the exception of costiveness, no symptoms point to this diseased state of the bowel, and the practitioner cannot have this important truth too strongly impressed upon his mind,—that *actual examination* by the finger or bougie, after the fæces have been evacuated, during which the patient should make an effort as if to go to stool, is the only means of detecting this disorder.

Hæmorrhoids have an intimate relation to costiveness. This affection, in its commencement, appears generally as a determination of blood towards the rectum, recurring periodically and irregularly, and may be produced by any cause which interrupts the free return of blood from the rectum. The pressure of fæces habitually retained in this bowel is, consequently, one of the chief causes from which this troublesome affection arises. It would be deviating from the subject of this article to enter into any lengthened statement regarding the pathology of piles; neither is it necessary here to enter at any length into the inquiry, whether they are to be generally regarded as merely a topical affection. Dr. Cullen was of opinion that the disease is purely local, and his reasons for so considering it were, that piles take place before the period of life at which a venous

plethora happens; that they frequently arise in females in whom a venous plethora determined to the hæmorrhoidal vessels cannot be supposed to occur; and that they happen to both sexes, and to persons of all ages, from causes which do not affect the system, and which are manifestly suited to produce a topical affection only. According to Martinet, "piles appear under the form of tumours, varying in size and more or less thickly set, arising from the dense cellular tissue which connects the mucous to the muscular coat, contained in a sort of cyst, thin, smooth, or sometimes villous in its interior, and adhering by its external surface to the submucous cellular membrane. In many instances these tumours are formed of a reddish vascular spongy tissue, or of a sort of parenchyma or fungous flabby tissue, analogous to the erectile. Sometimes they depend upon partial dilation of the veins, which may be easily proved by the introduction of a probe into the vessels."

Mr. Calvert, in his practical treatise on hæmorrhoids, makes a very proper distinction between the two kinds of hæmorrhoidal tumours, viz. the firm fleshy, tubercular masses which form the proper and genuine piles, and the dilated vein or hæmorrhoidal varix, which essentially differs from the former in morbid structure. It is scarcely necessary to point out the importance of a cautious examination of these tumours when they arise in persons of a costive habit of body. Their frequent connection with stricture of the rectum, with diseased uterus, with diseased prostate gland, and with prolapsus ani, all force upon us the necessity of carefully investigating all the circumstances arising in or near the rectum which may exert any influence in keeping up the costive state. (See HÆMORRHOIDS.)

The fact is incontestable, that piles are not only a common effect of constipation, but that they likewise frequently themselves become a cause of aggravating the previous inactive condition of the bowels. This manifestly arises from their offering a mechanical obstacle to the descent of the fæces; for by their number and magnitude they sometimes block up the lower part of the rectum. At the same time it is also by no means uncommon for these tumours, by their long continuance or frequent recurrence, to produce considerable thickening in the cellular membrane which surrounds the lower part of the rectum, and in this way materially to interfere with the action of the sphincter ani. Persons who suffer from hæmorrhoids are very subject to prolapsus ani; and the thickening which occurs in the cellular membrane near the anus often increases the uneasiness that arises from this cause. In the common accident of falling down of the lower part of the rectum, this bowel is generally soon replaced; but if there be thickening of these parts, an unyielding ring is sometimes formed which does not readily return, a circumstance which sometimes operates very unfavourably as an obstacle to the evacuation of the rectum. It must also not be forgotten that internal piles occasionally occur from the enlargement of the veins higher up in the rectum, and there offer a mechanical obstruction to the passage and discharge of the fæces.

But there is another mode in which piles may prove a cause of constipation,—by *spasm of the*

sphincter ani. These tumours are liable to become inflamed, and when they are so, the sensibility of the mucous tissue surrounding them is greatly increased. This is propagated to the *sphincter ani*, and sometimes violent contraction of this muscle takes place, and thus spasm of the *sphincter ani*, by impeding the evacuation of the rectum, becomes an occasional cause of constipation. The office of this important muscle is, so to close the extremity of the rectum as to prevent the escape of its fecal contents, unless when a voluntary effort is made for that purpose. But under some circumstances of increase of the sensibility of the mucous surface lining the lower part of the rectum and the verge of the anus, this muscle sometimes becomes spasmodically affected, or contracts with too much power, and in this manner offers a barrier to the evacuation of the rectum. When this condition arises, it requires a more than ordinarily powerful voluntary effort to pass the feces; and if they happen to be hardened and in large quantity, the evacuation is with great difficulty, or not at all, effected.

Spasm, however, and increased action of the *sphincter ani* may exist without our being enabled to detect any inflammatory or other local affection likely to call it forth, and thus may become in itself a legitimate cause of constipation. In delicate females of high sensibility, and who are of the idiosyncrasy usually called nervous, it is not unusual to observe obstinate constipation, the feces being retained in the rectum. On examination of the rectum we may fail to find any local cause capable of accounting for this effect, excepting a highly spasmodic state of the *sphincter ani*. In such cases the vehemence with which this muscle contracts on the slightest stimulus being applied to it is so great, that it is often with difficulty that, for a time, even the tip of the finger can be passed within its circumference. In short, the *sphincter* seems to partake of the increased mobility which characterizes the general system. When, however, such a state takes place, it must obviously oppose an obstacle to the passage of stools from the rectum; and we need not, therefore, further insist on the necessity, in all cases of nervous excitement, of taking the spasmodic affection of the *sphincter ani* into consideration, when endeavouring to obviate habitual constipation.

We have now passed under review the principal causes existing within the alimentary tube or in immediate connection with its functions, which concur in producing a constipated state of the fecal discharges; and we have only further to offer a few observations respecting those causes which may be termed external or adventitious, to conclude this part of our subject.

Among the most important of these are tumours existing in various parts of the abdomen, which, by their pressure upon different portions of the intestines, frequently obstruct the passage of the feces. When these tumours are of considerable size, they may in general be readily detected, and their connections by a careful examination to a certain extent ascertained. Those existing in the neighbourhood of the rectum, sigmoid flexure of the colon, and cæcum, are most likely to produce constipation. It is, however, in cases in which, in consequence of inflammation, adhesions and

connections of portions of the intestine have been formed, that obstruction of the bowels generally occurs. These adhesions may be such as materially to impede the ordinary and regular progression of the feces by interfering with the vermicular action of the muscular coat of the bowel, or they may be such as to produce complete obstruction by the constriction and pressure induced. The following case affords an illustration of these observations:—A woman of middle age, the mother of several children, had a tumour occupying nearly the whole of the abdomen, in which fluctuation was distinctly perceived. The urine was scanty and turbid, and there was much constitutional disturbance. Digitalis and other diuretic remedies were employed with the effect of inducing a free discharge of urine and the rapid subsidence of the tumour. Some months afterwards the swelling had partially returned, and the bowels had become constipated. The abdomen was now found irregularly tumefied and painful on pressure, but not much enlarged; and at this period fluctuation could not be satisfactorily made out. There was, however, obstinate constipation, vomiting, quick small pulse, shrunk countenance, and prostration of strength. She lingered some days in this state, but no means which could be employed produced any effect upon the bowels. On inspection both ovaria were found to be enlarged; the left was not much larger than a full-sized orange, but the right ovary occupied nearly the whole of the lower part of the right side of the abdomen, and upon being opened was found filled with fecal matter. The intestines and other abdominal viscera were so agglutinated together that it was impossible to trace any portion of them, but it appeared that the communication which had formed between the right ovary and the large intestine was at the spot where from the pressure complete obstruction must have been produced.

The importance of instituting an examination of the rectum in all cases of obstinate constipation has already been fully insisted upon. In the thirty-first volume of the Edinburgh Medical and Surgical Journal, a case is reported by Mr. Alexander, of Wooler, which, at the same time that it affords a singular and interesting example of obstinate constipation caused by the pressure of an enlarged and scirrhus uterus, forcibly shows the necessity of careful examination wherever there is any difficulty in tracing the constipated state to its cause. "The patient, a woman who had been labouring under habitual and in the present instance obstinate costiveness, stated that for a long time past she had had great difficulty in voiding her stools, which were always passed in small quantity, and very much flattened. Upon examination per anum the obstruction was found to be produced by an enlarged and indurated uterus mechanically compressing the rectum against the upper part of the sacrum. At a little distance from the anus a part of the scirrhus mass could be felt of a pyriform shape; and after the finger was carried over this, a still larger projection could be discovered extending backwards and upwards, and partially occupying the hollow of the sacrum; beyond this neither the finger nor any instrument could be passed. The coats of the rectum ap-

peared perfectly sound, and could be made to slip backwards and forwards over the surface of the tumour, indicating that, as far as the finger could be passed, there existed no adhesion between them and the morbid parts. The os uteri examined per vaginam was considerably dilated. Its lips and the inner surface of the cervix, so far as could be felt, were thickened and of a cartilaginous hardness. By introducing the fore-finger of one hand into the rectum, and of the other into the vagina, a considerable portion of the indurated mass could be as it were embraced between them, which could thus distinctly be felt to involve almost the whole substance of the womb." The passage was kept open for a few days by rendering the fæces liquid, but in the course of little more than a fortnight the obstruction became complete, all measures made use of to remove it being of no avail. In this state she lived nine weeks, during which time she suffered much from paroxysms of severe pain and from sense of distension. At the expiration of this period, probably from some change having taken place in the tumour, violent diarrhœa came on, under which she ultimately sunk exhausted. No inspection could be obtained. (*Edin. Med. and Surg. Journ. vol. xxxi. p. 220.*)

A similar effect upon the function of defæcation may be produced by displacement of the uterus—a morbid condition which, although not strictly speaking a tumour, yet by the unnatural pressure which it occasions upon the bowel, may act precisely in the same manner in obstructing the passage of its contents. An example of this kind is narrated in Hufeland's Journal, by Dr. Pitschaft, of Baden, and quoted by Dr. James Johnson in a late number of the *Medico-Chirurgical Review*:—"A woman who had passed through several difficult labours, suffered for three months (during which time the catamenia were absent) from various distressing feelings in the abdomen, and at length from a retention of urine and from a most obstinate constipation. The urine was discharged only by drops, and the use of the catheter was therefore required. For the space of twelve days no evacuations from the bowels could be procured, although all sorts of purgative medicines had been tried, and the distress of the patient was extreme from an almost constant tenesmus, complete loss of appetite, nausea, and a tympanic distension of the belly. Dr. Pitschaft was summoned to her relief; he at once suspected the existence of a retroversio uteri; and his suspicions were verified by a vaginal examination. The uterus was easily replaced, and anodynes and gentle aperients soon restored her to perfect health."

Other causes productive of constipation by pressure upon the bowels from without might be enumerated, but it will be sufficient in this place briefly to allude to diseases of the spinal column and undue prominence of the upper part of the os sacrum. Either of these causes may be instrumental, under certain states of the alvine discharges, in producing constipation. When the distortion induced by disease of the spine is considerable, the narrowing of the pelvic orifice which occasionally occurs is such as very materially to interfere with the propulsion of the fæces

through the lower bowel, and accumulation in the sigmoid flexure and descending portion of the colon is a necessary consequence. The projection of the sacrum may also occasionally act in a similar manner, namely, by narrowing the pelvis, and thus impeding the passage of the fæces from the lower portion of the colon into the rectum. It is necessary to keep these causes in mind, since in every case the degree of relief afforded must necessarily in a great measure depend upon a correct estimate being formed of the morbid condition from which the symptoms take their rise.

Treatment.—Perhaps there is no variation from the state of health to which the human frame is liable, in which the importance of correct rules of practice is less understood and appreciated than that under consideration, and certainly none in which the habitual comfort of a large proportion of the community is more intimately concerned. The annoyance arising from the constant necessity of taking aperient medicines is only to be conceived by those who have in their own persons experienced it, or have been in the daily habit of witnessing it in others. The habitual use of strong cathartics, the necessity for which is often induced by the practice of taking them, affords in but too many instances most forcible illustrations of the evil effects of empiricism, various instances of organic disease of the stomach and intestines being manifestly derived from their employment. We can scarcely therefore estimate too highly the importance of establishing those principles which may lead to a more correct mode of treating, not only the severe forms of constipation, but those minor degrees of this affection which, arising from various causes, are of daily occurrence, and require for the most part much care and attention to rectify. In the observations which follow we purpose to pursue the same divisions of the subject by which we have been guided in the preceding part of this essay; and by pointing out the relations existing between the various morbid conditions giving rise to this functional disturbance and the general principles of treatment applicable to each, we hope to lay down such rules as may prove serviceable in the management of a class of diseases which every practitioner will find to be of nearly equal extent with the practice in which he is engaged, and the correct treatment of which involves the comfort of almost every patient intrusted to his care.

We have referred simple constipation to debility of fibre, to deficient or altered secretions, to indigestible or improper food, to increased tone, to an oppressed state of the cerebral functions, and to an increase of one or other of the secretions from the skin, kidneys, and other organs not so immediately connected with the intestinal canal.

1. The indications of treatment in constipation arising from the first of these causes, where there is simple debility of fibre or loss of tone in the muscular coat of the bowels, are, manifestly, great care in the regulation of the diet, and such a combination of mild aperients with tonics as shall effect the object to be attained without inducing local irritation or over-excitement of any portion of the affected organs. A weak muscular organ may be completely paralyzed by over-exertion, at the same time that moderate exercise with appro-

priate support may restore its tone and enable it to fulfil its functions with efficiency and regularity. Nothing can be more injurious, therefore, in the convalescence from acute diseases, during which, as has been before shown, a degree of this weakened condition is always to be found, than the practice of giving powerful doses of cathartic medicine, because the debilitated intestines do not evacuate their contents with the same regularity and precision as when their powers are in the efficient state of perfect health. A protracted convalescence is the least evil likely to result from such a procedure, and we feel convinced that a recurrence of the original disease is not unfrequently produced by these measures. This is especially the case where the intestinal canal has been the seat of inflammation. In such cases it is of the first importance to guard against any thing capable of exciting local irritation of the debilitated organs, whether in the shape of food or medicine. The food should be altogether of liquid consistence until the bowels are disposed to act without the assistance of medicine, and to procure the necessary evacuations the mildest aperients only should be had recourse to. Castor oil, or a few grains of rhubarb and magnesia with aromatic powder, or the hydrargyrum cum cretâ with rhubarb, will be found in such cases safe and in general effective aperients; or a drachm of the sulphate of magnesia in infusion of rhubarb or chamomile with some tincture of bitter orange-peel may occasionally be taken with advantage. Should these measures fail, it is better to have recourse to enemata than to employ more drastic purgatives.

[Some cathartics are better adapted than others for developing the dormant impressibility of the whole intestinal canal. Such are the saline cathartics. The writer has found great advantage from the following combination:—R. Magnes. sulphat. ℥j.; Potass. bitart. ℥ij.; Aquæ bullientis Oij. M. The dose of this factitious mineral water is a wine-glassful, which must be taken every morning. By persevering in the use of this for some weeks, the tendency to constipation has been removed in some very obstinate cases. (*Practice of Medicine*, 2d edit. p. 153: Philad. 1844.)]

When, however, this state of debility has been of long continuance and unconnected with any preceding acute disease, as frequently occurs in persons of advanced life, it will be necessary to have recourse to more powerful measures. It is in such cases that the sulphate of quinine in combination with some of the resinous cathartics is often productive of the best effects. Four or five grains of aloes or cathartic extract with one grain of sulphate of quinine and a small quantity of some aromatic essential oil, given at intervals of eight hours, will be found to regulate the discharges from the bowels, and not unfrequently, after having been persevered in for a few days, the dose of the aperient part of the combination will require to be gradually reduced. It should be borne in mind, that from the accumulation which occasionally takes place in such instances, the fæces are apt to lodge in various parts of the intestinal tube. When this has taken place in the rectum, they may require to be broken down and removed by manual means, and where the

accumulation occurs in the colon or cæcum, which may usually be ascertained by careful examination of the abdomen, copious enemata should be thrown up, and the contractions of the bowel promoted by occasional frictions over the surface of the abdomen with stimulating liniments, and by the wearing of a tannel roller passed round the body so as to afford moderate compression and support.

[In the torpor of the intestines in which there is a disposition to form scybala, and to retain them in the cavity of the large intestine, Dr. Marshall Hall (*The Principles of the Theory and Practice of Medicine*, p. 398: Lond. 1837.) considers the principal remedy to be, a daily aloetic pill and a warm-water enema; and the plan will certainly succeed generally.]

2. When a deficient or vitiated state of the biliary, mucous, and other secretions poured into the intestines proves a cause of constipation, it will be necessary in the first instance to have recourse to measures fitted to correct the deranged function. We know of no medicine which exerts so powerful an effect in promoting and restoring the biliary secretions as mercury, and accordingly in some or other of its forms this agent is employed whenever the bile is supposed to be deficient in quantity or impaired in quality. There can be no doubt that where there is a torpid state of the liver, and much general oppression of the system with constipation, a full dose either of blue pill or of calomel combined with the compound extract of colocynth, at bed-time, and followed up in the morning by a solution of salts in infusion of senna, will often materially relieve the symptoms, and indeed may generally be had recourse to in the first instance with marked advantage; but unless there is evidence of inflammation existing in the liver, or some change in the structure in that or some other organ—in short, where the disease is simply functional, we do not feel disposed to recommend the plan of mercurialization to the extent to which it has been carried in such cases. The particular attack is certainly in many instances quickly removed under this treatment, but we doubt much whether there is not a greater disposition to a recurrence of the symptoms than where the case has been treated by other measures, less powerful indeed in the first instance, but perhaps on that very account more permanent in their effects. Where the deviation from health of the biliary secretion is but slight, and its effects are chiefly discernible in the constipation induced, we have seen the bowels brought into a regular state, and the evacuations restored to their natural appearance, simply by small doses of colocynth with Castile soap taken at regular intervals of eight hours, and that even in cases where this condition has been of long standing, and to remedy which the habit of taking large doses of strong cathartics had been acquired. The effect of this plan of treatment, when steadily pursued for some time, has been such as to require the gradual diminution of the quantity of the aperient, and at length its entire discontinuance.

Constipation, with pale colour of the evacuations, muddiness of the conjunctiva, and sallowness of countenance, is often found to occur in individuals of sedentary occupations and torpid

habit, in conjunction with a feeble circulation and highly nervous temperament. In such cases, large, or even moderate doses of mercurials are productive of very serious injury, either inducing great constitutional depression or considerable irritation in some part of the intestinal tube. Small doses, however, occasionally prove beneficial, as for instance, a single grain of blue pill with an equal quantity of extract of henbane and camphor, followed by a few grains of carbonate of ammonia in infusion of dandelion with a drachm of some bitter tincture, taken twice or three times daily, the bowels having been previously evacuated by a combination of some of the resinous cathartics. Under this treatment we have seen all the symptoms rapidly give way, the bowels becoming regular, the colour of the evacuations healthy, the conjunctiva and skin clearing in the very same individual in whom larger doses of mercury had induced local irritation of the intestinal mucous membrane to a very serious extent.

[Recently, ox gall has been strongly advised by Dr. Charles Clay, of Manchester, England, as a direct solvent of accumulated hardened feces, the consequence of defective quality or quantity of bile in the alimentary canal. The inspissated bile is given in pills in the dose of three or four grains, three or four times a day. Dr. Mettauer, of Virginia, (*American Journal of the Medical Sciences*, July 1843,) employs the inspissated bile of swine. It is very questionable, however, whether the bile of animals can be productive of benefit in such cases. It is, indeed, doubtful, whether the bile have any agency in stimulating the intestines to the propulsion of their contents; and hence any indication founded upon an affirmative view must be regarded as questionable. Sufficient observation has not been had to decide the matter.]

Of those more obscure cases, in which the secretions from the glands, follicles, and surface of the mucous membrane appear to be deranged, we have so little definite information, that in the present state of our knowledge it is scarcely possible to say what measures are most likely to be beneficial: but where the evacuations have been scanty and covered with slimy mucus, or have consisted almost entirely of a gelatinous matter, much benefit will be derived from a combination of blue pill with ipecacuan in moderate doses, given at proper intervals, until the stools become more healthy, and followed by the tincture of benzoin in doses of from ten to fifteen drops three times daily. Where there is reason to suppose that the secretions from the mucous membrane are very viscid and adherent to its surface, the croton oil will be found a valuable remedy in obviating the attendant costiveness.

3. In the treatment of cases where a slight degree of constipation has been induced by taking improper food or that which is indigestible in its nature, the first object is fully to evacuate the bowels of their contents, which may be done by almost any of the usual cathartics,—for instance, five grains of calomel with eight or ten of compound extract of colocynth, followed by the common black draught, after an interval of six hours, or on the following morning, according to circumstances. The subsequent measures will, of

course, be chiefly dietetic, such as the prohibition of that species of food which has been found injurious, and the recommendation of that which is more soluble in the secretions of the stomach, and more readily assimilated in the subsequent parts of the processes of digestion and nutrition. Should more permanent disturbance have been produced, and the secretions have become disordered so that the constipated state continues, it will be necessary to have recourse to the measures recommended under the preceding division.

It is, however, in constipation arising from this cause that we find those severe cases of obstruction of the bowels which not unfrequently demand all the resources and all the perseverance of the physician to conduct to a successful termination. Some hours after a hearty meal, in which there has been either excess in the quantity of food taken, or inattention to its quality, the bowels will become constipated, at the same time that there is a sense of distension of the abdomen generally, with fulness and uneasiness on pressure in some part of the larger intestines. Under these circumstances a dose of aperient medicine is taken, which may either give rise to considerable pain without affording any relief, or may be rejected by vomiting. More powerful cathartics are now given, and the distended bowel, through the injudicious and hasty use of such measures, is irritated into inflammation, and much and often irremediable mischief done before medical advice is had recourse to. The first efforts of the physician, under such circumstances, should be directed to subdue the inflammatory action by general and local bleeding, and having accomplished this object, without which all that can be done for the relief of the patient must be in vain, he may direct his attention towards the removal of the obstruction and procuring the evacuation of the contents of the bowels. We will not say that in no instance where constipation arises from undigested food, is the removal of it to be attempted by aperient medicines, for if the patient be seen before any threatening of inflammation has taken place, it may be right to give a full dose of calomel combined with cathartic extract and extract of henbane; but if this fail of its effect, and local uneasiness be induced, or if the medical practitioner be called to see his patient under the circumstances before-mentioned, it will be desirable to avoid giving purgatives by the mouth, and to endeavour to remove the obstruction by the use of copious enemata, assisted by frictions of the abdomen, &c. The following case, though one of frequent occurrence, will perhaps point out the mode of treatment to be pursued in such cases better than more general observations.

A man of middle age had experienced a severe attack of colic with constipation, for which he took some strong cathartic medicines without relief to his symptoms, but with the effect of inducing considerable tenderness in the left iliac region, where there was also some fulness. Leeches were applied to the seat of the pain with immediate relief, and after the pain had subsided the bowels were readily evacuated by enemata, followed by a saline aperient. In the course of a few days, in consequence of some irregularity in diet, his bowels became again constipated. Three grains of calo-

mel, combined with eight of compound extract of colocynth and three of the extract of henbane, were ordered. No evacuation followed, but the pain returned in the left iliac region, and was now accompanied by general tenderness and tympanitic distension of the abdomen, and some nausea and disposition to vomiting. He was bled from the arm, and leeches were twice applied to the abdomen within a few hours, and afterwards warm anodyne fomentations. Under these measures the inflammatory symptoms gave way, the tenderness and tension of the abdomen subsided, but the descending colon, just above the sigmoid flexure, could be felt distended, and the part was uneasy when pressed. Copious enemata of thin gruel and of salt and water were repeatedly thrown up, and as there was some difficulty experienced in passing them, the rectum was examined, and a bougie introduced as far as it could be passed without giving pain, but no unnatural state of the lower bowel was detected. The enemata were returned at first without change, but subsequently they became more and more coloured. The obstruction now appeared to descend; gentle friction was made over the part with castor oil, and the enemata were persevered in, till at length a considerable quantity of fecal matter, in a dissolved and fluid state, came away. The local uneasiness then completely subsided, and the bowels were subsequently regulated by a teaspoonful of sulphate of magnesia with fifteen drops of tincture of henbane, taken in peppermint water every morning. The duration of the constipation in this case was eight days. An enema of cold water, as recommended by some of the French practitioners, was thrown up once, but without producing any apparent effect; and as the measures employed were found to be gradually effecting their object, it was not thought necessary to have recourse to others, the success of which might have been doubtful. Among those means which have been recommended in such cases, the dashing of cold water over the lower extremities has succeeded in removing the obstruction where other measures have failed; and the warm bath is frequently a very effectual remedy. The principles of treatment, however, to be kept in view are manifestly to subdue and keep down inflammatory action, and steadily to persevere in soliciting rather than in forcing the evacuation of the contents of the bowels.

4. Where a constipated state of the bowels is produced by increased tone, it is scarcely such as to require remedial measures for its removal, and is best counteracted by taking a greater proportion of ripe fruit or well-boiled vegetables, or other food of a slightly laxative nature.

5. The treatment to be followed in cases where the constipation is complicated with and the effect of an oppressed state of the functions of the nervous centre, may be deduced from the observations which we have already had occasion to make in the first part of this paper, while considering this cause of the functional disturbance. The attention must, in all such cases, be directed to relieving the cerebral or spinal oppression by the application of leeches to the temples or by drawing blood by cupping from the back of the neck, at the same

time that efficient doses of aperient medicines are given to act upon the bowels. The use of calomel is especially beneficial in such cases, probably on account of the tendency of this medicine to equalize the circulation.

Children seem to be very liable to this form of constipation, and in consequence of the predisposition which the age of infancy gives to hydrocephalus, it becomes a subject requiring close and anxious attention. Whenever, therefore, there is a confined state of the bowels existing in a child, accompanied with heat of the scalp and any dullness or heaviness of expression, it is of the first importance carefully to watch the progress of the case. From two to ten leeches, according to the age of the child and severity of the symptoms, should be immediately applied, and from one to three grains of calomel, with four or five of jalap given and repeated according to circumstances. When the head has been relieved by the local depletion, the subsequent operation of the cathartic will be materially assisted by the employment of the warm bath.

The obstinate constipation which occurs in females of an hysterical constitution, and where spinal irritation has been ascertained to exist, requires a mode of treatment materially differing in many respects from that which is adapted to other forms of this functional derangement. In such cases it will be necessary to apply leeches and blisters over the painful vertebrae, with other measures recommended under the head of spinal irritation. The most efficient aperients will be found to be combinations of aloes with myrrh, galbanum, and other antispasmodics, together with terebinthinate enemata, and where the symptoms of hysteria are more decidedly marked, clysters containing assafoetida will occasionally be found successful when other remedies have failed of their effect. In a very interesting case reported by Dr. O'Beirne, (*New Views of the Process of Defecation, &c.*), in which there was most obstinate constipation, (no feces, it is affirmed, having been passed for six months,) attended with great constitutional disturbance, and subsequently ascertained to be connected with spinal irritation, immediate relief to the constipation was experienced from the employment of the tube and syringe, as recommended by the author in cases of constipation. A gum-elastic tube was introduced into the sigmoid flexure of the colon, and an injection thrown up through the tube with the effect of removing, in less than two minutes after the withdrawing of the tube, an enormous mass of solid fecal matter. The patient was not, however, restored to health till proper measures had been adopted for the cure of the spinal disease.

6. In the case of excessive secretions from other organs of the body inducing constipation of the bowels, the obvious indication is to moderate the activity of the disordered functions, and to restore the general equilibrium; but as this is a subject which scarcely falls within the compass of our present object, we shall content ourselves with referring to such of the essays in the preceding pages of the *Cyclopædia* as relate especially to these diseased states, and in which the measures to be pursued in such cases will be found detailed.

In the second class of cases, or those in which the constipated state is connected with and dependent upon obstruction taking place in some part of the intestinal tube, the treatment will often be found to require the greatest circumspection.

1. The frequent connection of this condition with hernia is one which should ever be borne in mind, and in no instance is it of more importance to ascertain the cause giving rise to the attack than in the cases where constriction of the bowel arises from this source. A careful examination should therefore always be made, to ascertain this point, and should a portion of intestine be found displaced and incapable of being reduced, no time should be lost in requesting the assistance of the surgeon. The measures to be subsequently pursued fall under the department of surgery, and will be found detailed in the valuable works of Sir Astley Cooper and others upon this subject, with which that branch of the science of medicine is enriched.

2. For the treatment of constipation, when it arises from inflamed states of the serous and other textures forming the coats of the bowels, we must refer to the articles ENTERITIS and PERITONITIS; and where it occurs in connection with what has been considered spasmodic constriction of the muscular coat, to the article COLIC. We have already expressed our opinion respecting the infrequency of the existence of spasm as a cause of constipation and colic, and shall therefore only further observe, that the measures which are commonly found successful in such instances, viz. local blood-letting, frictions, anodyne fomentations, and the internal exhibition of opiates, are precisely those which are calculated to moderate the action of the propelling fibres of the muscular structure, which by the twisting pain experienced in these affections would appear to be in a state of partially increased activity above the distended portion, rather than of fixed spasmodic constriction below it.

3. The treatment of that form of constipation which arises from an affection of the cæcum, must be regulated by the kind and degree of disease existing in that part. If there be reason to suspect that the cæcum has become distended with fecal matter, but without any chronic inflammatory thickening of the intestinal tunics having taken place, then a plan of stimulating purgatives may answer well the object we have in view. Two pills, for example, may be given every other night, containing five grains of blue pill and five grains of compound extract of colocynth, and a mixture may be directed twice a day, of carbonate of soda, compound decoction of aloes, and infusion of quassia; in addition to which an enema of salt and water may be injected by means of the syringe every morning, taking care that a sufficient quantity of fluid shall be thrown up to pass into the cæcum.

If, however, there be reason to suppose that the inactive state of the cæcum arises from, or is connected with, a chronic inflammatory action in the mucous, muscular, or peritoneal coat of this intestine, then it will become necessary to conjoin local bloodletting and blistering with the purgative plan, and the kind of purgative must be changed. Calomel, in conjunction with cathartic extract, may then be given every night, and a saline aperient,

consisting of sulphate of magnesia, carbonate of magnesia, and peppermint water, may be administered every four hours. If the symptoms do not give way to these measures, it will be desirable to employ the mercurial inunction over the abdominal surface, or, what appears to answer still better, to use an ointment consisting of one ounce of the mercurial ointment with half a drachm of hydriodate of potash. An ointment thus formed is singularly efficacious in promoting the absorption of thickening produced by chronic inflammation. In some obstinate cases of inactivity of the cæcum, we have seen the best possible effects follow the use of the compound gamboge pill, ten grains of which may be given every night at bed-time, and may be continued until the tumour which is felt in the region of the cæcum is lessened by the free evacuation of the bowels. It is surprising to observe the immense discharge of offensive fecal matter, bearing the appearance of having been long retained in the bowels, that is passed away in some examples of constipation connected with accumulation in the cæcum; and those accustomed to watch the progress of such cases would scarcely be disposed to believe that so much could be retained in the intestinal canal. Where once the disposition has taken place in the cæcum to allow its contents to accumulate, and thus to form a large pouch full of feces, it requires much caution in diet and regimen to prevent a recurrence of the same affection, and indeed we believe in many instances, despite of all the care that can be taken, this occurrence cannot be averted. A due attention to exercise of the body, and a proper regulation of the diet, taking the precaution to eat such things as are light of digestion and of rather an aperient quality, will often for a length of time secure a due degree of peristaltic action in this part of the intestinal canal, and preserve it from undue distension. In addition to this, the application of a stimulant mercurial plaster over the part, and the frequent use of an enema, especial care being taken that a sufficient quantity of fluid is injected into the colon, are very important.

The treatment of constipation which depends upon a diseased condition of the colon, requires great discretion in the use of remedies; for if in this case irritating cathartics are injudiciously used, much mischief may be produced, and there can be no doubt that the continued use of violent cathartics may go far to occasion permanent stricture of the colon.

When it happens that from any cause the colon has not for some time passed on its contents, but has allowed the feces to accumulate there, spasm of the muscular bands of this intestine is sometimes produced. This is not a state in which the use of drastic purgatives can be of any service; on the contrary, they may increase the spasmodic action and add to the griping pains, without relieving the bowels of their load. The exhibition of a dose of calomel and opium, with half an ounce of castor oil, repeated every four hours, will in such cases often act freely upon the bowels, and relieve the pain.

Where the longitudinal bands of this part of the intestines are in a painful state, it is more especially necessary to avoid inducing any appearance of dysenteric motions by the use of irritating ca-

thartics, such as *seena*, &c., but those of a milder and more soothing nature may be employed. Sometimes, in an inactive state of the colon, stools are passed containing much mucus and very little faecal matter, whilst at the same time a large quantity of faeces may be retained in the cells of the colon. The daily use of uniritating injections is in this case often attended with much advantage, and the decoction of linseed is particularly suitable for the purpose. It is not, however, well to trust entirely to enemata. The use of alterative and gently aperient medicines will greatly assist in bringing about a more healthy action of the colon: one grain of blue pill and one grain of extract of henbane taken three times a day, together with a mixture consisting of fifteen grains of sulphate of magnesia, one drachm of mucilage, and an ounce and a-half of water, will very frequently greatly assist in discharging the accumulation from the colon, and in bringing about a healthy secretion from its mucous membrane.

If constipation be depending upon an inactive state of the colon, unconnected with any disease of its mucous membrane, the compound extract of colocynth in combination with calomel may be given at bed-time twice a week, and a *senna draught* the following morning. This plan, however, should not be long continued, but after a time recourse should rather be had to daily enemata of salt and water, or of gruel. It is in this form of constipation, when of an obstinate nature, that we think much benefit arises from the use of croton oil, one drop of which may be given in combination with soap every four hours; or half a drop of the oil may be administered with cathartic extract and calomel, in the proportion of four grains of the former to one of the latter, every four hours.

Should constipation be dependent upon stricture, either in the ascending portion or in the sigmoid flexure of the colon, it is usually attended with peculiarly severe pain and much flatulence. It is here of particular importance to avoid all violent and irritating medicines; for the most part the preparations of mercury are not of any avail, and if calomel is given, it should be combined with an anodyne. As an aperient, sulphate of magnesia in small doses, dissolved in water, and the addition of a few drops of laudanum, and given every three or four hours, when assisted by injections, will often succeed; or castor oil in small doses frequently repeated, and combined with a few drops of laudanum, will act upon the bowels without exciting much pain.

It is of great importance, when stricture of the colon exists, to be enabled to use some remedy, which, without proving in any way irritating, may keep up the peristaltic action of the bowel. The tincture of benzoin is a medicine of this kind, and we have often known twenty drops of it taken three times a day succeed in keeping the bowels active, in some instances of constipation apparently dependent upon some stricture of the colon. In constipation also of this nature we observe the happiest effects from the occasional use of aperient saline mineral waters. The waters of Leamington or Cheltenham have often succeeded in giving temporary relief to many persons who have looked for it in vain from other remedies.

When the cause of obstruction exists in the sigmoid flexure of the colon, we have the disease more within reach than in its ascending or transverse portions. If, therefore, the ordinary measures which are employed fail in getting rid of the faecal accumulation, we may sometimes obtain relief by passing a hollow flexible tube into the colon, which if possible should be carried through the strictured part. We are then enabled to inject the fluid immediately through the affected part, and in this manner the colon is sometimes called into action, and a very large quantity of faeces is passed away. It is difficult to say how much fluid may in some of these cases be thrown up, it depends so much on the degree of dilatation that the colon will admit of in particular instances. The quantity we have known to vary from less than a pint to as much as a gallon. This latter quantity we remember to have seen frequently thrown up in an old gentleman, who for years had been the subject of constipation from enormous accumulations in the colon, which appeared not to be the result of stricture in any part of it, but merely from want of action in its muscular fibres. In this case, after constipation of long duration, as much as a gallon of salt and water has been thrown up every morning for a week successively, and scarcely any faecal matter would for several days pass; but at length the repeated use of the injection would call the muscular fibres into activity, and then an enormous mass of faecal matter would be parted with, sometimes amounting to so great a quantity as to render it a matter of astonishment how the colon could have been so far distended as to contain so large an accumulation. This was an instance of paraplegia; and it is in cases of this kind that we believe the colon, without any stricture, is most liable to become enormously distended by its faecal contents.

A modification of this practice has lately been recommended by Dr. O'Beirne of Dublin, in his work on the Process of Defaecation, which he considers to be applicable in most cases of constipation. His plan consists "in the introduction of a large-sized gum elastic tube through the anus into the sigmoid flexure of the colon, and, after giving exit to such flatus and fluid faeces as may happen to escape, adapting to it a proper syringe, and throwing up such purgative fluids as circumstances may make it necessary to select." For more particular details we must refer to the work itself, and to the cases with which it is illustrated.

[The common mode of throwing enemata into the rectum only by the ordinary syringe or by the bag and pipe is often exceedingly ineffective. If we desire to have the full benefit of the injection, the plan, recommended by Dr. O'Beirne, and now in constant use, is indispensable.]

4. When constipation depends upon relaxation of the rectum, we cannot expect to produce any great effect upon the disease by remedies taken into the stomach. It may nevertheless be sometimes desirable to improve the general tone of the alimentary canal, and to stimulate the muscular fibres of the relaxed intestine. With this view the use of a mixture twice or three times a day, composed of carbonate of soda, infusion of *seena*, and decoction of bark, will often prove beneficial

But in this affection, as Mr. Chevalier very properly observes, "the principal and most certain relief is to be obtained from the proper employment of glysters, the composition of which is to be regulated by circumstances. At first those of a mild aperient nature should be preferred, and thrown up by a syringe; and these should be repeated after regular intervals, so as to reaccustom the rectum to empty itself in an habitual way. Gruel, the decoction of mallows, broth, or milk with some honey, will answer the purpose very well; but more permanent good will be derived by using afterwards the infusion of chamomile, or the old decoction *pro fotu*, which, by gently stimulating the torpid surface of the bowel, may bring on a proper contraction of its coats. Where the very lowest part of the rectum continues so dilated as to allow the upper still to descend, from four to six ounces of a strong decoction of oak-bark, or an infusion of galls, thrown up as gently as possible every night, will be attended with the most beneficial effects. If this be not readily retained, a little starch, or a few drops of tincture of opium, or both, may be added to it; and care should be taken, at the same time, so to regulate the diet and medical treatment, that the upper part of the intestinal tube may be excited to due action, regularly, but not violently."

5. It is particularly important that judicious management should be adopted to keep the bowels properly open in stricture of the rectum. So much mischief may be done by irritating the bowels by drastic purgatives, that no reflecting practitioner will now venture to use this class of aperients where stricture of the rectum exists. But we may often, by mild and frequently repeated doses of gentle aperients, which have a tendency to keep the fæces in a liquid state, succeed in preventing severe constipation from taking place. The remedies which are most beneficial in this state are combinations of small doses of simple extract of colocynth, extract of henbane, and blue pill, to be repeated every or every second night, castor oil taken in the dose of a teaspoonful every second or third morning, or one drachm of sulphate of magnesia dissolved in six ounces of water, and taken every morning. We have known instances where, by this means, life has been apparently much prolonged in stricture at the lower part of the rectum, as the fæces have been kept continually liquid, and all accumulation above the strictured part has been prevented. On the same principle, great benefit occasionally arises in constipation from stricture of the rectum, by having recourse to the use of mineral waters. During a residence of three weeks or a month at Cheltenham or Leamington, we have known persons thus affected greatly relieved, and the bowels kept in an open state, without any irritation of the strictured part being thereby produced.

We must not, however, trust to these or any other remedies given by the mouth, as, fortunately, the cause of constipation in this case is sufficiently near the anus to allow of remedies being there applied, and sometimes with great effect, to remove it. The stricture may sometimes be dilated by means of bougies, and the mechanical obstruction to the evacuation of the fæces in this way

removed; or we have it in our power to throw up glysters through the strictured part, thus rendering the fæces more pultaceous and more readily transmissible through the narrowed part of the intestinal tube.

There may be doubts as to the applicability of bougies in every case of stricture, the irritation produced by them being so great as to counterbalance any advantage that may be expected to be derived from their use. Where the stricture is of a scirrhus or carcinomatous nature, there is but little prospect of any benefit being derived from their employment, and we have oftentimes known, where the introduction of the bougie has been attempted in such cases, that the pain arising from it was so great, that the patient would rather suffer from the disease than the remedy. Indeed, it is obviously most judicious in this form of the malady to abstain from using any means that cause irritation, and all that we can attempt in this unpromising condition is to relieve the bowels of their load with as little disturbance of the affected part as possible. On this account glysters of milk and water, or decoction of linseed, are preferable to those of a more stimulating nature; and where the evacuation produced by their injection is productive of much pain, it will be desirable even to allay the irritation thus occasioned by a small glyster of landanum and starch.

It is, however, in strictures which are originally of a spasmodic nature, and in which afterwards thickening and induration are occasioned by an effusion between the muscular and villous coats, that bougies are used with greatest advantage. But surgeons seem very properly to be far more cautious than they were formerly in the employment of the bougie, even in these cases. Mr. Salmon is entirely opposed to the daily use of the bougie. He maintains that the advantage derived from dilatation of the passage is counterbalanced by the frequency of the irritation, and informs us that since he has ceased to use the bougie daily, and made it his practice to introduce it only once every three or five days, he has effected the required dilatation more rapidly. The manner of introducing the bougie we will give in the words of Mr. Salmon: "A full-sized bougie, not less than eleven inches in length, thoroughly softened and well oiled, adapted to the shape of the passage through which it is to be passed, is to be introduced with the convexity of its curve towards the sacrum, in which way it is to be passed upwards and backwards about two inches through the third portion of the bowel, provided it gives no pain; for the introduction will commonly produce an uneasy sensation. We continue to propel the bougie in the same direction, about three or three and a half inches higher, or through the second portion of the rectum. The point of the instrument will now bear directly upon the hollow of the sacrum, and the but-end towards the left side of the body. With the view, therefore, of avoiding the sacrum, and of accommodating the instrument to the great curve of the rectum, we change its position by describing the segment of a circle from left to right, with the but-end, turning it upwards, at the same time continuing to propel the instrument. Having

described this segment, we shall have carried the bougie full four inches farther, or to what may be considered the extent of the rectum. But it is yet to be introduced into the sigmoid flexure: we therefore slightly depress the but-end of the instrument, at the same time propelling it upwards till the whole is fairly within the sphincter. Upon encountering obstruction, trifling pressure is to be maintained for a minute or two; and if under this careful pressure the pain increase, and the instrument remain stationary, it is to be withdrawn, the next size introduced, and so on from above downwards, till we ascertain the size of the bougie, which passes with trifling pain or difficulty fairly into the sigmoid flexure."

We have here given, we believe, the latest and best authority with respect to the use of the bougie; and, without denying the utility of bougies in some cases of constipation from stricture of the rectum, we must again repeat that the irritation of the bougie is sometimes more intolerable than the stricture itself. We, therefore, prefer in all cases of this nature, where any degree of irritation is produced, trusting to the daily administration of an enema of gruel or of linseed tea, which will generally, unless the contraction is to a very great extent, succeed in emptying the rectum, and in checking the further progress of the disease.

With regard to dividing the stricture by the knife, as a means of relieving constipation, we believe it is now rarely practised; and, indeed, the numberless instances in which fatal peritoneal inflammation has succeeded to that practice are quite sufficient to deter us from further trials of it.

As regards the management of constipation where it is connected with *hæmorrhoids*, it would require a full consideration of the manifold circumstances which should regulate our treatment of the latter affection to enable us to do full justice to this question. *Hæmorrhoids* and constipation stand so immediately in the relation of cause and effect, that it is often difficult to determine their mutual dependence upon each other. It is the general opinion that the frequent necessity for the use of cathartics, and more especially those of a drastic nature, as aloes, colocynth, scammony, &c., is the chief cause of the appearance of *hæmorrhoids* in constipation; but there is after all a great source of fallacy in this conclusion; for it must be evident that the same constitutions which require the frequent administration of purgatives are also those most liable to attacks of *hæmorrhoids*. We must therefore not too decidedly determine that the use of cathartics is the cause of *hæmorrhoidal* tumours.

There can, however, be no question that when *hæmorrhoidal* tumours have made their appearance, and more especially when they become inflamed, and the cellular membrane surrounding them thickened, it requires much caution in giving medicines for the relief of constipation. It is always, under such circumstances, of great moment to determine how far the *hæmorrhoidal* tumours themselves, and the thickening of the cellular membrane at the lower part of the rectum, are producing mechanical obstruction to the expulsion of the *feces*; and if so, to direct such local means as are likely to remove them. For

example, if much inflammation exist in the tumours and the parts adjacent, it will be desirable to abate it by the application of leeches and the use of anodyne fomentations; and we should, at the same time, relieve the bowels by the exhibition of some aperient which will not prove irritating to the inflamed piles. A pill consisting of two grains of blue pill and two of extract of henbane may be given, and with it a dose of castor-oil, varying from two drachms to half an ounce; which treatment will generally succeed in relieving the immediate obstruction and suffering arising from the piles, and make it more easy subsequently to command the action of the bowels by enemata. As an habitual aperient to keep the bowels in a laxative state, sulphur has long been employed in *hæmorrhoidal* affections, and is most suitable in combination with supertartrate of potash and given twice a day, so as to prevent the bowels becoming costive. When obstruction has taken place from piles, a more active aperient, as before stated, will be necessary.

But perhaps the most troublesome state of constipation, as connected with piles, is that in which, from their long existence, thickening of the cellular membrane of the lower part of the rectum, forming a sort of ring around the sphincter, takes place. Under this state it often becomes necessary to employ local means to diminish the obstruction thus occasioned. On examination, we sometimes discover that the thickening may be diminished, and the obstruction to the *feces* lessened, by the removal of one or more of the tumours, and wherever this is found to be the case, we should not delay adopting this necessary means of relief. Considerable difference of opinion exists as to the best way of removing *hæmorrhoidal* tumours, some preferring excising them by the scalpel, whilst others make use of the ligature. There are advantages in each mode of procedure. By using the ligature we avoid all risk of *hæmorrhage*; but the irritation that is occasioned sometimes becomes serious, and the inflammatory action occasionally extends far up the rectum: this more especially occurs, if any portion of the mucous membrane lining the lower part of the bowel should happen to be included in the ligature. When, therefore, the mucous membrane of the rectum extends over the *hæmorrhoidal* tumour, a ligature, except in an extreme case, should never be applied. But there are other means besides the removal of the *hæmorrhoidal* tumours whereby the obstruction arising from them in the lower part of the rectum may be diminished. When the extremity of the rectum becomes filled by several tumours of a chronic nature, the compression of them by the introduction of a bougie into the rectum every or every other day will often lessen their size, and thus facilitate the evacuation of the *feces*. Astringent applications may also be resorted to for the purpose of removing *hæmorrhoidal* tumours. Strong solutions of sulphate of zinc in the less severe cases, and the application of the gall-ointment, often produce very beneficial results.

But necessary as it is to attend to the local affection, when constipation is aggravated by thickening of the mucous membrane of the lower part of the rectum and by *hæmorrhoidal* tumours,

still we must bear in mind that much also is to be effected by diet and proper regimen, the object of which should be to keep the bowels in a soluble state. The occasional use of mineral waters, and especially those of Harrogate, deserves much attention, and will greatly assist our endeavours to relieve this kind of constipation. We have also known instances of this nature, in which the daily use of a drachm of Epsom salts dissolved in six ounces of water has greatly relieved the inconvenience arising from the obstruction produced by hæmorrhoidal tumours. It is, however, unnecessary to dwell longer on a part of our subject more especially treated of in the article **HÆMORRHOIDS**.

Spasmodic affection of the sphincter ani—is a very troublesome in some persons who are subject to obstinate constipation. Where it arises from the presence of an irritable or inflamed pile, or from chronic inflammation of the mucous membrane lining the extremity of the rectum, these affections must be attended to and removed by appropriate treatment. Sometimes the removal of the painful pile becomes necessary; and sometimes the application of leeches to the extremity of the rectum affords relief, when the spasmodic affection depends upon chronic inflammation of that part. We do not, however, always find, when we have removed the pile or the chronic inflammation of the rectum, that the spasmodic affection of the sphincter gives way, in which case the constipation still continues. Great benefit will then be derived from the use of an opium suppository, or from passing a bougie into the rectum every other day, allowing it to remain there from twenty minutes to half an hour each time, under which treatment the spasm will usually give way.

In some individuals of high nervous excitement, spasmodic affection of the sphincter ani exists alone, without any piles or inflammation of the mucous membrane of the rectum. We have found soothing glysters injected daily, and the use of the bougie every other day, generally remove this very troublesome form of constipation. These measures should be combined with a plan of treatment calculated to invigorate the system and to allay nervous irritation.

The treatment of constipation, when it is ascertained to arise from the pressure of tumours, must necessarily in the greater proportion of cases be merely palliative. Where the tumour admits neither of removal nor cure, the keeping the bowels in a soluble state by castor oil or other mild aperients, and the use of enemata, are almost all that can be done towards alleviating this condition. Change of position, when adhesions of the tumour to the neighbouring parts have not been formed, may in some instances be of service; and when the pressure arises from displacement, as in the case before detailed, in which constipation of twelve days' duration attended with much suffering arose from a retroversion of the uterus, the restoration of the displaced part to its natural situation will afford immediate relief. In narrowing of the pelvis from undue prominence of the sacrum, or other cause producing accumulation of feces in the colon, the measures required are similar to those which have already been recommended for the removal of this accumulation,

where it depends upon stricture seated at the upper part of the rectum. The circumstances impeding the transit of the feces in each case are so far the same, that the passage through which they are to be propelled is narrowed or constricted; but in the one instance it is by a cause seated in the coats of the bowel, in the other by one acting from without. In this latter case, however, there is not the same suffering from the use of the necessary means, as the inner surface of the bowel is not in so irritable a condition; and the cause, though perhaps incapable of removal, is at the same time not likely to progress with the same rapidity.

Previous to making these observations to a conclusion, we shall endeavour to impress the importance of attention in all the slighter and merely functional forms of constipated bowels, to two or three general directions, which should always be given to those who are liable to suffer from this state. It is of great consequence in all such cases to establish regularity, both with respect to the times of taking food and the general tenor of the daily habits. The tendency to periodical returns of the same condition of the system has been frequently observed, both in the state of health and in that of disease. In disease the regular occurrence of the evening exacerbation in irritative fevers—of the paroxysms in intermittent and neuralgic affections at the same hour of the day—of epileptic attacks at weekly or monthly periods, afford familiar instances; while in health the regularity with which the returns of appetite and disposition to sleep occur are equally striking. It is, therefore, a point of considerable importance in these cases of constipation to make the attempt at an evacuation at a certain regular hour daily; for when once the habit is formed, the call to evacuate the bowels at the same hour will rarely fail.

Regular and sufficient exercise is a most necessary adjunct in these cases, as nothing tends more to predispose to constipation than close attention to sedentary pursuits. Where this is a necessary part of the habitual occupation, too much stress cannot be laid upon setting apart a portion of each day for the exercise of walking. In many of those who suffer from constipation, the powers of the mind are much exercised; and where this is the case, daily ablution of the head with cold water, with the occasional use of the shower-bath, will be found especially beneficial. Indeed, these measures may always be used with advantage where the powers of the system are not in too debilitated a condition to admit of their employment.

To these precepts, which it is in the power of every one to follow, we shall only further add, the importance of avoiding late hours at night, and of rising early in the morning. Indulgence in the habit of lying in bed, is peculiarly pernicious in predisposing to constipation. The perspiration, both sensible and insensible, is increased; and as a necessary consequence, the urinary and other secretions are diminished; in addition to which, the skin is kept in a debilitated condition, and from the intimate sympathy existing between this organ and the intestinal canal, the due performance of the functions of the latter is necessarily interfered with.

CHARLES HASTINGS,
ROBERT J. N. STREETEN.

CONSUMPTION. (See PHTHISIS.)

CONTAGION. (from *contagium*, *contagio*, *contingo*, *con* and *lango*, Lat.)—By this term is meant the propagation of disease from one individual to another; though it is sometimes used, both in speaking and writing, to denote the matter by which the propagation is effected. In certain cases, those of inoculation, we have perfect knowledge that this propagation is produced by the communication of a noxious matter from the individual first affected to him who receives the disease, and from analogy, and from our inability otherwise to explain the effect on the system, we infer that in all cases of contagion there is a communication of such matter. The body secondarily affected has the property of again generating and communicating to others a similar matter, the disease produced in every case being the same in kind as that existing in the body where the matter causing it is engendered. Diseases thus produced, and possessing the power of engendering such a matter, are said to be contagious, and the matter generated is called contagious matter, or contagion.

All examples of disease produced in one human being by the application of matter derived from another do not come within the scope of this definition. For instance, in the case of certain dissection-wounds, or in the examples related by Mr. John Hunter, of disease produced by the transplanting of teeth, there is no reason to think that the individuals from whom the matter was derived, laboured under any disorder similar to that which was engendered, nor is it ascertained in either case that the disease possesses the power of propagating itself. But were it distinctly proved that either disease possesses such a property, then would it be contagious, though arising from a non-contagious source: for we are not justified in denying that a contagious disease may be generated by other morbid causes than contagion.

Contagious diseases may be divided into those whereof the contagious matter acts only by positive contact between the individuals communicating and receiving the disease, or by its transference in a visible form from one person to another by inoculation; and into those which, though communicable by contact, and in some cases by inoculation, are besides capable of transmission from individual to individual through the medium of the atmosphere. Contagion is therefore immediate or mediate—contactual or remote.

To the former division are to be referred syphilis, gonorrhœa, sivevens, framboesia, itch, porrigo, Egyptian ophthalmia, cow-pox, and probably pellagra and the mentagra of the ancients: to the latter, small-pox, chicken-pox, measles, scarlatina, [?] hooping-cough, [?] plague, typhus, hospital gangrene, influenza, [?] puerperal fever, and, according to the opinion of some persons, yellow fever, and cholera of India. It has been shown, too, by Dr. Wells, that erysipelas occasionally manifests a contagious property. There are two other diseases which were formerly considered contagious, lepra Græcorum and lepra Arabum (elephantiasis). The former is unquestionably not contagious, and from the observations made by the late Dr. Adams in the lazaret-house at Punchal, there is every reason to think the latter

equally devoid of this quality. Of the two diseases communicable from inferior animals to man, hydrophobia and glanders, it is not ascertained that they may be transferred from one human being to another, which certainly would have been the case with respect to the former, had it possessed the property of remote contagion. The opinion entertained by many veterinary surgeons, that the latter is communicated by contact from horses to the human species, has been amply confirmed by the researches of Dr. Elliotson of St. Thomas's Hospital: whether it be further communicable from one human being to another is not ascertained.

Of the nature of the matter of contagion we know nothing; but attempts have been made to ascertain the laws which regulate its diffusion through the atmosphere. The following are some of the results of these attempts which have been given to the public; although there is reason to think that they do not merit implicit confidence. Dr. Haygarth informs us that in 1777 he began to ascertain by clinical observation according to what law the variolous infection, and, in 1780, according to what law the febrile contagion is propagated. He is of opinion that the pernicious effects of the variolous miasms are limited to a very narrow sphere. In the open air and in moderate cases he supposes that the infectious distance does not exceed half a yard; and hence, he says, it is probable that even when the distemper is malignant, the infectious influence extends but a few yards from the source of the poison. He is of opinion that the contagion of fever is confined to a much narrower sphere than that of small-pox. (Letter to Dr. Percival, p. 8.)

By Dr. Clarke we are informed that the most malignant fever does not render the atmosphere infectious further than a few feet from the patient, or from the contagion preserved in clothes, furniture, &c.; and daily observation, he remarks, confirms the opinion that a person must remain a considerable time within the sphere of infection to receive it. (Report to the Committee of the Newcastle Dispensary, 1802.)

The poison of plague has been said to be so fixed, that to be affected by it requires almost contact, unless the patient's breath be inhaled, by means of which the disease is readily communicated. We have already intimated a suspicion that these restrictions on the sphere of contagion have been imposed with more precision than sound induction warrants; but we believe it may be considered a rule that within this sphere the danger is greater, other things equal, in proportion to the proximity to the patient.

Certain circumstances influence the extent of contagious diffusion. Of these the most distinctly ascertained are atmospheric impurities; for it is ever observed, and we believe it may be predicated of every disease possessing the property of remote contagion, that its contagious matter is propagated to greater distances in a dirty, crowded, and ill-ventilated apartment than in one of which the air is pure; whilst diffused through an atmosphere of the latter description, it is speedily deprived of its noxious properties. The same principle applies to articles of dress and furniture; those which are contaminated with animal secretions

and effluvia being much more readily impregnated with contagious matter than those which are clean. At the same time it must be remarked, that the neglect of cleanliness implies the multiplication of foci of contagion from the foul clothes and the presence of the discharges from the bodies of patients, and the accumulation of contagious matter from the neglect of ventilation; and hence, though filthy apartments are hot-beds of pestilence, part only of their effect is to be ascribed to foul air.

Besides these auxiliaries of contagion acting in a limited district, there are others more extensively diffused, of which the influence is important. Some of these are well known, whilst others are cognizable only by their effect on the propagation of disease. The effect of those, the nature of which is ascertained, varies in the case of different contagions. The diffusion of plague, for instance, is favoured by a temperature high within a certain degree; whilst it is checked, if not altogether extinguished, by the cold of winter, and likewise by very high temperatures, such as the heat of certain parts of Africa in summer, as mentioned by Alpinus, and that of the Harmattan winds. Typhus, we know, prevails at low degrees of heat, as likewise do measles and scarlatina; and so of different contagions, we find the effect of temperature on them varies in the case of different diseases. A moist and still atmosphere, may, if we mistake not, be declared favourable to the propagation of all contagious disorders; whilst it is sometimes suddenly checked by strong commotions in the air, such as storms and hurricanes.

But besides these appreciable atmospheric states, which in one way or another influence the diffusion and action of the matter of contagion, there are conditions of the air favourable to its diffusion, or otherwise, of the real nature of which we are ignorant beyond their influence over the propagation of disease. It has occurred to every medical man to see diseases, justly considered contagious, unusually prevalent in one season compared with another, though there may have been no discoverable difference in the atmospheric states to explain this variety in their prevalence; and to see them, on the other hand, decline and finally disappear long ere individuals susceptible of the contagion were wanting, without there having been any appreciable change in the state of the air to account for that in the disease. This atmospheric peculiarity, to which the name *epidemic constitution* has been sometimes applied, occasionally appears to possess a limited locality; for we find a contagious disease prevailing in a town or village, whilst places in the neighbourhood escape, though there is a constant intercommunication between the infected and healthy districts; or such a disease may spread extensively in one town, whilst in another, similar as to the habits and character of the population, and not remote in situation, it may exist, but be by no means so prevalent.

A distinction has been proposed between diseases transmissible from one human being to another, and between the terms applied to them, founded on the influence exerted by atmospheric peculiarities over their propagation. It has been suggested that the word contagious should be

limited to diseases which are capable of transmission under any circumstances of the atmosphere, pure or impure, such as measles or small-pox; whilst those which are communicable only in impure or vitiated air, as some have conceived typhus and certain other diseases to be, it has been proposed to designate by the term infectious exclusively. It will be understood that a corresponding distinction is intended between the words contagion and infection. In the first place, it may be remarked that the distinction between the diseases to which the terms are proposed to be respectively applied is hypothetical; for atmospheric impurities and peculiarities appear to have an influence on the transmission of all diseases, and it seems very questionable whether any disease, not in its own nature communicable, is rendered so by such impurities and peculiarities. Again, the words have long been used by medical men, when speaking of the transmission of disease, as strictly synonymous, and they have applied them indifferently to small-pox and typhus; and the attempt to restrict them in an unwonted manner has been productive of confusion, such limitations having the same pernicious effect as needless neologism. It may be remarked, however, that infection, though in the ordinary language of the profession strictly synonymous with contagion when employed to denote the transmission of disease, is used in a sense which the latter word does not admit, that of contamination by any thing injurious to the human frame; for which see INFECTION.

Of the diseases enumerated as contagious, small-pox, measles, scarlatina, and hooping-cough affect individuals but once in the course of their lives; at least this is a very general rule. The privilege of furnishing immunity from future attacks has been claimed, too, for yellow fever; but it seems very questionable whether the exemption afforded by it be of the general nature of that enjoyed by those who have undergone the exanthematous diseases and hooping-cough. It is indeed doubtful whether the comparative immunity furnished by attacks of that disease be any thing more than part of the general seasoning process by which the constitution becomes hardened against the influence of certain climates and their diseases. Were it unequivocally established, yet would it furnish no material evidence in favour of the supposition of this disease being contagious, unless the furnishing of exemption from second attacks were a property of contagious diseases generally, which is not the case.

A period generally intervenes between the application of contagious matter and the occurrence of the disease which it generates, varying in different diseases, and in different cases of the same disease; for instance, in scarlatina this period is said to range from three to five days, but occasionally extends to twenty-one, (Dr. Malon, Med. Trans. vol. v. art. xi. ;) in measles from ten to fourteen; in natural small-pox from six to twenty-one; and in the inoculated disease from four to eighteen; whilst Dr. Whytt's very unhappy experiment showed the interval for inoculated plague to be only three days. The contagion of typhus is sometimes instantly felt in the system, as in an example which the late Dr. Gregory used to relate

in his lectures, of an individual who instantly sickened and became affected with fever on kicking some chaff thrown out of a bed on which a patient ill of fever had lain; and in another mentioned by Dr. Tweedie, in his *Illustrations of Fever*, of a nurse in the Fever Hospital, who sickened whilst examining the evacuations of a patient, and passed through a most severe form of fever. Dr. Marsh's observations upon the origin and latent period of fever (Dublin Hospital Reports, vol. iv.) abound with striking instances of the instantaneous occurrence of the disease on the application of its cause; but the interval from the application of the poison of typhus to the production of its effect, there is reason to think, extends frequently to three weeks or a month, and even sometimes to sixty-eight days, (*Bancroft on Yellow Fever*, p. 515.) The latent period of the poison of hydrophobia is longer than that of any other disease we are acquainted with. This period in the case of some diseases is not one of perfect health. In that of typhus a great degree of nervousness, inappetency, mental dejection, and debility often precede for days or weeks the symptoms which denote the commencement of the febrile movement in the system. It has occurred to the writer to observe cases in which the low but exhausting degree of indisposition attending this period has constituted the greater part of the disease which has destroyed the patient. He has visited persons who, though they had felt themselves indisposed for weeks, had persevered in their accustomed avocations in spite of this feeling, which they thought lightly of, and have then suddenly sickened with the worst symptoms of the last stage of typhus, and expired within forty-eight hours. An author already quoted, Dr. Marsh, deserves the thanks of the profession for calling their attention to the importance of this period and its proper management.

The most certain evidence we can have of a disease being possessed of a contagious property is its being communicable by inoculation. By this is meant the transference of a visible and palpable fluid, through which we must suppose the subtle matter of contagion to be diffused, from one individual to another, or from one to another part of the same individual. It is designedly practised, as is familiarly known, in small-pox and cow-pox, and also, from improper motives, in purulent ophthalmia. The application of the matter of gonorrhœa to the eye of the person affected with it is an example of the second kind of inoculation mentioned. Inoculation of one individual from another is possible in all cases in which a morbid matter, capable of being transferred by art, is engendered, of which examples in addition to those mentioned may be found in both divisions of contagious diseases. Some disorders, too, which do not during the life of the patient generate a matter which may be artificially transferred, have yet appeared to be communicated in this way by dissection-wounds; a description of cases very distinct from those adverted to of such wounds, in which the individual dissected did not die from a disease of the same nature as that produced in the injured individual.

The other proofs are, repeated examples of

persons contracting disease from contact with persons labouring under it, or from being near to them, or from being in the same situation with respect to fomites. An inference may be drawn, too, from the exemption of individuals from a disease who sedulously avoid the sick and fomites, compared with the liability of those who neglect such a precaution. By fomites are meant matters, such as goods of any kind, clothing or furniture, which, having been near the sick, are impregnated with the emanations from their bodies. This may happen to the clothes of individuals who visit them; and in this way an attendant or visitor of patients may communicate a disease to others though he escape it himself, being secured from it in certain cases by having previously laboured under it; in others by insusceptibility of that peculiar contagion, as is frequently exemplified in puerperal fever. It is obvious that the poison may by accumulation exist in a very concentrated state in fomites which have been long near the sick or in contact with them, and consequently we find that some of the worst cases of contagious disease are produced by their means.

With respect to diseases communicable only by contact or inoculation, all doubt of their contagious nature has long ceased; and of those enumerated in the second division, some, which cannot be propagated by inoculation, especially of the exanthematous disorders, are admitted by all observers to possess this property. But respecting others the agreement on this point among medical men is by no means uniform; and controversies have hence arisen as enduring and acrimonious as any recorded in the annals of medicine. The attempts to decide this perplexed question in the case of any disputed disease, must be made in another part of the work; but it belongs to this place to point out the tests, (which owe their value to their being proofs of the circumstances already mentioned, the reception of disease by direct intercourse with the sick, and immunity from it by rigid seclusion from them,) by which any individual case should be tried, and by which alone it can be decided.

1. Contagious diseases frequently spread in places previously healthy, shortly after the arrival in them of persons from infected districts. The same remark applies to fomites. It is the more apt to occur in the case of persons, if they be sick on their arrival or become so shortly after.

2. When a case arises in a limited district, the disease spreads gradually through it as from a centre towards a circumference, but more rapidly, *cæteris paribus*, in proportion to the density of the population, and the intercourse of the healthy with the sick.

3. Persons whose official duties bring them into habitual and close communication with the sick, such as the medical officers and other attendants on public institutions which contain many cases of a disease, are affected with it in a greater proportion than other members of the community similarly circumstanced with themselves, the intercourse with the sick excepted. The number infected from among the different classes of such attendants bears a proportion to the closeness and duration of their communication with the sick;

for instance, the nurses, and in military hospitals the orderlies, are more frequently attacked than the medical officers.

4. The contagious quality of a disease may be inferred from frequent instances of the success of measures taken to prevent its propagation, such as the early removal of the sick. The importance of the evidence to be derived from this source cannot be more clearly shown than by the following statement of Dr. Alison: "We should have little difficulty in pointing out above a hundred houses where a single case of fever has occurred, where the patient has speedily been removed and the place cleaned, and where there has been no recurrence. But we should hardly find five houses in all the closes of the old town of Edinburgh, in which a patient in fever has lain during the whole or even during the half of his disease, in which other cases of the disease have not shown themselves."*

5. Those who seclude themselves from all communication with the sick and with those who visit them, and receive no commodities which have been in their possession or near them, escape the disease; whilst persons similarly circumstanced in all respects, the seclusion excepted, are attacked by it. The same rule applies to countries or districts secluded by quarantine or other regulations from neighbouring countries, similar in soil and climate, where disease is prevailing; though it must be acknowledged that the cases are rare in which a precise conclusion can be drawn from this latter case of exemption.

6. An inference favourable to the supposition of a disease being contagious, may be deduced from the circumstance of there being nothing in the soil or climate where it prevails fitted to engender other causes of disease, such as malaria. A similar inference may be drawn, when disease is prevailing in a limited district, from the cleanliness observed there, and the consequent exemption from infection which might be occasioned by the effluvia from decomposing animal and vegetable recrement. The previous state of health, too, of the district or country, particularly as regards the disease which is the subject of investigation and diseases of the same kind, may furnish the medical reasoner with powerful arguments.

It must be remarked that, in all investigations into disputed cases of supposed contagion, as many tests as possible should be brought to bear upon the points; and that these tests should be secured by a specification of all particulars which tend to show that malaria was not an agent in the production of the disease respecting which the controversy exists. A reference to a few examples of the successful application of the tests will be the best means of putting the reader in possession of the nature of the detail required for the security of his argument.

Those of Dr. Alison have already been referred to, and the reader may be assured that he can consult none more valuable.

In Dr. Tweedie's *Clinical Illustrations of Fever* the following instance is given of the successful

application of the third test, the prevalence of disease among persons officially employed about the sick.

"Every physician, with one exception, (the late Dr. Bateman,) who has been connected with the Fever Hospital, has been attacked with fever during his attendance, and three out of eight physicians have died. The resident medical officers, matrons, porters, domestic servants, and nurses, have one and all invariably been the subject of fever; and the laundresses, whose duty it is to wash the patients' clothes, are so invariably and frequently attacked that few women will undertake this duty. The resident medical officer was attacked with fever, and it became necessary to appoint some one to perform his duties. The first person who thus officiated took the precaution of sleeping at home, yet his duties were soon interrupted by an attack of fever which confined him a considerable time. He was succeeded by an individual in robust health, a disbeliever in the doctrine of contagion. He performed his duty only ten days when symptoms of severe fever appeared.

"There is no security in this narrative, striking as it is, against the favourite argument of the non-contagionists; but the following collateral circumstances present an obstacle to the intrusion of malaria, which only bigotry or the spirit of partizanship can enable it to surmount. The Fever Hospital stands in the centre of a large field, where the production of malaria is exceedingly improbable, and on the same lawn, and within a few yards of it, stands the Small-Pox Hospital; but no case of genuine fever has occurred among the medical officers or domestics of that institution for the last eight years." The relation these facts bear to the argument is sufficiently manifest.

In the case of plague, of the contagious nature of which it would be easy to accumulate proofs, the following example, selected from hundreds, of the influence of fomites, special seclusion from the sick, and close intercourse with them, illustrates well the nature of the evidence to be derived from the third and fifth tests. When the plague was prevailing in Valetta, in Malta, in 1813, the strictest precautions were used by the inhabitants of the Augustine Convent situated in the town to exclude the disease. At length, however, a servant, contrary to regulations, went into a part of the town where the disease prevailed, and purchased clothes supposed to be infected. Soon after he returned he confessed what he had done, and was immediately shut up, together with one of the brotherhood who volunteered to attend him. Both of them were taken ill and died, but no other person in the convent suffered. A disbeliever in contagion would attribute the disease of the servant to exposure to the malaria of the district in which he bought the clothes; but the monk's malaria must have existed in the convent:—how strange that it should have smitten only one of the brotherhood, and he the individual who alone had intercourse with the sick servant!

There can be no better exemplification of the first test than the occurrences in the Island of Ascension in 1823. This island, remote from any other land, of volcanic origin, and the surface

* On Epidemic Fever, Edin. Med. and Surg. Journ. vol. xxviii. p. 241, where the reader will find most of the tests enumerated successfully applied, to show the contagious nature of the fever of this country.

of which consists of volcanic ashes, excepting in one point called the Green Mountain, elevated 2500 feet above the level of the sea, where there is a thin earthy soil favourable to vegetation, but which is very dry, whilst the volcanic surface is said to be dry, arid, and barren, was uninhabited until 1815, when a few British troops were stationed there on Buonaparte's arrival at St. Helena. During the seven years which elapsed from the 7th of March, 1816, to the 7th of May, 1823, but two fatal cases of fever had occurred in the island. On the 20th of April of the latter year, the ship *Bann* arrived there from Sierra Leone with yellow fever on board, which had attacked ninety-nine of the crew, and ultimately destroyed thirty-four of them. Forty-five men, ill of fever, were landed on the island from this vessel. Eight days after the arrival of the *Bann*, one case of fever occurred among the inhabitants; but eighteen days after, or on the 7th of May, fever of the same character as that which prevailed on board the ship, showed itself most decidedly; and from this time until the 16th of June, or within six weeks, fifteen persons died, of twenty-eight who were attacked with the disease, out of a population consisting of only thirty-five marines, with some women and children.*

This case is valuable so far as a much-litigated point of pathology is concerned, but it owes much of its value to the specification of collateral circumstances; such as the nature of the soil of the island, and its previous comparative exemption from fever, which render it improbable that malaria of a degree of intensity sufficient to produce such a disease, had been generated there. At the same time it must be remarked that some cause of fever was endemic at Ascension, for twenty-three cases had taken place in its small population during the seven years preceding the arrival of the *Bann*, viz., ten cases of continued fever, eleven of bilious remittent, and two simply returned fever; and of these cases two had been fatal, one of bilious remittent, the other of continued fever. It may be observed, too, that islanders, who rarely receive the visits of strangers, are liable to be attacked with sickness of some kind on their arrival, though the visitors may not be unhealthy; as we understand is occasionally exemplified among the Shetlanders. Hence we cannot conclude *positively* that the disease was imported into Ascension; but it must be acknowledged that this case wears more the air of importation than any which has been given to the public—indeed most other attempts to prove importation have been signal failures—and that a few more cases equally striking would set the question of the contagion of yellow fever at rest for ever.

The subject would be left very imperfect if we did not bestow some attention on the question, how far contagious diseases may be produced by other causes than contagion? By admitting that the matter of contagion is the product of a diseased vital action, we are by no means forbidden the supposition that the diseased vital action required to engender such matter may occasionally owe its origin to other causes.

* Official Report of the Fever, which appeared on board his Majesty's ship *Bann*, &c., by W. Burnet, M. D.

To commence with the simplest case,—if any member of a family becomes affected with catarrh, arising from catching cold, how constantly do we find it passing successively from individual to individual of the family, till the whole are infected, in the manner of contagious disease, though there be no reason to think that the individual first affected received it from any other source than cold, or cold and moisture.

The itch appears to be engendered by mere filth, but when thus produced is manifestly contagious. Some forms of porrigo, too, arise spontaneously, but yet are disseminated through schools and families from the individuals in whom they have thus arisen.

Certain soldiers of a regiment may have suffered at some previous time from Egyptian ophthalmia; they may have been cured of the disease and remained free from all symptoms of it for months, or even years; and the regiment shall consist partly of such men, and partly of men who have never had ophthalmia. If one or more soldiers who have previously suffered from the disease, have the eyes inflamed from exposure to the sun's rays, cold, or intoxication, and the inflammation is so considerable as to produce secretion from the conjunctiva, and the regiment is at the same time in barracks, so that the soldiers are brought into habitual contact, the disease will spread in the manner of a contagious disease, affecting equally those who had previously suffered and those who had not; though the individuals first affected had not been perhaps for years within the reach of any supposable contagious source. The writer is not stating a mere hypothesis, but a matter which has fallen more than once under his own observation. Is it supposable that any poison had lurked inactive about the eyes of these men for so long a period? or, is it not much more probable that, the eyes being disposed to a certain form of disease, the contagious matter was really the product of the inflammation arising from the common causes mentioned?

If from over-crowding, imperfect ventilation, or neglect of cleanliness, or all conjointly, any single sore in the ward of an hospital becomes affected with the disease called hospital-gangrene, it extends to all the sores of the locality. The affection of these, it is true, may be justly ascribed to the common pernicious influence; but let the causes of this influence, over-crowding, defective ventilation, &c. cease, and cases of healthy sores be admitted, and the existence of the contagious principle diffused through the air, or adhering to fomites, is speedily manifested in the character of the sores; and this will continue till the place is evacuated and subjected to a thorough disinfecting process.

The experience of the whole profession proves that erysipelas generally arises independently of contagion; but the facts adduced by Dr. Wells leave it beyond all question that this disease is occasionally communicated by intercourse with the sick.† Whether it owes this property, which it certainly displays but occasionally, to some peculiarity in the nature of the disease, or to ex-

† Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, vol. ii. p. 213, &c.

trinsic circumstances, does not appear to be ascertained.

It has already been remarked that certain circumstances of crowding, filth, and imperfect ventilation, favour the propagation of contagious diseases; but there is every reason to think that the contagious fever of this country may not only be aided in its diffusion by these circumstances, but may actually be engendered by them. We often see in epidemic seasons, fever, not traceable to any other source, springing up in the abodes of the poor, apparently produced by the concentration of human effluvia, and the decomposition of animal and vegetable recrements, though possessing a contagious character when thus engendered. This mode of generation appears often to take place in seasons of scarcity, when physical privations and the depressing passions render the poor a more easy prey to disease, and by depriving them of the moral energy required to preserve order and cleanliness in their dwellings, fit these for engendering infection; whilst the want of clothing and fuel leads them to block up every chink and aperture by which fresh air might gain admittance. The same origination of a contagious disease from a non-contagious source is observed in the typhus of crowded hospitals, jails, and ships, instances of which are so numerous and familiar to the profession that it would be to waste the reader's time to quote individual examples. It does not seem necessary to examine into the question, whether the miasmata produced by the effluvia of congregated human beings, conjointly with filth and its consequent animal and vegetable decomposition, be identical with those generated by the diseased vital actions existing in fever; for in the present state of our knowledge of the subject we have not the means of deciding it. No inference can fairly be drawn from the identity of the effect, for certain diseased states are produced by a variety of remote causes, this expression being employed in the sense usually annexed to it by medical men.

How far other diseases, which according to the very general opinion of the profession depend exclusively on a specific poison for their diffusion, may in some instances owe their origin to common causes, or such as are independent of contagion, it might appear presumptuous to say. That their diffusion is influenced by atmospheric causes, is beyond all question, and there are phenomena displayed by some of them which tend to excite at least a suspicion that such causes may occasionally engender them. To select an example from the exanthemata:—scarlatina appears suddenly in the latter end of autumn; many are simultaneously attacked—so many at the commencement of the epidemic, that it is wonderful where the foci of contagion exist to contaminate them: in its course it manifests unequivocal signs of contagious power; it disappears sometimes suddenly, at others gradually, but long before subjects susceptible of the disease are wanting: no cases are seen for some months; and in the following autumn the same course is recommenced, and the same phenomena are again displayed. Where lurks the poison whilst thus in abeyance, or does it exist any where? Similar doubts and difficulties might be suggested by cir-

cumstances connected with the prevalence of measles and hooping-cough.

From the preceding observations it is manifest that the subject is one of great intricacy, and that an ample field is open to the cultivation of the diligent, ingenious, and candid. It is to be regretted that the researches into this very difficult and important subject should generally have been conducted rather with a view to support some preconceived notion, than in the spirit of honest and zealous inquiry after truth.

Means of preventing the propagation of contagious diseases.—These may be succinctly stated to be, the separation, as far as is consistent with humanity, of the sick from the healthy; cleanliness of the person of the patient, and cleanliness and free ventilation of his apartment; the immediate immersion in hot water and subsequent washing of all clothes, &c. removed from his person, which might become fomites; the avoiding, on the part of the attendants, of needless and long-continued proximity to the sick, inhaling their breath, and standing in the current of air which passes over them; and the supporting of the general health of the attendants by nutritious diet and the rest which nature requires. (For further instructions, see DISINFECTION and VENTILATION.

JOSEPH BROWN.

CONVALESCENCE. This term is applied to denote the period or intermediate state between the cessation of a disease and the full restoration of health. When we speak of convalescence from disease, it is implied that there has been indisposition of a more or less serious character, and of some duration, as it is obvious it would be improper to apply this term to ailments of a trifling description. The transition from disease to convalescence, and from convalescence to health, which is seldom sudden, more especially in chronic disorders, is announced by the disappearance of the more prominent characteristic symptoms.

Convalescence is observed to be not only more slow but less permanent in chronic than in acute diseases. It is also modified, in some respects, by individual circumstances: thus, in infancy and childhood it is shorter than in the middle or advanced periods of life; it is likewise more protracted in persons of a feeble constitution, and in those who have undergone long-continued rigorous antiphlogistic treatment, or who have had profuse hemorrhage. It has been asserted that convalescence is in some instances influenced by climate, and that recovery takes place sooner in temperate than in hot countries.

The changes which indicate the stage of convalescence vary according to the nature of the previous illness. They are much less remarkable in chronic than in acute disease. In chronic affections the restoration of the functions of the part affected is very slow and imperceptible: if there has been much emaciation, the flesh and bodily vigour are slowly regained, even though the local disease have been completely removed. Convalescence from acute disease, on the other hand, is more rapid and perceptible, and is announced by the cessation of the more severe symptoms, general as well as local. The frequency of the pulse abates, the heat of the skin diminishes,

the thirst decreases, the various functions are gradually restored to their natural state: the tongue becomes clean, the appetite for food returns, and the patient enjoys intervals of refreshing sleep. Besides general signs of amendment, the change from disease to health is evinced in the improved aspect of the countenance: this has always been regarded as a sure criterion of returning health; indeed it may be laid down as an axiom deduced from experience, that unless improvement in the countenance accompany the amendment in the symptoms, the condition of the patient is unsatisfactory. The state of the intellectual powers also becomes improved on the approach of convalescence—there is greater mental energy—the memory, judgment, and imagination, assume their former activity, though continued mental effort sooner induces fatigue than in health. Convalescents from acute disease, however, show great sensibility to external impressions, particularly to extremes of heat or cold; they evince also a morbid nervous susceptibility, and are therefore more prone than usual to irascibility.

Another circumstance which often materially interferes with convalescence, is the supervention of some other disease during this period. It is by no means unusual to find that the original disease from which the invalid was recovering is from some cause suddenly renewed, for it should be remembered that a predisposition having been given by the previous disease, the symptoms may be reinduced by the application of less powerful exciting causes than those which produced the disease in the first instance. In other instances we find that some accidental inflammatory disease appears, and places the convalescent again in danger. This often happens in cases of continued fever; and in the eruptive fevers some accidental symptoms occasionally arise which materially interfere with convalescence. Thus, in small-pox, after the eruptive stage has passed over, secondary fever often supervenes, which may be in some cases traced to some local disturbance; and we not unfrequently observe in this disease, as well as in measles, a troublesome form of ophthalmia which is tedious and often dangerous to vision. In measles, the convalescence is very frequently interrupted by some other local inflammation, generally of the lungs, or by the supervention of glandular disease, more particularly in the advanced period of the disorder. In scarlet fever the stage of convalescence is also occasionally protracted by various symptoms, which often prove tedious and difficult to subdue. Anasarca swelling of the extremities of an acute character, with or without internal effusion; glandular enlargements, inflammation of the ear, inflammation of the large joints, irritation of the mucous membrane of the bowels, are among the more troublesome sequelæ which materially retard convalescence in this disease.

Besides these general circumstances which are observed in convalescence from acute and chronic diseases, there are others which characterize recovery from particular affections. It will be found to be a general rule that recovery takes place more slowly in primary than in symptomatic fevers. This slow recovery from fever, strictly so called, is owing to the more general affection of the solids,

as well as to the more tedious nature of the disease, which often, in spite of the most judicious measures, runs on for an indefinite period. In inflammatory disorders, on the other hand, when the local affection is subdued, the febrile symptoms in general gradually abate, so that the patient is not only convalescent in a comparatively short time, but the stage of convalescence is also of proportionably limited duration.

In diseases of the brain the functions of this organ are seldom at once completely restored; hence, in the stage of convalescence, we often observe various imperfections either in the intellectual powers or in some of the senses, and these may continue even after the causes which induced them have been removed. When the cerebral affection has been attended with paralytic symptoms, the muscular movements often remain in some degree impaired for a considerable time after the individual may be said to be convalescent. This imperfect state of the muscular power may exist alone, or it may be associated with some defect of the mental functions, or of some of the senses. From these various morbid conditions of the nervous system the invalid may ultimately completely recover, or more or less imperfection may continue for life.

In convalescence from pulmonary diseases, some symptoms often remain which indicate the previous affection, such as cough, or slight acceleration of the breathing on any sudden or unusual exertion. When these symptoms continue, it is evident that the lungs have not regained their healthy condition; that although the progress of the malady has been arrested, it is not wholly subdued; and consequently that it is very liable to be again induced on the supervention of even a slight exciting cause. The same continuance of slight symptoms is often remarked in diseases of the abdominal viscera. In dyspepsia the digestive organs very slowly recover their tone, the convalescence being often protracted by errors in diet; and after the more prominent symptoms have ceased, the stomach remains for a long time exceedingly sensitive, and never fails to give ample evidence of displeasure, when oppressed with food of an improper quality, or with greater quantity than it can readily digest. In inflammation of the mucous membrane of the intestines too, there is often for a long time a troublesome state of the bowels, besides great tendency to renewal of the inflammatory action which may have just ceased, on the application of a very trivial occasional cause; hence the necessity of attention to minute dietetic precepts in this class of diseases.

After these general observations, we shall offer a few remarks on the management of convalescence. It is almost unnecessary to say that this must vary according to the nature of the previous disease, its intensity, and the special circumstances which each individual case presents.

In external diseases the principles of treatment are not only more obvious, but the application and the effects of remedies more nicely regulated, than in internal disorders, and for this obvious reason, that the progress of the disease can be ascertained with almost unerring certainty. The state of an internal organ can only be known by symptoms, which it must be admitted give too often uncer-

tain and imperfect indications of its actual condition. There is, however, one among many important advantages of the knowledge of the nature and treatment of surgical diseases to the medical practitioner, that it enables him to form a pretty exact estimate of the value of curative measures, and of the circumstances which advance or retard recovery.

In cases of ophthalmia, it is well known that it is imperative to abstain from all use of the eye, not only during the treatment, but for some time after the inflammation has been subdued. Any deviation from this obvious principle is immediately followed by such effects as are generally sufficient to bring conviction of its importance. The same necessity for caution in cases of inflamed joints comes almost daily under notice. If, therefore, such precautionary measures are necessary in external diseases, in which the various changes are evident to the senses, they are equally requisite in those of internal parts, more especially of the inflammatory kind, in which the changes which the organs undergo are almost precisely the same, while there is the same tendency to relapse, or renewal of the diseased condition, after any irregularity in the management or conduct of the convalescence.

It is quite evident that the first indication in the management of convalescence is to avoid those causes which primarily induced the disease. Another obvious principle is, that the measures to be pursued should always have reference to the nature of the previous disease, and the organ or parts which have been affected. This principle will at once suggest the propriety of abstaining from those circumstances which require such exercise of any organ which has lately been diseased, as might endanger a renewal of the morbid action. Thus, for instance, in recovery from disease of the brain, whatever entails on the patient undue mental effort, should be deferred to a more distant period. In affections of the organs of respiration or of circulation, whatever tends to excite the one or the other must be avoided. It will also be necessary to regulate not only the various functions, but the diet, exercise, and likewise the temperature of the apartment. In convalescence from diseases of the alimentary canal, the practitioner will have to attend to the state of the bowels, but more particularly to the proper regulation of the patient's food. These examples might be extended; but enough has been advanced to illustrate the principles we have endeavoured to inculcate.

Another important circumstance in the management of convalescence is the proper administration of remedies. This must be regulated by particular indications. In some instances, it may be necessary to continue for a time the employment of the remedies which were administered during the disease; for instance, after recovery from dropsical diseases, it may be useful to continue the purgatives or diuretics till the convalescence be nearly established. In other cases the remedial part of the treatment may be entirely suspended, giving occasionally such medicines only as particular circumstances may require.

The most important department of the management of convalescence is the proper regulation of diet. It is almost inconceivable how many errors are constantly committed in this respect, chiefly

from want of conviction, on the part of the patient, of its important influence on his recovery, and occasionally from misconception, on the part of the medical attendant, of the principles on which the diet should be conducted. It is a common error to suppose that the debility, which is the almost invariable consequence of acute disease, and which is more perceptible when the invalid first attempts to make exertion, is to be removed by nourishing food and stimulating drinks: it is no unusual circumstance to meet with such erroneous impressions even in cases of muscular relaxation from cerebral disease. When indiscretion is committed under such circumstances, the previous disease, which had just been subdued, is very generally rekindled, and all the primary symptoms are thus reproduced.

Such errors are more liable to be committed in cases of tedious convalescence, where there is a state of undefined indisposition, attended with impaired vigour, so that the invalid does not gain strength, or perhaps loses it progressively. If the state of the organ that was primarily diseased be examined, the cause of the slow recovery will, in the majority of instances, be detected. The disease has possibly not been wholly subdued, or it may from some cause have been renewed. Under such circumstances the folly and hazard of adopting a stimulating plan of diet and tonic remedies is apparent; the only rational indication is to arrest the disease if it be not entirely subdued, or have been reinduced.

The necessity of proper regulation of the diet is greater in convalescence from acute than from chronic diseases; it becomes the more necessary when the previous disease has been severe and protracted, or, though not protracted, when rigorous antiphlogistic measures, and especially large evacuations of blood, have been employed. The tendency, however, of chronic visceral disease to assume, perhaps suddenly, a more active form, should always be kept in view, as well as the fact that nothing is more likely to induce such excitement than errors of diet. It would lead to tedious repetition were we to point out those forms of chronic disease to which this remark is applicable: in such an article as the present, general principles only can be given, which the practitioner may apply to individual cases.

The return from the bland unirritating food which has been allowed in the active stage of acute disease, to food of a more nourishing quality, should be gradual: the first step should be to substitute another article of the same class of farinaceous food, increasing by degrees the quantity, which should be divided into portions to be taken at short intervals. Milk, particularly asses' milk, is a very suitable article of diet for delicate convalescents, and especially children. Another progression may be made by substituting a weak infusion of animal food with a moderate quantity of farinaceous admixture, either of arrow-root, prepared barley, rice, or stale bread. If the condition of the patient admit of it, the liquid nourishment may be abridged, and a very small allowance of solid animal food allowed. Great care should be taken in the selection of, and mode of dressing, the animal food. In general, mutton is most easily digested, and, if it agree, may be preferred exclusively for the first eight or

ten days, or exchanged occasionally for chicken. The propriety of first allowing white fish as being a more digestible kind of food for convalescents is questionable. It affords certainly a less quantity of nourishment than animal food, (though this advantage may be gained by diminishing the allowance of the latter,) but it is certainly more difficult to digest, and therefore less suited to the convalescent, besides that it affords opportunity for indulging in condiments and additions of an improper kind. In the advanced stage of convalescence from acute disease, if there be nothing to forbid it, one or two glasses of sherry, mixed with water, may be allowed. When the convalescence is completed and the health restored, a more liberal scale of diet may be gradually adopted, though for a very long time great care should be exercised, so as to avoid any articles which are likely to disagree. It should also be impressed on the mind, that the quantity as well as quality of the food is to be regulated—indeed convalescents often suffer more from too much food, even of a proper kind, than from food of an improper quality.

The due regulation of exercise forms another important part of the management in convalescence. This should not be suddenly resumed—nor at any time carried to such an extent as to induce fatigue; and should be suitably adapted, not only to the powers of the invalid, but to his previous habits and condition of life. We have already shortly adverted to the necessary precautions in exercising the functions of the organs which have been previously diseased. It must be obvious that while all undue exertion of an organ is prohibited, the bodily exercise should be so regulated as not to produce excitement, which might not only be injurious, but endanger the safety of the organ previously diseased,

The necessity of suitable clothing in convalescence is so obvious to the invalid, that it seldom requires to be inculcated by the medical attendant. In temperate places, and more especially in those situations where the temperature is variable, it is necessary to protect the surface for a time by warm clothing, and particularly by flannel undergarments. Some delicate persons suffer so much irritation from the use of flannel, that it becomes necessary to interpose a linen under-dress, or to substitute calico. It should be explained to invalids that the use of woollen garments is not so much for the purpose of affording additional heat, as to protect the surface from sudden atmospheric changes, which, by chilling the skin or exciting the circulation, might reproduce the primary disease.

The atmosphere of the chamber to which the invalid is for a time confined should be frequently renewed; and while attention is paid to ventilation, the temperature should be duly regulated. In the winter and spring months it should be kept as nearly at from 55° to 60° Fah., as possible, while the invalid continues weak. When he has regained his strength it may be gradually reduced, so as to enable him to bear the ordinary temperature of the season, first in an airy chamber, and afterwards in the open air. When circumstances permit, nothing in general tends so much to promote and establish recovery as what is commonly termed *change of air*. In most instances, the

improvement in the looks and feelings of the invalid, very soon after he has removed from a confined to a more salubrious district, is remarkably striking.

For further illustration of this subject, however, we refer to the articles CHANGE OF AIR, and CLIMATE.

A. TWEEDIE.

CONVULSIONS (*convulsio*, from *convello*, to pull together.) By the term *convulsion* is meant a diseased action of the muscular tissues characterized by violent involuntary contractions, with alternate relaxations. This diseased action is common to the muscles both of voluntary and involuntary motion, but occurs much more frequently in the former. The term *spasm* has been applied by some to the inordinate action of the involuntary muscles; the term *convulsion* being more particularly reserved to designate the irregular contraction of the voluntary muscles. By Cullen and some other writers the term *spasm* has also been applied to the fixed contraction of parts. When the contractions have been of some duration, and are not quickly succeeded by alternate relaxations, they have been called *tonic convulsion*, as is exemplified in tetanus; whilst involuntary alternate motions of contraction and relaxation have been termed *clonic convulsions*, of which hysteria affords an example. The term *convulsion* has sometimes been exclusively appropriated to clonic convulsion; but as the principal difference between *clonic* and *tonic* convulsions consists in degree, and they both originate in the same causes, it is more convenient for practical purposes to include them under the same head. Very slight and quick alternate motions of contraction and relaxation constitute what is called *tremor*.

Convulsions manifest themselves in various degrees and under various forms. They occur as a symptom in the course of many diseases, and they sometimes assume such regular and well-defined characters as to constitute distinct and separate diseases; as, for instance, in the case of tetanus and hysteria. Convulsive affections have been classed by most nosologists among the *neuroses*, or nervous diseases. Sauvages, Vogel, and Cullen include them as a genus in the order *spasm*. Cullen defines this order "an irregular clonic contraction of the muscles, bordering on but short of lethargy." The presence or absence of lethargy depends, it will be seen, on the seat of the exciting cause. This genus contains a great many species; but he has made separate genera of several convulsive affections, such as hysteria, tetanus, and epilepsy. Dr. Mason Good's arrangement of convulsive affections is very complicated: they are included in the class *neurotica*. He makes one genus of tonic convulsions termed *entasia*, including tetanus, hydrophobia, wry neck, muscular distortions of the spine, cramps, &c. Another genus of clonic convulsions is termed *clonus*: this includes singultus, sternutatio, palpitatio, nictitatio, subsultus, pandiculatio. A third genus called *synclonus* comprehends tremor, chorea, shaking palsy, raphancia, and berberia. His last genus is called *sysspasia*, or comatose spasm, in which he places convulsion, hysteria, and epilepsy.

Convulsions have also been divided into primary and secondary; acute and chronic; continued and intermittent, &c.; but these divisions are unimportant, as they lead to no practical end.

There are attacks of simple convulsion, partial and general, that cannot be referred to hysteria, epilepsy, or any of the well-defined convulsive affections which have received generic names. These varieties of simple convulsion will form more particularly the subject of the present paper; and as convulsive affections are generally entitled, by the formidable character of their symptoms and the imminent danger which frequently attends them, to the attentive consideration of the practitioner, we propose taking a general view of their pathology, and of the principles which are to regulate their treatment.

Convulsions may be *local* or *general*; each part may be separately and successively affected, or the whole frame may be convulsed at once: in some cases the convulsive movements are confined to one side of the body. We shall first consider the manner in which different parts of the body may be separately affected with convulsions.

LOCAL CONVULSIONS.—When the eyelids are affected, if the convulsion is confined to the levator palpebræ superioris, the upper eye-lid is forcibly drawn up, and cannot be closed; the eye-ball consequently remains uncovered, and is exposed to painful irritation: this occurs sometimes as a local affection, especially in neuralgia of the supra-orbital nerve. If the orbicularis muscle be affected, the eye-lids are forcibly closed, and can with difficulty be separated. Slight convulsions of the muscles of the eye cause a rotatory motion of the globe from side to side or else upwards. This is a frequent symptom of visceral irritation, especially in children, in whom it often occurs during sleep. When these muscles are more violently convulsed, there is strabismus, or a violent contortion and rolling of the globe in the socket; or else the eye is firmly fixed, staring and protruding. The iris being possessed of contractility is susceptible of convulsive action; the pupil is then either very much contracted and immoveable, or else it is alternately closed and dilated by quick and irregular oscillations. Both pupils may be differently affected, one remaining fully dilated when exposed to light, whilst the other contracts; or one may remain stationary, the other being alternately contracted and dilated. There are in this respect great variations.

The convulsions of the muscles of the face give rise to a great variety of remarkable and opposite expressions. The whole of the features may be fixed and immoveable, or there may be a constant change of expression by the momentary contraction of separate muscles in quick succession; or the convulsions may affect only some of the features, causing, for instance, slight evanescent twitchings of the lips or distortion of the mouth; or else an elongation and drawing up of the commissures of the mouth. This last variety gives rise to a species of convulsive laughter, sometimes closely resembling the smile and laughter of health, especially in infants, but often more violent: this is the *risus Sardonicus* of the ancients. When the muscles of the jaws are affected, there may be grinding of the teeth or a vio-

lent clattering of the jaws; or else there is a permanent rigid spasm, rendering the lower jaw fixed and immoveable, as in trismus. Persons of a highly nervous temperament are sometimes affected with an habitual twitching of certain muscles of the face; these generally arise from constitutional causes, and are difficult to be remedied. Convulsions of the muscles of the tongue cause it to be violently twisted in the mouth so as to push out the cheeks, or else it is forcibly protruded; it is very liable in that case to be severely wounded by the teeth, and has in some rare cases been completely cut off. A tremulous state of the tongue when put out is a sure sign of general nervous debility.

When the muscles of the neck are simultaneously convulsed, the neck feels hard, and the head is drawn back; if only those on one side, the head is drawn to that side or partly turned round. There may be, from this cause, either a permanent rigid contraction, or a convulsive agitation, or a simple tremor of the head and neck. These modifications are observed in wry neck and *paralysis agitans*.

Convulsion of the muscles of the pharynx impedes deglutition, and gives rise to spasmodic dysphagia. The convulsions of the muscles of the larynx cause laryngeal dyspnoea and suffocation, and either various alterations or a total extinction of the voice: these are frequently symptoms of inflammatory and spasmodic croup. The sensations of stricture and strangulation in the throat which so often attend hysteria, chorea, hypochondria, &c., are owing to a convulsive state of the anterior muscles of the neck.

Convulsive affections of the muscles of the thorax (the intercostals, diaphragm, &c.,) are sometimes the primary cause of habitual dyspnoea or of violent paroxysms of cough and suffocation, constituting a variety of convulsive asthma. When the convulsions are severe, the breathing is very irregular: there are a few short inspirations and expirations; then a long intermission without any breathing, followed by several deep inspirations, with heaving of the chest and sighing; in some extreme cases the constriction of the chest has been so violent as to stop the breathing altogether and cause asphyxia. This irregular and occasionally hurried breathing gives rise to a corresponding state in the action of the heart, which becomes violently increased; there is a sudden and considerable rise in the frequency of the pulse, which might be mistaken for fever; the circulation subsides, however, with the paroxysm to its natural standard. A convulsive state of the diaphragm gives rise to hiccup, which is sometimes a most distressing and obstinate complaint.

The convulsions of the abdominal muscles cause in some cases a violent retraction and hardness of the abdomen; in some a convulsed agitation of the parietes of the thorax, bearing the closest resemblance to irresistible laughter; and in others a peculiar undulatory motion of the abdomen frequently observed in hysteria. It is not improbable that the globus hystericus depends on a partial convulsion of the abdominal muscles extending upwards to the diaphragm, and the muscles of the thorax, neck, larynx, and pharynx. The late experiments on the causes of vomiting

prove that the contractions of the abdominal muscles have as great a share at least in its production as those of the stomach. The sphincter muscles are often convulsed, as is seen in the tenesmus of dysentery, the dysuria of the irritable urinary bladder, and the retention of urine from permanent spasm of the sphincter vesicæ.

When the muscles of the trunk are affected with convulsions, the body is forcibly bent backward or else to one side: this is termed *opisthotonos*, and is a frequent symptom of tetanus. There is a partial and permanent rigidity of these muscles in muscular distortions of the spine. Painful cramps of the dorsal and lumbar muscles are sometimes experienced in acute rheumatism.

In convulsions of the upper extremities, the fingers are clenched on the hand and round the thumb, and the hand is turned in pronation; the fore-arm is bent on the arm, or moved backward and forward as in the act of striking. There may be very slight and partial convulsions of these muscles, discovered only by the startings of the tendons (*subsultus tendinum*) on placing the hand on the wrist; these sometimes indicate the approach of a severe convulsive fit.

Convulsions manifest themselves in the lower extremities by the strong retraction of the toes inwards and downwards, the legs and thighs being rigidly drawn up or alternately bent and extended. In these cases the flexor and extensor muscles are principally affected, and the adductors or abductors but seldom.

The involuntary muscles are also liable to be affected with convulsions, although much less frequently than those of voluntary motion. The action of the heart is sometimes very much increased and irregular in nervous palpitations, and in several of its organic diseases; or its motions may be suddenly stopped by a violent spasm of some duration, as occasionally happens in angina pectoris, and in cases of retrocedent gout or rheumatism.

The muscular coat of the stomach is subject to severe and painful spasmodic contraction in gastrodynia, and in cases of obstinate vomiting. There are strong partial spasmodic contractions of the muscular coat of the intestines, in the tormina of dysentery, the gripings of colic, the borborygmi and tympanitic affections of hysteria. The muscular apparatus of the urinary bladder is often thrown into a state of spasmodic irritation in diseases of the urinary organs. That of the uterus is susceptible of a sufficient degree of inordinate and convulsive action in the puerperal state to cause occasionally a rupture of the viscus, and the regulation of its contractions both before and during labour is always an important object in the practice of midwifery.

The different varieties of convulsions which have been described may exist separately, as distinct affections; they may be variously combined; and some of them may pass imperceptibly into each other.

GENERAL CONVULSIONS.—General convulsions consist of various combinations of the symptoms that have been described as characteristic of local convulsions. The mode of attack and progress of the paroxysm exhibit considerable variations. Sometimes the attack is sudden and without any

warning; but more generally there are some premonitory symptoms, especially in children, and in patients who have had previous attacks: of this kind are coldness of the extremities, vertigo, floating spectra before the eyes, starting at slight noises, peevishness and irritability of temper, alternate paleness and flushing of the face, disturbed sleep, irregular breathing, hiccup, cramps in the hands, legs, and feet, flatulent uneasiness of the bowels, and tension in the left hypochondrium. In some cases a sensation of creeping cold along the back, like an aura, creating shivering, is the premonitory symptom.

The paroxysm is ushered in by dull pain or a sense of weight in the head, drowsiness, flushing, vertigo, either loss of sight and a sense of complete darkness, or flashes of light and bright objects moving before the eyes, ringing of bells or the noise of roaring cataracts in the ears, sickness, pain and sense of oppression in the epigastrium, &c. These symptoms are quickly succeeded by general convulsive contractions of all the voluntary muscles and many of the involuntary, in the manner just described in the account given of local convulsions. The face is hideously distorted; the protuberant eye-balls roll rapidly in every direction with a wild stare and constant motion of the eye-lids; there is grinding or gnashing of the teeth, occasional protruding of the tongue and foaming at the mouth, with a deep hissing noise, occasioned by the hurried passage of the air in breathing through the teeth. When the respiration is laborious and very much obstructed, there is a dark redness of the face and scalp, and a purple colour of the whole body, together with a full strong pulse and violent beating of the carotids; in other cases the face is pale and the pulse small and contracted. Limpid urine is frequently voided in large quantities, and sometimes evacuations by urine and stool are expelled with great violence. The muscular force exerted in the course of the convulsions is in some cases enormous, shaking the entire room, and requiring five or six attendants to control the patient. Several authors relate cases in which the contractions have been of such intense violence that the teeth have been broken, blood has burst from the nose or been effused under the skin, producing general ecchymosis, and even limbs have been luxated or fractured. (Eph. Nat. Cur. Dec. Ann. 7.) The violence of the muscular contractions gives sometimes very severe pain. The occurrence of delirium, coma, and insensibility during or after the attack will depend altogether on the degree and manner in which the brain is affected. If the convulsions are symptomatic of organic disease of the brain, the paroxysms are likely to be attended with delirium, followed by coma and insensibility; when there is no organic affection, but merely functional disorder, as in the case of simple convulsions, the consciousness is not impaired, or only in a very slight degree.

The paroxysm may sometimes cease in a few minutes, when the patient immediately recovers; or after he has remained for some time under a sense of suffocation, the impeded circulation and all the other symptoms may be relieved by a sudden fit of sobbing and deep sighing, as in hysteria: but the paroxysm occasionally lasts for several

ral hours, as many even as twenty-four, at the end of which the patient falls into a profound and long-continued sleep, from which he awakes suddenly, unconscious of what has happened: languor, vertigo, and sickness generally succeed these prolonged attacks. The paroxysms may return again at uncertain intervals, and be thus renewed until they spontaneously subside. This is the most common course in puerperal and infantile convulsions. The fits may finally prove fatal by causing apoplexy or asphyxia, and this has sometimes happened in the first attack: not unfrequently they leave behind them paralysis, chronic epilepsy, chorea, permanent squinting, &c. In some cases the mental faculties have been destroyed, and the patient has been reduced to idiocy or imbecility. A remarkable case has been recorded in the Medical Repository, by Mr. Thompson, of Whitehaven, of loss of speech and hearing in a child six months old, who had been suddenly seized with convulsions: her vivacity remained and her health was unimpaired. She continued in this state until her sixteenth year, when, after the noise of a public rejoicing, she was observed to recover the sense of hearing, and she soon began to articulate. Convulsions sometimes terminate by critical evacuations; the paroxysm has not unfrequently subsided on the appearance of epistaxis; and there are cases on record where the convulsions always terminated by copious hemorrhage from the mouth, nose, and ears. Diarrhœa or vomiting are terminations of still more frequent occurrence. A state of profound syncope has sometimes supervened on convulsions; and there are instances recorded of the patient never rallying, and of its proving consequently fatal. But in cases of this description, after the excessive nervous exhaustion which generally follows a long-continued state of violent agitation of the whole nervous system, the patient may remain for a considerable time in a state of lethargy or torpor, without showing any signs of life, and still ultimately revive. It is under these circumstances that many horrible cases of premature interment are stated to have taken place, especially of women and children. The truth of some of these cases may be called in question, but there are others which appear but too well authenticated; and there are also undoubted instances of persons having very narrowly escaped being interred, whilst in the torpid condition now mentioned.

The paroxysm just described is a delineation of the severest form of convulsion. In the majority of cases the disease is of a much milder character: there is no affection of the intellect, local congestion, or fever; the convulsions affect only a few muscles at a time, extending in succession to the others; they may be confined to one side of the body, or attack both alternately: this constitutes the *convulsio erraticæ* of Good. The paroxysms may return only after long intervals more or less regular; the ordinary period in females is menstrual or lunar: this is the *convulsio recurrens* of Good. In some cases the muscles of respiration, and those especially of the larynx, appear to be chiefly affected, and the patient emits shrill or yelling sounds, which circumstance has

induced the same writer to form a separate variety with the name of *convulsio ejulans*.

An important variety of convulsions is that connected with the puerperal state; they may occur in the latter periods of pregnancy, rarely, however, before the sixth month; during parturition, or in the first few days after delivery. As a separate article is devoted to this form of convulsions, we shall merely state in general that its symptoms are in some degree modified by the close sympathy which exists between the uterine system and the sensorium; in consequence of which there is a greater tendency to oppression in the head than in any other variety of convulsions; the breathing is stertorous, and the muscular action peculiarly violent. (See CONVULSIONS, PUERPERAL.)

Convulsions are likewise of very frequent occurrence in infants, owing to their great mobility of frame. In these cases the convulsive motions, especially of the mouth, eye-lids, and fingers, are so excessively rapid that it is often difficult to follow them: this constitutes the *eclampsia* of Sauvages. We shall confine ourselves to this brief notice of infantile convulsions, as, in consequence of their great importance, they will also form the subject of a separate article. (See CONVULSIONS, INFANTILE.)

Convulsions may occur in the progress of a great many diseases. There is scarcely an acute disease with which they are not occasionally combined. They sometimes manifest themselves at the beginning of inflammatory and bilious fevers, and at the invasion also of nervous and malignant fevers, especially in hot climates. The rigours of the cold fit in the severer forms of ague have assumed sometimes the character of convulsions, and the patient has sunk under them, there not being sufficient power in the constitution to bring about a re-action. When convulsions occur in the latter stages of continued fevers in combination with delirium or coma, they generally indicate some dangerous affection of the brain. It should be remembered, however, that the salutary critical terminations of fever have been observed to be ushered in by some violent perturbation of the whole system, of which convulsions are occasionally a symptom; this apparent aggravation of the fever often deceives the attendants, who mistake it for the approach of death. The writer of this article experienced on the twenty-first day of a nervous fever, a most frightful fit of convulsions, attended with laughter, hysterical sobbing, violent protrusion of the tongue, vomiting, &c., which, however, were soon relieved by the bursting out of a profuse perspiration and a complete remission of fever. Convulsive paroxysms are not uncommon in the remittent fevers of infants; and unless the progress of the disease be carefully attended to, it may be mistaken for hydrocephalus. The distinction between the two diseases is obviously of considerable moment, for the latter is always attended with great danger, whilst the former is rarely fatal.

The eruption of the exanthemata, particularly variola, rubeola, scarlatina, &c. is not unfrequently preceded by convulsions. In such cases convulsions have been considered by the majority of

writers as a favourable omen; a few, however, have maintained an opposite opinion, and cases may sometimes occur that seem to justify this conclusion. When after a violent constitutional disturbance, attended with convulsions, only a very slight eruption makes its appearance, which quickly vanishes, the effort of the constitution is apparently unavailing: as the brain sympathizes strongly with affections of the skin, the irritation which should have been fixed on the skin may, in such a case, be transferred to the brain, and become the exciting cause of some dangerous cerebral disease; the convulsions will then be severe and frequently repeated, and they may ultimately prove fatal. Convulsions are also of frequent occurrence in hooping-cough and croup; in all inflammatory and organic diseases of the brain and spinal marrow; in some severe cases of organic disease of the heart, owing probably to an embarrassed state of circulation in the brain; and they have been observed, too, in calculous affections of the urinary bladder and kidneys. Acute diseases have sometimes terminated, as if by sudden transition, in attacks of chorea, epilepsy, &c.

It is well known that the closest sympathy exists between the brain and the genital organs. The development of these organs at the age of puberty is frequently productive of considerable constitutional disturbance and nervous irritation; this is more especially the case in females: the first appearance and regular development of the menstrual discharge is attended in some cases with a great struggle in the constitution, and may be characterized by convulsive paroxysms in combination with many other painful symptoms. The susceptibility of the nervous system being considerably increased, very slight moral or physical impressions are sufficient to excite convulsions. If the struggle ends in the full and regular development of the uterine functions, the convulsions disappear, and the health will be firmly re-established. It has been observed that chorea, epilepsy, and other diseases of youth, generally subside at this critical period, if the constitutional changes peculiar to it are not interrupted; but that these diseases become confirmed and aggravated, or others make their appearance, when there is not sufficient power in the constitution to bring about the accomplishment of this important end. The spontaneous cessation of the catamenia at the usual period of life is sometimes marked, like their first appearance, by considerable disturbance of the health, and convulsions either local or general are among the occasional symptoms of the climacteric diseases of women.

The convulsive affections connected with disorder of the uterine functions do not always follow the usual regular course, but assume sometimes an infinite variety of anomalous forms; appearing in combination with other formidable diseases, resisting for years every mode of treatment, and subsiding at last without apparent cause when least expected. The following is a general enumeration of the principal symptoms of these anomalous cases:—convulsive affections of the limbs or muscles of the trunk, sometimes resembling tetanus, chorea, or catalepsy; permanent spasmodic retraction of some of the extremities,

or weakness amounting sometimes to complete paralysis, which is often accompanied by remarkable convulsive contractions of the paralytic limbs; feeling of great weakness in the back, attended frequently with severe pain and excessive tenderness on pressure, confined to one part or extending along the whole of the spine; a variety of cerebral symptoms; intense headach, permanent or periodical; vertigo, tinnitus aurium, temporary delirium, mental alienation, or fits of lethargy; various neuralgic and convulsive affections of the face; sudden attacks of blindness; difficulty of deglutition; extinction of the voice or loss of speech. Severe paroxysms of dyspnoea, combined sometimes with violent palpitation; spasmodic affections of the alimentary canal; remarkable irritability of stomach and sometimes severe vomiting, which we have seen continue with very little intermission for several months; attacks of spasmodic colic, with immense tympanitic distension of the abdomen; obstinate constipation, and an extremely vitiated state of the biliary and intestinal secretions; sometimes distressing dysuria, at others retention of urine, the urine being generally clear and very copious, in some cases very turbid and scanty.

It would be impossible to describe the various extraordinary combinations under which the preceding train of symptoms may present themselves: there may be sudden and rapid transitions from one extreme to another; we have seen in the same patient well-marked symptoms of apoplectic coma and paralysis, epilepsy, catalepsy, tetanus, and maniacal delirium, succeed each other with incredible rapidity, and finally subside without any material injury to the health. The force exerted by the lady who was the subject of this case, during the paroxysms, was quite extraordinary. It frequently happened, during even the intermissions, that, when she took hold of a chair or any other object, her hand would suddenly contract upon it independently of her will, and with so firm a grasp that the utmost strength of two persons would be insufficient to loosen the fingers, and she would be obliged to wait until the spasm subsided of its own accord. In other cases the patients have laboured for a considerable time under apparent symptoms of formidable cerebral or spinal disease, such as apoplexy, hydrocephalus, paralysis, &c., and have ultimately recovered, although their condition was considered perfectly hopeless.

The pathology of these anomalous diseases is still involved in much obscurity; it is highly probable, however, that they have their origin in neuralgic affections of the brain and spinal marrow, and that the ganglionic nerves of the great sympathetic have also considerable influence in their production. Dr. Abercrombie has recorded several highly interesting cases of this description. One of the most remarkable is that of a lady aged twenty-four, who, during a period of above six years' illness, was affected in succession with hemiplegia, loss of speech, chorea, sudden attacks of blindness, convulsions of the muscles of the back, legs, and arms. These convulsions were occasionally so violent, that her body would be suddenly seized with a kind of convulsive spring, by which it would be thrown out of bed on the

floor, and from the floor back again into bed; at other times she would leap on the top of a wardrobe fully five feet high; the mind remaining all the while unimpaired. Subsequent to the preceding symptoms she suffered from difficulty of deglutition, and convulsive motions of the neck, producing for weeks together a constant rotatory motion of the head. The last-mentioned symptoms continued four years, with intervals of tolerable health of only a few weeks' duration. Menstruation was all along extremely irregular and scanty, and the bowels were torpid. The treatment during the six years previous to Dr. Abercrombie's attendance, had been copious, general, and local depletion; active purging and counter-irritation. She was of a pale and bloodless aspect, though not reduced in flesh. An entirely opposite plan of treatment was now adopted; three grains of sulphate of iron, combined with sufficient aloes to regulate the bowels, being exhibited three times a day. At the end of three weeks, a severe paroxysm of the rotatory motion of the head under which she was labouring, stopped suddenly; at the same instant menstruation took place in a more full and healthy manner than it had done for many years, and from that time she completely recovered. This case affords a striking example of the anomalous nervous affections in question, and is highly interesting from the result of the treatment.

The prognosis of convulsions is very uncertain; it depends on the nature of the causes, the age, the habits of life, and preceding diseases. When the affection is purely nervous, without fever, or any organic affection of the head, there is little to apprehend; but if the attack begin with symptoms of cerebral affection, or if it terminate in stupor or coma, the case is not free from danger. Acute organic disease is always attended with fever; simple nervous irritation is almost always without it. After a long-continued paroxysm, arising only from nervous irritation, the patient may fall into a state of stupor bordering on coma from mere excessive nervous exhaustion; this must not be mistaken for the coma of organic disease. Convulsions towards the end of fevers, or of inflammatory diseases of the brain, are always alarming.

We have already stated what were the conclusions to be drawn from the appearance of convulsions at the invasion of fevers and of eruptive diseases. Paroxysms of long duration are attended with danger. In those cases, in which from great nervous susceptibility convulsions are very easily excited, they more readily subside, and are the less dangerous; they are thus attended with less danger in women than in men, in youth than in old age. This fact had not escaped Aretæus, who said, *Mulieres nervorum distensionibus magis opportuna sunt quam viri, sed et frequentius etiam liberantur.*—Lib. i.

Causes.—The causes of convulsions are predisposing and exciting. The *predisposing* causes are either constitutional or accidental. Constitutions in which the nervous temperament predominates are the most obnoxious to convulsive affections. We know nothing of the essence of the nervous power, but one of the remarkable laws which regulate its operations is, that within

certain limits its irritability increases as its energy diminishes. The nervous temperament derives its essential characters from nervous debility, combined with an increased susceptibility to external impressions. This condition of the nervous system is commonly observed in persons of relaxed, debilitated, and delicate fibres; they are extremely sensitive to the action of all kinds of stimuli, whether physical or moral, and are endowed with great mobility of disposition and fickleness of temper; they are also frequently disposed by their laxity of fibre to plethora; and we shall see presently that over-distension of the blood-vessels is not unfrequently an exciting cause of convulsions. The nervous temperament is, however, sometimes observed in persons of a thin and delicate habit of body, and associated at others with a firm and rigid, though spare fibre. It is evident, from what has just been stated, that women and children will be more predisposed to convulsions than men or persons advanced in life.

The accidental predisposing causes are numerous, and most of them may become exciting causes. We may state, in general, that they are to be found in all external circumstances calculated to create debility either bodily or mental.

Exciting Causes.—It is generally admitted that the nervous power, whatever may be its nature, proceeds either from the brain singly, or the brain and nerves jointly. Although the muscles may appear to possess a certain degree of special irritability, it is incontrovertible that they derive their power of contraction from the nervous influence transmitted to them by the brain and different parts of the nervous system. The muscles of voluntary motion receive their nerves chiefly from the spinal marrow, and but few comparatively from the brain; the muscles of involuntary motion (the muscular textures of the thoracic and abdominal viscera) are mostly supplied with nerves from the ganglions of the great sympathetic, receiving only a few from the brain. The innumerable ganglia and plexuses of the great sympathetic appear to be formed principally by large and numerous branches coming from the spinal marrow. During a state of health, the contraction of the voluntary muscles is completely under the control of the brain, this organ being the seat of volition. But during convulsions the voluntary muscles are excited without the concurrence of the will, and are entirely withdrawn from its influence. Irritation in the brain alone is sufficient to produce general convulsions, in consequence of the great influence of that organ over every other part of the nervous system; but the existence of convulsions does not, on that account, always necessarily imply that there is an affection of the brain; it is easy to demonstrate by experiments that any kind of irritation applied either at the origin of the nerves in the spinal marrow, or in the course of the nerves themselves, will be sufficient to produce convulsions in all those muscular parts to which the nerves are distributed. A primary affection either of the brain or spinal marrow is not, therefore, essential to the manifestation of convulsions. Cullen, Dr. John Clarke, Brachet, and other writers have advanced the doctrine that convulsions are always the result of cerebral irritation; but this opinion is evidently

untenable. The occurrence of loss of consciousness in convulsive affections will depend on the brain being the seat of the disease, and on the manner in which it is affected; for a slight irritation of the brain, sufficient to excite convulsions, may exist without diminution of consciousness.

When the exciting cause acts on the brain, the convulsions are likely to be general, although partial convulsions are occasionally traced to some disease in the brain of very limited extent. If the exciting cause is applied to the spinal cord, all those parts receiving nerves from the portion of the cord below the seat of the irritation may be affected with convulsions: and if applied in the course of a nerve, the muscles to which that nerve is distributed will be alone affected; all convulsions produced in this manner may be considered as *primary* or *idiopathic*. But convulsions frequently occur in a very different manner, with respect to the seat of the exciting cause. Instead of its being applied either at the origin or in the course of the nerves, and the irritation being directly transmitted to their extremities, these pulpy extremities themselves receive the first irritating impressions from the various stimulating agents they come in contact with on the surfaces of the organs; these morbid impressions are then transmitted along the nervous fibres to the brain and spinal marrow, which organs communicate the irritation by reflection to the whole frame. The great sympathy of several organs with both the brain and spinal marrow becomes thus a prolific source of general disturbance to the entire nervous system, of which the uterine and digestive organs afford examples in the production of hysteria, and of various other convulsive affections. The convulsions occurring in the manner just described may be termed *secondary* or *sympathetic*. It is very remarkable that pain in any part, sufficiently severe to bring on convulsions, completely disappears during the fit.

The nervous power which acts on the muscles may be produced in excess or in deficiency, or it may be irregularly transmitted. The causes of nervous irritation are extremely numerous. One of the most simple is pressure: when applied mechanically to the brain of an animal, if slight, it causes convulsion; if great, numbness, paralysis, and coma. Pressure on the brain or spinal marrow may be the effect of congestion or inflammation. An habitual determination of blood to the head in people of a plethoric habit renders them very prone to suffer from convulsions. This is frequently the case in puerperal women. Inflammation of the membranes of the brain is generally attended with very violent convulsions, much more so than inflammation of the substance of the organ.

Among the other causes of pressure and irritation are to be reckoned extravasations of blood, the serous effusions of hydrocephalus, organic tumours, bony tumours or spiculae growing from the inside of the cranium, and injuries of the head with fracture and depression. Causes of a similar nature may affect the spinal marrow. There are other more indirect causes of cerebral irritation. It was observed by Morgagni, with respect to mechanical injuries, that the nearer they were to the head the greater was their influence on the brain;

that, for instance, a very slight cut over the orbit was more likely to excite cerebral irritation than a much severer wound in a more distant part. The severe cerebral irritation which sometimes attends dentition may be accounted for on the same principle. Carious teeth are often an active source of cerebral and nervous irritation, and have not unfrequently been the occasion of slight convulsions in individuals of very irritable temperament. The laceration of nerves is a very frequent cause of tetanus, or severe convulsions. It is singular that the muscles to which the injured nerve is distributed may be the last affected with convulsive action; convulsions, however, do not always follow inflammation of the nerves. Convulsions, either local or general, are likewise frequently occasioned by tumours compressing nerves in their course;* by contused and lacerated wounds of other parts, especially of ligaments and fibrous tissues; dislocations, compound fractures, &c., and finally, by intense pain, whatever be its source.

Gastric and intestinal irritation have always been considered among the most active causes of convulsions, especially in children; it may be sufficient to instance the convulsions occasioned by worms, and the distressing cramps so frequently experienced from the presence of acidity in the primæ viæ. We have already alluded to the great influence of the uterine functions on the brain and nervous system, and to their being a most frequent source of nervous irritation and convulsions. This arises in puerperal women from two causes—the distension and pressure of the uterus causing an accumulation of blood in the head, and the high degree of nervous susceptibility which attends the puerperal constitution.

Among the occasional causes of convulsions may be mentioned, exposure of the bare head to the heat of a burning sun; sudden transitions from heat to cold; suppressed perspiration; the suppression of eruptive diseases, such as variola, rubeola, and of many chronic cutaneous eruptions; and that likewise of old sores, and of the menstrual and hemorrhoidal discharges; the retrocession of gout and rheumatism, and of several other diseases. A strong excitement of the external senses sometimes produces great cerebral irritation. Very sensitive women have been thrown into convulsions by the scent of flowers, or by deeply impressive music, or the unexpected sight of an object either of interest or aversion: the effect of the smell of paint on some constitutions is also well known.

Moral emotions may be considered among the most powerful causes of convulsions, particularly when operating upon the sensitive minds of children. This is a point of considerable importance as respects the conduct to be pursued towards them, and the regulation of their dispositions. The exciting and the depressing passions act very differently; the first, as anger and excessive joy, throw the individual into a state of high excitement, causing a determination of blood to the head; the second, as fear, occasion a sudden collapse and prostration of the nervous power. There

* Sir H. Hallford mentioned, in a paper read before the College of Physicians, several cases of severe neuralgia of the infra-orbitary nerve, caused by the pressure of bony tumours within the infra-orbitary canal.

are numerous instances of an attack of epilepsy, chorea, or even of fatal convulsions, resulting from a sudden fright. Great mental exertion, loss of sleep, excessive anxiety, the abuse of spirituous liquors, by gradually exhausting the nervous energy, create an extreme degree of irritability, which has not unfrequently induced convulsive fits.

Convulsive affections are very much under the influence of habit; so that even after the removal of the exciting cause, there may be regular repetitions of the attack, in consequence solely of the portion of the nervous system which is affected having acquired a depraved habit. Many curious instances of this description are to be found in medical writings. These habits of recurrence are sometimes not broken off without great difficulty. Another peculiarity of convulsive affections is, that they can be acquired by the mere power of imitation. In sensitive children, and young females endowed with great nervous susceptibility and a lively imagination, the influence of example on the nervous system is very remarkable; the instances of individuals so constituted being seized with an attack of convulsions, chorea, or epilepsy, merely through the shock experienced by witnessing others affected in the same manner, are by no means uncommon. In the history of the dark ages, when superstition and fanaticism had a strong hold on men's imaginations, there are recorded several instances of nervous affections, combined with various hallucinations, having spread like epidemics, from the mere contagion of example. An extraordinary instance of the influence which the strong excitement of religious fanaticism is capable of exercising over the nervous system was seen as late as 1724 in Paris, during the persecution of the Jansenists: after the death of Deacon Paris, one of the highly revered chiefs of the sect, crowds of his followers went in pilgrimage to the place of his burial at St. Medard, where they fell on his tomb, and were apparently seized with the most violent convulsions: they asserted that, after passing through this ordeal, they arose miraculously cured of any disease with which they might be affected; and this practice was continued for a considerable time. Some of his disciples were no doubt impostors; but it is well authenticated that many credulous zealots actually worked themselves into convulsions by the mere power of their imaginations. Willis and several other writers state that convulsive affections of children have occasionally appeared as epidemics. A disease of this description carried off a great many children in Paris at the close of the last century; and it is remarkable that it attacked likewise young dogs.

Convulsions are also frequently produced by narcotic and irritating poisons. To obtain this effect, narcotics must be given in small doses; for if the dose be large, it may at once destroy the irritability, when coma and death will ensue without any struggle. The nux vomica seems to possess the specific virtue of exciting muscular contractility, and has on that account been successfully applied to the treatment of certain forms of paralysis. Most of the mineral poisons occasion convulsions by exciting violent inflammatory action. Exposure to the fumes of mercury and lead produces either a convulsive tremor or com-

plete paralysis, by weakening the nervous energy. The inoculation of the rabid virus is followed by the frightful convulsions of hydrophobia; and most of the other animal poisons have a similar property, though in a much milder degree.

Several of the causes we have enumerated have a direct tendency to excite in the brain or spinal marrow various degrees of congestion or inflammation; and there can be no doubt that in some cases this is the true pathological state of these organs. We must not, however, by any means consider this as the most common form of disease, for in the majority of cases the accession of the paroxysm is not attended by any vascular excitement, and there is merely a state of nervous irritation and functional disorder.

Convulsions are sometimes produced by a state of the brain the very reverse of plethora or vascular congestion; and when it is, on the contrary, deprived of the supply of blood necessary for the continuance of its functions. This often happens after a large and sudden abstraction of blood from the arm, or profuse hemorrhage, and during the last struggles of life. It should be remembered, therefore, that convulsions arise both from an increase and a diminution of vascular action; and that *nervous debility* is the essential character of that state of the nervous system in which they originate: *a repletione aut ab evacuatione fit convulsio*. is one of the aphorisms of Hippocrates. It is also deserving of notice that many of the appearances of vascular turgescence which may be observed in the brain and spinal cord in fatal cases of convulsion, are the mere accidental effect of the violent struggles of the patient in his last moments, the same as occur in all cases of violent death.

In the description formerly given of some *anomalous* convulsive affections, we noticed a variety of disorders of the thoracic and abdominal viscera, combined with great disturbance of the nervous system, and a violent convulsive action of many of the voluntary muscles; we stated that several of the complicated symptoms of those affections might perhaps be accounted for by a reference to the functions of the spinal marrow and of the great sympathetic or visceral nerve. Several ancient writers have conceived that many spasmodic, convulsive, and nervous diseases have their origin in affections of the spinal cord and great sympathetic. This was the opinion of Hoffman, Ludwig, Lieutaud, Burserius, Portal, &c. The functions of these divisions of the nervous system have been more accurately investigated since by Bichat, Legallois, and Ollivier; but the subject still remains involved in much uncertainty. They have made it, however, appear highly probable that many of the diseases of the thoracic and abdominal viscera are to be attributed to morbid conditions of the spinal marrow and of the ganglionic nerves of the great sympathetic. There can be no doubt that the sympathy existing between these two classes of nerves is much greater than is generally imagined; proofs of this are afforded by the great muscular debility of the lower extremities, and the severe cramps, which so commonly attend diarrhoea or dysentery, and chronic dyspepsia; and on the other hand by the attacks of diarrhoea, gastrodynia, and cramp

of the stomach, which are frequently the effect of cold and wet feet. In some chronic affections, moreover, of the thoracic and abdominal viscera, a careful examination of the spinal column has led to the discovery of one or several spots excessively tender on pressure, and by applying leeches or cupping-glasses and counter-irritants to those spots, we have seen in several instances severe palpitations of the heart, oppressive dyspnoea, gastrodynia, or great irritability of the stomach, relieved in a very remarkable manner: these are pathological considerations highly deserving of further inquiry.

[The greater part, if not the whole, of convulsive diseases may be referred mainly to the true spinal system of Dr. Marshall Hall, or, in other words, to the grey matter or chain of ganglia in the centre of the spinal cord. (See Dr. Hall's *Lectures on the Nervous System and its Diseases*: Lond. 1836; or, the *Physiological Works of Müller, Carpenter*; or, the writer's *Human Physiology*, 5th edit. i. 71: Philad. 1844.) In some of the cases, the mischief is in the spinal marrow itself, or is *centric*; but in the large majority of convulsive diseases, it is *eccentric*, or the irritation is conveyed to the spinal marrow by afferent nerves, and the morbid influence is reflected from the spinal marrow by efferent or motor nerves, so as to involve various organs. Strychnia, doubtless, acts *centrically*, or, in other words, upon the spinal centre, when it induces tetanic convulsions.]

Treatment.—In the account given of the pathology of convulsive affections, it is stated that they may originate in a variety of causes differing very widely in their nature, and that they are also considerably modified by age, sex, and temperament. The treatment adopted during the paroxysm must therefore be regulated by a careful consideration of all these circumstances. We must endeavour to ascertain whether the increased irritability of the nervous system, which is the primary source of all convulsions, proceeds from increased vascular action in the brain or spinal marrow, or from mere nervous irritation; and whether the exciting cause has its seat in the brain, spinal marrow, or course of the nerves, or the convulsions are to be attributed to the morbid condition of some other organ. If the convulsions occur in a full plethoric subject, with well-marked symptoms of cerebral congestion or inflammation, fifteen or twenty ounces of blood must be taken from the arm or jugular vein; and this may be repeated in ten or twelve hours, should the symptoms continue unabated; when the strength of the patient no longer admits of general depletion, or when the symptoms of vascular excitement are less urgent, local bleeding by cupping on the temples or nape of the neck may be employed, and in some cases may be conjoined with general bleeding.

In cases, however, depending chiefly on cerebral and nervous irritation, and characterized by a general delicacy of frame, spare habit of body, a pale face, small frequent pulse, irregular hysterical breathing, and other signs of a purely nervous temperament, copious bleeding is highly injurious, and only aggravates the symptoms by increasing the general irritability. There may be intermediate states, requiring a moderate degree of

local depletion, the discrimination of which must be left to the judgment of the practitioner. We must also add, that local plethora in the brain and other organs may sometimes exist with general debility, and that paleness and languor should not in such cases deter the practitioner from having recourse to local bleeding: the treatment of such cases requires, however, no ordinary degree of tact and caution. It is very important to bear in mind that the violence of the convulsions is not to be taken as a test of the strength of the patient, for no convulsions are more violent than those which occur after profuse hemorrhage and extreme prostration; and, as convulsions arise probably from mere cerebral and nervous irritation in a considerable proportion of cases, the practice of indiscriminate copious blood-letting in every case of sudden *fits*, so much in favour with the public and a portion of the profession, cannot be too strongly deprecated; the principles we laid down on this subject when treating of coma, apply equally to convulsions.

The application of *cold* is often of great service in convulsive diseases. Cold applications to the head are particularly beneficial, provided they be used assiduously; they may consist of cloths dipped in water and vinegar, or pounded ice put into a bladder; or a still better method is the affusion of cold water over the head, frequently repeated. The cold bath, which has been advised by some, may be suited to robust constitutions, but would be injurious, during the paroxysm, to the weak and irritable; the cold affusion, as recommended by Dr. Currie, is less objectionable, and in cases depending on pure nervous irritation, especially in hysterical females, the shock given by dashing cold water over the body has sometimes cut short the paroxysm, and prevented its recurrence. The same effect has been obtained by free exposure to cold air, especially in children, as recommended by the late Dr. Gregory, of Edinburgh. A free circulation of cool air round the patient is always most desirable.

The application of *heat*, through the medium of the warm bath, is highly beneficial and in very general use; it soothes, relaxes, and acts as a diffusible stimulus. The warm bath is therefore of great service in cases attended with a high degree of general nervous irritation, or in which cutaneous eruptions have been repelled, and particularly when there is a dry rough skin and great rigidity of fibre. The affusion of cold water over the head, whilst the patient is in the warm bath, or stands in warm water, is an excellent practice.

Purgatives have always been classed among the most powerful remedies in the treatment of acute nervous diseases; the operation of a brisk cathartic during the paroxysm has the effect in many cases of immediately subduing the violence of the symptoms, and more especially where they have been induced by a disordered state of the bowels: a combination of calomel and jalap is the most active and efficacious form of cathartic; in patients of a delicate constitution and in children, a preference should be given to the milder purgatives, such as calomel and rhubarb. When cathartics cannot be administered by the mouth, they will act almost as efficaciously in the form of injection. Whilst moderate purging is decidedly

beneficial, the repeated exhibition of drastic purgatives, which has been a favourite practice of late years in this country, cannot be too strongly condemned, as tending to induce a state of general exhaustion and nervous irritability similar to that which is the effect of excessive bleeding. No one can have been kept for a few days under the constant operation of brisk cathartics without feeling a considerable degree of languor and irritability. These objections are particularly applicable to the continued use of calomel and other mercurial preparations.

When the primary cause of all diseases was referred to the nervous system, and the various morbid phenomena were attributed to spasm and nervous debility, *opiates* and *stimulants* were largely administered on all occasions, and the death of the patient was often accelerated by over-excitement. In modern times, however, since the doctrines of inflammation have been so generally applied to the investigation of the nature of diseases, and their various symptoms have been referred to morbid conditions of the *vascular system*, practitioners have fallen into the opposite extreme, and laying aside all due consideration of the state of the nervous system, have employed such remedies only as tend to reduce excessive vascular action. In the class of affections under consideration, if the violent agitation of the nervous system continue, after adequate bleeding and purging, the administration of an opiate is clearly indicated, and will often be very advantageous. When prescribed under the circumstances stated, it should be given in large doses.

The external application of laudanum, in the form of frictions, combined with stimulating liniments, is an excellent mode of administering opiates, especially to children. Sometimes the direct application of opium to the skin, after the cuticle has been raised by vesication and removed, has been found a very efficacious method of exhibiting it.

The habitual use of opium creates, as is well known, an extreme degree of weakness and irritability of the nervous system. It has sometimes occurred that after the habit had been long acquired, and the opium has been suddenly withdrawn, the most formidable attacks of convulsions have supervened in consequence of the exhaustion and sinking of the nervous power; the patient must therefore be only very gradually weaned from his indulgence in the use of opium, some other less pernicious stimulant being, if possible, substituted. We have known the *spiritus ætheris nitrici* and camphor mixture given in such cases with considerable advantage. The above remarks are equally applicable to the abuse of spirituous liquors.

A variety of *antispasmodics*, such as ammonia, musk, æther, camphor, valerian, and other medicines of this class, have been recommended to mitigate the violence of the paroxysm; their powers, however, are so doubtful that they are not entitled to much confidence. These remedies appear sometimes to afford relief by facilitating the expulsion of flatus from the stomach and bowels. It may also be added, that when there are symptoms of acidity in the stomach, alkaline medicines combined with antispasmodics and aro-

matics may be given with advantage; a teaspoonful of calcined magnesia in some aromatic water has been known immediately to relieve a fit of asthmatic dyspnœa or severe cramps in the lower extremities.

Counter-irritation is beneficial when applied with due moderation; large blisters to the head are decidedly injurious, preventing the application of cold, and having rather a tendency to increase the cerebral irritation; small blisters are therefore preferable, and their revulsive effect is best obtained by applying them to the feet, calves of the legs, the inside of the thighs, or along the spine. Sinapisms and other stimulating poultices may be used in the same manner, or the feet and hands may be immersed in a mustard bath: these simple remedies of former times are too much neglected in the present day.

Convulsions arising from profuse hemorrhage or after excessive bloodletting, are generally attended with giddiness, fainting, dull throbbing, pain in the head, and a tendency to coma; under such circumstances we must have recourse to the administration of diffusible stimulants in small and frequently repeated doses: brandy in warm gruel is the stimulant, perhaps, to be preferred; it may be given alternately with carbonate of ammonia or æther. Whilst the head is kept cool by evaporating lotions, great care must be taken to preserve a due degree of heat in the extremities and on the surface of the body by the usual means.

In cases of convulsions from poisons, the first object will be to evacuate the stomach by the exhibition of powerful emetics, or the employment of the stomach-pump; the subsequent treatment must vary according to the symptoms and nature of the poison, as will be detailed under the proper head. We refer to other articles in this work for the treatment of convulsions occasioned by the action of lead and mercury on the animal economy; the modifications applicable to the treatment of puerperal and infantile convulsions are also detailed in their proper place.

The local treatment required when convulsions are occasioned by wounds of the nerves, or the laceration of any part of the body, will be specified in the article *TETANUS*. In convulsions depending on organic disease of the brain of long standing, the treatment, it is obvious, can only be palliative.

The regulation of the *prophylactic* treatment is of the highest importance in all convulsive affections, but more particularly in those anomalous, severe, and protracted cases which were described under a separate section. The paroxysms in such cases frequently resist every attempt to subdue them, and little can be done but to mitigate their severity. We stated that these anomalous affections are distinguished by considerable disorder in the functions of the uterine or digestive organs, and by a highly disturbed state of the nervous system, depending on some morbid condition of the brain, spinal marrow, or nervous apparatus of the great sympathetic; and that there is often great difficulty in ascertaining whether the disease originates in a primary affection of some portion of the nervous system, or in the morbid condition of any of the other organs. Our

attention should, therefore, be directed, after the removal of urgent symptoms, to the gradual amelioration of the general health, as the most effectual means of overcoming diseased action in particular organs.

Our remarks on the injurious effects of excessive *bleeding* and purging during the paroxysm are particularly applicable to the prophylactic treatment. It has frequently happened that the dull headach and vertigo, wrinkled brow, throbbing of the temporal arteries and carotids, convulsive twitches of the features, watchfulness and restless anxiety, with alternate states of chill and morbid heat, rapid, small, irregular pulse, and subsultus tendinum, which are sure indications of that extreme irritability of the brain and nervous system so appropriately called *cerebral erethism* by Dr. Whitlock Nicholl, have been mistaken for symptoms of inflammation; and this serious error has led to a perseverance in those very measures which have induced and are calculated to aggravate the morbid condition in question. Instances of this description have not unfrequently fallen under our own observation; and a remarkable one is afforded in the case we have quoted from Dr. Abercrombie. Although copious and frequent bleeding may appear to afford temporary relief when there are symptoms of plethora, it increases the laxity of fibre which so strongly predisposes to a plethoric habit. A tendency to plethora in the head will be best counteracted by occasional revulsive bleeding from the lower extremities: as, for instance, the abstraction of a few ounces of blood from the feet by means of leeches, or the opening of a vein, the bleeding being encouraged by immersion in a warm foot-bath. We have found this plan particularly useful in cases of suppressed or irregular menstruation, and by having recourse to it at the approach of the menstrual period, or on the first appearance of any of the symptoms threatening an attack of convulsions, we may often succeed in warding it off.* Bleeding along the course of the spine by leeches or cupping, particularly when there is tenderness on pressure, will sometimes relieve very distressing symptoms of dyspnea, palpitation, vomiting, and gastrodynia, or partial convulsions of the muscles of voluntary motion; this is a practice hitherto too much neglected. Leeches may also be applied with advantage to the rectum. It ought, however, to be made a general rule not to carry blood-letting to such an extent, with respect either to its frequency or amount, as to impair the general strength, unless there be decided symptoms of inflammation. Counter-irritation along the spine by means of blisters, tartar emetic ointment, and stimulating embrocations combined with opium, has been found a very useful adjunct to local depletion in convulsions depending on affection of the spinal marrow.

Whilst violent purging is to be deprecated, a moderate course of alterative *purgatives*, if judiciously managed, will generally form an import-

ant part of the prophylactic treatment. The function of secretion appears to be under the special control of the nervous system, whatever influence chemical affinity or galvanic agency may be supposed to have over the ultimate changes of the blood in the secreting organs: hence it is that in all cases of long-continued disturbance of the nervous system, we find the secretions vitiated, and becoming in their turn sources of irritation: this is well exemplified in chlorotic women, and in chronic mental alienation. The secretions, therefore, in nervous diseases should always be carefully examined, and means adopted to restore them to a healthy state. This is to be principally accomplished by the continued exhibition of mild purgatives for a certain length of time, so as to obtain free and natural evacuations, but stopping short of the irritating and debilitating effects of active purging. We must be guided in the selection, dose, and frequency of repetition of the aperients by the habit of body of the patient, the appearance of the tongue, and state of the stomach, and the nature of the alvine and urinary discharges. We have found a combination of equal parts of the *massa pilulæ hydrargyri*, *pilula rhei comp.* and *extractum catharticum*, produce the desired effects.

Tonic and *antispasmodic* remedies, given either singly or in combination with purgatives, are in general remarkably well suited to that state of the nervous system which predisposes to convulsions. We would observe, however, with respect to this class of remedies, that if given so as to create a high state of habitual excitement, their effects will be decidedly injurious. The practice, therefore, of administering indiscriminately strong doses of ammonia, ether, or valerian, and allowing a free use of wine, to nervous and hysterical women, is often highly improper. We can only expect to do good as far as we can succeed in gradually and permanently increasing the tone of the nervous system. This effect may be fully obtained by moderate doses of some of the tonic and antispasmodic medicines, given for a considerable length of time, in conjunction with gentle aperients. The preparations of iron and bark are the tonics generally to be preferred, for their great efficacy in restoring the tone of the nervous system whenever it has been gradually much impaired. Iron has also the advantage of acting as an emmenagogue, and correcting that deficiency and irregularity in the functions of the uterus which is so often the sole cause of the disordered state of the health: a striking instance of its power in this respect is afforded in the case of anomalous convulsive diseases already alluded to, as quoted from Dr. Abercrombie. We have used with considerable advantage, in similar cases, the carbonate of iron combined in a mixture with carbonate of ammonia and tincture of aloes; it must be given to the extent of between one and two drachms in the twenty-four hours: when carried beyond this dose, it remains accumulated and perfectly inert in the alimentary canal. The preparations of zinc, the solution of arsenic, the nitrate of silver, and several of the fetid gums have likewise been strongly recommended, and may no doubt on many occasions be given with benefit. All medicines acting on the nervous system lose

* Dr. Prichard, in his able work on Nervous Diseases, has given an excellent account of the convulsive affections which not unfrequently accompany disordered menstruation, and of the mode of treatment; to which the reader is referred for more ample details.

their effect by habit; and it is a good general rule to substitute occasionally one for another.

The cold and warm *bath* are still more valuable remedies in the prophylactic treatment of convulsions than during the paroxysm. The daily use of the cold shower-bath, with the feet immersed in hot water, and also cold sea-bathing in summer, tend powerfully to increase the tone of the nervous system. The warm bath or tepid shower bath must be ordered for delicate patients, too sensitive to bear the sudden impression of cold; out it is very desirable to lessen by degrees this extreme susceptibility, by lowering gradually the temperature of the water. We must in general be guided by the feelings of the patient and the vigour of the constitution in the choice of the cold or warm bath. There is a remarkable sympathy between the functions of the skin and those of the brain and nervous system; and it is always of great importance to excite a healthy action of the skin, which is generally dry and torpid, in persons subject to convulsive affections. The natural vapour-baths found in the caverns of the volcanic mountains in the neighbourhood of Naples were in great repute for the cure of convulsive diseases among the Romans, and are still much resorted to by the present inhabitants of the country. We have seen the use of vapour-baths attended with the very best results in some intractable cases of convulsions.

There are few things of greater importance in the treatment of convulsions than the regulation of the *diet*; for a disordered and irritable state of the stomach and bowels frequently operates as an exciting cause. In cases attended with general plethora and a tendency to cerebral congestion, the diet must be very spare; animal food and fermented liquors are to be entirely prohibited, and a milk and vegetable diet, with light broths, prescribed. By persevering in this soothing plan, attacks of convulsions threatening to assume the character of regular epilepsy have been completely overcome. In cases, however, of an opposite description, characterised by languor and irritability, the diet, although simple, should be nourishing.

The moral management of the patient requires attention; pains should be taken to remove him from the influence of every predisposing and exciting cause, such as crowded hot rooms, late hours, sedentary habits, mental anxiety, &c. It is of consequence to provide some occupation or diversion for the idle, in order to withdraw them from the study of their own feelings; as few things tend more to increase nervous irritability than a mind preying on itself. The power of volition over the functions of the nervous system is greater than is generally supposed. When convulsions recur from mere habit, this morbid habit has in some cases been completely broken by a strong and sudden effort of the will: it is advisable, therefore, not to encourage such patients to yield to their feelings by showing them too much sympathy, but rather to remonstrate with them temperately, insisting that they have it greatly in their power to resist the first approaches of the paroxysm, if they will only resolutely determine to exert it. It is quite certain that children have been frightened *out* of convulsions as well as

frightened *into* them; and it is by acting on the nervous system through the medium of the imagination, that quacks, soothsayers, and fanatics have acquired such celebrity in the cure of nervous diseases.

ADAIR CRAWFORD.

I. CONVULSIONS, INFANTILE. The present article is intended to include only those convulsive diseases which are either peculiar to the earliest periods of life, or are accompanied with such circumstances as modify the symptoms, and require some peculiarity in the treatment. Convulsions are so frequent in young children, and so often fatal, that it becomes of great importance to consider whether their nature, causes, and treatment are properly understood. Without hesitation it may be stated, that till very recently authors and practitioners were by far too apt to generalize in these cases, and the practice consequently degenerated into routine, and that often on mistaken principles. In most cases the convulsions of young children are symptomatic of some other disease, [or are eccentric;] but although the recollection of this fact is extremely important,—as upon the nature of that particular disease the treatment chiefly depends,—yet there is sufficient danger in the immediate attack to render it proper to give a full history, in the first instance, of the affection itself, the symptoms which are present, and the best mode of alleviating them.

History of the Attack.—Mr. North, in his excellent work on the convulsions of infants, has described various symptoms which may be considered premonitory of an impending attack, independently of the existence of any particular disease, and all of which evince an increased irritability of system. The most striking of these alterations in the child's usual habits are, the starting at very slight noises, a disturbed sleep, with frequent fits of crying from trifling causes, and great peevishness of temper. There is, also, often, a frequent fixing of the eyes, an oscillatory motion of the pupils, a momentary contraction, and again a sudden dilatation of the pupil, and a want of consent between the pupils of both eyes, so that one will contract whilst the other dilates. The countenance is alternately flushed and pale; sudden animation is followed by as sudden a fit of languor, and irregularity in the breathing, particularly with short catchings of the breath followed by long and deep inspiration. Hiccough, too, frequently occurs. The fingers are kept constantly twitching, or the hand is clenched, the thumb stiffly contracted on the palm, the toes drawn in, and the foot and wrist bent downwards. To these symptoms may be often added a peculiar blueness about the mouth, and a pinched countenance. Many of the above appearances, however, are overlooked by the attendants; and often without any warning whatever a convulsion takes place.

In the attack itself there is, says Dr. John Clarke, "a universal spasmodic contraction of all the voluntary and many of the involuntary muscles of the body, accompanied by foaming at the mouth, protrusion of the tongue, staring of the eyes, distortion of the eye-balls, laborious and obstructed respiration, sometimes accompanied with a violent redness of the face and scalp at the be-

ginning of the paroxysm, followed by a purple colour of the whole body at the end of it." This, however, is the history of a severe case: there may be only slight twitchings of the face or of the limbs, with a distorted eye, and bluish circle round the mouth. The limbs may be alternately relaxed and contracted, and only one part or one side of the body may be convulsed at the same time: in some instances this happens alternately with a similar affection of the other side several times in regular succession. As the paroxysm subsides, the convulsive motions become gradually less violent and less constant; the natural colour and appearance returns; the child takes a deep and full inspiration and is then able to cry; and frequently a refreshing sleep succeeds. The attacks may be renewed and again subside several successive times, till perfect relief is obtained; or, on the other hand, even the first paroxysm may be fatal. The convulsions may be momentary, or may last only for a few minutes; or they may continue, with but short intervals, for a great many days. Except the exciting cause of the paroxysm is of such a nature as to be attended with fever or disturbance of the intellectual functions, these characters are not essential to an attack of convulsions.

Pathology.—It has been laid down as an axiom by the late Dr. John Clarke, that "in every case of convulsion the brain is at the time organically affected, either directly or indirectly." As the management of the case depends essentially upon a correct view of this important question, it is highly necessary to investigate its accuracy. Mr. North has very ably exposed the fallacy of Dr. J. Clarke's assumption, and the errors into which a supposed existence of "head affection" has led many practitioners. That the nervous system is implicated in the immediate convulsion is not denied, but that the brain is "organically" affected, or that even a congested state of the vessels of the brain takes place in every case, is extremely improbable. The brain is often in a very opposite state to that of vascular excitement or plethora; being on the contrary, from the continuance of exhausting causes, placed in that condition of "diminished energy of the vital force," which leads to what has been called nervous irritability. The distinction between these two opposite states may be recognised by an observant eye with tolerable facility, and by attending to the previous history and condition of the patient, and to some peculiarities in the attack itself. Where there has been a hot skin, particularly of the head and face, a flushed countenance, a rapid and hard pulse, a suffused red state of the conjunctiva, a contracted pupil, with intolerance of light,—an excited circulation through the brain very clearly exists, probably leading on to inflammatory action. And again, where the child is heavy and stupid, the pupils dilated, the eyes occasionally or constantly contorted, and the power of fixing both on the same object much impaired; the pulse irregular or slow; the veins on the forehead, neck, and scalp, turgid and dark; the countenance bluish; the head large, occasionally hotter than natural; and the *fontanelle permanently elevated and convex*;—a congested state of the vessels of the brain, especially of the sinuses, evidently

exists. But on the other hand, it is very common to meet with convulsions where the child is pale and thin, the body wasted by illness or by violent and exhausting remedies, the skin cooler than natural, and the veins on the surface apparently bloodless. In such cases the head, at first sight, looks disproportionately large, but this will be found to be an erroneous impression, arising from the diminished bulk of the body and neck. In this description of case, also, there is a very important guide, (though not noticed in books on the subject,) viz.: the *fontanelle being depressed and concave*. Although there may be drowsiness and stupor, a dilated pupil and squinting, and although during the immediate convulsive paroxysm, by the violence of the muscular agitation, the countenance becomes flushed, the vessels of the scalp loaded, and the fontanelle elevated, yet this condition is only temporary, and any thing but a state of vascular energy or plethora can be supposed possible. The eyes of the profession have been opened latterly to this condition of the brain in infants, as simulating *hydrocephalus*, by the writings of Drs. Gooch and Marshall Hall; and the same valuable observations are quite as applicable to the subject of convulsions. It will be easily understood, therefore, how faulty must be the routine practice of abstracting blood, as a matter of course, in all cases of convulsions. [See Dunglison's *Practice of Medicine*, 2d edit. ii. 222: and his *General Therapeutics and Mat. Med.* ii.: Philad. 1843.]

Causes.—It has been already stated that infantile convulsions, in nearly every case, are to be considered rather as symptoms of other affections, and our mode of treatment must be in a great measure influenced by the supposed cause. It may be doubted, indeed, whether real idiopathic convulsions ever occur. These causes are so numerous that it would be nearly impossible to enumerate them all, and many can only be just alluded to, as the diseases themselves are treated of in other parts of this work.

From the first moment of birth a child is liable to convulsions, from pressure on the head during labour, or from mechanical injury in an artificial delivery; and there is not a malady which can occur during the early period of infancy which may not give rise to an attack. Retention of the meconium, stoppage of the urine, an ill-conditioned state of the umbilical cord after division, an irritable, relaxed, or loaded state of the bowels, a full stomach, air in the intestinal canal causing painful gripings and oppression, improper food, a strong glare of light, and loud noises, are amongst those causes which are most apt to occur in the first few weeks of infant life. As soon as the process of teething commences, from the great irritation and often febrile excitement produced, convulsions are liable to be brought on with every tooth, as it makes progress through the gums. Worms in the intestines frequently excite convulsions, their presence in the body being distinguishable by the usual symptoms. The sudden drying up of cutaneous eruptions, or of discharging sores behind the ears or upon the head, without keeping up at the same time a free evacuation from the bowels or elsewhere, is occasionally followed by convulsive attacks; and the onset or sudden sup-

pression of measles, small-pox, or any eruptive febrile diseases, is often accompanied by them. A fit of whooping-cough will often terminate in a regular convulsion from the violence with which the blood is driven to the head, and the difficulty with which it circulates through the lungs. The frequent improper drugging of children with ardent spirits, or patent medicines containing opium, for the purpose of keeping them quiet and procuring sleep, keeps the tender nervous system of an infant in such a state of irritability, that convulsions will very probably supervene; besides the chance of an over-dose at once inducing an attack. Convulsions may occur from mere pain, however caused, if severe and long continued,—the degree of pain required of course depending on the condition of the child at the time, as to an irritable or a plethoric state of the brain. In the same way, sudden frights, violent passions, fits of crying or of coughing, and any rapid rotatory motion, may be causes of attacks. Blows on the head, concussions of the brain, organic lesions of that organ, tumours, bony deposits, or coagula within the cranium, inflammation of the membranes, and either chronic or acute hydrocephalus, must also be enumerated among the causes of convulsions.

Infantile convulsions have been stated to be sometimes epidemic, but as Mr. North has very properly observed, it would be more correct to presume that from local causes some epidemic disease had prevailed, of which convulsions were symptomatic.

Prognosis.—In prognosticating the result of a convulsive attack, regard must be chiefly had to the causes, if they can be ascertained, the possibility of removing them being the ground on which we should rest our opinion; but though this will be our safest guide as to the probability, it must always be recollected that any single paroxysm, if severe and long-continued, may be fatal: we must also be partly guided by the constitution of the child; a very irritable constitution will be thrown into convulsions by much slighter causes than one more robust and of a less degree of susceptibility; the prognosis, therefore, in the latter cases should be more guarded.

Treatment.—The treatment of the immediate attack is generally well understood, even by mothers and nurses. The great point perhaps is not to attempt too much. A warm bath is usually the first thing tried, and will often alone be sufficient to abate the paroxysm, but is not to be used indiscriminately. [There is generally, however, so much hurry and confusion, and the warm bath is, withal, attended with so much inconvenience, that it has been abandoned by many. By some, friction with a warm flannel is substituted for it.] Other means are—dashing cold water on the face and head, wet cloths or pounded ice constantly applied to the scalp, [or to the neck and spine; (R. B. Todd, *Lond. Lancet*, April 30, 1842,)] clusters of aromatic distilled waters, or of assafoetida, combined with castor oil or the neutral salts; chafing the hands and feet with brandy or aether. Should the abdomen be distended with air, which is very commonly the case, a few drops of sal volatile may be given in peppermint-water, and the belly rubbed freely with the hand, or with any gently stimulating liniment. A purgative of an

active character, consisting of calomel with jalap or scammony, may be given if the child can swallow; or, should any improper article of food have been recently taken, an emetic should be administered. It is not always possible to collect accurate information on this point at the time, for it does not always follow that the offending aliment should have been very recently eaten. The writer attended a case where, vomiting being excited, immediate relief was obtained by the expulsion of several undigested raisins, which had been given to the child (four years of age) nearly a week before. It is the constant plan of some practitioners to abstract blood in all cases of convulsions in young children; but, as we have shown already, this is not to be defended in all cases by reason, nor does experience justify the practice. Where, however, a plethoric or too energetic condition of the vessels of the brain obtains, it is undoubtedly desirable to relieve the head by bloodletting. Very often, where there is an obstinately constipated state of the bowels, purgative medicines will not succeed in removing some offending matter from the intestines until cerebral pressure has been removed by taking away blood from the neighbourhood. For this purpose, opening the jugular vein is the readiest and perhaps the most effectual method; or, should it be preferred, cupping, or the application of leeches on the temples, or behind the ears, may be had recourse to. The quantity of blood drawn must depend on the strength of the child and the violence of the symptoms; and although on the whole, under such circumstances, children of a tender age bear the loss of a larger quantity of blood than would be supposed, very safely, yet care must be taken lest the child be brought into that state of exhaustion in which convulsions are very apt to occur from an exactly opposite cerebral condition. The writer of this article saw a plethoric child, of a year old, cupped to fainting during a severe convulsive attack, and no sooner had the faintness subsided, and the child was left bleached, with a *depressed* fontanelle, than a second and still more violent convulsion took place, from which it was with extreme difficulty recovered. Should the child be of an age at which the process of dentition would be at all likely to be going on, we should be overlooking a very essential part of the treatment if the gums were not to be freely and extensively scarified: long before a tooth is near the surface this is often of great service, and removes one of the most frequent causes of irritation. Should the case be one of great irritability of brain without plethora, after attacking the exciting cause where it is possible to remove it, should the convulsions still continue, antispasmodic medicines may be liberally administered, such as the assafoetida mixture, ammoniac, camphor, aether and musk, and even opium; but from the uncertain effects of the latter medicine on very young children, this must be done with great caution. Where there has been a very irritable state of the bowels, opium is particularly useful when combined with chalk and aromatics; the pulvis cretæ compositus cum opio of the Pharmacopœia is a convenient form, from the small quantity of the opiate which it contains; from one to ten grains may be given, according to the age of the child, and repeated

every hour or two, till the desired effect is produced. Most of the advertised *convulsive powders*, as they are termed, consist of chalk combined with musk and aromatics. In some instances, and not always in very weak and exhausted children, there is constitutionally an exceedingly irritable state of the nervous system, leading to convulsions resembling those of an epileptic nature. In these cases, tonics of a very decided character, iron for instance, have been found by the writer sometimes as useful as they have been long known to be in a more advanced age. A child *two months* old, large and fat, was seized with violent convulsions suddenly, the bowels having been disordered from bad breast-milk for a few days previously. The convulsions lasted for *seventeen days*, sometimes occurring three or four times in an hour, and never ceasing for more than four or five hours at a time. The fontanelle was depressed and concave always in the intervals of each paroxysm, and no blood was taken in consequence; the treatment consisting of antispasmodics, external applications, clysters, purgatives, and also of opiates, one drop of laudanum having been administered every hour for a considerable number of doses. This treatment was pursued for a fortnight with no permanent improvement. On the seventeenth day the bad success of the previous remedies induced the writer to try the carbonate of iron, of which five grains in honey were given every two hours for two days. After the second dose the face became florid, the fontanelle elevated, and the convulsions ceased. In the intervals of the fits the child took copiously of breast-milk, by means of a spoon, during the whole period. The infant remained well for a twelvemonth, and then died from hooping-cough.

[In the asphyxia, occasionally seen in the convulsive fits of children, it has been advised to practise artificial respiration by breathing into the mouth of the infant from the practitioner's own, closing its nostrils, compressing the thorax after each inflation, and observing the natural periods of frequency as nearly as possible.]

When the immediate paroxysm of convulsion has been subdued, its recurrence must be carefully guarded against by attentively investigating the state of the child's health up to the time of the seizure, and also avoiding and removing what may appear to have been the remote cause of the immediate attack. It is too much the fashion in all cases where fits have occurred, at once to begin a system of starvation and depletion. It is obvious that this plan can only be adapted to the cases where there are evident signs of plethora or of determination of blood to the head. Where exhaustion and emaciation already exist, a carefully graduated strengthening plan, both of diet and medicine, becomes proper, and, united with quiet, and a change to a purer atmosphere, will often answer our most sanguine expectations. It would only be useless repetition to detail the treatment proper to each of the many causes of convulsions enumerated above; we refer to the different disorders under their respective heads. It will be sufficient to recollect that when once children have been seized with convulsions, they are very likely to recur, even from causes very dissimilar to those which produced the first attack;

the brain remaining more susceptible than before. Every thing which may add to this susceptibility should be carefully avoided; the bowels should be regulated, the diet narrowly watched, both as to quantity and quality, the exercise kept within bounds, heated rooms and late hours interdicted, and even the moral and intellectual education should be conducted with reference to this condition of brain,—too great and too frequent mental excitement being highly pernicious.

Before concluding this article it is proper to notice that very young infants are often affected with what nurses call "inward fits." In these cases there is a rolling about of the eyes when asleep, a drawing down of the mouth with slight twitchings, frequent smiling during sleep, and occasionally a little blueness about the mouth. These symptoms are owing generally to distension of the stomach and to flatulence, and are easily dispelled by frictions on the stomach, back, and bowels, or a little sal volatile, or some of the aromatic distilled waters.

There is a convulsive affection of a very peculiar character which attacks very young children, and was described first by Dr. John Clarke, in his Commentaries on the Diseases of Infants. It has been named "*cerebral croup*," "*spasm of the glottis*," "*the crowing convulsion*," &c. The particular account, however, of this interesting disease, will be found in a separate article. See GLOTTIS, SPASM OF.)

[A peculiar form of convulsions has been described, which consists in bobbings of the head forward. These are slight at first, but in process of time they may become so frequent and powerful as to cause a complete heaving of the head forwards towards the knees, and then immediately relaxing into the upright position,—something similar to the attacks of emprosthotonos. (J. W. West: *Lond. Lancet*, Feb. 13, 1841.) The child does not lose its consciousness. Sir Charles M. Clarke, who had seen four cases of it, from the peculiar motion of the head termed it *Salaam Convulsion*. In some of the cases that have lived beyond the age of puberty, idiocy has occurred. The pathology of the affection is unknown. As remarked by the writer elsewhere, (*Practice of Medicine*, ii. 224.) it would be curious to observe, whether the lesion give any countenance to the views entertained by Magendie in regard to the cerebral seat of the forward impulsion, referred to under Chorea, (q. v.)]

C. LOCOCK.

II. CONVULSIONS, PUERPERAL. In a work not professedly devoted to midwifery, a notice of this formidable occurrence must of necessity be brief.

History of the Attack.—The real puerperal convulsions can scarcely be mistaken for any other disease, and when once seen and recognised are not likely to be soon forgotten. They may occur not only during the process of parturition, but also in the latter period of pregnancy, and again in the first few days after delivery. They are generally ushered in by certain precursory symptoms; but sometimes there is no warning whatever, or one so slight as to have escaped the notice of the attendant. Usually, however, preceding the attack there is dull pain and weight in the head, constant drowsiness, flushed coun-

tenance, with a full slow pulse, and partial or occasional failure of sight. At other times, or in other cases, the preceding symptoms are succeeded by sudden and most acute pain in the head, loss of sight, or the sensation of dark, or of bright, fiery objects moving before the eyes, ringing in the ears, and generally sickness, with pain and oppression at the pit of the stomach. The patient is then seized with twitchings of the face or a rigid contraction of the jaw, followed immediately by violent universal convulsions, resembling in many respects an attack of epilepsy. The face is distorted, the tongue protruded, with foaming at the mouth, and a peculiar deep hissing noise from breathing sharply through the closed teeth; the eyes are fixed or rolling irregularly, the pupils dilated, and the limbs are strongly and convulsively agitated. After a time the paroxysms terminate in stupor, with stertorous breathing, from which, after an uncertain interval, the patient will often awake suddenly, unconscious of any thing which has passed, and apparently well: shortly after, perhaps, the convulsions again return, and several successive fits of a similar character may recur. Apoplexy occasionally follows, and the patient may then die in the comatose stage; but this termination is not frequent where proper curative means have been employed. The occurrence of apoplexy may be considered rather as an accidental complication, not by any means necessarily attendant upon the disease.

Causes.—The immediate causes of puerperal convulsions are often very obscure. They appear sometimes to depend upon a loaded state of the vessels of the brain; at other times the brain appears to be influenced by distant irritation, either in the uterus or in the digestive organs; and again, in some cases, puerperal convulsions are induced apparently by a peculiar irritability of the nervous system. It has been remarked that there has been a greater disposition to puerperal convulsions in those patients who have been in early life subject to convulsive attacks, particularly of an epileptic character; and also in those who have suffered similarly in former labours, and have omitted those measures usually employed as precautions. That the uterine organs are in some way particularly implicated, is evident from the convulsions being of a character which may be said to be peculiar to the state of either pregnancy or parturition.

The immediate attack may be brought on by a loaded or disordered stomach, or by food, however small in quantity, of an indigestible kind. Some substances, shell-fish for instance, have been found very frequently to induce convulsions in the puerperal condition, when at other times they may have been taken by the same individual with perfect impunity. A sudden fright, afflicting intelligence, or any unexpected or depressing mental emotion may excite the paroxysm; hence it has been long remarked that unmarried women are more particularly likely to be sufferers from convulsions, from the circumstances of shame and distress under which their children are usually born. The violent straining caused by labour-pains, and even the disturbance of the frame by the earlier uterine contractions, causing a tempo-

rary rush of blood to the head, will sometimes bring on convulsions.

It must be recollected that although convulsions occur most commonly under the circumstances described, they occasionally take place also in a very exhausted state of the frame, when the system has been nearly drained of blood by excessive uterine hemorrhage, or other depletions. In these instances there is generally considerable danger, partly from the great irritability consequent upon the exhaustion, so that much slighter causes will produce more violent effects, and partly from the greater difficulty of applying remedial measures. In these cases the pulse is rapid and weak, and the countenance pale and bloodless. Half a century ago, puerperal convulsions were much more fatal than at present; for we are told by writers of the period, that upon an average, full half of the patients died; whereas now, as is well known, when properly treated, they usually recover.

[From the reports of different observers, collected by Dr. Churchill, (*The Theory and Practice of Midwifery*, Amer. edit., by Professor Huston Philad. 1843,) it would seem that about one case in four has terminated fatally; although this is doubtless more than the average. Examination after death throws little or no light on the pathological condition. Often, nothing morbid has been perceptible. At other times, there has been hyperæmia or effusion of serum. The neurine is doubtless affected, but in a manner at present not appreciated. The disease is, in other words, a neurosis.]

Treatment.—This is to be regulated especially by noting the cause of the particular attack. As a general rule it may be stated, that copious abstraction of blood in a large stream is the most efficient means of shortening the attack and securing the safety of the patient. Where the pulse is strong and full, and the frame robust, the quantity that may be taken with impunity and advantage is often very great; and where from circumstances it is difficult to procure a sufficient supply from the arm, the temporal artery may be opened, or cupping-glasses applied behind the ears or on the temples. [Advantage, too, may accrue from compressing the carotid arteries in the manner advised for several convulsive affections, (*New Remedies* 4th edit. p. 188: Philad. 1843.)] An active purgative, as scammony, senna, or jalap, combined with calomel in a full dose, may be given; or if there is a difficulty in swallowing, one or two drops of the croton oil may be smeared upon the back of the tongue. An injection of a stimulating and purgative character may also be thrown into the rectum; and for this purpose nothing perhaps is more effectual than turpentine. Cold washes, or bladders containing pounded ice may be applied to the head, and hot mustard poultices to the feet. The propriety of repeating the bleeding, and the time of doing so, either locally or generally, must depend upon the power of the patient and the state of the pulse as well as upon the continuance of the symptoms. In the comatose state, or in what may be called a more chronic stage of the disease, blisters to the head or to the back of the neck may be of service, but they are scarcely admissible previously. In this stage a free action should be kept up from the bowels, and

the turpentine enemata are especially useful. For some considerable time after the immediate symptoms are subdued, the patient must be kept perfectly quiet, all causes of irritation must be avoided, and the diet should be spare and simple.

[Whilst it is deemed advisable to diminish the quantity of the circulating fluid, the patient should abstain as much as possible from watery drinks, inasmuch as under the copious draughts from the circulating system, they would not fail to pass readily by imbibition through the coats of the blood-vessels, and supply the loss that had been sustained.]

Where the patient has been, before the attack, much reduced from exhausting illness, or from hemorrhage, we are not always to think it necessary to bleed, and to bleed furiously. Bloodletting must in such cases be had recourse to with very great circumspection; and if necessary at all, local bleeding, with the other remedies mentioned above, is all that we should venture upon. It is well known that dogs have been bled into convulsions, and it is probable that a similar condition of circulation in the brain exists in the cases now referred to. There has been much discussion as to the propriety of giving opium in puerperal convulsions, some having spoken very highly of its advantages, while others have decidedly thought it pernicious; but this difference of opinion has arisen solely from the want of distinction between the character of the cases to which it is or is not applicable. Experience of this fact has led the writer of this article to believe, that whilst opium is certainly injurious in puerperal convulsions of the class first described, it is often, especially when combined with full doses of camphor, most salutary in the latter, as well as in those cases of an hysterical character presently to be mentioned. From one to two grains of opium, with four or five of camphor may be given, and repeated every hour or two till the proper effect is produced; and in the exhausted cases described, the desired effect is to subdue the paroxysms, strengthen and steady the pulse, and restore colour to the countenance. Another point of dispute has been, whether emetics are appropriate remedies in these attacks,—the doubt arising from the supposed bad effects likely to occur from the violent efforts to vomit causing the blood to be impelled more forcibly to the head. Where the attack has been produced by a loaded stomach or by indigestible food, spontaneous vomiting has often happened with great and sudden relief to the patient, and in such cases, but perhaps only in such, benefit will often arise from seconding the natural efforts by administering an emetic.

The last inquiry of importance is, ought we to deliver immediately in all cases of puerperal convulsions where the child or the placenta still remains in the uterus? This is rather a question of experience than of reason; for although it may be said that the presence of the child of the placenta in the uterus may keep up the exciting cause, yet it is well known that convulsions will often occur at a considerable interval after delivery has been completed; neither are they always relieved by emptying the uterus, where they have begun before or during labour. Many object to

any artificial hastening of the birth, unless the child's head is within reach of the forceps, on account of the uterine irritation produced by the process of dilating the os uteri, to turn the child and bring it down by the feet. It may be stated generally, that the most experienced practitioners have agreed, that it is advisable to deliver, either by turning or the forceps, (whichever may be applicable,) whenever the parts are in a state to permit this to be done without much difficulty.

It may be proper to add to this account, that where convulsions have occurred in a former confinement, it is very desirable that in any future pregnancy the patient should be closely watched towards the latter part of the time: great quiet should be enjoined, the bowels should be kept regularly open, and the diet be spare; and should symptoms of general plethora appear, or of determination of blood to the head, bleeding is to be had recourse to.

There are occasionally puerperal convulsions of a less formidable character than those above described,—unless indeed they be mistaken for them,—and which consists rather of unusually violent paroxysms of hysteria than of proper convulsions; as, however, they may occur during, or shortly after parturition, they are very frequently confounded with them, and treated accordingly. The distinction may be easily recognised by the absence of stertor and perfect coma, by the great quantity of flatus discharged from the stomach and heard rolling about the intestines, by the globus hystericus, and by the rapid and remarkably contracted pulse during the fit, which becomes slower and more expanded in the intervals. The limbs, and particularly the body, are as strongly agitated as in the real puerperal convulsions, but the face is much less so. As it is too common for inexperienced practitioners to consider all convulsions connected with the parturient condition as alike, and to treat them on that supposition, it is important that these distinguishing marks should be accurately recognised, particularly as, although not uncommon, these cases have been scarcely noticed in works on midwifery. There is no necessity in these instances to bleed the patient, or to proceed to delivery, if that has not already taken place. All that is required is the free administration of the customary antispasmodic medicines, camphor, æther, ammonia, assafœtida, &c.; and in such cases opium or any other narcotic may be safely and beneficially exhibited. Cold water should be freely dashed upon the face, and much advantage will be obtained by warm frictions and stimulating applications freely applied to the stomach, bowels, and spine, which produce or assist the expulsion of flatus from the stomach, with great and rapid relief to the patient. Perfect quietude of mind and body is afterwards very important.

C. LOCOCK.

CORYZA, *nasal catarrh, gravedo, or cold in the head*, as it is variously termed, is an inflammation and altered secretion of the pituitary or mucous membrane, lining the nasal fossæ, usually arising from cold. Although considered a trivial disorder, there are very few, short of severe pain, capable of producing more bodily discomfort. As this is, however, commonly but of short duration,

it is chiefly on account of the coughs and bronchial affections to which it frequently leads, that coryza claims our attention.

It begins with a sense of fulness and obstruction in one or both nostrils, accompanied with the secretion of a thin colourless fluid. This flux comes on in an increased quantity from time to time, and the increase is always attended by aggravation of the uncomfortable feelings of fulness; whilst frequent sneezing, titillation in the nares and fauces, and a copious flow of tears from the full and injected eyes, show an acrimony in the discharge as well as an increased sensibility in the pituitary membrane. This property of the humour is further proved, in the progress of the disease, by the redness and excoriation of the end of the nose and the skin above the upper lip; and it may be considered a remarkable feature in the character of the inflammation. The sense of smell is always impaired, often entirely destroyed, and that of taste usually suffers more or less. Head-ach is a very common attendant; it is principally confined to the forehead, and accompanied with a feeling of weight and heat over the brows. The partial or complete obstruction of the nasal passages, although caused entirely by the tumefaction of the membrane, gives the feeling of their being plugged up by something, which induces frequent and ineffectual attempts to remove it by blowing the nose. From the same cause the voice is rendered thick and nasal. If the attack is severe, there is frequently considerable pyrexia, with loss of appetite, and pain of the limbs, and in almost every case there is an unusual feeling of chilliness and susceptibility of cold. The disorder is at its height generally about the third day, and then it begins to decline; the flow from the pituitary membrane becomes more scanty and viscid, the swelling and obstruction abate, while the head-ach and other symptoms are proportionately relieved. Between the fifth and the seventh day the disorder is entirely removed. Not unfrequently, however, fresh cold is taken from the slightest cause, and the coryza, with its attendant symptoms, is kept up for a longer time; and as long as the secretion is copious and thin, no amelioration of the other symptoms takes place. A very common consequence of the diminution of the coryza is the transfer of the inflammation to the mucous membrane of the trachea and bronchi, and, in fact, there are few cases of cold in the head which are not followed by more or less cough.

Causes.—The usual cause of coryza is, as we have before remarked, cold applied generally or locally, and it is the more likely to produce it, if the cold be applied to a part of the body in a state of free perspiration. But a sudden transition from cold to heat seems to be likewise capable of exciting it. A slight form of coryza may be caused by the contact of smoke or other irritating vapours with the nostrils; but this does not bear the same character. Coryza generally accompanies measles, and sometimes small-pox and scarlatina. It is likewise a principal part of the epidemic disease called *influenza*. Whether excesses of diet are really capable of exciting coryza, or whether, as is more probable, they only act as strongly predisposing causes, it is certain that a sore throat,

passing into a cold in the head, is a very common sequel of a debauch. It is commonly imagined that a cold in the head is rather a sign of strong health than otherwise: this is only so far true, that, in those liable to it, the cold affects a part of less importance; whereas if the lungs, the tonsils, or the bowels are naturally delicate, the application of cold is more likely to produce disease in these parts. Liability to take cold in any way must certainly be considered as a proof of weakness of the constitution, and where it exists in a great degree, such a succession of colds sometimes attacks an individual, that for months he is not free from the uncomfortable symptoms of coryza. Such protracted cases it is proper to separate from those chronic cases of profuse pituitous secretion, or *phlegmorrhagy*, [*blennorrhœa*,] which are sometimes met with, affecting the nasal membrane in the same way that pituitous catarrh attacks that of the bronchi. In these there is no inflammation, and the diseased secretion does not possess those irritating properties that are so characteristic of acute coryza. Nasal phlegmorrhagy, as some French writers term it, attacks those of debilitated and leucophlegmatic habit, and sometimes comes on periodically. The flux is occasionally very abundant, and we have known it sufficient to wet five or six handkerchiefs in two or three hours. In the intervals there is a cessation of secretion; but, as in pituitary catarrh, (into which it is apt to pass,) the membrane is generally left somewhat tumefied.

When coryza attacks infants, it sometimes so completely obstructs the nostrils as to interfere with the process of sucking the breast, in which nasal respiration is necessary. The child leaves off repeatedly, and becomes purple in the face, and fretful in a few seconds after each time that it takes the nipple. In such cases it becomes necessary to feed the child with a spoon.

Coryza does not lead to suppuration. Pus is sometimes secreted by the nasal fosse, but not in consequence of the coryzal form of inflammation, which terminates by the secretion becoming viscid, and then opaque, and then of a dirty greenish or yellowish colour, after which it returns to its natural state.

Treatment.—The coryzal inflammation does not require bleeding or any extensive evacuation. An aperient, followed by a diaphoretic, in strength proportioned to the severity of the symptoms; the pediluvium at night, with water as hot as it can be borne, which the addition of a little mustard will render still more effectual; abstinence from all kinds of stimulating food; and confinement to bed to keep up cuticular exhalation, are the measures generally resorted to; and if they have not the effect of shortening the duration, they certainly mitigate the symptoms of coryza. It is the common practice to drink copiously of tea, gruel, or some other diluent, during a cold: as long as this promotes perspiration it is of some utility, and although it augments the flow from the pituitary membrane, it has the effect of diminishing its acrimony by dilution. It is the acrimony of this discharge which re-acts on the membrane and keeps up the inflammation and its accompanying disagreeable symptoms. On this

circumstance depends the efficacy of a measure directly opposed to that just noticed, but to the success of which we can bear decided testimony,—we mean a *total abstinence from liquids*. To those who have the resolution to bear the feeling of thirst for thirty-six or forty-eight hours, we can promise a pretty certain and complete riddance of their colds, and, what is perhaps more important, a prevention of those coughs which commonly succeed to them. Nor is the suffering from thirst nearly so great as might be expected. This method of cure operates by diminishing the mass of fluid in the body to such a degree that it will no longer supply the diseased secretion. Any thing that may contribute to reduce the quantity of fluid in the body will assist in the plan of cure, and shorten the time necessary for it to take effect. It is, therefore, expedient to begin the treatment with an aperient, followed by a diaphoretic, as is usual, and this is the more necessary when any fever attends; but beyond this no further care need be taken, and the individual can devote himself to his usual employments with much greater impunity than under the ordinary treatment. The coryza begins to be *dried up* about twelve hours after leaving off liquids; from that time the flowing to the eyes and fulness in the head become less and less troublesome; the secretion becomes gelatinous, and between the thirtieth and the thirty-sixth hour ceases altogether: the whole period of abstinence needs scarcely ever to exceed forty-eight hours. It is then as well to return to the *moderate* use of liquids, as the first indulgence is apt to be excessive. It is not necessary to limit the solid food any more than to that which is plain and simple, except where there is acceleration of the pulse or gastric irritation, in which cases animal food should be proscribed. For the sake of comfort in mastication, the food should not be of the driest kind. Thick puddings and vegetables, with or without meat, will be the best dinner; and toasted bread, or biscuit, *merely moistened* with tea, or other liquid, for other meals. A single cup of tea is enough to bring back the coryza immediately, after twelve hours' abstinence has removed it. We doubt not that it will be said that this plan of cure is worse than the disease; and so it may be in some instances. It may be called always a choice of evils; but we do not believe that any one who is liable to severe colds, after once experiencing the amount of good and evil resulting from this method, would hesitate between them; and it is for them that we make it known. We have never witnessed any evil from this abstinence from liquids for the time prescribed; but it is not unlikely that it may do harm in persons with irritable stomachs, or in those liable to urinary disorders. Moderation in liquid food, which may be assumed as a corollary from what has been already said, is one of the best preventives against the bad effects of exposure to cold. When there is a large quantity of liquid in the system, there must be increased perspiration, and, therefore, greater risk from the effects of cold.

Chronic coryza, or nasal phlegmorrhagy, is a disorder which arises from deranged digestion, or some other functional ailment that has a tendency to diminish the tone of the fibre. It generally

attacks elderly people, and in all respects resembles pituitous catarrh of the bronchi, with which it is often vicarious.

C. J. B. WILLIAMS.

COUNTER-IRRITATION (from *contra* and *irritare*). This term, which is of recent introduction, has been adopted in medicine to designate any irritation artificially established with a view to diminish, counteract, or remove some other irritation or inflammation existing in the body.

Counter-irritation is generally applied on the external surface of the body; and although some external medicines, as purgatives, emetics, &c. probably in part owe their efficacy to the counter-irritation which they cause, we shall here restrict our attention to external counter-irritation.

To understand and determine the value of counter-irritation in the treatment of disease, it is necessary to inquire into the principles of its curative influence, and the laws of those actions on which that influence depends. Unhappily this inquiry is restricted by the limits of our knowledge on the subject of inflammation and irritation in general; but enough information may be gathered to regulate in a general way the employment of this remedy in practice.

Nature not rarely cures diseases by counter-irritation; and it was probably from her example that art first adopted the practice. It is a common case to see an inveterate functional disease subside on the appearance of a cutaneous eruption. This more frequently occurs in sub-inflammatory affections of the mucous membrane; but examples are not wanting in which mania, paralysis, chorea, and various other diseases have been similarly cured. The exanthematous and other eruptive diseases are probably cases of a somewhat analogous description; for whether the eruption be the direct result of a curative *molimen*, or effort of the constitution, or proceed from the peculiar affinity of the skin to a virus or morbid cause wandering in the body, its occurrence is within certain limits salutary. This is proved by the relief manifestly afforded to the internal functions, and sometimes by the moderation of the fever, on the external eruption of measles, small-pox, scarlatina, erysipelas, &c. Sometimes, it is true, the fever is increased by this event, and all the symptoms may in consequence assume a worse aspect. So, likewise, a chronic disease of the skin occasionally relieves a pre-existent disease of the mucous membrane; whilst in other cases it re-acts on and aggravates it.

Now such various and even opposite effects are equally produced from a new or counter-irritation artificially established in the system; and it is, therefore, obvious that, unless judiciously administered, this remedy may prove prejudicial instead of salutary. Experience continually proves that, under certain conditions of the system, a blister or other counter-irritant aggravates the inflammation which it was applied to remove. If we inquire what these conditions are, we shall find them chiefly to consist of an excited or irritable state of the general circulation, and a susceptibility or excessive sensibility of the nervous system. We shall find, however, that the remedies employed as counter-irritants have other effects

which in a considerable degree modify this qualification of their utility.

Having thus in principle limited ourselves in the expectation of advantages from counter-irritation, we may proceed to consider its effects and uses in the various forms in which practice has employed it.

Counter-irritation may with advantage be considered in relation to its degree, and to the different tissues or parts which it affects. We shall, therefore, notice successively the remedies called rubefacients; vesicants; pustular or empyematous counter-irritants; setons, issues, perpetual blisters; and cauterizing counter-irritants.

Rubefacients.—In the slightest degree, counter-irritation consists in an erythematic excitement of the capillaries of the skin, terminating in complete resolution, sometimes with desquamation of the cuticle. An application exciting this degree of counter-irritation is called *rubefacient*. Moderate degrees of heat, (between 100° and 150°,) whether dry or with moisture, essential oils and spirits, æther, mustard, pepper, the strong alkalies and acids diluted, or weak acids in a concentrated form, and the strong counter-irritants applied for a short time or diluted, act as rubefacients on the skin, and are severally used with a view to this degree of counter-irritation. Being unaccompanied by any evacuation except an increase of the imperceptible perspiration, the action of rubefacients illustrates, better than epispastics of the severer kind, the principle of counter-irritation; and the instances of their utility are neither slight nor rare. A flask of hot water or a bag of hot sand; a poultice formed of bread-crums or linseed-meal and hot vinegar, with various proportions of mustard or pepper; an ammoniacal liniment or an essential oil applied by friction; pieces of cotton or flannel wetted with æther or camphorated spirit, and laid on the skin, evaporation being prevented by covering them with the warm hand, are rubefacient remedies which are often successful in removing slight internal inflammations, and in moderating those which are more intense. An incipient sore-throat is often cured by an ammoniacal liniment applied to the anterior part of the neck; a slight bronchial or a rheumatic inflammation by the same, or by the application of cajeput or other essential oil on the chest or part affected; a gastric affection, marked by nausea, pain, and irritability of the stomach, and particularly when resulting from a powerful dose of medicine, is frequently relieved by a sinapism, or even a hot flask to the epigastrium; and a rubefacient property is joined to the derivative of a pediluvium, when, with the addition of mustard, pepper, or the strong acids, it is used to relieve the brain in fever with sleeplessness or low delirium. Some chronic inflammations of the slighter kind have likewise their more permanent rubefacient remedies. Thus a galbanum or a pitch plaster, occasionally rendered more irritating by the addition of a little cantharides, is of no small utility in chronic coughs and rheumatism. The old composition of soap plaster and muriate of ammonia, so useful for the knees of house-maids, is another example; but we may find one still more familiar in the effect of new flannel worn next the skin, which unquestionably

cwies some of its salutary influence to its rubefacient property. To these instances of rubefacients we may add friction and electric sparks, both of which are essentially rubefacients: the latter often produce a papular eruption; and the magnetic plates which have been recommended by some French physicians are asserted by Laennec to have a similar effect. These means, however, will be noticed under their respective heads.

Rubefacients, especially when extensively employed, are general as well as local stimulants; and although their local effect is such as to counterbalance their general effect in cases of low febrile excitement, they cannot be admitted where a generally phlogistic diathesis prevails; whilst in intense inflammations they must give place to the stronger kinds of counter-irritants.

Besides the examples of slight inflammation which we have adduced as fit cases for rubefacient applications, there are others of a mixed kind in which they are not less successful.

Spasmodic affections, particularly those attacking the stomach and bowels, various pains and aches, such as tooth-ach, ear-ach, &c., which seem to partake of a nervous as well as of an inflammatory character, are often more immediately relieved by hot flasks of fomentations, a mustard poultice or pepper plaster, than by any other remedy. These affections probably have more to do with congestion, or unequal distribution of the blood, than is generally supposed; and to this circumstance we are inclined to ascribe much of the efficacy of these applications: but it may also depend on the physiological law, that if the sensibility of a part is increased, that of the adjoining parts is diminished. In great depression of the vital powers, as in typhus fever, asphyxia, &c., the general stimulus of sinapisms, stimulant frictions, and the like, is advantageous; but we shall speak of this under the head of blistering counter-irritants.

The most active kind of rubefacient counter-irritants are *sinapisms* or mustard poultices; and their action is so speedy and energetic, that they are the most eligible remedies where a sudden local irritant is required. They are usually composed of flour of mustard and bread-crum in equal or in various proportions, moistened to the consistence of a poultice with hot vinegar. MM. Trousseau and Blanc, in the *Archives de Médecine* (Septembre, 1830.) have detailed some curious experiments on the composition of sinapisms. They found that vinegar very much impaired the stimulant properties of the brown mustard commonly used in France, which contains the husk as well as the flour of the seeds, and they therefore recommended that sinapisms be made with water. The English mustard powder, however, which is the yellow farina separated entirely from the cortical part of the seed, is equally efficacious when mixed with vinegar and with water. Sinapisms made from mustard recently ground act more promptly than those from mustard which has been for some time kept. MM. Trousseau and Blanc tried the admixture of alcohol with sinapisms, but found it inferior to either vinegar or water. Dr. Paris recommends the mixture of oil of turpentine to quicken the operation of sinapisms; its efficacy depending on its extracting the essential

oil, in which the stimulant quality of the seeds resides. Sinapisms produce, in the course of a few minutes after application, a sense of heat, which increases to a smarting and burning pain of almost intolerable intensity. After a while this subsides, and is succeeded by a feeling of weight and fulness, with active throbbing of the arteries. In the course of twenty or thirty minutes the burning pain again returns, and unless the patient be insensible from some cerebral affection, he can never bear the application of a sinapism beyond three quarters of an hour. The effects on the skin are remarkable. Applied for a few minutes, a sinapism does not produce a redness in proportion to the pain; but a short time after its removal the part becomes of a scarlet colour. When left on for ten minutes and upwards, the skin becomes of a deep crimson or purple colour, which remains long after all sensation has ceased. Vesication is sometimes irregularly produced after forty or fifty minutes' application, but it is imperfect, and greatly disproportioned to the degree of inflammation. The intensity of the inflammation is such that there is considerable risk of gangrene supervening, if the sinapism remain applied for more than an hour. As long as sensation is preserved, the excessive pain would be a security against its being too long applied; but in cases of stupor and insensibility it should not, therefore, be permitted to remain beyond an hour. The pain excited by sinapisms may be allayed by cold applications, or, according to MM. Trousseau and Blanc, by cataplasms of hyoscyamus, belladonna, and stramonium leaves, or by ointments containing extracts of these plants. Sinapisms are classed here because their rubefacient is their most salutary property; vesication and gangrene being their occasional or accidental rather than their desired effects. In the inflammation of organs which sometimes comes on in the progress of fever, in nervous and spasmodic disorders, and in inflammations dangerous rather from their seat than from their extent, they are remedies of the greatest value.

Vesicants.—The next degree of counter-irritation which we shall notice is that in which the excited capillaries throw out a serous fluid, which detaches the cuticle from the cutis, and raises it in blisters. The more powerful of those agents which we have noticed as rubefacients, if kept applied for a sufficient length of time, produce this effect; but their vesicant is not always in proportion to their rubefacient property; and others which are more certainly and exactly vesicants, are more generally preferred. Several vegetable juices produce an eruption of small blisters; as that of some kinds of ranunculus, clematis, &c. But the Spanish blistering-fly, the *cantharis*, or *melœ vesicatoria*, is the remedy which best answers as a vesicant, and is the one almost solely employed. The active property, according to the researches of Robiquet, appears to reside in a peculiar principle soluble in æther and in oil, to which is applied the name of *cantharidin*. The form, therefore, in which it is most successfully applied is in a compound of the powdered flies with hog's lard, or some such oleaginous substance, and a due proportion of wax or resin to give it the consistence of soft plaster. This spread on leather, or any other convenient

substance, and applied to the skin, soon produces a sense of heat and pricking in the part, attended, if the application is large, with some excitement of the circulation and quickness of the pulse. If it be removed in two or three hours, its effect is merely rubefacient, and no blistering is produced; but if it be allowed to remain for a space varying in different individuals from five to ten hours, the skin will be found raised in large blisters filled with a yellowish serum, which continues to rise after the blister has been removed. In some cases they do not appear until after it has been dressed; and it is, therefore, unnecessary to keep the plaster on until they are formed, or till, as it is commonly expressed, the blister rises. When the blisters are fully risen, they are snipped with a pair of scissors, which allows the serum to escape; and if it be intended that the part should heal, it is dressed with simple ointment spread on a linen rag. The serosity continues to escape, and sometimes to raise fresh blisters, for some hours after; these must be treated as before, and the dressing renewed twice in twenty-four hours.

The discharge of serum produced by blisters renders them evacuants as well as counter-irritants; and this property must be taken into account in judging of their remedial powers. Until the vesication is complete, they have all those general stimulating effects which we have noticed as belonging to counter-irritants in general. But the serous effusion greatly modifies this, inasmuch that after a blister is dressed, it is common to find the pulse weaker than before its application. The first excitement of a blister often communicates itself to the mental faculties; its discharge commonly causes a general depression, with a disposition to sleep. These different effects are much more marked in some individuals than in others, and are necessarily modified by the existing disease. But cantharides have properties of a peculiar kind, which not infrequently exert an influence on the general operation of blisters. When their active principle is absorbed into the system, it proves very irritating, and in a peculiar manner affects the urinary organs, causing strangury and even bloody urine. To obviate this, it is commonly recommended to persons during the operation of a blister to drink copiously of dilute mucilaginous liquids; but we cannot refrain from expressing our conviction that this practice defeats much of the good effect of the blister. In many inflammations, particularly in those of the thoracic cavity, a chief object of blisters is to restrain the effusion of serum internally, or to promote its absorption; and this they do by extracting serum from the mass of blood in the adjoining vessels. But if liquids are thrown in such quantities into the stomach, they are rapidly absorbed into the circulating fluids, counterbalance the effect of blisters as local evacuants, and reduce them to simple counter-irritants. In such inflammations we are convinced by experience of the advantages of abstinence from any bulk of liquid, and would, therefore, look for other means to avoid the irritating effects of absorption from a blister. This may pretty effectually be obtained by interposing between the skin and the blistering plaster a piece of thin gauze or muslin, moistened

with oil, which being a menstruum of the blistering principle, transfers its effects to the skin, whilst the gauze or muslin prevents the particles of fly from adhering to the skin, after the separation of the cuticle has rendered it an actively absorbing surface. By taking care, also, not to allow the blister to remain on longer than is necessary, we may generally avoid these unpleasant consequences: six hours is generally sufficient; for whether the blister may have risen or not, if the skin at this time appear very red and inflamed, the vesication will almost uniformly take place after its removal. It has been asserted that by boiling the cantharides their peculiar effect on the kidneys is prevented, while their blistering power is unimpaired: of this we cannot speak from experience.

Before concluding our remarks on the remedial powers of blisters, we shall add a few cautions for their management. The due contact of the blister with the skin is of importance; and this may be effected either by a bandage or by a few strips of adhesive plaster: but if too great a pressure be exercised, it will restrain the inflammation of the capillary vessels, and no vesication will ensue. It is not advisable to apply a blister to an excoriated surface, as the absorption of the acrid matter and its unpleasant consequences are very apt to ensue. When, from peculiar idiosyncrasy, blisters produce great irritation, local or general, the addition of a little powdered opium or acetate of morphia to the plaster may give relief. An excess of inflammation, which occasionally ensues after the rising of a blister, sometimes with erysipelatous or eczematous appearances around it, is best relieved by poultices, which are proper applications whenever it is desirable to moderate the irritation. When the blistered part shows a disposition to gangrene, which is not unfrequently the case with children, it must be treated on general principles, as by stimulating or other applications, solutions of chloride of lime or soda, and bark exhibited internally. To avoid this consequence in children, it is advisable never to allow the blister to remain on more than six hours; and a poultice should be substituted if the inflammation be at all high.

Simple blisters, or, as the French term them, *vesicatoires volans*, (in contradistinction to those which are kept discharging by an after application,) are remedies much and deservedly esteemed in the cure of inflammations. As rubefacients, or simple counter-irritants, they yield to sinapisms and other remedies which we shall presently notice; but their effect as local *depletories* gives them a superiority over most other counter-irritants. In common with the other remedies of this class, they are unfit for the first stages of extensive acute inflammation; but when the general excitement of the circulation, and the intensity of the orgasm, have been so lowered by blood-letting and other means, that the temporary irritation of the blister may be borne without risk, its action becomes highly salutary; in the first instance drawing off the irritability from the diseased part, and then removing or exhausting it by an effusion of serum. This effusion proves the means of so *deriving* to the blistered part, that the morbid exhalations in other parts are re-absorbed and

drained off; and hence blisters, more than rubefacients, are adapted to inflammations of serous membranes. Besides the caution required not to apply blisters at too early a stage, it is generally necessary to beware of placing them too near the seat of inflammation; for their contiguity may greatly aggravate it, causing two inflammations, as it were, to run into one. This must be left to the discretion of the practitioner; but it may be suggested that in inflammations of the pleura, — in those superficially affecting the pulmonary substance, as indicated by auscultation, — in those attacking the membranes of the brain or the larynx, it is better to place the blister on some part adjoining rather than immediately over the affected part; and to make up by extent of the surface blistered, for any diminution of effect from distance. In fact, in all acute inflammations large blisters are to be preferred to small ones; for the irritation from the latter is nearly as great, without the same good effects. In chronic inflammations the case may be somewhat different, as it is usually necessary to apply a succession of blisters; and the weakening effects of a large discharging surface might make small ones preferable. Of chronic inflammations, those affecting the serous and mucous membranes receive the most benefit from blisters. In pleuritic and peritoneal inflammations accompanied by effusions, their evacuant effects are likewise of decided utility; and with this view they should be of large size. But in inflammation of the parenchyma of the viscera, and in that of membranes without much liquid effusion, the more powerful counter-irritants are of greater efficacy.

We have already noticed that rubefacients are sometimes valuable in continued fever, on account of the stimulus which they convey to the vital powers; and we may extend this observation to blisters, which, judiciously administered, are often doubly useful, both by the general excitement which they afford, and by their local counter-irritation and evacuation relieving the several internal organs, which almost constantly suffer in these fevers. But, equally as in the case of acute inflammations, during the stage of synocha or morbid excitement they must be excluded as injurious. It requires much nice discernment to decide on the time at which blisters may with advantage be used. Dr. Rush considered that there is a period in all fevers at which they would prove salutary; but we shall not attempt here specifically to define it. (See FEVER.) By counter-irritants or revulsives of the most prompt and powerful kind, as boiling water, some signal cures have been effected in the worst forms of fever; the patient having been by them at once awakened to consciousness from coma or extreme collapse. M. Marjolin cites his own case as an example of this treatment; and Dr. Macintosh records one which occurred in his practice eight or ten years ago: and we have heard of other instances of its success. As there is a great risk in the subsequent effects of the local injury, which generally tends to gangrene, this practice can only be resorted to in extreme cases.

What has been said of rubefacients in spasmodic and convulsive disorders may be equally applied to blisters, which are in fact the form gener-

ally resorted to, although full blistering is probably inferior to sinapisms repeatedly applied for a short time. There is likewise a state of general irritability of the system, accompanied with various and occasionally fugacious pains, but without hardness or fulness of the pulse, that is often greatly relieved by the application of a blister, which seems to localise the irritation, and thus relieve the system.

An exception is commonly taken to the use of blisters in the case of inflammation of the kidneys and other parts of the urinary apparatus, on account of the irritating effect of cantharides towards those organs through absorption; and although this may generally be prevented by attending to the precautions which we have before enumerated, it is acting safely to prefer some other counter-irritant. This leads us to say a few words on other vesicating remedies.

All those irritant agents which act in the most prompt and energetic manner, without destroying the cuticle, raise it at first into blisters filled with a serous fluid. Thus, boiling water, or its vapour, the concentrated alkalis, or metal heated in water, as recommended by Sir Anthony Carlisle, produce this effect. Intense heat, the strong acids and some metallic salts corrugating and destroying the cuticle, act more immediately as escharotics. But this mode of blistering is very unmanageable, as the inflammation accompanying it is of a diffuse and uncertain character, and often leads to severe sloughing. There is a method of applying the vapour of boiling water in a jet, by means of an eolipile, or vessel with a narrow orifice, which might be so regulated as to produce vesication without proceeding deeper; and the liquor ammoniæ triturated with an equal weight of hogs' lard may be applied, so as to produce full blistering in fifteen or twenty minutes; but unless great speed is desirable, these agents, even thus modified, are not eligible as mere vesicants.

Pustular or Empyematous Counter-Irritants.—We have hitherto referred to those degrees of artificial external inflammation which terminate in resolution or serous effusion. There is, however, an important class of counter-irritants, affecting the cutaneous texture more deeply, and determining the secretion of pus. A blistered surface sometimes spontaneously takes on this degree of inflammation; and the same effect is frequently brought on by particular applications to it; but as these methods of counter-irritation are of a mixed kind, we shall presently return to them under the head of *issues* and *setons*, and here notice particularly those applications which bring on suppurative inflammation of the skin in the form of pustules. The sulphuric and nitric acids, their escharotic power being blunted by dilution with oil or lard, produce an inflammation, which soon assumes the form of pustules, small and distinct, or large and confluent, according to the proportion and strength of the acid used. But the substance most eminently calculated to excite the pustular inflammation is tartarized antimony. We owe the introduction of this medicine as a counter-irritant to the late Dr. Jenner, who employed it in the form of ointment, in the proportion of one part of the salt to five of spermaceti ointment. It has since been extensively employed in practice, and

is almost as generally used as a pustular irritant, as cantharides are to produce vesication. In our own hands we have found it so manageable as well as effectual a counter-irritant, that we consider it a remedy of equal importance with the blistering fly itself; but, as much of its efficacy depends on the method of its application, before describing its advantages we shall premise some precautions on this point.

Tartar emetic exerts no corrosive or solvent power on the cuticle; it therefore sometimes happens that considerable difficulty is experienced in making the cutis feel its effects, and this obstacle is of course greater where the cuticle is naturally dense or thick. To obviate this we recommend the part to be previously excited, either by friction with warm flannel or a flesh-brush, or by some stimulating application of a penetrating quality, such as camphorated spirit or strong vinegar, or a mustard poultice applied for a few minutes. When the vascularity and sensibility of the skin have been thus exalted, the tartar emetic ointment is to be rubbed in, and it will then take a more equal as well as more certain effect: instead of having a few large and unmanageable sores produced in two or three days, as is often the case in the usual method, a vivid erythema immediately succeeds, which in the course of a few hours breaks out into a thick crop of pustules, the size and course of which vary according to the strength of the ointment and the duration of its application. On these points it is not easy to lay down any absolute rule; for, as in the operation of blisters, much depends on the individual constitution. We generally prefer an ointment of considerable strength, for instance, made with one part of tartar emetic and two of simple ointment. If the fullest effect be desired, the friction, both preparatory and with the ointment, should each be persisted in for fifteen or twenty minutes. This generally leads to the speedy formation of confluent pustules, which go on to maturation. To diminish this effect it is best to shorten the period of friction with the ointment; and where we wish for the slightest degree of counter-irritation, it is generally sufficient to *smear* the ointment on the part previously excited by dry friction, or by some of the other applications before enumerated.

Another mode of counter-irritation by tartar emetic is, the employment of a saturated aqueous solution: the elegance and convenience of this form render it peculiarly eligible where the ointment might be considered disgusting. It is expedient to make the solution as warm as the skin can bear it, as the heat both enables the water to dissolve more of the salt, and quickens the effect on the skin. The part being previously excited as for the ointment, the solution is to be gently rubbed on it by means of a piece of flannel, and continued for a longer or shorter time, according to the degree of effect desired. The pustules thus excited are usually small and numerous, and unless the application have been continued for some time or repeated, they dry up and heal speedily. As this application leaves no marks or scars, it is particularly suited to females, who generally renounce all medicaments which may leave a trace behind. Plasters sprinkled with tartar eme-

tic in powder have been greatly recommended ; but we have found their operation very uncertain ; in some cases inefficient, and in others causing a frightfully ulcerated surface, which the removal of the plaster necessarily exposes. After the application of the tartar emetic, whether in ointment or in solution, the part should be covered with a piece of rough flannel, which, if it be desired, may be made still further to promote the effect by a little ointment smeared on it. By this system of management tartar emetic may be made to produce any degree of counter-irritation, from a papular or erythematous blush to an extensively suppurating sore.

Pustular or suppurating inflammation thus excited is generally more permanent and profound in its counter-irritant influence than vesication. The formation of pus requires a greater development of vital action, a higher degree of local irritation than serous effusion, without proving more stimulant to the system. For this reason we consider the tartar emetic counter-irritant better adapted than blisters to remove deep-seated parenchymatous inflammation, even of the acute kind ; and although it must not supersede the free previous use of depletory measures, yet it may be employed with less hesitation than blisters, inasmuch as the absorption of the medicine into the system proves antiphlogistic instead of irritating. That such an absorption does take place is probable from the nausea which sometimes attends the use of the medicine ; and we have known in a few instances violent vomiting ensue.

In the method which we have recommended for its application, counter-irritation with tartar emetic may be brought to its greatest effect of copious suppuration in from ten to twenty hours, and a full pustular eruption may be brought out in five. This rapidity of effect places it on a par with blisters ; and the greater intensity of its inflammation renders it a better counter-irritant. It is perhaps inferior to them in pleurisy, meningitis, and those inflammations in which the principal danger arises from serous effusion. In gastritis, likewise, its tendency to excite vomiting may render it objectionable. In most other acute inflammations, if its proper application be attended to, we prefer it to blisters, and in none has it proved more beneficial than in those of the lungs and air-passages.

In chronic inflammation the efficacy of tartar emetic counter-irritation is more generally acknowledged. We have found it far more beneficial than either blisters or setons in chronic bronchitis and pertussis ; and if we can venture no further, we may unhesitatingly assert that we have seen it retard the progress of tubercular consumption. An eruption excited and renewed on the chest, sometimes on one side, sometimes on the other, seems in these cases to act as a safety-valve to the system, letting off any incipient disposition to inflammation ; and thus, without much impairing the strength, enables the body to bear tonics, and a more generous diet than it would otherwise support. It has been found of signal utility in diseases of the joints and of the bones, and is preferred by some surgeons to moxa.

Numerous cases of epilepsy, chorea, and other convulsive diseases, also cases of mania, paralysis,

and neuralgia, have been recorded, in which tartar emetic counter-irritation on the nape of the neck, along the spine, or the course of a nerve, has produced relief, and even a cure. But as in these disorders the scientific physician must see pathological causes of very various nature, it would be irrational to assert that the remedy in question is universally applicable to them. As often as they arise from, or are aggravated by, some local inflammation, irritation, or congestion, we can at once perceive its utility ; but we can never be reasonably confident in our expectations of success when we remember how often there are immediate organic causes for these diseases. In these and other complaints, nature not unfrequently throws out a hint in the form of a spontaneous eruption ; and the physician may with great advantage be instructed by it, and second her efforts by means of this remedy. From the facility with which this counter-irritation may be excited and kept up for any length of time by a slight fresh application, it is well adapted to remove or prevent inflammations of the eyes, ears, and fauces, which sometimes engraft themselves on the habit, and are very difficult to remove.

A remarkable effect has been observed to ensue in a few cases from the use of tartar emetic ointment ; namely, an irritation, sometimes very severe, of the genital organs. We have never seen this except in cases where the ointment had been used for several days in succession, which is rarely necessary according to the method which we have recommended for its use.

When the inflammation excited by tartar emetic runs too high, it may, as in the case of blisters, be moderated by a warm bread poultice, which does not interfere with the progress of the pustules.

Perpetual blisters, issues, and setons.—We have delayed to notice these counter-irritants, because they are of a mixed nature, and occasionally partake of the qualities of all those which we have already described. The inflammation which they excite is of very various degrees of intensity, and the discharge which they occasion is sometimes purulent and sometimes serous.

Blisters are kept open by removing the raised cuticle by scissors, and by applying, instead of the ordinary dressing, an ointment or cerate of an irritating quality. A small portion of cantharides is sometimes used for this purpose, but the bad effects of its absorption, which frequently ensues, raise a great objection to it. A cerate containing euphorbium and the unguentum resinosum has likewise been employed with the same view. But the ceratum sabinæ is that most commonly resorted to ; and, if duly managed, it is capable of maintaining a more equal degree of irritation and discharge than any other. It is, however, necessary to attend to the strength of the cerate applied ; and if discharge be the principal object, it ought to be applied in a diluted form. Blisters kept open in this way, without profoundly affecting the skin, sometimes yield a copious secretion of pus, and then prove most salutary. With a continuance of the same application, however, this very commonly becomes thinner and again serous ; and in time the part is habituated to the irritation, dries up, and heals. To prevent this, it is necessary to

remove the films of coagulable lymph which form upon it; to keep down vegetations by touching them with nitrate of silver or burnt alum; and occasionally to cleanse the surface by an emollient poultice, or by warm fomentations with flannel. By changing the stimulating ointment, the irritation and discharge may be preserved much longer than when one only is employed. On the whole, however, this method of counter-irritation is troublesome and uncertain, and may well be superseded by a succession of blisters, or by tartar emetic.

By *issues* and *setons* irritation is applied more profoundly, being brought immediately into the subcutaneous tissue itself. The former are made by producing an opening in the skin, either by incision, by a blister, or the application of some escharotic substance, such as potassa fusa, nitrate of silver, muriate of antimony, &c., and introducing some foreign body, as a pea or a glass bead, into it, which keeps up the irritation, and forms a constant ulcer. In producing the ulcer by means of caustics, it is necessary to limit the operation, and defend the adjacent parts by a piece of adhesive plaster, with an aperture in it of the required size of the ulcer. A bit of potassa fusa placed in this aperture in the course of four or five hours forms an eschar, surrounded by an areola of inflammation. This eschar being dressed with citrine, or other stimulating ointment, begins to detach itself and to secrete pus in the course of four or five days, and after that falls off, leaving an ulcer more or less profound.

Setons are made by passing a lancet-bladed needle, with a fasciculus of thread or silk attached to it, through a portion of the integuments (pinched up between the finger and thumb), so that the threads are left in, with the ends hanging out at each orifice. To increase the irritation, the thread is anointed daily with the unguentum resinosum, and shifted or renewed to keep the wounds open or discharging. The necessity for the renewal is superseded by substituting a long strip of caoutchouc or of lead for the threads. The inflammation at first excited by setons is sometimes so intense as to require the application of poultices to moderate it; and their dressing and management require many precautions which it is the province of surgery to teach.

Issues and setons, when in full operation, excite a phlegmonous inflammation, attended by a discharge of an abundant thick pus. This is most frequently the case with setons, and with issues formed by caustics; and these are, therefore, the most powerful and profoundly acting of their kind. But like perpetual blisters, they are apt, with the same material of irritation, to become indolent and callous, and the secretion serous and less abundant. When energetic, these remedies are of great utility in chronic inflammations of various kinds. If any distinction can be made as to the kinds in which they are most serviceable, it may be suggested that the circumscribed textural inflammation of viscera are peculiarly benefited by their use. When in a more moderate form, and secreting serum, they act rather as evacuants, and have been, not unaptly, compared to a new secreting gland in the system. They thus occasionally prove safeguards against apo-

plexy, palsy, and other diseases of repletion; although implicit reliance ought not to be placed on such means. For the same reason they are proper adjuncts in the cure of long-continued cutaneous disorders, preventing any ill effects from the suppression of the natural counter-irritation. So, likewise, in all cases where setons or issues themselves have been for some time used, it is proper to be cautious in suppressing them, by doing it as gradually as possible, and carefully ensuring the free action of the bowels and other secretory organs. As a means of restraining the growth or diminishing the size of tumours and bronchocæles, setons have been found of some use; and the drains which they afford have likewise checked the increase of dropsical effusions.

[There are other agents, which, according to their mode of application, are capable of inducing more than one of the effects already mentioned. When *croton oil*, for example, is rubbed in small quantity, and for a short time, on the surface, it induces inflammation of the skin, which gradually disappears of itself. When the friction is longer continued, pustules are caused, which, when they are numerous, run together or are confluent; and, around the spot where the confluent eruption is seated, papulæ appear over a wider extent, which are transformed into pustules, and are surrounded by a red base or areola. Commonly, the eruption is perceptible in twelve hours after the first friction; but at times not until a later period. In the course of from three to six days, the eruption again disappears. The eruption is never so painful as that induced by the ointment of tartrate of antimony and potassa.

Frictions with croton oil are adapted for all cases in which local counter-irritation is required. It is important, however, to bear in mind, that the oil may be absorbed, and act on the bowels, and may not, therefore, be adapted for intestinal disorders, in which counter-irritation is indicated. If the skin be thick, and insensible, it may be well to rub it previously with flannel, or to apply first a rubefacient, especially when it is desirable to produce the effect speedily. On the other hand, when the skin is excitable, the croton oil should be mixed with from one to four or five parts or more of olive oil, oil of turpentine, or soap liniment. (See the writer's *General Therap. and Mat. Med.* ii. 265: Philad. 1843.)

The *essential oil of mustard* is occasionally used wherever a counter-irritant is needed. It is used either in the form of friction, or where a more powerful effect is needed, by dipping strips of linen, of the proper size, in the oil, and suffering them to dry on the part. Burning pain immediately succeeds, and is often so insupportable, that the patient objects to wait until the linen is dry. (*New Remedies*, 4th edit. p. 463: Philad. 1843.)

Ammonia has been employed to excite rubefaction and vesication. The *pomnade ammoniacale* of Gondret has long been used in chronic affections of the brain, incipient cataract, amaurosis, &c., being applied to the top of the head. (Gondret, *Considerations sur l'Emploi du Feu en Médecine*, &c.: Paris, 1819; and *Traité Théorique et Pratique de la Derivation*, &c.: Paris, 1839.) The formulæ for summer and for winter,

recommended by M. Trousseau, (*Journ. des Connais. Med. Chir.* cited in *Medico-Chirurg. Rev.*: July, 1840) are as follows: for summer, three parts of lard, one of suet, and four of liquor ammoniac; for winter, equal parts of lard and liquor ammoniac. More recently, a stronger and a weaker ammoniated lotion have been extolled extravagantly as counter-irritants by Dr. Granville. (*Counter-Irritation, &c.*, Lond. 1838, or Amer. Med. Library edit.: Philad. 1838.) The milder of these is made as follows: *Liq. ammon. fort.* f.ʒi.; *Spirit rosamarin.* f.ʒvi.; *Tinct. camphor.* f.ʒii. M.; the stronger as follows: *Liq. ammon. fort.* f.ʒx.; *Sp. rosamarin.* f.ʒss.; *Tinct. camph.* f.ʒii. M. Raspail (*L'Experience*, 24 Juillet, 1840) has recommended the following lotion, the effects of which, he says, are often instantaneous in relieving intolerable headach: *Liq. ammon.* p. 100; *Aque destillat.* p. 900; *Sodii chlorid. purif.* p. 20; *Camphor.* p. 2; *Essent. ros.* q. s. The whole to be mixed cold. A piece of linen is to be steeped in this solution, and applied over the part of the head which is the seat of pain, care being taken that none of the fluid passes into the eyes.

The stronger of Granville's lotions gives rise, in a few minutes, to vesication over the whole surface to which it is applied, almost as rapidly, indeed, as if boiling water were placed upon the part. The strength can be regulated so as to produce either full vesication or simple rubefaction, by varying the quantity of the liquor ammoniac. As a general rule, the application should be seldom continued longer than from one to six or eight minutes. But, in order to excite the higher degrees of counter-irritation, as vesication and cauterization, as much as ten or twelve minutes may be necessary.

The mode of applying these liquid counter-irritants is first to impregnate with them a piece of cotton or linen, folded six or seven times; or a piece of thick or coarse flannel; and then lay either of these on the spot, pressing with the hand, at the same time, very steadily and firmly on the compress, over which there should be placed a thick towel doubled several times, so that not only the evaporation of the lotion may be impeded, but the hand employed in pressing the compress on the part, may not suffer from direct or indirect contact with the liquid. Care must be taken that the ammonia does not reach the eyes or nose. (Granville, *op. cit.* Amer edit. p. 39.)

There can be no doubt that the ammoniated counter-irritants are valuable agents in all diseases that are benefited by a sudden and powerful revulsion, and especially in different forms of neuralgia. One great objection to them is, that they are apt to induce sloughing and sores difficult to heal. Care may prevent these; but at times they occur in spite of every precaution. (*New Remedies*, p. 197.)

Cauterizing Counter-Irritants.—By this term we designate all those operations in which heat, in such degree as to cause disorganization of the part, is applied as a counter-irritant. The common effect of all these is the formation of an eschar, or dead slough, surrounded by a more or less intense inflammation, which causes the separation of the dead part and the production of an

ulcerous cavity in its place. The local inflammation, thus excited, may be very intense, and the suppurative discharge very perfect; and this kind of counter-irritation is proportionately energetic in its effects on the disease, in the same manner as others. But there seems to be another peculiar result from the application of vehement heat: namely, a strong impression, or shock, on the nervous system, which in certain diseases is not without its salutary influence.

Heat, with a view to cauterization, is applied by heated metallic instruments, burning substances, boiling water or its vapour. Instruments of iron or copper, heated to different degrees of incandescence, are sometimes used to produce local irritation and sores. This operation, which is called the *actual cautery*, produces, more than any other method, that shock to the nervous system to which we have just alluded. It has been found useful in checking violent convulsive diseases, such as epilepsy, hysteria, and local spasms. It is difficult to judge whether its efficacy depends on the pain, or on some other change wrought in the nervous system; the effect is certainly some times produced before such a degree of local inflammation has been excited as could act by vascular counter-irritation.

A red-hot iron is sometimes used to form issues; and for this purpose it is applied with considerable pressure to the part for eight or ten seconds, and repeated if it is wished to make the ulcer deep. A portion of skin and of the cellular texture underneath is thus killed, and forms an eschar, which in the course of six or eight days is sloughed off, and the ulcer produced may be treated as an issue. The painful and formidable nature of this operation excludes it from general adoption; and, with the exception of the cases just alluded to, we do not know that it can claim any superiority over that with caustic, which is attended with little pain. The good effects of the actual cautery are, perhaps, obtained with least attendant inconvenience when the metal is heated to a white heat. Thus applied, it immediately destroys the vitality and sensibility of the part; and if the surrounding skin is protected by coverings of wetted paper or other suitable substance, in the way which has been recommended by Dr. A. T. Thomson, the suffering of the patient is much diminished, and the advantages of the remedy are with more certainty procured. The actual cautery is more frequently resorted to in surgery for the destruction of malignant productions and morbid poisons.

There is a method of cauterization, called by surgeons *transcurrent*, which partakes more than the preceding of the nature of a counter-irritant. It consists in lightly passing an iron, heated to a cherry red, on the surface of the skin in parallel lines, at such a distance from each other that an intervening space may be left free from inflammation. In this way long narrow eschars are formed, which in the course of eight or ten days are enlarged; whilst the whole surface becomes highly inflamed, and is not relieved from the painful and phlogosed state of a common burn until a copious suppuration ensues, which often lasts for a fortnight or more. The fever and irritation which this process occasions forbid its employ

ment in any but very chronic and indolent cases. It has proved very successful in removing chronic enlargements of the joints, and the remains of rheumatic affections.

Cauterization by substances in the state of combustion has of late years been practised to a considerable extent in the form of what is termed *moxa*. This method is said to have been adopted from Japan, where moxas are made of a down obtained from the leaves and tops of a species of *artemisia*, made into a cone, which when lighted burns spontaneously. The pith of the stalk of the sun-flower and of other *helianthi* likewise possess this property, which is owing to a small quantity of nitre in their composition. The material generally employed in Europe for moxas is cotton, rendered downy by carding, and made into a roll an inch long, and from half an inch to two inches in diameter. This is held by a forceps or wire, with one end in close contact with the skin, whilst the other is set on fire; the adjoining parts being protected by wet pasteboard or linen. The combustion is supported either by blowing or fanning, or by a slight impregnation of nitre previously given to the cotton. The sensation produced by the burning of a *moxa* is first that of warmth, rather agreeable than otherwise; this soon increases, as the fire approaches the surface, becomes itching, then more and more painful, and attains its acme of intensely sharp scalding pain when the combustion reaches the skin, which smokes and becomes crisp under it. The neighbouring skin is vividly inflamed, puckered, and sometimes slightly blistered. The eschar thus formed is deep, and requires a fortnight or upwards before it is separated. The ulcer formed discharges pus abundantly, and by the aid of a pea may be converted into an issue.

The gradual manner in which heat is communicated to the part in the burning of a *moxa* causes it to penetrate more deeply than any other form of actual cautery. Hence as a remedial agent it is well adapted to make an impression on deep-seated inflammation; and in diseases of the spine and its contents, in scrofulous and rheumatic swellings of the joints, in chronic diseases of the liver, kidneys, and other internal organs, in paralysis and neuralgia, it sometimes proves more effectual than any other remedy. It is often necessary, however, to employ several moxas in succession; and if the disease be of some extent, several simultaneously, before the good effects become apparent. Moxas may be applied with greatest advantage as near as possible to the diseased part; but if their effect is intended to be deep, it would not be proper to apply them on parts where cartilage, tendon, or bone are close under the surface.

Moxas are sometimes applied with a view to counter-irritate without producing an eschar. The moxas in this case are made of sun-flower pith, or of light cotton impregnated with nitre. The combustion is effected without blowing, and is not suffered to reach the skin. Under this form, frequently applied, they have been found useful in promoting the absorption of indolent effusions in joints and cold tumours. It is probable that much of their effect in these cases depends on the stimulus which they impart to the organic sensi-

bility of the diseased tissues which cannot be included in their counter-irritation.

[Various forms of *moxa* have been proposed. Mr. Leney (*London Medical Gazette*, July 15, 1842) soaks a piece of lint in a strong solution of nitrate of potassa, dries it, and cuts off pieces of the size of the thumb-nail, which he fastens, with thin adhesive plaster, over the seat of pain; sets fire to the opposite extremity, and then applies the blow-pipe. The pain during the process is very severe; but the Irish, he affirms, prefer it greatly to the application of a blister. Professor Gräfe (*La Lancette Française*, Jan. 26, 1839) employs moxas made of wafers, dipped in a mixture of three parts of oil of turpentine and one part of sulphuric ether. Before applying this inflammable matter to the skin, it is necessary to remove carefully the superfluous liquid. These moxas are said to ignite readily, burn promptly and uniformly, and do not crepitate.

Of late, a plan for exciting vesication on the surface has been adopted, which must be regarded as a kind of *moxa*. It produces rapid vesication, but is said to be complicated, and attended with intense pain, (Granville, *op. cit.* Amer. edit. p. 21 and p. 42.) A piece of linen or paper, cut of the requisite size, is immersed in spirits of wine, or brandy. It is then laid on the part to be blistered; care being taken that the moisture from the paper or linen does not wet the surrounding surface. The flame of a lighted taper is applied quickly over the surface, so as to produce a general ignition, which is exceedingly rapid. At the conclusion of this operation, the cuticle is found detached from the true skin beneath. In cases of convulsions, the region of the spine has been treated in this manner, and with good effect. (C. J. Edwards, *Provincial Med. and Surg. Journ.* Jan. 1842. See, also, the writer's *New Remedies*, edit. *cit.* p. 441.)]

A cauterizing effect may be produced by boiling water, or better by its vapour. The best method of effecting this is by an *colipile*, or vessel with a narrow tubular mouth, and kept boiling by means of a lamp. The jet of vapour issuing in full force from this is directed against the part, which is covered with thick pasteboard or linen, with an aperture of the form and size of the part intended to be cauterized. The pain caused by this operation is very severe, and the slough formed very deep. It most resembles *moxa* in its effects; but the wound produced by it is less manageable, and more apt to involve the surrounding parts.

C. J. B. WILLIAMS.

CRISIS, CRITICAL DAYS. (See DISEASE.)

CROUP.—(*Synonyms*—*Cynanche trachealis*, *C. laryngea*, *C. stridula*, *Angina polyposa*, *Suffocatio stridula*, *Morbus strangulatorius*, &c.) We prefer croup to the other appellations, inasmuch as it does not convey an erroneous notion of the nature of the disease which it designates: that disease is not a mere *cynanche*, or *quinsy*. It will be shown that inflammation, which is the characteristic of the order of diseases to which croup belongs, is not confined to the throat, but generally extends through the ramifications of the bronchi; therefore, *C. trachealis* and *C. stridula* ought no longer to be retained as nosological

terms. The terms *suffocatio stridula* and *morbus strangulatorius* are indefinite, and would equally apply to the various affections in which those symptoms of croup—the *inspiratio strepens*, *vox rauca*, and *tussis clangosa*—are engrafted on other diseases, and which will be treated of under their respective titles.

This disease was honoured with the attention of the greatest man of the present age—if he can be called great who had no just sense of moral grandeur. In consequence of the general order which Napoleon issued from the head-quarters of Finkenstein,* many essays on croup were written by foreign physicians of ability, in which nothing is omitted in illustration of that disorder which industry could collect or method could arrange.

Occasional Causes.—In the early part of his professional life, the writer of this article lived on the coast of the Firth of Forth, where croup may be considered an endemic disease, and where every facility was afforded for cultivating an acquaintance with it. During the last twenty-two years, while practising medicine in Dublin, his opportunities of witnessing croup have not been unfavourable, especially when attending a dispensary. While discharging that duty, he had frequent occasion to observe the disease among the ragged and half-starved children of the poor who live near the canals which surround the city; or in Ringsend, near the estuary of the river Liffey; or in Sandymount, lying between Dublin and its bay: indeed the disease is prevalent, in the latter end of winter and in spring, along the whole of the eastern and northern coasts of Ireland. With respect to its prevalence along the rest of the sea-coast, no inquiries were made; his inquiries, however, sufficiently confirm the received opinion relative to the principal occasional cause of croup, viz. that in Ireland, as in Scotland, it is chiefly produced in the neighbourhood of large bodies of water, running or stagnant, fresh or salt.

History.—The disease may occur at any period from the second or third month after birth to puberty. The younger children are when weaned, the more liable are they to croup. After puberty it scarcely ever occurs. Some families, those especially in which the children are of a sanguineous temperament and full habit, are much more liable to the disease than others. It often attacks children who have not fully recovered from a previous illness. It is liable to recurrence, at distant intervals, upon exposure, not merely to an atmosphere which has been influenced by passing over a large body of water, but to any of the causes which produce common catarrh.

Hoarseness, in very young children, does not usually attend common catarrh; and hence when

observed in a child living in a district which generates croup, this symptom is always much more deserving of attention, especially if accompanied with a rough cough, than it would be after puberty. This remark may be supposed scarcely worthy of the reader's attention; but having had innumerable opportunities of ascertaining that inflammatory affections of the mucous membrane of the larynx and bronchi in children owe their complexion to the mode of treatment adopted during the first six or eight hours of the attack, when no other symptom but hoarseness exists, we consider the observation important to parents whose children are liable to croup, and consequently to their family physician.

In the approach of an attack of croup, which almost always takes place in the evening, probably of a day during which the child has been exposed to the weather, and often after catarrhal symptoms have existed for several days, he may be observed to be excited, in variable spirits, more ready than usual to laugh or to cry, a little flushed, occasionally coughing; the sound of the cough being rough, like that which attends the catarrhal stage of the measles. More generally, however, the patient has been for some time in bed and asleep before the nature of the disease with which he is threatened is apparent; then, perhaps without awaking, he gives a very unusual cough, well known to any one who has witnessed an attack of the croup; it rings as if the child had coughed through a brazen trumpet; it is truly a *tussis clangosa*; it penetrates the walls and floor of the apartment, and startles the experienced mother—"Oh I am afraid our child is taking the croup!" she runs to the nursery, finds her child sleeping softly, and hopes she may be mistaken. But remaining to tend him, before long the ringing cough, a single cough, is repeated again and again: the patient is roused, and then a new symptom is remarked; the sound of his voice is changed; puling, and as if the throat were swelled, it corresponds with the cough: the cough is succeeded by a sonorous inspiration, not unlike the kink in pertussis—a crowing noise, not so shrill, but similar to the sound emitted by a chicken in the pip, (which in some parts of Scotland is called the roup, hence probably the word croup;) the breathing, hitherto inaudible and natural, now becomes audible, and a little slower than common, as if the breath were forced through a narrow tube; and this is more remarkable as the disease advances. A blush of inflammation may sometimes be detected on the fauces, and in some rare instances a slight degree of swelling round the larynx, and the child complains of uneasiness in his throat, and says he is choking. The ringing cough followed by crowing inspiration; the breathing, as if the air were drawn into the lungs by a piston; the flushed face; the tearful and bloodshot eye; quick, hard, and incompressible pulse; hot, dry skin; thirst, and high-coloured urine—form a combination of symptoms which indicate the complete establishment of the disease.

Sometimes the symptoms enumerated subside about midnight, even in the absence of medical treatment; perhaps to return in the course of the following evening. From seven or eight o'clock till midnight this complaint is always at its height,

* Ce fut au quartier général de Finkenstein le 4 Juin, 1807, que S. M. L. et R. donna l'ordre d'ouvrir un concours sur la maladie connue sous le nom de croup; et c'est en exécution de cet ordre que son excellence Monsieur le ministre de l'intérieur mit la question suivante au concours.

Déterminer, d'après les monumens pratiques de l'art, et d'après des observations, les caractères de la maladie connue sous le nom de croup, et la nature des altérations qui la constituent; les circonstances intérieures et extérieures qui en déterminent le développement; ses affinités avec d'autres maladies; en établir, d'après une expérience constante et comparée, le traitement le plus efficace; indiquer les moyens d'en arrêter le progrès et d'en prévenir l'évasion.

but in general, unless the patient be treated with promptitude and judgment, the disease may be expected to terminate fatally; a new order of symptoms, the second stage of croup as it is called, taking place in the course of the next day.

When the first or inflammatory stage of croup just described has not subsided or received a check, the cough, from being loud and sonorous, becomes husky and suffocative; it resembles the cough which attends tracheal phthisis, and cannot be heard at any distance from the bed; the voice is whispering; the respiration wheezing; the countenance pale; lips livid; the skin motley; the eyes languid; the iris with less colour than natural;* the pupils dilated; the tongue loaded, and with purplish edges; thirst considerable; skin much less hot; and the stools dark and fetid. In this, the second stage, or that of suppuration, the breathing may often be remarked most free in positions which are generally least favourable to easy breathing, as, for example, when the head is low and thrown back. When the breathing is a struggle for life, the patient sometimes will suddenly obtain relief, which, however, in general is only temporary.

From the state described in the last paragraph comparatively few patients recover. The eyes now become hollow; the countenance sinks; the circulation gradually fails; the extremities are cold and swollen; jactitation and drowsiness occur; the respiration becomes frequent, interrupted, and laborious; and, after gasping for a longer or shorter time, the child dies;—the duration of the disease being varied according to the stamina of the patient. When fatal, croup at an average occupies a period of four days. Sometimes, however, the second stage is prolonged for two or three weeks, and the patient, expectorating freely, slowly emerges from a condition which repeatedly had appeared hopeless. Along with puriform fluid, of which the sputa chiefly consist, there is sometimes expectorated a white soft tubular matter like macaroni stewed in milk, which is called the membrane of croup.

Prognosis.—The danger to which a patient in croup is exposed may be easily computed by any experienced practitioner who will bestow some consideration on the first or inflammatory stage of the disease. In this stage the hoarseness and cough (unaccompanied with the pulse of inflammation), how distinctive soever of croup, do not imply the existence of danger; a hard ringing cough, followed by a crowing inspiration, will often take place during several successive nights; and these symptoms may exist without danger, so long as the breathing is free and pyrexia absent. Very active treatment may not be required, but vigilance will be necessary. The medical attendant must be within call, and see the child more than once in the course of the evening, and take care that he is under the eye of a steady and experienced nurse, by whom he may, without delay, be certified of any symptom indicative of stricture of the glottis or inflammation of the bronchi. While the breathing is inaudible and the

pulse quiet, all may be considered, so to speak, as safe; but when the child crows in inspiration, when the breathing is audible, the air as if forced through a narrow tube, dry rather than wheezing—a sound which any one may voluntarily produce by contracting the glottis while he inspires,—or when the respiration is cooing or croaking, danger is present; inflammation has seized the larynx, has caused tumour and great irritation there, and has extended into the bronchi. This is no longer a case for *expectation*, but for action. On the other hand, when the cough becomes loose, the voice more natural; when the symptoms of inflammation abate, while no symptom of the second stage exists; we may give all reasonable encouragement. In the stage of suppuration the prognosis is always unfavourable; but a prudent physician in prognosticating the issue of any disease of childhood ought not to deliver himself without reservation; he ought ever to be ready for any contingency unfavourable or favourable; his prognostication ought to be declared, to use the words of a late eminent physician, to be “subject to the uncertainty of all medical opinions.”

Diagnosis.—The diseases which are liable to be mistaken for croup are the following:—

1. *Measles.*—This disease often resembles croup so much, that the most experienced physician need not be ashamed of mistaking the catarrhal symptoms, which, with a ringing cough, usher in the former disease, for the latter. This he will the more readily do, unless he knows that the measles are in the neighbourhood, or that the patient, some twelve or fourteen days before, was exposed to their contagion. Upon the efflorescence taking place in the measles, the symptoms resembling croup disappear.

2. *Cynanche pharyngea.*—When inflammation runs very high in this species of quinsy, we have known it extend to the larynx, and croup thereby has been simulated; but cynanche pharyngia will not be mistaken for croup, even under such a complication, if the fauces be carefully inspected, and if it be recollected that cynanche pharyngea is attended with complete dysphagia, whereas in croup the patient can always swallow with ease.

3. *Cynanche membranacea* or *maligna.*—This disease, when the morbid action descends from the fauces into the larynx, is more liable to be mistaken for the croup than any other. In croup, therefore, the fauces, which are scarcely, if at all, inflamed, ought to be examined with care, thus to distinguish it from cynanche membranacea, or any congeneric disease. If the fauces are discovered to be spotted, as it were aphthous, encrusted with a membrane, or apparently sloughy, the disease is not croup. Moreover, cynanche maligna, being propagated by contagion, often occurs in several persons of a family or neighbourhood at the same time, and can be traced from house to house, while croup is non-contagious. When two of a family have been attacked at the same time with croup, which we have often known to be the case, it has always manifestly appeared that both had been exposed to a cold damp atmosphere, or to some other adequate occasional cause.

* This paleness of the iris, which often attends the advanced stage of diseases, especially of the lungs, and which is a very unfavourable symptom, has, we think, been overlooked.

4. *Hysteria*.—Hysteria, which mimics so many diseases, not unfrequently assumes the character of croup. By the first case of this kind which he witnessed, the writer of this article was so completely deceived that he ordered the patient, a young lady who never had menstruated, to be let blood, and he remained during the operation. Before she had lost more than a cupful of blood, she fell into hysteric catalepsy. The vein, of course, was immediately closed, and by means of draughts of camphor julep, Hoffmann's anodyne liquor, with five or six drops of the acetum opii in each draught, her croup was easily cured: but hysteria exhibited itself in various forms before she finally recovered. Whenever a physician is called to a young lady said to be affected with croup or inflammation of the windpipe, let him bear in mind that hysteria sometimes acts the part of croup to the very life, and even although he cannot detect any overt act of hysteria, let him look narrowly into the history of the patient, and carefully study her diathesis before he delivers his opinion. Moreover, the patient's age will always be a guide to a true diagnosis, croup not occurring in adult age, or even in adolescence, and hysteria being rare before puberty.

SPASMODIC CROUP.—The symptoms of croup which depend upon stricture of the glottis differ so in degree, (sometimes suffocation appears impending, sometimes the breathing is nearly natural,) as to prove in many attacks the existence of spasm; this, however, is spasm caused by inflammation, for which no antispasmodic will be equal to venesection. That inflammation in this disease often spontaneously is resolved, the spasm depending upon it subsiding at the same time, is unquestionable, and has given rise to a belief entertained by those chiefly who have overlooked the evidences of inflammation, that there is a purely spasmodic species of croup; we therefore take the opportunity which presents itself of observing that the hysteric affection just alluded to is the only species of spasmodic croup with which we are acquainted. The term spasmodic croup has been applied to affections of very different kinds, by which many discussions have been excited. We are convinced that the difficulty attending these discussions has arisen chiefly from that fruitful source of error, the misapplication of terms. The designation spasmodic croup we have reason to believe has often been applied to the hysteric affection which we have just described. It has also been applied to a well-known disease of infancy, which one of our latest authors describes as follows: "Spasmodic croup occurs in very young children, and appears at the commencement of the period of dentition: sometimes earlier, and but very rarely after the child has reached its third year. The crowing noise which some infants make in respiration, and which nurses occasionally consider as a sign of thriving, is nothing more than the air rushing through the aperture of the glottis in a state of spasmodic constriction; and wherever this symptom appears, (however well the infant may seem in other respects,) it is always advisable to pay attention to it, and remove the source of intestinal irritation, which will generally be discoverable. In some

instances the constriction is both slight and momentary, and the spasm never produces either unpleasant or dangerous consequences: in others it is longer continued, and the infant works and struggles for breath, becomes purple in the face, and is apparently dying when the spasm begins to relax, and a long-drawn, crowing inspiration sets all things to rights again. In the fatal cases of spasmodic croup, death is extremely sudden: the infant may be apparently in good health, and in a moment he makes a violent effort to inspire, which occasions something like a faint scream or cry, becomes black or swollen in the countenance, and dies before assistance can be procured." Now this is a graphic description of a disease of which an account will be found in Dr. Clarke's Commentaries on the Diseases of Children, there entitled, "a peculiar species of convulsions in infant children," which has also been sometimes called chronic croup, sometimes inward fits; and which is furthermore distinguished by a clenching of the hands upon the thumbs, and a bending of the toes downward and inward, by which the foot appears slightly clubbed. This affection, which ought never to be called croup, is not attended with cough. On dissection there is no trace of inflammation in the windpipe; the seat of the disease, it can scarcely be doubted, being in the brain.

Having repeatedly observed the symptoms which in children are supposed to constitute a non-inflammatory variety of croup, and to which most frequently the term spasmodic croup is applied, symptoms which may be found in Dr. Good's valuable work, *The Study of Medicine*, embodied under the title of *Laryngismus Stridulus*, viz., "sense of suffocation commencing in the night; voice shrill and croaking; countenance flushed and swollen; distressing struggle for breath;"—we were naturally anxious to determine their true nature; and as it appeared that these symptoms took place at the time of night when croup is generally at its height; that they were brought on by causes which produce croup; that they occurred in individuals and families liable to croup; that they were most certainly relieved by the internal remedy most efficacious in croup, namely, an antimonial emetic; and, on the other hand, when it was considered that genuine inflammatory croup often invades suddenly and without any catarrhal symptoms preceding, and that its most formidable attacks will often subside as the symptoms of the supposed spasmodic croup are represented to do, without remedial treatment; there appeared to us no sufficient grounds for establishing a spasmodic variety of the disease. A sounder conclusion could not be drawn relative to spasmodic croup than that with which the late Dr. Kellie ends an able letter on this much-contested point. "After embarrassing myself a long time about spasmodic and inflammatory croup, and using my opportunities of observation to the best advantage of which I was capable, with the view of establishing the diagnosis of these two diseases, I came at length to persuade myself that there was truly no essential difference between them, other than what arises from degrees of violence, and the obvious circumstance of intermis-

sion and continuance." (See *Dr. Kellie's Letter*, Pathology of the Larynx and Bronchia, by J. Cheyne, M. D., p. 136.)

Predisposing Cause.—There would be less difficulty in explaining the nature of the predisposing cause of croup, did we know why the disease ceases at puberty. The difference between the glottis of a child of three years and of twelve is scarcely perceptible; whereas at puberty the aperture of the glottis is quickly enlarged in the male in the proportion of ten to five, in the female of seven to five; at the same time the bronchi enlarging, and the voice undergoing a corresponding change. Upon the windpipe and bronchial system, changed in their constitution, enlarged and invigorated, the occasional cause of croup is no longer able to produce an adequate impression: it may be conjectured, then, that in the immature state of the organs affected we are to look for the predisponent cause of croup.

Pathology of Croup.—Upon dissection, appearances are displayed which satisfactorily account for the symptoms of this disease. The symptoms, as the reader must have observed, are those of inflammation affecting the air-tubes of the lungs. The sound of the voice, the sense of strangling, (which the writer well recollects, having had a dangerous attack of the croup when he was not a very young child,) prove that the larynx is much affected; while the state of the complexion in the second stage, even when the uneasiness in the throat is relieved, the quickness of the breathing, the cooling respiration, the puriform sputa, would show that the inflammation has extended through all the branches of the bronchial tubes. Nay, the examination of the body after death, explains the sudden relief which the patient sometimes unexpectedly obtains in the second stage of the disease, as also the ease which he finds in positions generally unfavourable to free breathing.

The mucous membrane is found inflamed, and, in consequence of this inflammation, the larynx, trachea, and bronchial tubes are generally lined with a membranous substance, varying in consistence, of the same sort with that which, as has been observed, is sometimes expectorated: this substance, in a fluid form, fills the bronchi. In the trachea it is soon dried, and there it obtains form and consistence; it is often partially detached. Evidences of inflammation may generally be discovered over the whole of the mucous membrane of the lungs; the cavity of the lungs is always full of fluid; the interstitial cells are sometimes filled with serum; nay, we have known parts of the lungs hepatized, and inflammation to extend not merely to the parenchyma, but to the serous membrane, in consequence of which we have seen fluid effused into the cavity of the pleura. In many dissections the lungs have a solid feel, do not recede when the thorax is opened, and cannot be compressed.

The membrane of croup has been found partially detached, which will account for its being sometimes coughed out; and as children often swallow what would be expectorated by adults, there is reason to think that it is much oftener transferred to the stomach, upon which the struggle within the larynx ceases for a time; and this

explains the gleams of hope afforded in the second stage, which, however, for the most part are gradually obscured by the steady advance of bronchial inflammation and effusion. The relief obtained in unfavourable positions may be explained as follows: the trachea has its capacity increased by being stretched to the full extent, which happens when the head is thrown backward; whereas when the patient sits, which is generally the easiest posture in difficult breathing, the head falls forward, and the membrane, especially if it be in part detached, being doubled together, fills the trachea at one point, and completely obstructs the passage of the air.

Prophylaxis.—When croup has once occurred in a family, it will probably renew its visits, and will attack the same child or some of the other children on a future occasion; the physician therefore should instruct parents with regard to prevention. If possible, children liable to croup ought to live at a distance from bodies of water. They ought not to occupy warm rooms, or have a superfluity of bed-clothes. Beginning in summer, they ought to be sponged with cold water every morning, and rubbed dry with a coarse towel. In winter and spring they ought to wear flannel next their skin, and to have the neck covered. They ought not to drink fermented liquor. Their diet at all times, although nourishing, ought to be light; and finally, when the weather is cold and damp, and especially during the prevalence of the east wind, they ought not to be in the open air between October and May.

Treatment.—When a child becomes hoarse, and begins to cough, let every kind of stimulating food be withdrawn; let him be confined to an apartment of agreeable warmth; have a tepid-bath; and take a drachm of the following mixture every hour, or every two hours, if it produce sickness:—

R Vini ipecacuanhæ ℥iij.

Syrupi tolit. ℥v.

Mucil. acaciæ ℥i. M.

and all danger will probably be averted. Whereas, if no change be made in the quality of the food, and if he be sent into the open air, he will probably undergo an attack of bronchitis or croup.

When the breathing becomes affected in croup, or when there are symptoms of inflammatory fever, an emetic should be given without delay, and blood should then be drawn from the arm, or, in very young children, from the jugular vein, unless very great relief should follow the operation of the emetic.* Next we would give the patient a powder consisting of calomel and James's powder, probably two, three, or four grains of the former, with two or three grains of the latter, and we would then have him put in a tepid-bath, and supplied with diluting drinks. Every third hour, the calomel and James's powder ought to be re-

* We have adopted the following expedient, with excellent antiphlogistic effects, in violent inflammation of the lungs occurring in a robust constitution. Having ordered an emetic to be given, in eight or ten minutes after, before sickness has commenced, we have had a vein opened, and have found, before ten or twelve ounces of blood had flowed, that the patient has become sick, vomited freely, and fallen into a state of colligation, which has lasted for a considerable time,—a powerful impression being thus made, at a small expense of blood.

peated: if it should not, after a third dose, affect the bowels, a dose of castor oil may be given.

The quantity of blood drawn from a child under two years of age ought not to exceed five ounces; in a child of seven or eight it may amount to eight ounces. But one venesection will seldom suffice in a severe case of croup; it will very often be necessary, in two or three hours, to repeat the operation. When a second blood-letting fails to moderate the symptoms, we generally order leeches to be applied to the upper extremity of the sternum; three or four to an infant, ten or twelve to a child of as many years old. Leeches ought not to be applied to the region of the larynx, as children, in croup, will be found most impatient of the degree of pressure necessary to stanch the bleeding when profuse.

If manifest improvement be not produced by the application of the leeches, and if it be judged unsafe to have more blood drawn, a blister ought to be applied to the lower part of the sternum, and a solution of tartar emetic given. The dose of tartar emetic may be from a quarter to a half grain, and this may be repeated, according to its effect, and to the urgency of the attack. Sickness ought to be excited, and hence the dose, if it have no such effect, ought to be repeated in half an hour, and, if great prostration be not produced, the dose ought afterwards to be repeated hourly while symptoms of inflammation continue.

These may appear violent measures, but be it remembered that, in a vast many cases, the fate of the patient will be decided within twelve hours; nay, there are cases in which the inflammatory stage will be over in six hours from the commencement of the disease.

[In mild cases of croup, not preceded by bronchitic or pulmonic disease, in which the child is suddenly attacked with croupy cough and breathing at night, with little or no fever, the disease appears to be more spasmodic than inflammatory, and is generally removed by an emetic, with or without the warm bath. Such cases are often treated at home, without disturbing the medical attendant, by the Hive or Croup Syrup of Dr. J. R. Coxe,—the mel. scilla compositum of the Pharmacopœia of the United States,—the dose of which, as an emetic for children, is from ten drops to a fluidrachm, repeated every fifteen or twenty minutes, until vomiting is induced.]

With respect to the treatment of the second stage of croup, or that of suppuration, little can be added to what may be found in a work on the Pathology of the Larynx and Bronchia, published by the writer of this article many years ago. In that publication it is recommended to give half a grain of tartarized antimony, dissolved in a table-spoonful of water, to a child two or three years of age, every half hour, till sickness and vomiting are produced; and in two hours after the last act of vomiting the same process is to be recommenced, and so repeated while the strength will admit. The following case suggested this mode of treatment: a child, with disordered bowels, so delicate as not to admit of being let blood, was threatened with croup, every night, for five or six nights. Whenever the breathing became difficult, the child took as much of the antimonial solution as induced vomiting, and invariably with relief to

the difficult breathing. Perceiving that in croup, then pretty generally supposed to be a disease of the trachea, every part of the inner surface of the lungs, from the larynx through the ramifications of the bronchial tubes, was in general affected, and considering that nothing could more effectually moderate the vascular action in that organ, and at the same time dislodge the exudation which fills the bronchial tubes, than the solution of tartar emetic, all reliance was placed on that remedy in the second stage of croup, more especially as it was found that bloodletting in that stage only accelerated the death of the patient. The solution of tartar emetic was prescribed the more freely, from a child having been observed to take six or eight grains of tartar emetic, without vomiting being produced. In few cases has the writer known children survive the second stage of croup; in all of these, however, they recovered while using a solution of tartarized antimony: "Emetics he had repeatedly given in the second stage of croup, but in these cases of recovery the patients were kept sick for two or three days with scarcely any interval. With the exception of tartar emetic no medicine with which he is acquainted is entitled to confidence in the second stage of croup: calomel uncombined, as recommended by Rush, he has often given without benefit. Indeed, tartar emetic in croup, so as to produce continued nausea, has been his sheet-anchor since 1799." (Essay on Cynanche Trachealis, or Croup, by *J. Cheyne*, M. D. Edin. 1801.)

As there is in inflammations of the mucous membrane of the bowels a point of time, when life being rapidly on the ebb, a patient may sometimes be rescued by the substitution of opiates and cordials for the antiphlogistic regimen; so also is there, in bronchial inflammation, a time when we may with advantage lay aside all lowering remedies and give burnt brandy and ammonia, to which may be added calomel, with a minute quantity of opium, and the application of spirit fomentations to the surface. Gasping, failure of the pulse, and a clay-cold surface, show that our only faint hope is in cordials: it must be admitted, however, that a clear discovery of the point at which this change of treatment ought to take place is the reward of clinical experience alone, and cannot be made in the closet.

In the treatment of this disease we have but one point more to consider, namely, the propriety of attempting to remove the membrane of croup by means of a surgical operation.

Considerable difficulty will attend this operation. The larynx of a child from two to twelve years of age is a very narrow tube, not more than three-eighths of an inch in diameter; consequently, to admit the introduction of a pair of forceps, the cartilages must be cut across to a considerable extent, involving bleeding from the thyroid veins, which sometimes has been productive of suffocation. But even were the larynx laid open without hemorrhage, disappointment will probably arise from the state of the adventitious membrane, which sometimes possesses so little cohesion as not to admit of being laid hold of by an instrument for the sake of detaching and removing it; nay, in some cases in which the

inflammation is intense, there is no appearance of a continuous membrane, the secretion from the inflamed surface existing in the form of shreds and detached portions. "Dans plusieurs cas, et tout récemment encore, des médecins très-distingués ont pratiqué la trachéotomie sur des individus affectés de suffocation et de voix croupale, qu'ils regardaient comme dépendantes du croup. L'opération d'abord, et l'ouverture du cadavre ensuite, ont prouvé qu'il n'y avait pas de fausses membranes."—*Guersent Dictionnaire de Médecine*, tome vi. p. 213.

Before having recourse to the operation, supposing it easy, safe, and likely to end in the extraction of the adventitious membrane, it will be proper to ask, is the false membrane in the larynx, which it is the object of this formidable operation to remove, in general the cause of the patient's death? We apprehend not. First, because in several dissections which were long ago made with a view of determining the effect of the membrane of croup in obstructing the larynx, it so happened that within that membrane a space was left for a current of air sufficient to support life: in these bodies the cellular substance of the lungs was distended with serum, the ramifications of the bronchi were filled with puriform matter, by which the air was excluded, and the bronchial membrane was universally inflamed, thereby preventing the arterialization of the blood: the children had perished from the lungs being unable to contain a quantity of air sufficient to support the circulation, and from the bronchial membrane being unable to act upon that reduced quantity. Secondly, because when the membrane of croup, fully formed, is expectorated, the disease is generally fatal, even when all the benefits of the operation are obtained. If the disease were confined to the larynx, then, and then only, would bronchotomy be advisable. The following are the very pertinent remarks of Mr. Porter on this subject:—"But bronchotomy has in many cases of croup been successful. True; but where are the thousand instances to the contrary that might be brought against each single one of these? I have performed the operation myself on the child, and have seen it frequently done by others, and in no one case has the life of the patient been saved. I have known and heard of it often, but never understood that it produced a recovery. Most practitioners are fond of publishing cases of successful operations, but are not so willing to make known those of an opposite description, from an idea that these supposed failures might lower them in public estimation; but these detached and solitary expositions of fortunate surgery are calculated to produce very serious injury, if they encourage others to similar attempts, in the hope of similar results. If it was possible to place a list of those cases in which bronchotomy had proved unserviceable, in array against those wherein it had seemed to be useful, it would be scarcely necessary to advance any further argument in proof of its uncertainty; and medical men would rather turn their attention to the improvement of that internal treatment, which will generally be efficacious if resorted to in time, than look for advantage in the performance of an operation from which experience holds out such

slender hopes." (*Observations on the Surgical Pathology of the Larynx, &c.* by *W. H. Porter*, A. M. &c.)

[The testimony for and against the operation has been given elsewhere: (See the writer's *Practice of Medicine*, 2d edit. i. 246: Philad. 1844.) It would appear, that of 140 operations, 112 terminated fatally.]

Improvement of the internal treatment of croup will, in all probability, chiefly flow from the acquisition of more clear and determinate views with respect to the nature of that disease. Some of the latest authors on nosology have formed a juster conception of croup than their predecessors did, having classed it with diseases of the lungs and not of the throat. Swediaur represents croup as a genus of the order Phlegmasiæ, and entitles it Bronchitis; Young as a species of the genus *Cauma*, or inflammatory fever, under the title of *Cauma Bronchitis*; and Good includes it under the genus *Empresma* or visceral inflammations, calling it *Empresma Bronchlemmitis*, or membrane-like inflammation of the bronchi. The latest of these authors observes that croup essentially consists in an inflammation that spreads through the whole range of the windpipe, from the larynx to the minutest ramifications of the bronchi.

This is a juster view of the matter than that of some of our contemporaries in France, who have endeavoured to identify croup with affections primitively of the fauces, beyond which they often do not extend; affections some of which in their constitution are the opposites to croup. MM. Bretonneau, Guersent, and others, have endeavoured to prove that croup and epidemic angina maligna are one and the same disease; that although there may be some little variety in their seat, there is none in their nature: "M. Bretonneau a démontré que l'angine maligne épidémique est une véritable inflammation pelliculaire, semblable à celle du croup. Il a prouvé ensuite, que ces deux maladies, identiques quant aux altérations pathologiques, ne diffèrent que par rapport au siège qu'elles occupent."—*Guersent*, l. c. It is strange, that among a people remarkable for their minute and patient study of disease, and their refined arrangements, croup and cynanche maligna should be considered identical, because of a certain gross resemblance between them, because in both there may often be found an adventitious membrane, and because in the latter, when the diseased action is extended to the windpipe, there may arise some of the symptoms which belong to the advanced stage of the former. What real identity can there be between two diseases, the one caused by cold, the other by contagion; the one always purely inflammatory, the other generically typhoid; the one requiring a decidedly antiphlogistic treatment, the other local stimulants of the most powerful kind, tonic medicines and cordials—bark and wine, according to the procedure of our fathers? If we yield ourselves to this figment of our ingenious neighbours, we must, in the present instance, relinquish one of the great advantages which nosology affords, namely, a ready means of distinction between diseases similar in appearance but different in their essence.

If this attempt at the identification of contraries should succeed, it is obvious that the treatment of croup, which at present is simple, will hereafter be complex, difficult, and uncertain. To bear out this assertion, we shall briefly examine some parts of the chapter which Laennec has written on croup, assuming it as a fair representation of the opinions of his countrymen. I prefer an appeal to Laennec, as (although in point of practice he is often marvellously deficient) the genius of that great observer, and the ability of his translator, have obtained for his treatise on the diseases of the chest, authority in Britain as a work of pathological reference.

Laennec tells us that "sometimes croup is confined to the bronchia and their branches, there being no trace of it in the larynx and trachea." This fact would require to be established. "More commonly, as has been shown by Bretonneau, the inflammation commences on the tonsils or the pharynx, and from thence spreads at the same time downwards to the larynx, and upwards to the cavity of the nostrils, which latter it sometimes entirely covers. Occasionally the false membrane extends to the stomach." Again, "If the disease commences in the fauces, spots of a yellowish or greenish colour, surrounded by a deep red, are at first perceived on the tonsils, the pillars of the veil of the palate, or the back part of the pharynx; these specks gradually extend, unite, and increase in thickness, so as at last to form a complete crust like that of inflamed blood, lining the whole entrance of the fauces, and extending in a greater or less degree into the larynx, trachea, and bronchia." Such incrustations, proceeding from an inflamed membrane, and extending into the larynx, every experienced physician is acquainted with, in croup, and in scarlatina anginosa also, inflammation and incrustations, extending from the fauces to the larynx, may often be observed; and we doubt not that such appearances are observable in a species of angina which can be classed neither with angina maligna nor with scarlatina anginosa,* but in genuine croup, as it occurs in Scotland and Ireland, never.

If it be objected that the diphtherite of M. Bretonneau and the croup of Cullen are different diseases, and that the French physician endeavours to identify with croup a form of angina, under the name of diphtherite, with which English physicians are unacquainted, or have not described in their writings; we would meet the

* We have seen instances of membranous angina, (occurring during the prevalence of gastric fever,) which did not appear to belong either to croup, or to scarlatina anginosa, and which a French physician would probably have considered as specimens of diphtherite, or, it may be, of croup. We recollect attending in one family two children who died of angina, accompanied with an exudation of concrete lymph, which from the symptoms must have lined the upper part of the windpipe as well as the fauces: this exudation, as it appeared on the fauces, we considered to be a slough, the discovery of Bretonneau not having been made. Many years after, three children, also in one family, were affected in a similar manner, during a similar epidemic constitution, two of whom died.

These cases were not attended with an efflorescence of the skin, nor were they traced to contagion, but we cannot affirm that the disease was not epidemic. At the period of the occurrence of the last three cases, a similar incrustation often covered the fauces of those who were labouring under gastric fever, to which disease we were inclined to think that this angina was allied.

objection by calling the attention of the reader to the following passage in Laennec, wherein a disease, which is either croup or angina or an ideal affection, is upon the authority of MM. Guersent and Bretonneau termed croup. "In some cases of croup, such as occur in hospitals, the state of the system is very different, there being evident marks of a septic change in the fluids of the body: the pulse is but little accelerated, the skin harsh and dirty, the debility extreme and the breath fetid, even when no gangrenous specks appear: this variety is, by Guersent and Bretonneau, denominated asthenic. Asthenic croup would seem occasionally to be propagated by infection." Asthenic croup! croup with an unaccelerated pulse, fetid breath, and propagated by infection!—Laennec, after describing croup, talks of that affection resulting from a gangrenous angina, in which eschars are distinguishable before the appearance of the false membrane, and in which the gangrene is indicated by its peculiar odour. If the disease of M. Bretonneau be not croup, let it henceforth be known as *diphtherite plastic angina*, *angine couenneuse*, or *angina membranacea*, or let the next observer invent a new name more to his taste; only let him not term it croup, which is a title already applied to an affection of a very different kind, which belongs to another order of diseases.

[Almost all pathologists admit, that the essential character of croup is a violent laryngo-tracheitis, with tendency to the exudation of plastic lymph; but the generality of British and American practitioners regard it to be very different from the diphtheritic inflammation that occurs in diphtheritic stomatitis and pharyngitis, described by Bretonneau and Laennec. In *primary croup*, as it has been termed by Dr. Stokes, the accompanying fever is symptomatic. It is this which is met with in childhood; whilst *secondary croup* is a symptomatic affection, and is the croup of the adult—the *diphtherite* of Bretonneau. Between these two forms of croup Dr. Stokes has pointed out the following differences:

PRIMARY CROUP.

1. The air passages primarily engaged.
2. The fever symptomatic of the local disease.
3. The fever inflammatory.
4. Necessity for antiphlogistic treatment, and the frequent success of such treatment.
5. The disease sporadic, and, in certain situations, endemic, but never contagious.
6. A disease principally of childhood.
7. The exudation of lymph spreading to the glottis, from below upwards.
8. The pharynx healthy.
9. Dysphagia either absent or very slight.
10. Catarrhal symptoms often precursory to the larygeal.
11. Complication with acute pulmonary inflammation common.
12. Absence of any characteristic odour of the breath.

SECONDARY CROUP.

1. The laryngeal affection secondary to disease of the pharynx and mouth.
2. The local disease arising in the course of another affection, which is generally accompanied by fever.
3. The fever typhoid.
4. Incapacity of bearing antiphlogistic treatment, necessity for the tonic, revulsive and stimulating modes.
5. The disease constantly epidemic, and contagious. [?]
6. Adults commonly affected.
7. The exudation spreading to the glottis, from above downwards.
8. The pharynx diseased.
9. Dysphagia common and severe.
10. Laryngeal symptoms supervening without the pre-existence of catarrh.
11. Complication with such changes rare.
12. Breath often characteristically foetid.]

The directions given by Laennec relative to the treatment of croup evince a judgment in this matter, perplexed and distrustful of itself and of the resources of medicine; a disposition to temporise, arising, as we may infer, from his conception of the nature of the subject being clouded.

"In doubtful cases," he says, "it would seem preferable rather to omit bleeding than to destroy by injudicious depletion the powers requisite for the separation and excretion of the false membrane." As to the question of bleeding in croup when the disease is once established, no doubt ought to exist, unless perhaps we may hesitate with respect to its stage. If the patient is in the first or inflammatory stage of croup, no experienced physician will omit bleeding; if in the second, or that of suppuration, no physician will propose it. If it were doubtful to which stage the symptoms belonged, it would be preferable to bleed: the anæps remedium ought to be preferred. Bloodletting would probably bring relief if the patient were still in the first stage, and by that measure little would be taken from our hopes were he in the second, from which so few recover. Nothing but the mingling together of incongruities and consequent misapprehensions of croup could have induced an eminent physician like M. Bretonneau to make so dangerous an observation as the following: "I am forced to declare, contrary to the received opinion, that bleeding in croup has done harm, and accelerated rather than retarded the spread of the coriaceous inflammation. I did not abandon this measure till after reiterated proofs of its injurious effects." Physicians need not be told not to bleed in cyananche maligna,—it never was their practice to do so, nor would they willingly bleed in any form of membranous angina; but if they renounce bloodletting in the first stage of croup, which they are taught to do by this sweeping dogma of alleged experience, they will part with the best shaft in their quiver. This is no question of nosological subtlety; if so, we would have kept aloof: it is a matter of life and death.

We shall conclude these observations with one more quotation from Laennec. "All practitioners who have had occasion to see a good deal of this disease, will readily admit that these measures, although very rational and conformable to the results of experience in the treatment of inflammatory diseases in general, are nevertheless rarely sufficient, and that very few well-characterised instances have yielded to their influence." Such a conclusion naturally flows from an attempt to identify a sthenic and an asthenic disease. The reader may be assured that the practice of medicine would be much more satisfactory than it is, were the nature of every disease as well understood, the principles of treatment as clear, and the results as uniform as in the instance of genuine croup. If croup is considered as purely an inflammatory disease, and, in consequence, if the treatment of it be rigidly antiphlogistic, the event, when timely aid is afforded, will be almost invariably favourable. If, indeed, the golden opportunity is lost, and the first stage is allowed to pass without proper assistance being given, while the importance of his profession in his own eyes must be enhanced, the physician can accomplish comparatively little, and the gloomy reflection of Laennec, being modified, may be assented to, namely, that very few well-characterised instances of croup, in the second stage, will yield to the influence of measures even the most rational and conformable to the results of experience.

French physicians have of late so honourably and successfully distinguished themselves by their zeal in the prosecution of pathology, that we would readily yield them our confidence, did we not know that such a disposition of mind ought ever to be resisted. The same rule ought to guide our researches into the nature of disease which governs the student in a much higher department of knowledge, viz. "Prove all things;" to which very well may be added on the present occasion, "hold fast only that which is good." J. CHEYNE.

[Notwithstanding the strong remarks of Dr. Cheyne, the difference between idiopathic or primary, and symptomatic or secondary croup, is now, as before remarked, admitted by pathologists; and hence it becomes necessary to make some observations on the treatment of the latter, or what has been called **Croup of the Adult**, which is connected with the same diphtheritic habit that gives occasion to diphtheritic stomatitis and diphtheritic pharyngitis. The remarks as to pathology and therapeutics, made under the latter disease, are equally applicable to the present. Mercury administered so as to affect the system, has been given with the view of diminishing the plastic tendency of the blood, and cases are recorded in which severe diphtheritis of the air-passages appeared to yield to it. Great reliance has, however, been placed on the topical applications recommended in diphtheritic pharyngitis, and especially on the muriatic acid, nitrate of silver, and alum, applied in the manner recommended under chronic laryngitis. (q. v.) Tracheotomy has likewise been advised in diphtheritic laryngo-tracheitis, when urgent symptoms arise that threaten suffocation. Perhaps in such cases it might be more serviceable than in primary croup, in which there is so frequently a combination of bronchial and pulmonary inflammation. It has been proposed also with another view, to introduce through the aperture the local applications that have been found useful. Fragments of the pellicular exudation have been occasionally expelled through the opening, and through it agents, as calomel, have been introduced to act on the morbid surface. Eight grains of calomel, introduced in this way, appeared to M. Bretonneau to afford marked relief in one case. Powdered sugar and powdered alum have been blown into the larynx through the aperture in the same manner. One of the great advisers of topical agents introduced into the larynx, M. Trousseau, seems, however, to have less confidence in them than formerly. They are not much employed. (*Practice of Medicine*, 2d edit. ii. 247: Philad. 1844.)

ROBLEY DUNGLISON.]

CUPPING. (See BLOODLETTING.)

CYANOSIS, (*κίανος νόσος*) *morbus caruleus*, blue disorder, blue jaundice of the ancients, a morbid appearance which consists in the skin assuming a blue, purple, or violet colour, especially in those parts where the cutaneous capillary vessels are superficial, as on the cheeks and lips.

This colour may be a symptom of many different diseases; but in some instances it is of so marked a purple, and the accompanying symptoms are so variable, that most physiologists have

given this affection its denomination from the colour developed, in preference to one from any assemblage of symptoms; thus constituting the appearance of an idiopathic disease under the appellation of cyanosis. Whether they are justifiable in so doing is questioned by others, who consider the blue colour as indicative of a cachectic or scorbutic habit, or attributable to other causes.

Cyanosis is generally accompanied by difficult respiration, palpitation of the heart with diminution of the natural temperature, an irregular or intermitting pulse, and is often attended with dropsical symptoms, the face especially, in addition to the purple colour, being bloated and oedematous: all these symptoms are much aggravated by any exertion.

When this disorder first attracted the notice of physicians, it was considered to depend on an ulcerated state of the foramen ovale. A few cases where this imperfection occurred were first observed in young subjects, who survived but a short time, the blue colour being intense, and the arterial system supplied with dark venous blood, to the circulation of which through the arteries this tint was attributed. This view was confirmed by the observations of several distinguished anatomists; Senac, Morgagni, and others, reporting that they had in such instances found free communications between the right and left cavities of the heart, which should not have existed. This view appeared to be confirmed by chemical facts, with relation to the blood not having undergone that change in the lungs which vivifies it and fits it for the general circulation; as well as from the symptoms which those subject to such affections had suffered previous to death,—dyspnoea, diminished temperature, weakness, languor, and an engorged state of almost every organ; symptoms generally associated with a want of the due oxygenation of the blood in the pulmonary circulation.

Although cyanosis is often found in connection with an open state between each side of the heart, many cases have also occurred where this imperfection has been absent, and yet in which all the symptoms of cyanosis have presented themselves. Corvisart was one of the first who put this opinion upon record; stating that a permanent blue colour of the integuments was often connected with an unnatural communication between the cavities of the heart, but that many facts induced him to say we could not always arrive at the same conclusion. Several examinations after death occurred to him and others of his contemporaries, in which, though the blue colour had been strongly marked during life, there was no communication between the opposite sides of the heart. The writer of this article has met with some cases of this description, inasmuch that for some years he began to doubt the necessary connection between the blue colour of the skin and such a free communication. On the other hand, he has seen several cases where there was a free opening between both auricles and ventricles which must have subsisted for many years, and yet in which there was no cyanosis. In one of these cases, which is published in vol. i. of the Medical Transactions of the College of Physicians in Dublin, (New Series,) the communications were so large and so

free that the heart might be considered single, or consisting of one auricle and one ventricle: in this instance there was no cyanosis. Nearly similar appearances occurred to Fouquier, Breschet, and Bertin; and indeed have occurred to all those who have been conversant with the diseased appearances of the heart. One case in particular was met with by Breschet, in which the left subclavian took its rise from the pulmonary artery, and yet there was no blue colour in the parts supplied by the ramifications of that vessel.

[A case has been published by Professor Huss, of Stockholm, (*Gazette Méd. de Paris*, 14 Févr. 1843.) in which there was a communication between the aorta and pulmonary artery without cyanosis; and, more recently, (*Edinb. Med. and Surg. Journ.*: Oct. 1843.) Dr. Craigie has inferred, from a case related by him, as well as from several others, *first*, that the open state of the foramen ovale is rarely a primary and solitary lesion; *secondly*, that when it is a solitary lesion it is not injurious, and the venous blood of the right auricle is not thereby necessarily mixed with the arterial blood of the left auricle; and *thirdly*, that in opposition to what has been hitherto usually taught, the open state of the foramen is, in a large proportion of cases, the means of prolonging life,—an imperfectly oxygenized blood being adequate to maintain vital action. (See ASPHYXIA.)]

It would appear, then, that the mixture of venous with arterial blood will not necessarily produce cyanosis, and that the foramen ovale may be open, allowing this admixture to take place, without the disease in question being the result.

Difficult questions, no doubt, will arise with respect to the consequences of the want of oxygenation in the blood. How is a limb deprived of arterial blood to maintain its heat? How can it preserve its vitality, or retain its colour? It is probably because the circulation is free and unembarrassed, and that there is no obstruction to the depletion of the extreme capillaries. A free and uninterrupted circulation of the blood through the capillary system appears to be necessary to the maintenance of a proper colour in that fluid: stagnation or obstruction impairs it in proportion to its amount. John Hunter included a portion of an artery between two ligatures, thus inducing a stagnation in the intercepted fluid: the result was a change of colour from bright red to purple in the blood thus separated and brought to a state of rest. In all instances also of ecchymosis and petechial extravasion, the effused patches or points assume a purple hue.

A partial stasis, then, in the capillaries, whether venous or arterial, on the surface, should more or less exhibit a purple tinge; and such actually takes place in some morbid states not usually noticed.

Towards the close of fevers terminating fatally, and in other disorders where the functions of the nervous system are much impeded, and the circulation consequently begins to fail, we have often observed the purplish colour in the lips, cheeks, and inside of the mouth; appearances which may be evidently seen long before death. And what is this but a cyanosed state, induced by a stagnation in the capillary system, which now wants

its propulsive power, when deprived of the nervous energy?

All the anatomical observations on this subject, however, confirm the fact, that in every instance of cyanosis examined after death, the right cavities of the heart have been found enlarged, dilated, or thickened, whether there was accidentally an opening or not. Corvisart, in particular, enumerates a blue or violet colour of the face and lips as appertaining to organic lesions in the right cavities of the heart, and of the whole venous system, which is in a great measure under their guidance.

In persons of an advanced age, affected with disorders of the heart, this bluish tint is not uncommon, and generally occurs in concurrence with an injected or dark colour of the mucous membranes. In these disorders, towards the close of life, there generally occurs some obstacle to the aortic circulation; this obstacle is generally connected with hypertrophy of the left ventricle; stagnation of blood in the lungs then takes place; and to this succeeds passive dilatation of the right cavities of the heart.

It has been further observed that infants at birth are often cyanosed: this may arise either from the impermeable state of the lungs, or from want of action of the respiratory muscles, especially after tedious and difficult labours. Inflation of the lungs, and other aids, frequently remove this blue tint by exciting respiration.

A want, then, of renovated arterial or oxygenated blood is not the only cause of cyanosis; it appears to depend also on obstructed pulmonary circulation, or other impediments to a free return of the blood to the right cavities of the heart.

A bluish or cyanosed appearance on the surface is known also to take place when nitrate of silver has been administered internally; and this tint has in some instances become permanent. The nitrate, in all probability, is decomposed, and oxide of silver becomes deposited in some part of the superficial cutaneous tissue.

The tinge imparted to the skin in liver diseases differs altogether from the violet hue peculiar to affections of the heart. There is a variety of jaundice described by Dr. Baillie, in the Transactions of the College of Physicians of London, which he calls the black jaundice, where the colour in some degree approximates to the blue tinge; but in the disease described by him the colour is more of a leaden or sooty character. In some few instances, where there was melanosis of the liver, the tint of the skin has appeared to the writer of this article unusually dark, and differing from the ordinary colour observed in hepatic affections. But in all these instances the distinctive characters are sufficiently striking. The state of the circulation and of the respiration is almost sufficient to afford a diagnosis; and there are other characteristic symptoms sufficiently impressive and well known, which need not be enumerated.

Bluish and bruised patches occurring in purpura, and in ecchymosed states, do not require notice further than that they are often connected with obstructed circulation in the lungs and through the heart, or with failure in the nervous energy; but for information respecting these the reader is referred to the article PURPURA.

With respect to the treatment of cyanosed affections, it is obvious, when it is considered that they depend on organic lesions, that no general plan suited to cure idiopathic cyanosis can be laid down. The radical or complete removal of such disorders is quite beyond the reach of our art. The treatment must be palliative, depending of course on the precise mode of lesion in the individual instance to be treated.

In all cases it is important to maintain a healthy state of the digestive functions by suitable diet and the use of such medicines as regulate the bowels; as the functions of the liver and other organs of assimilation are principally deranged, for want, in some instances, of blood properly renovated in quality, and in others from the circulation not being sufficiently free and unobstructed through these organs.

Acute pulmonary affections often supervene in subjects of this description; and bloodletting and the other usual aids are required more promptly than in ordinary instances where there is no such complication. But it may be observed that persons advanced in life, or even at earlier periods of existence, when weakened by protracted suffering, do not bear sanguineous depletion well. It has been already remarked also, that sufferers from this disease are frequently affected with dilatation of the right cavities of the heart, and that in a passive form; in these cases bloodletting, which, except in cases of excessive sanguineous plethora, affords only momentary ease, is often followed by great prostration of strength.

When this disease is attended with dropsical symptoms, the remedies usually resorted to in dropsical affections will afford temporary relief.

In those cyanosed disorders where the strength is much reduced, the circulation languid, and the temperature below the natural standard, considerable benefit will be derived from wine, cordials, and stimulants; and opiates will control symptoms arising from tumultuous and irregular action of the heart. It is important to maintain a tranquil state of both mind and body; active exertion is nearly precluded in such disorders, but gestation in the open air is most useful in mitigating the symptoms and prolonging life.

[In the *Cyanosis of the New-Born*, *Cyanosis neonatorum*, Professor Meigs (*Proceedings of the Amer. Philos. Society at the Centennial Meeting*, May, 1843) lays great stress on the effect of position. He recommends that the child should be placed on its right side, with its head and shoulders inclined upwards, upon pillows, and be kept in this position for hours. "Upon placing the child thus, its septum auriculorum becomes a horizontal plane, supporting the blood in the left auricle. The weight of that blood presses the valve of the foramen ovale into coincidence with the plane of the septum, and closes the patulous orifice. The succeeding injections of blood take their proper route to the lungs and the system, so that a few acts of the respiratory muscles give sufficient doses of oxygen to the blood to diminish, and to rapidly remove, the excess of carbon, and the child is cured."

Rest is, doubtless, an important agent in many of these cases in establishing the circulation properly; but, on the other hand, a smart blow on

the breech not unfrequently effects the same object more speedily. Where the cyanosis is owing to positive malformation, no agency will be of any permanent advantage. (*Practice of Medicine*, 2d edit. i. 489 : Philad. 1844.)

CYSTITIS. Cystitis, or inflammation of the bladder, exists in various degrees, from that slightest form which is indicated by an increased secretion of mucus from its lining membrane, to the intensely inflamed state which runs rapidly on to gangrene. Although the several inflamed conditions of the bladder are so intermingled, and pass so gradually one into another, that they require to be viewed in close connection in order to be clearly understood; yet it is useful, for practical purposes, to distinguish between the highly inflammatory or acute cystitis, and the mild or mucous form to which Lieutaud gave the name, now generally applied to it, of *catarrh of the bladder*.

I. ACUTE CYSTITIS.—Acute inflammation of the bladder is known to exist by burning pain in the region of that organ, pain at the extremity of the urethra, tenderness of the hypogastrium, and frequent calls to void urine, which is expelled in small quantities and with distressing spasms. The local symptoms of inflammation are accompanied with the usual constitutional disturbance, ushered in by smart shivering, and denoted by frequent tense pulse, hot skin, thirst, loss of appetite, constipated bowels, and much restlessness. As the disease advances, the pains shoot from the bladder to the anus, the loins, down the thighs, and even to the epigastrium; complete retention of urine takes place, and the distended bladder is felt as an oval tumour rising tense above the pubes. The tenderness, which was at first confined to the hypogastrium, diffuses itself over the whole abdomen; obstinate vomiting of bilious fluid and hiccup take place; delirium comes on, coma or convulsions at length supervene, and death follows. The urine, during the progress of the inflammation, undergoes several changes. At the commencement it is high coloured, as in other inflammations; then becomes mingled with flakes of coagulated albumen, or with blood, bloody urine being more especially observed when the disease has been induced by a poisonous dose of cantharides: as the disease proceeds, the urine acquires a highly offensive odour from its ammoniacal and putrescent condition, resembling more the washings of putrid flesh than human urine.

In this brief sketch of the symptoms of acute cystitis, we may trace the progress of the inflam-

mation from the mucous coat of the bladder, which is the most irritable and the most readily affected by disease, to the muscular tunic, and lastly to the peritoneal. Anatomists have well remarked that the first of these membranes is but loosely connected by cellular membrane to the second, and this still more loosely to the third; but they have erred in believing that acute disease is not speedily communicated from one to the other. A strong and indissoluble sympathy links them altogether, and renders them prone to follow each other in the train of inflammation.

When acute cystitis, instead of commencing within the bladder, is communicated from some of the adjacent parts, as the uterus, the rectum, or the immediately adjoining cellular tissue, the order in which the coats become successively inflamed will be different; and the muscular or peritoneal coat will then be the first affected. It is rare for the whole mucous membrane to be seized at once with inflammation: most commonly it affects the portion lining the neck of the bladder,—sometimes the upper fundus, at other times the anterior part, at others the posterior,—and involving the orifices of the ureters, it obstructs the entrance of the urine, causes the ureters to become distended, and producing pressure upon the kidneys, in this manner speedily proves fatal.

A slight degree of inflammation, or perhaps we ought to say irritation of a mucous membrane, causes an increased secretion from its surface; a greater converts the natural mucus into a puriform fluid; and a still higher degree of inflammation replaces the secretions by an effusion of plastic lymph. This progression we find in the inflammatory affection of many other mucous surfaces besides that of the bladder; of which the exudation of croup, and the false membranes discharged from the alimentary canal and the uterus, are examples. The last change produced in the mucous membrane of the bladder by inflammation is gangrene, which sometimes affects the whole surface; at other times it appears in patches; and in either case it is often found that at one spot all the tunics have become sphacelated, perforation has taken place, the urine has escaped into the peritoneal cavity, and thus destroyed the patient.

When cystitis is prolonged, the mucous membrane becomes ulcerated, and the ulcers, when small, bear no remote similitude to primary syphilitic sores, by their excavated surfaces and raised margins; a fact which we have had opportunities of verifying by dissection. Ulceration is often more extensive, for the whole interior of the bladder has been found eroded, and in some instances the muscular fibres of the organ have been exposed as if by the knife of the anatomist. When ulceration of the mucous coat deepens and penetrates through the other tunics of the bladder, it is usually accompanied by the effusion of plastic lymph exterior to the ulcer, which thus glues the neighbouring parts together, and prevents the escape of the urine: but instances have occurred in which an ulcer of the bladder has terminated in perforation, just as from gangrene, though more slowly, and in like manner has proved fatal. The existence of ulceration of the bladder cannot be certainly known during the lifetime of the patient; but there is always reason to suspect it when dis-

case of that organ has been of long continuance, when the pain is unceasing and excessive, and when pus is distinctly detected in the urine. We must not, however, expect to see pus in a separate state, for it is rarely discharged without a copious admixture of mucus; and this we have known to be the case when dissection revealed ulceration both of the kidney and bladder.

Inflammation of the muscular tunic of the bladder may arise either in the membrane itself, or be communicated from the adjacent textures. In some cases the inflammation of this membrane has induced circumscribed suppuration, (*Chopart, Maladies des Voies urinaires, t. i. p. 453:*) in others the pus has been infiltrated extensively among the muscular fibres (*Bonctus, Sepulchretum, lib. iii. sect. 23*) of the bladder. Extensive abscesses have also been found between the muscular and peritoneal coats; and death has in this manner been produced in numerous cases of lithotomy. *Chopart* relates a very interesting case of large abscess around the bladder, which occurred in the practice of *Moreau*. In this case, that distinguished surgeon, after making an opening above the pubes, struck his bistoury into a suspected spot near the anus, and formed a counter-opening, by which he succeeded in saving his patient.

Inflammation of the peritoneal coat is often the close of a fatal disease of the bladder; but that it takes place under other circumstances, without any dangerous consequences, we have sufficient evidence from the old adhesions not unfrequently found connecting this part to the omentum, to portions of the intestine, to the uterus, or to the rectum. In a recent case of diseased prostate, the omentum was found attached to the peritoneal covering of the upper fundus of the bladder.

In all prolonged diseases of the urinary bladder, when frequent ineffectual attempts are made to evacuate its contents, the muscular coat acquires an extraordinary increase of size and firmness, separating into distinct bundles, which project on its internal surface, and leave spaces through which the mucous membrane is forced, thus forming small pouches: this is not the consequence of inflammation, but of increased muscular action. There is, however, an indurated and thickened state of the bladder which is produced by inflammation, and of which *Frank* has given an interesting example, where he was led to conclude that the whole anterior part of the bladder was in a state of callous induration. (*J.P. Frank, De Curand. Hom. Morb. tom. v. Retention. Mucoso-Lymphat. Vesicæ.*)

When acute cystitis is about to terminate favourably, and the violence of the disease has spent its force, the natural mucus of the bladder is increased in quantity and altered in its appearance: it separates from the urine on standing, and forms a ropy gelatinous-like fluid,—the complaint passing into that milder form which has been named catarrh of the bladder.

Causes.—Acute cystitis is induced by direct injuries, as by wounds, contusions, severe exercise on horseback, prolonged travelling in a carriage over rough roads, the introduction into the bladder of foreign bodies, as bougies and sounds: the latter are too often incautiously used: indeed to

the examinations made under such circumstances may, in some instances, be traced the fatal result of the subsequent operation of lithotomy. Calculi themselves also produce cystitis, commonly of the mild or chronic form, or catarrh of the bladder. All mechanical obstructions to the discharge of the urine, as strictures of the urethra, enlargement of the prostate gland, and calculi lodged in the neck of the bladder, may prove causes of cystitis. It is induced likewise by exposure to cold and moisture, by excess in drinking, by the internal use of cantharides, and even by their application to a highly sensitive and partly abraded surface, as in *Ambrose Paré's* case of the lady who was cured of an obstinate eruption in the face by blistering. (*Œuvres, fol. p. 777.*)

Cystitis also takes place by continuous inflammation spreading along the mucous membrane from the urethra in gonorrhœa, or from the kidneys when they are diseased. It may likewise be communicated by an extension of inflammation from adjacent parts; from the translation of migratory diseases, as gout and rheumatism; or from the recession of cutaneous eruptions: these are, however, causes of chronic rather than of acute cystitis.

Treatment.—The treatment of acute cystitis is to be commenced by free venesection and the warm bath, which may be followed by leeches to the perineum and groins. Should the bladder be much distended, its contents ought to be evacuated without delay, but until some impression be made on the local inflammation, the introduction of the catheter will be exceedingly painful, and productive of no permanent relief. A full dose of calomel ought to be given, combined with a grain or two of opium; and after some hours the bowels may be relieved by castor oil or an emollient enema. Free perspiration ought to be kept up by *Dover's* powder and the cautious use of antimonials; while warm opiate fomentations or poultices, bags of heated salt, or bladders filled with hot water, are applied to the pubes and perineum. Diluents should be freely given, and the patient restricted to a spare diet of the mildest kind of food. When cystitis has terminated in the formation of abscess, this ought, if within reach, to be evacuated as early as possible by a free and depending opening; while the tendency to hectic is checked by cool air, tepid sponging, and the mineral acids, and the strength of the patient is supported by gentle tonics and light nutritious diet. When ulceration has fairly established itself within the bladder, the resources of our art are rarely of much avail; but we are not warranted in assuming that such cases are altogether incurable; for instances are recorded, and some have come under our own observation, in which health has been restored after calculi and other foreign bodies have escaped by ulceration from the bladder. The sufferings arising from ulceration of the bladder are remarkably mitigated by the full action of calomel and opium, and by the formation of issues over the pubes. Benefit has also been obtained from the administration of uva ursi, pareira brava, and the weak saline and aerated mineral waters.

Of the practice of injecting mucilaginous diluents and mild astringents into the ulcerated blad-

der, we cannot speak from experience; but we feel strong doubts of its efficacy, and are disposed to think that the operation would prove irritating and injurious.

When acute cystitis has arisen from calculus in the bladder, the obvious remedy is extraction, as soon as the subsidence of urgent symptoms will permit. If cystitis can be traced to the translation of gout or rheumatism, the application of irritants to the situations where these diseases previously existed, and the administration of colchicum, must be had recourse to, while the means already mentioned for subduing inflammation of the bladder are carefully put in practice.

II. CHRONIC CYSTITIS.—This form, which has also been called *mucous* cystitis, and catarrh of the bladder, was at one period considered an uncommon disease; the laborious and accomplished Hoffmann designated it "rarus vesicæ affectus." It exists either in connection with a febrile state of the body, or with simple irritation of the bladder or its adjoining and associated parts. Generally it is met with as a sporadic disease, but like the affections of some other mucous membranes, it may prevail epidemically. Gunther describes such an epidemic as prevailing in the autumn of 1782. (*Sömmering, Ueber die tödlichen Krankheiten der Harnblase und Harnröhre alter Männer.*)

Symptoms.—The symptoms of chronic cystitis are, frequent calls to void urine, with more or less pain in the region of the bladder and at the extremity of the urethra, either before or during the process. There is also, in most cases, tension of the hypogastrium, which may depend either on increased sensibility of the bladder, or on distension from urine. In all cases there is discharged along with the urine an increased quantity of mucus, somewhat altered from its natural appearance. Even in health a slight mucous cloud is deposited from the urine in cooling; but in the disease we are now considering, the quantity is greatly augmented, sometimes bearing the enormous proportion of more than one-half of the whole fluid discharged from the bladder. (*Chopart, tom. i. p. 415.*) It is usually voided suspended in the urine, from which after a time it subsides, forming a jelly-like substance, so viscid and tenacious as to be with difficulty detached from the bottom of the vessel. At other times the mucus is discharged from the bladder in a separate state, and of so thick a consistence as to obstruct the passage of the urine, and even to plug up the catheter. The mucus, which was at first pellucid or grey, becomes in the progress of the complaint yellowish, then greenish, sometimes streaked with blood; and at length, when ulceration is established, largely mixed with pus. The character of the mucus is always alkaline, and the urine often of the same nature—ammoniacal, sometimes highly fetid.

The pathological changes discovered in cases of chronic cystitis are chiefly, injection of the mucous membrane, occasionally enlargement of the veins, and when the disease is of long standing, overgrowth and thickening of the mucous tissue. Ulceration is likewise often observed to have taken place at the close of the disease, when it has been severe and long protracted on other

occasions acute cystitis has supervened on the catarrhal affection, presenting after death the usual marks of the disease.

Causes.—Chronic cystitis, or catarrh of the bladder, originates in many and various causes. It has sometimes occurred at the crisis of fevers, as the mode in which solution has taken place; in other instances it has alternated with mucous discharge from the bronchi. Exposure to damp and cold, and to sudden variations of temperature, has given rise to the disease: it has also, as well as the acute form, originated from the translation of gout and rheumatism, and the repulsion of cutaneous eruptions. But its most frequent causes are calculus in the bladder and enlargement of the prostate gland. It occurs much more rarely among the young than the old, and among females than males,—circumstances which are to be explained by reference to the peculiarities of the female, and to the period at which the prostate usually becomes the subject of disease. On more than one occasion we have traced a distinct connection between mucous cystitis and a strumous habit; causes having produced it in individuals of this constitution, which would not have been sufficient to excite the disease in those of a more robust constitution.

Treatment.—Catarrh of the bladder, though classed with inflammatory diseases, rarely requires the employment of depletion, unless when the pain in the region of the bladder is considerable, and then the application of leeches is usually sufficient. Should the disease appear in connection with other mucous discharges, and be accompanied with febrile symptoms, the warm bath, the saline mixture, and opiates; and if it have arisen from the translation of gout or rheumatism, or the reperussion of cutaneous eruptions, free perspiration, and stimulating the part where the previous disease was fixed, will be proper. In gouty and rheumatic cases the administration of colchicum offers the best mode of cure. When the affection depends on an enfeebled constitution or scrofulous habit, the mineral acids, bitters and astringents will be found beneficial. Of astringent remedies the best are pareira brava, uva ursi, kino, and catechu. But in this form of the disease more advantage is often derived from stimulants of the urinary organs, such as the turpentine, and above all small doses of copaiba and cubeb pepper. [Turpentine, with the catheter kept constantly in the bladder, comprised the treatment usually adopted by Dupuytren at one time.] In such cases, also, change of air and sea-bathing on a dry and open shore have been productive of much benefit. The diet ought to be mild and nutritious, consisting of milk, eggs, farinaceous substances, and a moderate proportion of animal food. In almost all instances of this disease, spirituous liquors, even in moderate quantity, are injurious; cases however do occur when a small quantity of generous wine will be found beneficial.

All irritation of the sexual organs should be avoided; and if the patient have contracted improper habits, they must be abandoned before any hope of cure can be held out. The patient ought to spend much of his time in the open air, using gentle exercise: he should reside, if possible, in a dry and elevated situation, and ought to be al-

ways warmly clothed, wearing flannel next the skin. More benefit will often be found to accrue from a careful adherence to these directions regarding diet and general management of health, than from the employment of any medicine.

The injection of the bladder with mild diluents, such as barley-water, afterwards rendered more stimulant and astringent by the admixture of some mineral water, has been practised and highly recommended by Dessault, Chopart, and others; and we are inclined to think that advantage may be derived from the mere distension of the mucous membrane under catarrhal disease; just as gleet discharges from the urethra are cured by the introduction of a full-sized sound or bougie.

[Where the disease is manifestly connected with an atonic condition of the parietes of the bladder, the catheter or *sonde à demeure* becomes indispensable, through which appropriate injections may be sent into the bladder.

In the more chronic forms, Sir Benjamin Brodie has injected nitric acid largely diluted. At first, the proportion ought not to be more than one minim to two fluidounces of distilled water; but afterwards the proportion may be doubled. The bladder should be first washed out with a little tepid water; the acid solution should then be injected, and be allowed to remain not longer than thirty seconds. This may be repeated at first every two days, and afterwards every day. Should the injection be followed by pain and other evidences of inflammation, or the urine be tinged with blood, the repetition must be postponed. Injections of tar-water, along with the internal use of turpentine, were highly extolled by M. Dupuytren. (*La Lancette Française*, 8 Avril, 1837.) The iodide of iron would make a valuable injection in such cases. Injections of soot have likewise been used with benefit. (*New Remedies*, 4th edit.: Philad. 1843.) In very obstinate cases, it has been advised by M. Lallemand to cauterize the interior of the bladder. (See the writer's *Practice of Medicine*, edit. cit. ii. 73.)]

When catarrh of the bladder, &c. depends on the presence of a calculus or other foreign body, no cure can be effected without extracting what causes the irritation; but after its removal we sometimes find it necessary to administer tonics and urinary stimulants, such as have been already named, before the discharge will cease. And in all cases of this nature the operation should be immediately followed by a careful attention to the state of the cutaneous surface; and warm clothing should in an especial manner be enjoined.

When the disease arises from enlargement of the prostate gland, the only remedies which can be of avail are those suited to the treatment of that disease.

W. CUMIN.

DEAD, (PERSONS FOUND)—Under this head we propose to treat of those causes by which life is suddenly or quickly extinguished in persons previously in the apparent enjoyment of good health. Cases of this kind are peculiarly the objects of legal investigation by the coroner; and as all medical men are liable to be called on to assist him with their professional information and opinion, it is of the utmost importance that clear notions of the true nature of the phenomena

that present themselves should be entertained. The object of such inquiry being to ascertain whether death was natural or owing to some accidental cause, the whole subject of sudden death may be conveniently arranged under two heads,—namely, 1. sudden death from natural causes: 2. sudden death from violent causes; comprehending under the latter every variety, whether the result of accident or of criminal intention.

Our first duty on the discovery of a supposed dead body, is to ascertain whether any spark of life still remain, by rekindling which animation may be restored; and this leads us, before entering on the causes and phenomena of sudden death, to consider the states of body that may resemble death, and to point out the means of discrimination between those cases in which life is really extinct, and those in which the exercise of the vital power is only suspended. Nothing is more certain than death; nothing is at times more uncertain that its reality: and numerous instances are recorded of persons prematurely buried, or actually at the verge of the grave, before it was discovered that life still remained; and even of some who were resuscitated by the knife of the anatomist. Pliny, who devotes an entire chapter to this subject, entitled “*De his qui elati revixerunt*,” amongst other instances gives that of the Roman consul Avicula, who being supposed dead was conveyed to his funeral pile, where he was reanimated by the flames, and loudly called for succour; but before he could be saved, he was enveloped by the fire and suffocated. Bruhier,* a French Physician, who wrote on the uncertainty of the signs of death in 1742, relates an instance of a young woman, upon whose supposed corpse an anatomical examination was about to be made, when the first stroke of the scalpel revealed the truth: she recovered, and lived many years afterwards. The case related by Philippe Pue is somewhat similar. He proceeded to perform the Cæsarean section upon a woman who had to all appearance died undelivered, when the first incision betrayed the awful fallacy under which he acted. A remarkable instance of resuscitation after apparent death occurred in France, in the neighbourhood of Douai, in the year 1745, and is related by Rigaudeau, (*Journal des Sçavans*, 1749,) to whom the case was confided. He was summoned in the morning to attend a woman in labour, at a distance of about a league. On his arrival, he was informed that she had died in a convulsive fit two hours previously. The body was already prepared for interment, and on examination he could discover no indications of life. The os uteri was sufficiently dilated to enable him to turn the child, and deliver by the feet. The child appeared dead also; but by persevering in the means of resuscitation for three hours, they excited some signs of vitality, which encouraged them to proceed; and their endeavours were ultimately crowned with complete success. Rigau-
deau again carefully examined the mother, and

* “*Dissertation sur l'incertitude des signes de la mort, et l'abus des interventions et embaumens précipités.*” Bruhier mentions 180 cases in which persons still living were treated as dead; of these, 52 were buried alive, 4 were opened before death, 53 revived spontaneously after being placed in their coffins, and 72 were supposed to have died when they really had not.

was confirmed in the belief of her death; but he found that, although she had been in that state for seven hours, her limbs retained their flexibility. Stimulants were applied in vain; and he took his leave, recommending that the interment should be deferred until the flexibility was lost. At five P.M. a messenger came to inform him that she had revived at half past three. The mother and child were both alive three years after. There is scarcely a dissecting-room that has not some traditional story handed down of subjects restored to life after being deposited within its walls. Many of these are mere inventions to catch the ever-greedy ear of curiosity; but some of them are, we fear, too well founded to admit of much doubt. To this class belongs the circumstance related by Louis, the celebrated French writer on medical jurisprudence. A patient who was supposed to have died in the Hôpital Salpêtrière, was removed to his dissecting-room. Next morning Louis was informed that moans had been heard in the theatre; and on proceeding thither he found, to his horror, that the supposed corpse had revived during the night, and had actually died in the struggles to disengage herself from the winding-sheet in which she was enveloped. This was evident from the distorted attitude in which the body was found. Allowing for much of fiction with which such a subject must ever be mixed, there is still sufficient evidence to warrant a diligent examination of the means of discriminating between real and apparent death: indeed, the horror with which we contemplate a mistake of the living for the dead should excite us in the pursuit of knowledge by which an event so repugnant to our feelings may be avoided.

Life consists (at least as far as we can perceive,) in the presence of a preserving principle, proper to all organized beings, and peculiar to each species, which opposes itself continually to the influence of the physical and chemical agents that surround us. The effects of these agents in altering the forms and nature of inorganic substances we daily witness, while our frames resist them in every latitude. This power, in conjunction with sensation and motion, constitutes the state of life; a state which subsists as long as this power remains. But we do not see this power; it only renders itself sensible by the motions given to the heart, lungs, and other organs; and it is by the existence of these motions, that we generally judge of the existence of life. This isolated abstract principle cannot subsist, as far as we know, without the instruments by which it makes itself visible; it is for this reason that these are to be particularly considered on the present occasion, without in the least, however, diverting us from the consideration of a great first cause. If life depends upon the presence of a force or power continually opposed to the action of physical and chemical laws, real death will be the loss of this force, and the abandonment of organized bodies to these agents; while apparent death will be only the suspension of the exercise of life, caused by some derangement of the functions which serve as the instruments of vital action. This suspension must last for a considerable time, if we may judge by the cases collected by credible authors, to some of which we have alluded, and by

the numerous instances of drowned persons restored to life after long submersion. From this definition of life and death, it would follow that putrefaction is the only evidence of real death; but in many instances it would be attended with much inconvenience, and often with danger, to wait for this confirmation of the extinction of life. In malignant diseases, and during times of severe general sickness, the keeping of bodies disinterred until putrefaction announced the reality of death, would be a measure fraught with considerable risk to the lives of the survivors. It then becomes desirable that we should be acquainted with those signs by which we may judge that life is extinguished by the interruption of its functions.

As respiration is a function most essential to life, and at the same time the most apparent, the cessation of it may be considered as an indication of death. But as in certain diseases and states of great exhaustion it becomes very slow and feeble, so as to the casual observer to appear quite extinct, various methods have been adopted for ascertaining its existence. Thus, placing down or other light substance near the mouth or nose; laying a vessel of water on the chest, as an index of motion in that cavity; holding a mirror before the mouth in order to condense the watery vapour of the breath; have all been proposed and employed, but they are all liable to fallacy. Down, or whatever substance is employed, may be moved by some agitation of the surrounding air; and the surface of a mirror may be apparently covered by the condensed vapour of the breath, when it is only the fluid of some exhalation from the surface of the body. We, therefore, agree fully with the judicious observations of Dr. Paris (*Paris and Fonblanque, Med. Jur. vol. ii. p. 10.*) on this subject. "We feel no hesitation in asserting that it is physiologically impossible for a human being to remain more than a few minutes in such a state of asphyxia as not to betray some sign by which a medical observer can at once recognise the existence of vitality; for if the respiration be only suspended for a short interval, we may conclude that life has fled for ever. Of all the acts of animal life, this is by far the most essential and indispensable. Breath and life are very properly considered in the Scriptures as convertible terms; and the same synonym, as far as we know, prevails in every language. However slow and feeble respiration may become by disease, yet it must always be perceptible, provided the naked breast and belly be exposed; for when the intercostal muscles act, the ribs are elevated, and the sternum is pushed forward: when the diaphragm acts, the abdomen swells. Now this can never escape the attentive eye: and by looking at the chest and belly, we shall form a safer conclusion than by the popular methods which have been usually adopted."

The absence of the circulation of the blood has been looked on as a certain indication of death; but this is a test not much to be depended on, for it is well known that persons may live even for hours, in whom no trace of the action of the heart and arteries can be perceived. In applying this test, it is necessary to remember that it often occurs that the pulse at the wrist cannot be felt if the limb be extended or everted; but if it is bent,

and the hand turned inwards, it becomes perceptible. We should, therefore, perform this movement, by which the artery is relaxed, and the passage of the blood is facilitated when only feebly propelled. Sometimes, also, the artery can be felt between the thumb and first metacarpal bone when it is not to be found at the wrist. It is well to seek for the artery at the bend of the arm, as the pulse can often be felt there after it has left the wrist. In these examinations it is necessary to press very lightly, lest we should obliterate the pulsation altogether; and care should be taken to guard against mistaking the beating of the arteries in one's own fingers for that of the artery under examination. The trial should be made at every part where large arteries pass; and sometimes the proceeding of laying the body on the left side, and placing the hand under the region of the heart, may be adopted. The stethoscope may be used with great advantage in these cases, as any motion of the heart will be sure to become sensible through the aid of this instrument.

The temperature of the body has also been proposed as a guide, but this is very fallacious, as it is well known that the cooling of a body after death is influenced by many circumstances, such as age, habit of body, and the disease of which the person died. With respect to age, it has been observed that the bodies of young persons retain their heat longer than those of old. In fact, in old age, the winter of life as it has been termed, death is scarcely any thing more than to become cold; and in those cases the temperature of the body is rapidly reduced to that of the surrounding medium. Hence we derive a caution in judging of priority of death among a number of bodies overwhelmed by the same accident; for the body of a young person found warm, and that of an old one found cold, would not indicate that the former had survived the latter. This will be more fully treated of in another article. (See SURVIVORSHIP.)

The habit of body has also been observed to exert an influence over the rate of cooling after death, and it is found, *cæteris paribus*, that fat bodies lose their heat sooner than lean, but putrefy sooner. The disease which has destroyed life is a powerful controlling agent in the loss of temperature after death. Thus it has been long known that in apoplexy the body retains its heat for a considerable time. This has been particularly noticed by Portal. Again, in that disease or accident frequently witnessed in tropical climates, the "coup de soleil," we are informed by Badoch that the bodies of the sufferers remain warm much longer than in other forms of death. In most kinds of asphyxia except that by drowning, but especially in asphyxia by noxious gases, the dissipation of the animal heat is greatly delayed. In cases of the latter description, Orfila found the heat preserved for twelve hours after death; and we are informed by Samoelowitz, that during the great plague at Moscow, the bodies of those who were speedy victims to that disease preserved their temperature much longer than the bodies of those who die by ordinary diseases. Besides these cases in which the animal heat is preserved to an unusual length of time after death, there are others in which it is rapidly lost during life, and even

when there is no danger of death, as in some forms of hysteria, and in syncope. It is also an effect of submersion in water, and is usually observed in the bodies of those restored to life after drowning. Flexibility of the limbs succeeding their rigidity is one of the most characteristic signs of death: we say succeeding their rigidity, because so long as the limbs are flexible, if the flexibility has not succeeded stiffness, we may presume that there are some remains of life. We are indebted to Nysten and Louis for some valuable observations on the occurrence and duration of the cadaverous stiffness. The rigidity of the muscles commences in the trunk and neck; it then spreads to the thoracic extremities, and finally reaches the legs and feet, and in subsiding it follows the same course. Its duration is in proportion to the lateness of its occurrence, it being found to continue longer in those cases in which it commences latest. Its energy and duration are always in a direct ratio with the degree of development and energy of the muscular system at the moment of death: thus it is extremely strong in the bodies of athletic individuals, in those who die of tetanus, or who are asphyxiated by noxious gases whose deleterious action does not affect the contractility of the muscles. In all animals, the moment when stiffness commences is that in which the vital heat appears to be nearly extinct. Professor Louis, from observations made upon more than five hundred subjects after death, found that at the moment of the absolute cessation of the vital movements, the articulations began to become stiff even before the loss of animal heat. Foderé has verified the justness of this observation several times in hospitals, and concludes that the flexibility of the limbs is one of the principal signs by which we may judge that a person is not dead, although there is no other sign of life. During the whole time this contraction of the muscles continues, they resist the action of chemical forces, and it is only when suppleness is restored that putrefaction commences. Nysten regards this stiffness as a measure of the resistance opposed by organic to chemical forces. Life on the point of extinction seems to take refuge in the muscles, and there causes the spasms we speak of, and during their continuance is able to resist the operation of chemical forces.

The occurrence of the cadaverous stiffness is subordinate to the same causes that influence the loss of temperature. We have seen that old age favours the dissipation of animal heat, and in like manner it is observed that the muscular rigidity comes on soonest in the bodies of old persons. The habit of body in which the temperature is longest preserved is that in which stiffness of the limbs is slowest in its invasion; thus the bodies of full and fat persons remain longer flexible than those of meagre and lean. And again, those diseases which are followed by a long continuance of warmth are also remarkable for leaving a corpse in an equal degree flexible; while those in which the body is rapidly cooled, as hæmorrhage for example, favour the approach of the muscular spasm; and after death from these, the body becomes soonest and sometimes suddenly stiff. From this concurrence between the spontaneous cooling of the dead body, and the supervention of the cadaver-

ous stiffness, it might be presumed that accidental cooling would be followed by a similar effect; and this is precisely what takes place; for bodies left exposed in cold situations, as on a field of battle, are found to become rapidly stiff.

The rigidity of the body is a criterion of great value, as it points out the general contraction of the muscular fibre that occurs shortly after dissolution; but in regarding it as a test of death, it is necessary to guard against mistaking the stiffness that arises from other causes for the cadaverous stiffness. In persons frozen but not yet dead, or, in other words, susceptible of reanimation, the rigidity of the body is very great, but on close examination it is found not to be confined to the muscular system, but to pervade all parts of the body. The breasts, belly, and skin, are all equally hard with the muscles, to which alone the stiffness is confined in that from death. This, coupled with the crackling noise caused by forcible flexure of a joint, will be sufficient mark of discrimination between the two. Moreover, it can scarcely be a source of error, because it is an effect of the accident to which the person has been exposed, and if it does not yield to the appropriate remedy (the gradual application of heat), it will be an indication that the subject is really dead.

The stiffness that occurs in certain forms of syncope and convulsive diseases can never be confounded with cadaverous rigidity, if proper attention be paid to the facts connected with it; for in the former case it takes place immediately after the invasion of the disease, and always precedes apparent death, while the body still preserves a considerable degree of warmth; whereas the cadaverous stiffness is not observed until some time after death, and when the heat of the body is scarcely sensible. In all stiffness of this kind there is much difficulty in moving a limb; so far it resembles that from death; but after having bent the limb, on ceasing to apply the force, it immediately flies back to its former position; while the dead limb, on the contrary, remains in the position in which it is placed. If death really takes place in any of these convulsive diseases, the muscular contraction ceases with the extinction of the nervous influence to which it was owing, and the true cadaverous stiffness succeeds at the proper time, and runs its usual course. But above all, the termination of the cadaverous rigidity in flexibility serves to distinguish it from every other, and is a certain indication of dissolution.

That peculiar cast of countenance termed from its first describer the *Hippocratic*, has been regarded by some as another sign upon which reliance may be placed in judging of the reality of death. It is thus described by Hippocrates: "The forehead wrinkled and dry; the eye sunken; the nose pointed, and bordered with a violet or black circle; the temples sunken, hollow, and retired; the ears sticking up; the lips hanging down; the cheeks sunken; the chin wrinkled and hard; the colour of the skin leaden or violet; the hairs of the nose and eye-lashes sprinkled with a yellowish white dust." Such is the alteration in the human physiognomy that usually takes place after death. But it is also produced by the near approach of death; often by the sight of imminent danger;

and is also commonly observed in criminals at execution, whatever may be the degree of tranquillity assumed. Moreover, those who perish by sudden death, or of short diseases in which dissolution is not expected, preserve their usual physiognomy; while, on the other hand, the countenance may be pale, ghastly, and contracted in nervous and hysterical affections without extinction of life. Finally, there are some individuals whose integuments during life have a leaden and cadaverous aspect, and whose countenance during natural sleep puts on an appearance little removed from the Hippocratic. From these causes we think that little reliance can be placed on the countenance as a test of death.

The changes that take place in the eye after dissolution are remarkable, and have been regarded by some authors as satisfactory indications of death. These are, the cornea becoming opaque, and covered with a thin slimy membrane, which breaks in pieces when touched, and is easily removed by wiping; and general flaccidity of the eye-ball, which may be perceived by placing the finger on the upper eye-lid and moving it gently over the surface of the eye; when the point of the finger will sink on coming over the cornea, and a distinct ring will be felt, marking the attachment of this membrane to the sclerotic coat. Certainly these signs are valid in many forms of death, but they do not exist in all, and are therefore not infallible. The reason why they are sometimes present and at others wanting, is evident when we consider the causes upon which these changes depend. The cornea owes its brightness mainly to the tension of the eye-ball, produced by a full secretion of the humours. This is proved by evacuating a portion of the humours of a recent eye, when the cornea will become flaccid and opaque; or by taking an eye some time dead, and with the cornea already opaque, and compressing the humours towards the anterior part, when the cornea will reassume its brightness. We find the appearance of the living eye influenced by the same cause, and hence we see the dim cornea in very aged and meagre persons produced by a deficiency in the ocular in common with every other secretion. We do not speak of the *arcus senilis*, but of the general opacity of the cornea observed in such individuals. Hence we can understand why in death after long illness, when the powers of reparation have been for a length of time impaired, the eye should exhibit its want of fullness by a flaccid and dim cornea. On the other hand, we are led to expect, when death takes place suddenly in a healthy person, that the eye will preserve its lustre for a much longer period; and this experience confirms; for it has been observed that after death by apoplexy, asphyxia, prussic acid, &c. the eyes preserve their integrity for a considerable time, owing to their being at the time of death in a state of tension by the due secretion of the vitreous and aqueous humours. Moreover, it has been observed that in severe diseases of long continuance, and even in some affections of the mind, the eyes have become dim and shrunken, although death may not happen, and thus another source of fallacy arises.

Different physical tests have been proposed for doubtful cases, such as incisions, burns, blisters

cupping, flagellation, &c.; but of these it may be said that there are so many instances of disease affecting the nervous system, in which their application causes no sensation in the sufferer, that they will be still less likely to produce any effect on the sensorium in a body nearly deprived of life. The influence possessed by galvanism in the production of muscular contraction in the living body has led to its adoption as a test of death; and with certain limitation it is one of considerable value; for although the muscles retain their contractility for some time after absolute death, yet if the death be real, they soon lose it, and become insensible to this stimulus. On the other hand, if the least spark of life remain, the contractility will be also present, and on the application of the galvanic fluid it will be evidenced by contraction. Galvanism thus becomes a test not of life, but of the reality of death, for if the muscular fibre does not obey it, there can be no doubt that vitality is extinguished. It should be recollected, however, that different parts of the muscular system retain their contractility, and consequently their obedience to the galvanic stimulus, for different periods after death. (*Dict. des Sciences Méd. art. Mort.*) Nysten found, in the body of a guillotined criminal which was given to him immediately after execution, that the contractility of the left ventricle was extinguished in forty-nine minutes after decapitation; that of the stomach, intestines, and urinary bladder continued for fifty-six minutes; while that of the right ventricle and diaphragm remained for two hours. He found the locomotive muscles lose their contractility in proportion to their free exposure to the atmosphere, and those that were not at all exposed continued excitable during four hours; but the auricles of the heart, although in contact with the air during the whole time, did not cease to contract, when stimulated for four hours and forty minutes. From many similar opportunities of observation possessed by Nysten, he concludes that the muscles cease to be influenced by galvanism after death in the following order: 1. left ventricle; 2. intestines and stomach; 3. urinary bladder; 4. right ventricle — this retains its contractility under galvanism for one hour; 5. œsophagus, for half an hour longer; 6. iris; 7. muscles of animal life; 8. auricles.

We have now alluded to the chief criteria of real death; and we may conclude this part of our subject by stating that those most entitled to consideration are flexibility subsequent to rigidity of the joints; loss of contractility of the muscles under galvanism; and incipient putrefaction. These are not liable to any important fallacies: the rest are, for the reasons already mentioned, more or less equivocal.

It now remains, before we proceed to consider the causes of sudden death, to make a few observations on the changes which the human body undergoes after dissolution; and we prefer doing so in this place, because the subject naturally follows that which we have just discussed, and also because a knowledge of the attendant phenomena and their causes is often of the highest importance to the medical jurist in enabling him to determine the length of time a body submitted to *in situ* inspection may have been dead; or the period

at which dissection may be attempted with a prospect of useful results. It is sometimes of the utmost moment to the surviving relatives of an individual found dead, that it shall be determined at what time death took place; of this a case mentioned by Dr. Male (*Elements of Juridical Medicine*, p. 101) serves as a good illustration. At the Lent assizes, held at Warwick in the year 1805, a cause was tried in which a gentleman, who was insolvent, left his own house with the intention (as it was presumed from his preceding conduct and conversation) of destroying himself. Five weeks and four days after that period, his body was found floating down a river. A commission of bankruptcy having been taken out against the deceased a few days after he had left his home, it became a question of great importance to the interests of his family to ascertain whether he was living at that period; for if it could be proved that he was not, his property would remain untouched by the legal proceedings. From the changes which the body had undergone, it was presumed that he had drowned himself the day he left home; and to corroborate this presumption, the evidence of Sir George Gibbes of Bath was required, as he had lately been engaged in experiments on the changes produced in animal substances by immersion in water. He stated on the trial that it required five or six weeks to effect changes similar to those observed in the body of this individual; and upon this evidence the jury were of opinion that the deceased was not alive at the time the commission was taken out, and the bankruptcy was accordingly superseded.

A few weeks back the writer of this article, in passing along the canal on the south side of Dublin, on a Saturday, observed a crowd collected on the bank; on approaching, he discovered the object of their attention to be the body of a man recently withdrawn from the water. None of the bystanders knew anything of the individual, or of the time at which he had been drowned; but, from the fresh appearance of the body, the general belief was that he had fallen in the preceding evening. From certain appearances (to be more fully treated of hereafter) the writer was induced to doubt the truth of this supposition, and to assert that the man had lain in the water for at least five days. An accidental circumstance served to corroborate this opinion. Seeing the individual well dressed, and not observing any hat, the writer inquired whether one had been found with him, to which he received a negative answer; when a boy, who lived in the neighbourhood, came forward and mentioned that a hat and handkerchief were found in the water at that place on the previous Tuesday morning, just five days from the time of finding the body. These articles were afterwards proved to have belonged to the deceased. This was a case in which, from the appearances presented by the body, very positive testimony could have been given as to the length of time that had elapsed since death; and in case any question similar to that in the preceding instance was pending, such testimony must have been of the highest importance.

The changes that take place in the body after death may be divided into those that occur before and those that follow the invasion of putrefaction.

To the first stage belong diminution of temperature, contraction of the muscles constituting cadaverous stiffness, and lividity of certain portions of the surface. We have already taken notice of the causes by which the loss of heat and muscular rigidity are influenced, and therefore it is unnecessary to allude to these phenomena at present. The extensive lividities usually observed on the back parts of the body shortly after death, are entirely owing to gravitation; the blood, still fluid, and no longer kept in its proper course by an impelling power, obeys the physical law by which it is inclined to seek the most depending situations, and this takes place in the interior as well as on the exterior of the body; of which we have examples in the gorged state of the posterior portion of the lungs, and in the vascular turgescence exhibited by the gastro-intestinal mucous membrane in the lowest part of depending convolutions. (*Trousseau*, Dissertation inaugurale. Paris, 1825.) That all these appearances are the result of gravitation is proved by the fact that we can produce them in other situations by altering the position of the body; thus, if it be turned on the face, instead of remaining as it usually does on the back, the skin of the face, breast, belly, and anterior parts of the limbs will be found livid, while the back will retain its natural colour, and the congestions in the interior of the body will all be found in the anterior part of the organs. Nay, the lividity, having formed on the back, can be made to disappear, if the body is turned before it becomes cold, and the blood coagulates. Of this the writer has convinced himself by experiment. As it has happened that these lividities have been mistaken for the effects of violence, and suspicions of murder having arisen therefrom, it is necessary, in judging of such appearances, to take into consideration the attitude in which the body may have lain during the first few hours after death, the great extent of surface occupied by them, and the absence of any effusion or infiltration of blood into the cellular tissue. We shall have to recur to this subject when we come to treat of the effects of blows on the dead body, and their resemblance to the consequences of injuries inflicted during life.

The second stage is marked by the occurrence of putrefaction. This is a process peculiar to organized substances, and it seems to follow as a consequence of the manner in which their ultimate elements are combined during life. These elements are few in number—oxygen, hydrogen, carbon, and nitrogen constitute the great bulk of organized substances. Other elements, as phosphorus, sulphur, iron, lime, potassa, and silica, are occasionally present, but in quantities so small as not to invalidate the statement just made. But we find these elements combined in various proportions, and thus constituting the different proximate principles of which our bodies are made up, such as fibrin, albumen, gelatine, urea, stearine, elaine, cholesterine, &c., which in composition differ from each other chiefly in the proportion of their component elements. Now these combinations are not such as the ultimate elements have the greatest disposition to form; in other words, their natural affinities lead them to different combinations and to the production of more permanent

compounds, namely, water, carbonic acid, ammonia, &c. This disposition is controlled by vitality, and as long as it continues, the operation of chemical laws seems suspended; but as soon as life is extinguished, the elements abandon their former combinations, and enter into new ones, and this constitutes putrefaction. The presence of nitrogen expedites this process, and hence vegetable substances, which with few exceptions are deficient in this element, undergo the change more tardily and imperfectly; and some animal substances, as, fats, oils, cholesterine, in which nitrogen is absent, are little disposed to the putrefactive fermentation.

The human body, in common with other animal substances, suffers this dissipation of its principles after death; but as the phenomena attending this change are not constant as to time, order, and results, it is necessary to inquire into those causes that influence its course.

The conditions necessary to the speedy putrefaction of a dead body are the exposure to air, moisture, and a moderate degree of heat. The presence of air, however, does not appear to be essential, although its exclusion retards the process. Putrefaction in vacuo was denied by Gay-Lussac, but some experiments by Guntz of Leipsic have proved the possibility of its occurrence. He took some pieces of human flesh, and having freed them from any air that might be lodged among the fibres by plunging them into mercury, he passed them into jars inverted over and filled with the same fluid. The flesh rose to the top of the jar, and the apparatus was kept in a moderate temperature. Putrefaction went on, but at a slower rate than if the air had been admitted. In a few days the flesh became soft and pulpy, and of a grey colour. Gas was generated, which was found to be carbonic acid gas, and some highly fetid fluid covered the surface of the mercury: the flesh had lost one-third of its weight. He also ascertained that blood alone will putrefy in vacuo. For this purpose he placed the forefinger of his left hand under an inverted jar filled with mercury, and then made an incision into the integuments. The blood rose to the top, and in five days it was found to be undergoing putrefaction; an accident by which the apparatus was upset prevented an analysis of the product. These experiments show that though the presence of air expedites the process, it is not essential.

A moderate temperature is a most important condition. If the heat be too high, it prevents the occurrence of putrefaction by rapidly dissipating moisture; and if too low, the process is equally arrested, and, it would appear, from the same cause,—for the fluids being converted into solids by congelation, are as efficiently deprived of the power of assisting putrefaction (so long as they continue in that state) as if they were altogether removed. The practice of packing salmon in ice for the purpose of preserving it fresh during long voyages is a familiar illustration of this point. But the most extraordinary instance on record is the preservation of the mammoth discovered some years ago in Siberia enclosed in a block of ice, on breaking into which the animal was found entire and fresh. This being a specimen of an extinct species of animal, it is of course impossible to cal-

culate the number of centuries it must have been enveloped in its icy tomb. Below 59° Fahrenheit, the process is slowly performed, and at 32° it is altogether suspended. The temperature most favourable to its perfection is from 60° to 80° or 90°. This is the range of the thermometer during our summer, and hence at this time putrefaction most readily goes forward.

Moisture is an indispensable condition. This is shown by the readiness with which substances otherwise disposed to putrefy are preserved by drying, as smoked meats, fish, &c.; and still more strikingly by the preservation of animals buried in sand. Caravans in crossing deserts have been overwhelmed by the shifting sands, and the bodies of men and camels have lain for centuries until exposed by the same cause, when they were found dry, shrunken, but without any signs of having undergone putrefaction. Instances of this kind have occurred in Egypt, Arabia, and Persia. Chardin (*Traité des Exhumations Juridiques*, par MM. Orfila et Leseur, vol. i. p. 382.) mentions the preservation of certain bodies in the sands of Corassan (Persia), where they had been buried two thousand years.

It is supposed that the preserving power possessed by some burying-places, as the vaults of the Cordeliers at Toulouse, and those of St. Michan's, Dublin, is owing to the dry and absorbent nature of the surrounding soil. In these situations bodies rarely putrefy, but they undergo a process of natural mummification. The products of putrefaction, when conducted under favourable circumstances, are—water, ammonia, carbonic acid, carburetted hydrogen, sulphuretted hydrogen, phosphuretted hydrogen, nitrogen, and hydrogen gases, and there remains a friable matter of a deep brown colour containing the salts of the body and some carbon.

From these cursory observations it must appear that the transformation of the dead body will be influenced by the medium in which it is placed. The media existing naturally, and to which all others may be referred, are the earth, air, and water. But as these do not exist in a purely separate state, being found mixed together,—as air impregnated with water, water with air, and earth with both,—the term *group* may be given to these combinations. Thus we have earthy group, watery group, and aerial group, by which are meant the combinations usually existing between these media. A group is called cold when the temperature is below 32°; cool between 32° and 60°; warm between 60° and 100°; and hot when it is above 100°.

The metallic oxydes and salts which enter into the composition of the earth exercise but a small influence in the transformation of a dead body. The action of this medium depends upon the greater or less exactness with which it excludes the access of air and water. Thus sandy soils which quickly absorb water, and argillaceous soils which collect water round a dead body, differ materially in their effects; in the former decomposition goes on slowly, and is sometimes, as we have seen, altogether prevented; in the latter putrefaction readily takes place, and sometimes the transformation into adipocire is effected. Fresh ground or gardens which are rich in mould, and the soil

of church-yards, appear to act as a sort of ferment which assists putrefaction; for it is found that flesh enters sooner into the putrefactive process when surrounded by substances already undergoing that change.

We have alluded to the formation of adipocire, and it is necessary, before we leave this part of our subject, to make a few observations on this curious phenomenon. Adipocire, so termed from its resemblance to fat and wax, is a peculiar substance of a soft ductile nature and whitish colour, produced by dead animal substances undergoing decomposition under particular circumstances. We are indebted to Fourcroy for the first scientific account of this peculiar transformation. His attention was directed to it on the occasion of the celebrated exhumations practised at the ancient burying-place *Des Innocens* at Paris, in the years 1785, 86, 87, when from fifteen to twenty thousand bodies were removed for the purpose of eradicating this cemetery. This spot differed from common burying-grounds, where each individual body is surrounded by a portion of the soil. It was the burying-ground of a large district, wherein successive generations of the inhabitants had been deposited for upwards of three centuries. The remains of the human bodies immersed in this mass of putrescence were found in three different states, according to the time they had been buried, the place they occupied, and their relative situations with regard to each other. The most ancient were simply portions of bones irregularly dispersed in the soil, which had been frequently disturbed. A second state, in certain bodies which had always been insulated, exhibited the skin, the muscles, the tendons, and aponeuroses, dry, brittle, hard, more or less grey, and similar to what are called mummies in certain caverns. The third and most singular state of these soft parts was observed in the bodies which filled the common graves or repositories. These were cavities thirty feet in depth, and twenty on each side appropriated to contain the bodies of the poor. Each cavity contained between 1000 and 1500, packed side by side in rows, without any intervening earth; so that it might be considered, when filled, as an entire mass of human bodies separated only by two planks of about half an inch thick. The first of these receptacles opened in the presence of Fourcroy had been closed for fifteen years, the coffins were in good preservation, but a little settled, and the wood had a yellow tinge. When the covers of several were taken off, the bodies were observed at the bottom, leaving a considerable distance between their surface and the cover, and flattened as if they had suffered a strong compression. The linen which had covered them was slightly adherent to the bodies, and with the form of the different regions, exhibited, on removing the linen, nothing but irregular masses of a soft ductile matter of a grey-white colour. These masses environed the bones on all sides, which had no solidity, but broke by any sudden pressure. The appearance of this matter, its obvious composition and its softness, resembled common white cheese; and the resemblance was more striking from the prints which the threads of the linen had made upon its surface. The grave-diggers asserted that they never

found this matter in bodies interred alone; but that the accumulated bodies of the common graves only were subject to this change. Fourcroy remarked that the conversion appeared in different stages of advancement, so that in various bodies the fibrous texture and colour, more or less red, were discernible within the fatty matter; that the masses covering the bones were entirely of the same nature, offering indistinctly in all the regions a grey substance, for the most part soft and ductile, sometimes dry, always easily separated in porous fragments, penetrated with cavities, and no longer exhibiting any traces of membranes, muscles, tendons, vessels, or nerves. By examining this substance in the different regions of the body, it was found that the skin is particularly disposed to this remarkable alteration. It was afterwards perceived that the ligaments and tendons no longer existed, or at least had lost their tenacity, so that the bones were entirely unsupported, and left to the action of their own weight. In all the bodies so changed, the abdominal cavity had disappeared. The integuments and muscles of this region being converted into the white matter, like the other soft parts, had subsided upon the vertebral column, and were so flattened as to leave no place for the viscera; and accordingly there was scarcely ever any trace of them observed in the almost obliterated cavity. The thorax was also flattened, and its viscera were no longer discernible. Sometimes an irregularly rounded mass was found, which appeared to have arisen from the fat and fibrous substance of the heart. The features of the face were converted into adipocire, and no longer distinguishable, and some of the same matter occupied the cavities of the mouth and orbits. The cranium constantly contained the brain, changed into a similar substance. From various observations, it was found that this fatty matter was capable of enduring in these burying-places for thirty or forty years, and is at length corroded, and carried off by the aqueous putrid humidity which there abounds.

Adipocire, according to M. Chevreul, consists of margaric acid, oleic acid, a little bitter substance, of an orange-coloured principle which tinges the acid, of a trace of odorous principle, of ammonia, very small quantities of lime and potass, and some salts. The alkalis we have mentioned partly saturate the margaric and oleic acids. The latter exists in a very small proportion relatively to the margaric, which abounds in this substance. It is easy to perceive from this analysis that adipocire is a soap with double acid and ammoniacal base. Sometimes, however, the acids are found combined with lime. This has been observed when bodies undergo the change in water containing carbonate or sulphate of lime: and also in earth permitting the infiltration of water which has dissolved these salts in its progress through it. In both cases the ammoniacal soap is first formed, and is then decomposed by the calcareous solution; margarate and oleate of lime, and carbonate or sulphate of ammonia being the result. To prove that such is the case, the following experiments were made by Orfila and Leseur.

On the 4th of December, 1828, they interred a stomach, a portion of skin with the subjacent cellular tissue, two testicles, and an omentum, all

belonging to the human subject. Each of them was enveloped in linen, and placed in a small deal box, which was buried at a depth of two feet and a half. They were disinterred on the 30th of July, 1829, seven months and twenty-seven days after having been deposited in the ground. In place of the stomach they found about half a drachm of adipocire not in the least ammoniacal, but composed of margaric and oleic acids and lime. The skin presented here and there the appearance of adipocire, and furnished on analysis a calcareous soap; the testicles were similarly transformed. The omentum had preserved its aspect and structure in several places, whilst in others it was changed into a yellowish fatty mass, having the odour of Roquefort cheese, and composed of lime and the acids mentioned above. These distinguished experimenters, although pretty certain that the presence of the calcareous soap at the expense of the ammoniacal, in these substances, was owing to the rain-water in filtering through the ground having dissolved some of the calcareous salts, which having thus got access to the interior of the wooden box, decomposed the ammoniacal soap, and changed it into calcareous, nevertheless thought it necessary to prove by direct experiment that it really was so. Accordingly they prepared an ammoniacal soap with pure stearic acid and caustic ammonia, and plunged it into a solution of sulphate of lime. At the end of three weeks, on examining the soap, it was found entirely changed into stearate of lime, and sulphate of ammonia was formed. They made also another experiment: two human stomachs were buried, one in a leaden box enclosed in a wooden one, the other in wood alone: seven months afterwards they were taken up. The stomach contained in the wooden box was transformed into a soap partly ammoniacal but chiefly calcareous, whilst that enclosed in the lead offered no trace of saponification, and was but little altered.

"It is manifest," say they, "that, in this last experiment, the progress of the putrefactive process had been greatly retarded in consequence of the double envelope, and particularly of the leaden cases; and every thing leads to the conclusion, that if the apparatus had remained under ground as long as was requisite for converting the stomach into soap, this soap would have been of the ammoniacal and not of the calcareous kind." (*Traité des Exhumations Juridiques*, tom. i. p. 366.)

Adipocire is only formed when fat and some azotized substance are found together. The fatty matter furnishes the margaric and oleic acids, and the other the ammonia. This is proved by the following circumstances. Entire dead bodies, or entire parts of a dead body, such as a head, one of the limbs, or the thorax, parts in which are found skin, fat, muscles, &c. are changed into adipocire in stagnant or gently moving water, but isolated muscle furnishes but a small portion of this substance, and that only when it is rich in fat. Fat washed, freed from blood, and separated from parts which contain azote, is not transformed into adipocire. Neither does the fibrine of the blood, when perfectly washed and free from fat, undergo the change. Orfila found that portions of skin previously deprived of the subjacent cellular tis-

sue, were not saponified after eight months of inhumation; while similar portions of the skin of the same individual, to which the cellular substance was left adhering, and buried during the same time, were converted into adipocire. It appears that a sojourn of about three years in the ground is necessary for the complete transformation of a body, and that the change goes forward more quickly in water; and it is only when a number of bodies are buried in the same grave, that the process is perfect, those at the bottom being the first to undergo it. A thick stratum of earth over the grave is necessary, in order to confine the gases given out in the first stages of putrefaction.

[A medico-legal question has arisen respecting the length of time which a body must remain in water, in order that this transformation of the tissues may take place. (See the writer's *Human Physiology*, 5th edit. i. Philad. 1844.) Dr. Gibbs found, that by macerating muscle in water for about a month, he was only able to obtain a small quantity of adipocire. Dr. Harlan observed, that the integuments of a cranium were, by maceration, converted into it in about six weeks; but in some experiments instituted by Mr. Taylor, (*Manual of Med. Jurisprudence*, p. 515: Lond. 1844,) the conversion of muscle and fat to adipocire was not complete in stagnant water under two months.]

The chief object of the medical jurist to whom a dead body is submitted for inspection, is to ascertain the cause of dissolution. In order to assist in this investigation, we will follow the arrangement already proposed.

I. DEATH FROM NATURAL CAUSES.—Death is the inevitable condition to which all bodies that possess life must, sooner or later, be reduced. This termination of their existence forms a grand distinction between organized and unorganized matter. The gradual termination of life, or natural death strictly so called, is very different in its phenomena from the more common or accidental death. In natural death man expires, as it were, in detail; the external functions and those of the animal life being almost annihilated, whilst those of organic life still remain in vigour. The active powers gradually desert each organ; digestion languishes; secretion, absorption, and capillary circulation are arrested; the general circulation is then suspended in the large vessels; and lastly, the contractions of the heart cease. In accidental death, the general circulation and respiration are first arrested, while the other functions are successively and slowly extinguished. So that it has been said that in the former life is first extinguished in the parts, and then ceases in the heart, the influence of death being exerted, as it were, from the circumference to the centre; while in the latter it ceases first in the heart, and then in all the parts, death proceeding from the centre to the circumference. The termination of life termed natural death is a very rare occurrence in the human species in a civilized state; animals often reach it; but the cessation of existence from mere old age has become with us a rare phenomenon. Haller estimates the average probability of human life, and deduces the conclusion that only one individual in fifteen thousand reaches the hundredth year. Accidental death, in contradistinction to

natural death, becomes, therefore, an object particularly worthy of attention. This may take place in two ways—either as the slow and gradual termination of a lingering disease; or as the sudden result of some great disturbance of the animal economy, and then called sudden death, as in apoplexy, hemorrhage, concussion, asphyxia, &c.

We now come to consider the natural causes of sudden death, and our observations upon them must be necessarily brief, as it would not be possible to enter into detail upon them in this place; a circumstance not of much consequence, as they are most of them treated of in separate articles through this work. However, we may notice some of the most frequent and remarkable. These are apoplexy, rupture of an aneurism or of a large vessel into one of the cavities; bursting of purulent cysts or other collections of fluid, or of blood-vessels into the air-passages; ossification of the valves of the heart; rupture of this organ; asphyxia idiopathica.

Apoplexy may attack at any age, but in the great majority of cases the age is above fifty years: certainly it may be said to be a disease rather of the decline of life. It is a disease which in some instances may be mistaken in its early symptoms, and may terminate fatally in situations which preclude any observation of the event. Those most predisposed are of a full plethoric system, with large head and short neck. Diseases of the blood-vessels of the brain, such as ossification of the arteries, aneurism, and obstruction of the sinuses, lead to rupture of their coats; and it is well known that hypertrophy of the heart sometimes produces apoplexy. In ordinary cases an examination of the brain sufficiently develops the complaint. Blood is usually found in some part of this organ, rarely on the surface, more commonly in or about the corpora striata or optic thalami, or effused into the ventricles. In old apoplectics who have had many shocks, cysts enclosing clots of blood are found; and the brain surrounding them is often observed in different stages of inflammation or ramollissement. (See APOPLEXY.) It should be borne in mind that persons seized with apoplexy may fall from a height, and thus bear marks of external injury which might mislead a superficial inquirer as to the cause of death. In cases of rupture of internal aneurisms, or purulent cysts, or of ossification of the valves of the heart, an examination of the body will exhibit the true nature of the disease. The last of the natural causes of sudden death which we have mentioned is that peculiar disease termed by Mr. Chevallier "asphyxia idiopathica." A case of this rare and remarkable affection came under the observation of the writer a few years ago. The subject of it was a healthy woman, forty years of age, in the ninth month of pregnancy. She complained suddenly one evening of weakness and sickness of stomach, and on making an effort to vomit, she fell back and expired without any struggle. The writer examined the body the following day, and inquired diligently after every cause of death in each of the cavities; but he never saw more healthy organs, and, taken altogether, certainly never a sounder body. But the state in which the heart was found led to a discovery of the nature of the case. The pa-

rieties of this organ were entire, but quite flaccid, and all its cavities were empty; while its proper veins were much distended with blood. This so exactly resembled the appearances described by Mr. Chevallier, and the manner of death corresponded so fully with that of the cases he mentions, that it was thought justifiable to refer the cause of death to the disease just alluded to. Mr. Chevallier accounts for death in these cases by supposing a sudden loss of power in the vessels, chiefly in the minute ones, to return the blood to the heart; in consequence of which this organ, after having contracted so as to empty itself, and then relaxing, continues in that state for want of its accustomed stimulus, and so dies. We mention this in order to show that such cases are sometimes to be met with, and that it is necessary to be prepared to detect them. For further information we must refer to the paper alluded to.

II. DEATH FROM VIOLENT CAUSES.—The wide extent of this division, and the great importance of the topics included in it, render it of the deepest interest to the medical jurist. The violent causes of sudden death may be reduced to seven heads, viz. *asphyxia, poisoning, wounds, burning, cold, starvation, and lightning.* From the very able manner in which the subject of asphyxia has been handled in a former part of this work, little remains to be said upon its general phenomena and theory. (See *ASPHYXIA*.) Asphyxia may be defined the suspension of the function of respiration, and consequently of the circulatory and cerebral functions. The interruption may affect primarily either the mechanical or chemical phenomena of expiration. The mechanical are the motions of the parietes of the chest, producing inspiration and expiration; the chemical are the disappearance of oxygen from the air taken into the lungs, the disengagement of carbonic acid gas, and the conversion of the venous into arterial blood. Asphyxia may commence by the cessation of either of these classes of phenomena; but in whichever it first begins, it speedily involves the other, and both are soon equally suspended. A violent compression of the thorax, such as is produced by the falling of heavy beams of timber, portions of buildings, roofs of mines, &c. a double wound giving entrance to the air into both cavities of the chest, rupture of the diaphragm by which the abdominal viscera gain admission to the chest, the effusion of large quantities of fluid into the pleura,—all these put an end to the mechanical phenomena of respiration by interrupting the motions of the thorax. In other cases these motions cease, but from a different cause; we allude to paralysis of the muscles that move the parietes, which happens when the spinal marrow is cut across, or is pressed on above the origins of the phrenic nerve, or above the third cervical vertebra, or when the whole nervous energy is destroyed, as by lightning. Most commonly, however, it is the second class, or the chemical phenomena of respiration, that cease first; and the motions of the chest are only interrupted because the black blood, which is then driven into all the organs and especially into the muscles and brain, does not carry along with it the power of excitation necessary to carry on the functions of these parts. This interrup-

tion of the chemical phenomenon may be produced in various ways: thus sometimes there is total interception of the passage of air into the lungs, as when an animal is placed in vacuo, or is smothered, drowned, or strangled; at other times, an acrid fluid does enter these organs, but is not possessed of the principle necessary to act on the blood contained in them, such as azote and hydrogen gases. It may be that the gas inhaled is endowed with deleterious properties; either that it irritates the lungs, as the sulphuric acid gas, muriatic acid, and ammoniacal gases; or that it acts upon the whole animal economy as a poison, such as carbonic acid gas, nitrous acid, carburetted hydrogen and hydro-sulphuretted gases. Thus we find that, by the total interception of all air, or by the inhalation of noxious gases, the chemical phenomena of respiration may be arrested. It is to this we shall direct our attention at present, as the cases in which the mechanical phenomena are first affected are more rare, and will be afterwards considered in treating of death from wounds or bruises, and from lightning.

The causes that produce death by asphyxia are drowning, hanging, and strangulation, smothering, and the inhalation of noxious gases or air deprived of oxygen.

The physiology of **Drowning** having been already fully discussed in the article *ASPHYXIA*, we shall proceed to consider the medico-legal questions that may arise in the case of a body found in water. These may be arranged under the following heads:—1. whether the body was immersed before or after death; 2. whether the individual has fallen in by accident, has drowned himself, or has been thrown in by others.

1. The inference that the person was living at the time of immersion is drawn from an attentive examination of the external state of the body, and from a careful anatomical investigation. The body of a drowned person usually presents the following appearances. It is commonly very cold, apparently even colder than the actual temperature; the limbs are more or less stiff according to the time that has elapsed since death; the visage is swollen, often dark-coloured, but sometimes pale; the eyes are half open and the pupils dilated; the mouth is filled with froth; the tongue is advanced beyond the teeth; and the chest and belly are elevated, the latter being often much distended. This state of the body is common to those who perish in cold clear water, as the sea, rivers, &c.; but the body is sometimes drawn out warm, although death is so complete that animation cannot be restored, the countenance violet-coloured, and the veins of the neck turgid. This happens in drowning in warm fluids or in alcoholic liquids, or in marshes where deleterious gases are disengaged, or when the person has fallen into the water in a state of intoxication. The ends of the fingers are often found rubbed or scraped, and dirt or sand, of a nature similar to that of the bottom of the water, is perceived under the nails. Coupled with these is the negative sign furnished by the absence of any lesion that could have caused death previous to submersion. The internal appearances disclosed on opening a drowned body are generally the following. The epiglottis is found elevated, and a quantity of

froth fills the trachea and bronchi; the lungs are dilated and gorged with blood; black and fluid blood is found in the right cavities of the heart in a much greater quantity than in the left. The diaphragm is depressed, and water of a nature similar to that in which death took place is discovered in the stomach. In the head there is turgescence of the blood-vessels, more or less intense as the death has been more or less speedy, and in proportion to the amount of struggling made by the individual. Orfila, (*Archives G n. de M d. Ao t, 1827,*) in a memoir read at the Academy of Medicine, has reviewed all the signs given by authors for determining whether immersion took place before or after death; and the conclusion he draws is, that there is no certain sign of submersion during life but the presence of water, similar to that in which it is found, in the stomach and air-passages; provided that, with reference to the stomach, the water has not been swallowed before submersion, and has not been injected after death: and with respect to the lungs, that the water shall have penetrated to the last unbranching ramifications, and has not been injected before death; and that the body shall not have remained long in a vertical position in the water, so that the water might have entered after death. It would appear from this that we possess two certain signs of submersion during life; but the restrictions imposed on them are such, that, taken apart from others, they are almost useless in the great majority of cases. In speaking of water in the air-passages, Orfila must have meant the froth formed by this fluid with the air; for it is very seldom found in substance in this situation. Devergie (*Annales d'Hygi ne et de M d. L g. t. ii. p. 432;* [*and M dicine L gale, 2d edit. ii. 392:* Paris, 1840] states that in a great number of cases he could find but very slight traces of water in the trachea; and in two only did he observe it in any quantity. Indeed, from the observations of Cullen, (Letter to Lord Cathcart,) Goodwyn, (Connection of Life with Respiration,) and Meyer, (Medical Repository, vol. iii. New Series,) it is plain that a very small quantity of water enters the air-passages in drowning; and this is speedily converted into froth by the motion given to it in the attempt at respiration. On the subject of this froth, Devergie makes some interesting observations, the substance of which is as follows:—It is commonly white, consisting of numerous and very small bubbles, constituting a lather rather than a froth properly so called. It never adheres to the trachea by mucus, but is in immediate contact with that tube. All the bubbles that form it have a watery envelope, easily broken, and often on opening the trachea the greater part disappear like soap-bubbles. The froth of drowned persons, then, has but little analogy with the expectoration of pneumonia or catarrh; and it is sufficient to have attentively observed it to avoid confounding them. Its formation necessarily brings with it the idea of vitality, for it cannot take place without motion, an impulse communicated to a fluid and a gas in mutual contact.

In order to appreciate its mode of formation, and the value that it may possess as a sign of submersion during life, it appears necessary to inquire

how it is produced in other cases than asphyxia by submersion. In pneumonia, for example, the individual is induced to expectorate because the extreme bronchial ramifications are filled with mucus, and the air can no longer reach them, and come into contact with the blood to effect the necessary changes. The invalid expels a frothy matter, because the mucus secreted under the influence of bronchial irritation is beaten and mixed up with the air by the alternate and quick efforts of inspiration and expiration, which constitute coughing. The formation of the froth takes place more easily as the irritation is nearer to the last bronchial ramifications, when the tubes, being of a smaller diameter, are more easily obstructed. It is, on the contrary, produced with great difficulty in the trachea, on account of the great dimension of this canal. In drowned persons similar phenomena take place, after they have expelled a part of the air contained in their lungs. They are soon solicited by the desire to respire; a small quantity of water enters the trachea, and causes a most distressing stimulus, of which we have a proof in the great suffering experienced by persons into whose larynx a drop of fluid has accidentally fallen while swallowing; a brisk and sudden expulsion of the water is effected, but it is rarely complete: the portion which remains dissolves a little mucus, and becomes viscid, whilst, at the same time, new inspiratory efforts draw in a new quantity of water: from that time the air, agitated with this fluid, rendered more viscid, constitutes the froth. This is formed with more difficulty in the trachea than in the last ramifications of the bronchi; and consequently we esteem its existence in the superior part of the trachea as a more certain sign of the life of the individual at the moment of submersion than when it is met in the extreme branches. This phenomenon does not leave very durable traces of its existence, for it is sensibly diminished, and even often disappears under the influence of putrefaction. The portion of the air-passages where it is preserved during the longest period is at the bifurcation of the trachea. In winter it may be discovered in most cases after eight or ten days, but later it completely disappears. It is true, that if we except the water contained in the stomach, the other signs of submersion have not a more extended duration. It should be understood that the water thus taken into the lungs is not, as it was formerly supposed, the true cause of death; an opinion to which Baron Larrey seems to incline in his *M moires*. The experiments of Goodwyn have shown that a much larger quantity of water than that which is found in the lungs of drowned animals, may be introduced into the air-passages without causing death. Thus, he passed into the lungs of a cat, through an opening in the trachea, two ounces of water; a large quantity when compared with the size of the animal. It had, immediately, difficulty of breathing and a feeble pulse; but these symptoms soon abated, and it lived several hours afterwards without much apparent inconvenience: after this he strangled it, and found two ounces and a half of fluid in the air-tubes and cells.

The presence of water, then, in the lungs of drowned persons in the form of froth is to be con-

sidered as an accidental and not essential circumstance, although it is one of very constant occurrence. If this fluid is found in large quantity, and in substance, that is, not beaten into froth, the inference would be that it had passed in after death. With respect to the presence of water in the stomach, it has been proved by many authors to be a constant occurrence; and when it is discovered in this organ, and is identical with that in which the body is found, it furnishes a strong indication of submersion during life, being a necessary consequence of the act of deglutition. For it has been proved by Fine, Orfila, and Marc, that it is never found in bodies plunged into water after death, and cannot be made to enter the stomach without the assistance of a tube passed into the œsophagus.

[A circumstance, which influences materially the quantity of water contained in the stomach, is the depth of water in which the individual was drowned. This is shown by some experiments instituted by Mr. Taylor. (*Elements of Medical Jurisprudence*, p. 121.) A cat was lowered to the depth of 55 feet in the Thames; another was held two feet below the surface. The stomach of the first cat contained a large quantity of water; that of the second scarcely any. A third cat was permitted to rise repeatedly to the surface. The stomach of this cat was distended, but not so much as the one that had been lowered to the depth of fifty-five feet. The influence of pressure of water is, therefore, considerable; and as has been remarked by Dr. Guy (*Principles of Forensic Medicine*, Part 2, p. 317: Lond. 1843,) it is probable, that where the water is very deep, the pressure of the fluid may overcome the resistance offered by the collapse of the œsophagus, even although the animal died previously to submersion.

It is proper to remark, that where water has entered the stomach, it may not be found there after death. If the head be permitted to hang down lower than the stomach, the water will run out. Two cats were drowned in nine fathoms of water. After having remained at this depth for half an hour, they were removed, and suspended with the head downwards. Water drained freely from them, and on examination of the bodies three days afterwards, none was discovered in the stomach or alimentary tube. (Taylor, *op. cit.*)

From the above-mentioned circumstances the following conclusions are drawn by Devergie: 1. that almost all the signs, taken singly, do not prove that the individual was living at the moment of immersion; 2. that the one which furnishes the strongest presumption is the existence of froth placed in immediate contact with the lining membrane of a sound trachea; 3. that this sign acquires a value greater as its situation is nearer to the mouth; 4. that water in the air-passages is a sign of little value, for if it can penetrate the trachea after death, and extend even to the last bronchial ramifications, as Orfila has shown, it becomes almost useless; 5. that water in the stomach is one of the most constant signs, but its value is greatly diminished by the difficulty of proving its identity with the fluid in which the body has been immersed; 6. that if each sign taken singly gives no certainty, the assemblage

of all in the same individual may enable a positive conclusion to be drawn.

The proofs that death occurred before immersion are drawn from the absence of all those signs just enumerated; thus the thorax and abdomen will be found flat,—no excoriation of the ends of the fingers,—no dirt or sand under the nails,—no turgescence of the cerebral vessels,—and no froth in the air-passages. The lungs will be collapsed, and the diaphragm will not have passed the natural line. The stomach will be found not to contain any of the fluid in which the body is found, and in addition to these negative proofs, marks of violence may be discovered on the body quite sufficient to account for death. These marks are divided by Fodéré, (*Méd. Lég. tom. iii. p. 112.*) into three classes: 1st. those which are totally independent of any connexion with the circumstances of drowning. Of this nature are the usual signs of poisoning; a regularly formed ecchymosis round the neck, indicative of strangulation, or wounds inflicted by fire-arms or cutting instruments. All these lesions have an essentially distinct character which cannot be mistaken, and hence the evident importance of examining carefully the external appearance of all bodies found in water. It was by pursuing such an investigation that Deveaux discovered, in the body of a woman found in water, a penetrating wound under the left breast, made by a very small instrument which had reached her heart. 2dly. Marks of violence which may have resulted from accidents attending submersion, or may be caused by previous homicide, such as unequal irregular wounds which do not penetrate far into the body, contusions, fractures, and luxations. In all such cases we should ascertain, if possible, the height from which the individual may have fallen, and the resistance he may have encountered in the fall. The rapidity of the current, and the roughness of the banks of a river may also cause extensive wounds. Dr. Fine remarks that the rapidity of the Rhone, and the numerous mills erected on its side, often produce most shocking wounds in the bodies which are driven against the stakes in the stream, or are drawn into the machinery. 3dly. There may be lesions received after death. These are to be distinguished from those inflicted during life by the lividity and flaccidity of their edges, the absence of tumefaction and redness, and want of hemorrhage, or, if the latter be present, by the fluidity of the blood.

2. It being ascertained that the subject was immersed while living, it is often of importance to be able to say whether the drowning was the result of accident, of suicide, or of homicide. The solution of these questions is to be obtained by an examination of what may be termed the external circumstances of the case. The locality of the water may be such as to account for the deceased having accidentally fallen into it, or its situation may at once preclude the possibility of such an event. Indications of struggling on the brink, such as tearing of the ground, and many footsteps, together with ecchymoses on the person of the deceased, may lead to the supposition of homicide. Thus, in the case of Mr. Taylor, who was murdered at Hornsey in December 1818, marks of footsteps deep in the ground were discovered near

the New River; and on taking out the body, the hands were found clenched, and contained grass which he had torn from the bank. (*Paris and Fonblanque*, Med. Jur. v. iii. p. 41.)

However conclusive the existence of ligatures on the hands and feet of the deceased may appear,—as to the question of the forcible interference of others, it should be recollected that suicides have sometimes adopted such precautions in order to insure their death. There are some instances on record, in which the individuals seem to have pursued this course. (*Op. cit.*) In June 1816, the body of a gauging-instrument maker, who had been missing for some days from his home, was discovered floating down the Thames. On being taken out, the wrists were found tied together and made fast to his knees, which were in like manner secured to each other. He had been in a state of mental derangement for two years. The cord with which he had tied himself was recognised as one that had hung from the ceiling over his bed, by which he used to raise himself up, as he had been confined to bed for some weeks. He was a good swimmer, and it was presumed he had taken this precaution to prevent himself from employing that power. The verdict returned was, “found drowned.” The other instance was that of a man, aged twenty-eight, who with a wife and child was reduced to great distress. On a certain day he took an affectionate leave of his family, declaring he would not return until he had procured some employment by which he should be able to buy bread for them. The following day his body was taken out of the New River with his hands and legs tied. A card with his address was found in his pocket, and also three-pence; when he left home he had five-pence, and it was supposed he had purchased the cord with the deficient sum; the verdict brought in was “insanity.” Another case of a similar nature has been lately published. It was that of a gentleman who was found in the Seine at Paris, having his feet, wrists, and neck tied with a cord. After detailing the appearances of the body, the reporter concludes with the following note: “Mr. X— had bound his neck, limbs, and hands by means of a rope with slip knots, in order to put it out of his power to aid himself when in the water, and thereby to render certain the execution of his suicide.” (*Ann. d' Hygiène et de Méd. Lég.* t. ix. p. 207. [See, also, his *Médecine Légale*: Paris, 1840.]) We mention these cases to show how cautious a medical man should be in forming an opinion in similar instances, and how necessary it is to weigh well every circumstance before he expresses that opinion before a legal tribunal.

It is often, as has been already mentioned, of the highest importance to the survivors, that an approximation to the time that has elapsed since death should be arrived at. For assistance in such an investigation, the medical jurist will turn in vain to the systematic works on legal medicine, it being only within the last few years that any accurate information on the subject was possessed by the profession. We are indebted to M. Devergie for the first essay on this interesting subject, one concerning which the most vague notions were entertained previously to the publication of the memoir alluded to, in the year 1829. The

observations of M. Devergie are entitled to much consideration, from the unrivalled opportunity afforded for their formation. He was authorized to carry on his investigations at the establishment called “La Morgue” in Paris, a building on the banks of the Seine, to which are transported all bodies found dead in the city and its environs, and where they are exposed during three days for the purpose of recognition by their friends. The number thus exhibited exceeds three hundred annually, and includes all manner of violent deaths. In case of the sudden disappearance of an individual, his friends repair to the Morgue, and leave with the porter an accurate description of his person, his clothes, and the period at which he was last seen; and when a body is brought in, it is carefully examined, and if it corresponds with any of the descriptions that have been left, notice to that effect is sent to the persons interested, who come and claim it. The number of persons recognised is very considerable; in the first six months of the year 1829, out of 148 bodies 116 were claimed. Of this number 62 were drowned, of whom 45 were recognised. Being thus furnished with positive information as to the time of immersion and that of finding the body, Devergie was enabled to prosecute his inquiries with great accuracy. He found that in general no change takes place on the exterior before the fourth or fifth day, and the cadaverous rigidity frequently continues two, three, or even four days after immersion. This is probably owing to the coldness of the medium in which the body is placed. About the fourth or fifth day, the skin on the palms of the hands begins to whiten, and this change of colour takes place particularly on the ball of the thumb, and the fleshy eminence on the inner side of the palm over the metacarpal bone of the little finger, together with the lateral surfaces of the fingers. The back of the hand does not partake of this colouring, and the rest of the body presents nothing particular. On the sixth or eighth day, the skin at the back of the hand begins to whiten; at the same time that the sole of the foot has acquired a similar tinge: the skin of the face is softened, and of a more faded white than the rest of the body. On the fifteenth day, the face is slightly swollen and red; a greenish spot begins to form on the skin over the middle of the sternum; the hands and feet, with the exception of the dorsum of the latter, are quite white, and the skin of the palm of the hand is wrinkled. The subcutaneous cellular tissue of the thorax is reddish, and the cortical substance of the brain takes on a green colour in the upper part of that organ. At one month, the face is reddish brown, the eyelids and lips are green and swollen, the neck is slightly green, and a spot of about six inches in diameter, brown in colour and with a green areola, occupies the superior and middle part of the sternum. The scrotum and penis are enormously distended by gas, the latter being sometimes in a state of erection from that cause. The skin of the hands and feet is quite white and very much wrinkled, presenting the appearance of having been long enveloped in a poultice. The hair and nails are still very adherent. The lungs are emphysematous, and fill the cavity of the chest overlapping the heart,—a condition different from that

which these organs present at a more advanced period. At a month and a half, besides the appearances first mentioned, the neck and thorax are found very green, and the cuticle begins to detach itself round the base of the hand where it joins the wrist. At two months, the body is covered with slime, which penetrates through the clothes. The face is enormously swelled and of a brown colour, the lips are tumefied and separated so as to expose the teeth. The skin on the middle of the abdomen, as well as that of the arms, forearms, thighs, and legs, is still in a natural state. This is a most remarkable fact, and establishes a striking difference between the progress of putrefaction in water, and when the body is exposed to the atmosphere; in the latter case, the abdomen being the first part to manifest any change. At this period the skin has become detached from the hands and feet, and having the nails attached to it, forms as it were a glove. The skin and nails of the feet are longer in separating than those of the hand. The hair begins to fall off, and is easily removed by pulling. The veins are almost completely empty of blood and commonly distended with gas. The inner surface of the arteries is red, and that of the trachea between the cartilages presents the same colour. If at the moment of death the right cavities of the heart were gorged with blood, the internal surface of the ventricle is of a jet black colour; and in contrary cases an analogous appearance is presented on the opposite side. Devergie considers this a most important diagnostic mark of death by asphyxia. At two months and a half, the green colour of the skin extends to the arms, forearms, and legs; the nails are completely detached from the hands and feet; some adipocire is formed on the cheeks, chin, breasts, arm-pits, and anterior part of the thighs: the abdomen is greatly swollen by putrefaction within; the muscles at this period preserve their natural colour, and do not appear altered in texture. At three months and a half, there is observed destruction of the scalp, eye-lids, and nose, to such an extent as to make it difficult to tell the age of the individual. The skin of the breast is generally of a greenish brown; the centre of the abdomen is of an opaline colour, and scattered with small ulcerations caused by the water. Larger corosions are found in different parts of the body. The hands and feet are completely naked of skin. The lungs no longer fill the thorax, but leave between them and the pleura costalis a space filled with reddish serum. At four months and a half, occurs complete destruction of the face and scalp, leaving the skull bare; the remains of face, the neck, and anterior part of the thighs is entirely converted into adipocire; and small eminences, indicating the commencement of calcareous incrustation, are observed on the prominent parts. The brain presents traces of adipocire in its anterior part. Devergie has not classified the changes that take place at more advanced periods. The period from which we have extracted the foregoing account has been severely criticised by Orfila, (*Traité des Exhumations Juridiques*, t. ii. p. 83,) who endeavours to overturn the facts and doctrine contained in it. But we think he has been satisfactorily and triumphantly replied to by Devergie, (*Annales d'Hygiène pub.*

et de Méd. Lég. t. v. p. 429, [and *Med. Légale*, i. 229,]) who adduces as the best proof of the validity of his conclusions, four cases, in which the periods of immersion, varying from fifteen days to one, two, and eight months, were ascertained with the help of his table.

As the physiological phenomena observed in persons dead from hanging and strangulation are nearly the same, we shall consider them together in the present section, pointing out the differences between them as we proceed.

Notwithstanding the authorities of Boerhaave, Morgagni, and Portal, who imagined that apoplexy was the immediate cause of death in hanging, it is now generally admitted that the event is owing to suffocation. This opinion is confirmed by the experiments of Gregory and Brodie, from which it appears that if an artificial opening be made into the trachea of an animal, below the ligature by which it is suspended, it will continue to live. But we must admit that other injuries are sometimes inflicted, of themselves sufficient to account for death, such as compression of the nerves of the neck, and fracture or dislocation of the spine. With respect to the former, Dr. Paris remarks: "Although the pressure of a ligature on the nerves of the neck cannot be considered as the immediate cause of death in hanging, yet Mr. Brodie has very justly observed that if the animal recovers of the direct consequence of the strangulation, he may probably suffer from the effects of the ligature upon the nerves afterwards. Mr. Brodie passed a ligature under the trachea of a guinea-pig, and tied it tight on the back of the neck with a knot: the animal was uneasy, but nevertheless breathed and moved about. At the end of fifteen minutes the ligature was removed; on the following morning, however, it was found dead. On dissection no preternatural appearances were discovered in the brain, but the lungs were dark and turgid with blood, and presented an appearance similar to that which is observed after the division of the nerves of the eighth pair. 'I do not,' observes Mr. [Sir B.] Brodie (manuscript notes), 'positively conclude from this experiment that the animal died from an injury to the eighth pair, but I think that such a conclusion is highly probable; and it becomes an object of inquiry whether a patient, having recovered from hanging, may not in some instances die afterwards from the injury of the *par vagum*.'" (*Paris and Fontblanque*, *Med. Jur.* v. ii. p. 44.) Fracture or dislocation of the spine, when they do take place, must of course contribute to the speedy death of the individual; but these accidents are very rare, even when the fall is great, as in public executions. In numerous instances that have come under the observation of the writer, this cause of death was never observed. As in the case of drowning, two questions present themselves for solution by the medical witness: 1. whether the individual was suspended before or after death; 2. whether it was an act of suicide or of murder. An individual found suspended may have been killed in different ways; first, he may be hung up after having been murdered; and again, he may have committed suicide by hanging after having previously tried to destroy himself by other methods, in which he has failed, as by fire-arms

cutting the throat, &c. In the first case we might be led to mistake murder for suicide, and in the second suicide for assassination. It is necessary, then, to be aware of the signs by means of which death by strangulation in general may be distinguished, in whatsoever manner it may happen. These are lividity and distortion of the countenance, protrusion of the eyes, which are frequently suffused with blood, projection and wounding of the tongue by the teeth. The latter depends upon the position of the rope: if it be below the cricoid cartilage, the tongue is pushed out; but if it presses above the thyroid cartilage, it is carried along with the *os hyoides* backwards. In addition, we have the mark of the cord around the neck forming a livid depressed circle; the fingers usually bent, the nails blue, and the hands nearly closed, with swelling of the chest, shoulders, arms, and hands, and sometimes ecchymoses in these situations; also semi-erection of the penis, and *emissio seminis*. Cases of death by hanging occasionally present themselves in which the countenance is pale; this arises from the suddenness of death in some individuals, and particularly if the spine be dislocated. On dissection, the body presents nearly the same appearances as those described as caused by drowning, with the exception of water in the air-passages. A bloody rancus issues from the mouth and nose; but this is very different from the froth of drowned persons. The principal vessels of the head and neck are filled with blood, and sometimes ruptured. With respect to the bruised mark of the rope round the neck, it is stated by M. Klein (*Journal de Méd. prat. de Hufeland*, 1815) to be an uncertain sign,—an opinion founded on fifteen cases of suicide by hanging, in all of which it was wanting. Remer, (*Annales de Hygiène pub. et de Méd. Lég.* tom. iv. p. 166,) of Breslau has more lately investigated this subject on an extended scale, and out of one hundred cases collected by him, eighty-nine presented the sigillation on the neck in an evident manner. In one case, instead of ecchymosis, the skin was found of a yellowish brown colour, like parchment; in two others the skin was excoriated; in another putrefaction prevented any certain examination; and in nine cases it is expressly mentioned that ecchymosis was wanting. It follows from this, that out of one hundred hanged persons, nearly one-tenth were found without a bruised mark. But if this proportion is sufficiently great to induce medical jurists to withhold unlimited confidence in this sign, it is at the same time too small to destroy the validity of the general rule, that such impressions are found in hanged persons. In all the cases that have come under the observation of the writer, the mark of the rope was most distinct. These were all executed criminals, in whom, from the nature of the ligature and the height of the fall, such impressions might be expected; but even in the most unfavourable circumstances the ecchymosis has been strongly marked. Remer (*loc. cit.*) mentions that it has taken place notoriously in those found strangled in a position in which either the feet or the knees had not left the ground. In all the instances observed by us, the ecchymosis did not occupy the part of the skin with which the rope was in contact, but formed two lines on

either side of it, one above, the other below; while the intervening portion, the part actually compressed by the cord, resembled dark-coloured parchment.

It is quite necessary that the medical jurist should not be content with the discovery of a blue ring on the neck, but that he should cut into it, in order to examine the extent of the extravasations, and the injury done to the parts in its neighbourhood. The height of the fall must cause a difference in the injuries inflicted on the parts composing the neck. When the individual falls from a considerable height, as in public executions, the lesions produced are very extensive. Dr. Houston (*Dublin Hosp. Reports*, vol. v. p. 317) has published an account of some dissections of criminals in whom the similarity of injury is most remarkable. "Both the individuals were strong plethoric men, executed for murder. Their death was evidently caused by strangulation. The cervical vertebræ were unbroken, and the spinal marrow and brain presented no trace of injury. In both, the sterno-mastoid muscle, on the right side (the opposite to that on which the knot of the rope was applied) was ecchymosed, contused and broken; that of the left side was only slightly bruised. The *os hyoides* and thyroid cartilage were completely severed from each other. The *omo-hyoid*, *sterno-hyoid* and *thyro-hyoid* muscles, were so bruised and lacerated, that only some stretched shreds of them remained to hold the parts together. The *thyro-hyoid* membrane was also torn across, and the *epiglottis*, pulled from its root to the back of the thyroid cartilage, had passed up with the *os hyoides* and tongue into the back part of the mouth. The skin alone remained unbroken, and interposed between the rope and the cavity of the pharynx. This was the only region of the neck which gave evidence of much injury; the great vessels and nerves all escaped unharmed. In two other criminals, which more lately I have had an opportunity of examining, precisely the same effects had been produced by the rope on the soft parts of the neck, and without any injury to the brain or spinal marrow." The preparations from which the above statement is taken are preserved in the museum of the Royal College of Surgeons, Dublin. The semi-erect condition of the penis, and emission of semen, are signs which, although frequently met with, are not constantly found in hanged persons. Thus Klein, in the memoir alluded to, states he did not perceive them in any of the instances examined by him, and Remer found them only in the proportion of three to four. In some of the cases examined by the writer they were wanting, but in the majority there were evident traces of excitement of the organs of generation. The practice adopted by worn-out libertines, of causing themselves to be half hanged in order to arouse their dormant generative power, is a proof that some effect is produced on these organs by suspension. But as erection is not constantly found in hanged persons, we cannot accord to this phenomenon much value as an indication of death by strangulation, unless when accompanied with other characteristic signs. It adds, then, to the certainty of this kind of death, but it is no proof when it exists alone, for it has been found in other forms of violent death;

and its absence is no proof of the contrary. A remarkable proof of the occurrence of this phenomenon in hanging is given by M. Guyon, (Anderson's Quarterly Journal of the Med. Sciences, vol. ii. p. 151,) surgeon-major at Martinique, who attended the execution of fourteen persons, with a view of ascertaining the truth respecting the disputed subject of emission. Being situated near them at the place of execution, he observed the penis of all become erect at the moment of strangulation, and immediately after five of them made water abundantly. An hour after execution he found in nine of them the penis in a state of semi-erection, and its canal filled with a kind of matter with which the shirt was too profusely impregnated to allow it to be supposed that it came from any other organ than the prostate.

[In some experiments made at Lancaster, Pa., upon the body of a criminal executed there in 1839, it was observed, that there was an ejection of fluid from the urethra, but no erection. This fluid when examined afterwards by the microscope, was found to be mucus, and to contain no spermatic animalcules. (*Amer. Journ. of the Med. Sciences*, May, 1840, p. 26.)]

The second question is, whether it was an act of suicide or of murder. It is admitted by most medical-legal writers that this is a difficult and unlikely method of committing murder, unless the assailants be numerous and powerful. Dr. Smith remarks, "It is perhaps not going too far to say, that a man cannot be hung alive by others, unless his hands be previously tied, and probably his legs also." Accordingly, when a body is discovered hanging, the first impression is usually that the individual has hung himself. But this opinion should not be confirmed until an accurate investigation has been made into all the external circumstances connected with the occurrence. It should first be ascertained that death has been caused by strangulation; for it has happened that crafty murderers have destroyed their victims in some other manner, and then suspended the body in order to create the suspicion of suicide. But supposing strangulation to be recognized, particular attention should be paid to the part of the neck which bears the impression of the ligature, and the kind of mark left by it. Thus, if we find the track of the cord to be low down, and to pass horizontally round the neck, while another and fainter impression exists at the upper part, taking an oblique course, it should excite suspicion that manual strangulation had been resorted to in the first instance, and that the body had been hung up after death. An examination of the dress and person of the deceased will sometimes aid the inquiries of justice by pointing out the signs of resistance and struggling, or robbery. It is necessary, however, to judge of any marks of external violence with great caution, for although they may generally be esteemed proofs of homicide, they may have been purely accidental, or have been inflicted by the individual previous to voluntary suspension. De Haen records the case of a person who, while hanging, inflicted several wounds on his face; and Ballard (p. 409,) mentions a case of suicide, in which the individual first cut his throat partially. The following interesting case is related by Dr. Male. (*Juridical Medicine*, p.

243.) "An apprentice-boy in my neighbourhood, working alone in an attic, tied one end of a rope loosely round his neck, whilst his master was from home, probably without any intention of destroying himself, and twisted the other round the projecting part of the top of a door, the planks of which were irregular and somewhat divided; a small stool, on which he stood, slipped from under him, when he fell forwards, striking his temple against the corner of a box which cut him to the bone; he lay along the floor, his head and shoulders only elevated a few inches above it; the cord not being tied had run nearly its whole length, and then caught between the planks of the door, in which state he died. The wound was magnified by popular rumour into many, and vengeance was denounced against the innocent master, who was accused of having first killed and afterwards suspended the boy. On examining the boy, the mark of the cord was found to extend from ear to ear; the vessels of the brain were turgid, the thyroid cartilage broken, the nails blue, and the hands firmly closed. From this and other important circumstantial evidence, the coroner's jury were convinced that the charge was unfounded." It should be recollected that a person may be hanged accidentally, and therefore the usual verdicts of insanity, or *felo de se*, are not to be given in all cases where proofs of homicide do not exist, without due caution. A remarkable instance of this kind is related by Dr. Gordon Smith, (*Principles of Forensic Medicine*, p. 236,) which occurred in April 1821, in Northamptonshire. A girl, aged thirteen, was swinging in a brough, and near the rope used by her for that purpose was another for the purpose of drawing up slaughtered sheep. In the course of the exercise her head got through a noose of this second cord, which pulled her out of the swing, and kept her suspended at a considerable height until dead.

[Mr. Taylor (*Elements of Medical Jurisprudence*, p. 173,) relates another case. A boy, ten years old, had been amusing himself by fastening a piece of plaid gown to a loop in a cord which was suspended from a beam in the room. In the act of swinging he raised himself up, and gave himself a turn, when the loop of rope suddenly caught him under the chin, and suspended him until life was wholly extinct. A playmate witnessed the occurrence.]

We have said above that it is difficult, without an overwhelming force, to hang an individual against his will; but, on the other hand, it is surprising with what facility death may be accomplished by this means, in situations which at first view would seem to preclude its possibility. The late Prince of Condé, who committed suicide on the 27th of August 1830, was found hanging to a window-shutter, with his feet touching the ground and his knees bent. The attitude in which the body was found raised some suspicion of foul play, and a most accurate investigation of all the circumstances connected with the event was instituted, from which it appeared to have been a case of voluntary suicide. An interesting memoir (*Annales de Hyg. pub. et de Méd. Lég.* tom. v. p. 156,) on the subject, was published in January 1831, in which are related several instances of self-destruction by hanging, where the

bodies were found in the most extraordinary situations and attitudes, accompanied with plates of the same. In one a man was found in a granary hanging by a cotton handkerchief made fast to a rope which stretched across; the knees were bent, so that the legs formed a right angle backwards; the feet were supported on a heap of grain, over which the knees hung at a distance of a few inches. In another, a prisoner was found hanging to the bars of a window so low that he was nearly sitting on the ground: he had previously tied his hands together. In a third, the body was found in a vertical position, with the heels resting on a window-stool. In the fourth, an Englishman, a prisoner in Paris, hung himself in his cell, which was an apartment with an arched roof, and at the lower part of it was a grated window, the highest part of which was not near the height of a man; nevertheless he hung himself to this grating, and was found almost sitting down, with his legs stretched out before and his hips within a foot and a half of the ground. In a fifth, the attitude of the body was similar to the first: the man had suspended himself to a large iron pin driven into the wall to support the bed-curtains, and his feet, bent at a right angle, rested on the bed, while his knees approached it within a few inches. In a sixth, the point of suspension was so low that the person (a female) was obliged to stretch out her legs, one before resting on the heel, the other behind resting on the toes, in order to accomplish her purpose. In a seventh, a female was found stretched at the foot of her bed, the legs, thighs, and left hip, lying on the floor; the upper part of the body was raised, and suspended by a cord fixed on the neck, and fastened to the hospital-bed. There are other cases recorded in the memoir alluded to, of persons found hung in equally extraordinary situations, but we think it unnecessary to particularize them. A few years ago a man, aged seventy-five, destroyed himself at Castle Carey by fixing a cord round his neck while sitting on his bedside, leaning forward till his purpose was accomplished. His wife, who had for years been bed-ridden, and therefore not likely to have been fast asleep, was in the room during the transaction, and knew nothing of what was going on. (Beck's Med. Jur. by Darwall, p. 283; [or 6th edit. ii. 139: Philad. 1838.]) In order to show the power of the will and firmness of resolution in certain suicides, we quote the following case from Remer, (loc. cit.) "Une femme alla, avec l'intention de se pendre, de la chambre où ses enfans se trouvaient, dans celle où ils couchaient. Sa fille aînée, âgée d'environ huit ans, la suivit bientôt, et la trouva pendue; la fille exerça tant de tractions sur sa mère pour a détacher, qu'elle y parvint en rompant le lien. Alors la mère, qui avait toujours la corde au cou, repoussa son enfant dans la première chambre, la reprit, et lui ordonna, ainsi du' à ses frères et ses sœurs, de rester où ils étaient, revint sur ses pas, et se pendit une seconde fois. Les enfans allaient chercher du secours, mais il n'était plus temps." From these cases we learn how quickly consciousness must be destroyed in this form of death; for were it not so, some exertion would be made by the individuals to save themselves after the experiment had been tried to a certain extent.

Strangulation, properly so called, differs from hanging in the individual not being suspended; but whether death be caused by suspension or a ligature drawn tight, or by the hand alone, or any other pressure on the trachea, the physiological phenomena are the same. Strangling is a more common method of committing murder than hanging, arising from the greater facility with which it is accomplished. A remarkable instance of this is that of Dr. Clench, who was strangled in a hackney-coach in London, in 1692, by two men, who called him out in the night under pretence of taking him to visit a patient. After driving about the city for more than an hour the two individuals left the coach, and the coachman found Dr. Clench sitting in the bottom with his head against the cushion. He was quite dead, and had a handkerchief around his neck, in which was a piece of coal placed just over the windpipe. The coachman had not the slightest knowledge of the transaction, having heard no noise while driving the carriage.

The appearances presented by strangled persons, when a ligature has been employed, do not differ much from those already detailed, as characteristic of death by hanging. The position of the rope-mark constitutes the chief point of distinction; if it is not at the upper part of the neck, there can be no doubt the person was not hanged: dislocation of the neck is not to be expected, but the cartilages of the larynx and trachea frequently suffer. The track of the ligature in strangling is horizontal, and usually rather low down on the neck. A question has arisen as to the possibility of strangling being resorted to for the purpose of suicide. Upon this subject Fodéré remarks: "Je dirai relativement au second chef de la question, qu'en général les impressions circulaires laissées par la simple strangulation forment seules une présomption d'homicide, parcequ'il n'est guère possible de se donner la mort par ce moyen, les mains cessant de faire force au moment où la compression commence à s'exercer." (Méd. Lég. tom. iii. p. 174.) Notwithstanding this opinion he relates a case communicated to him by Desgranges of Lyons, on which the Society of Medicine were consulted, and replied that voluntary strangulation was possible. The case was that of an individual found strangled in a hayloft by a handkerchief which had been tightened by a stick. Another case of a similar description is given by the same author. One of a more recent date is recorded by Dr. Dunlop, (Beck's Med. Jur. by Darwall, p. 290,) on the authority of a navy-surgeon, a friend of his. A Malay, who on board of a man-of-war in the East Indies had made repeated attempts to commit suicide, at last succeeded by the means alluded to. He tied a handkerchief round his neck, and with a small stick twisted it several times, and then secured it behind his ear to prevent its untwisting. Jealousy was the cause assigned for the act. The well-known case of General Pichegru, who was found strangled in prison, in Paris, during the consulato of Buonaparte, gave rise to various suspicions and the rarity of this form of suicide, together with a general disbelief in its possibility, served to strengthen the common fame of that day, that he had been thus privately murdered in order to

avoid the risk of a public trial. Certainly the condition in which the body was found seemed to point to such a conclusion. It was lying in bed on the left side, in an easy attitude, with the knees bent, and the arms lying down by the side, with a black silk handkerchief twisted tightly round the neck by means of a stick passed under it. The cheek was torn by the ends of the stick in its rotations. In allusion to this case, Remer (*Ann. de Hyg. et de Méd. Lég. t. iv. p. 186.*) observes: "Je n'ai d'ailleurs ici aucune intention de me constituer le défenseur d'un homme qui a trop versé de sang pour ne pouvoir pas prendre facilement sur lui un meurtre de plus. Bien mieux, j'accorde que ce genre de mort n'est que très rarement le résultat d'un suicide, mais je doute que sur cette seule considération, et sans autres preuves plus fortes, on puisse absolument affirmer qu'il y a eu meurtre." Indeed, when we consider the number of cases, that occur, of suspension, some of which we have mentioned, where the position in which the body is found establishes with what promptitude the loss of sense must have taken place, or how strong the desire of self-destruction must have been when the resolution was once taken, we think it is going too far to deny the possibility of death by voluntary strangulation, however cautious we may be in receiving testimony on the subject.

Persons destroyed by manual strangulation exhibit, instead of the circular ecchymosis on the neck, irregular patches corresponding to the fingers of the assailant. We must not expect, however, to find the internal mark of suffocation so distinct as in cases of hanging, because the closing of the air-tube not being so complete, the functions of respiration and circulation go on in some measure for a longer time. Traces of violence on the chest and limbs are also frequently observed in consequence of the struggling and force employed in the act.

[In rare cases, strangulation may be accidental. An extremely dissipated, drunken, and disorderly woman went to bed intoxicated, and was found strangled in her bonnet-strings. It appeared that she went to bed with her bonnet on, and falling out of bed, her bonnet became fastened between the bedstead and the wall, and she, being so drunk as to be unable to loosen the strings, was, in consequence, strangled. (*Guy, op. cit. p. 336.*)]

Death by **smothering** is nearly allied to the former. It consists in cutting off the supply of air to the lungs by forcibly closing the mouth and nostrils. This form of death is more usually accidental than intentional, because, unless in the case of very young or old feeble persons, it is a difficult method of committing murder. Children have been smothered in bed accidentally, by the nurse or a pillow, overlaying them in such a manner as to close the mouth and nostrils. Persons in a state of intoxication may be smothered accidentally by falling with the face in mud, shallow water, or the like, and being unable to extricate themselves they perish by suffocation. But drunken persons are also easily destroyed by intentional smothering, of which the woman Campbell murdered by the notorious Burke and Hare in Edinburgh in 1828, furnishes a melancholy example. This was the last of three charges of

murder laid in the same indictment as having been committed within six months in the same way, and for the same purpose, of supplying subjects for the anatomists' dissecting-room; and there is now no reason to doubt that, in conjunction with their two accomplices who turned king's evidence, they had carried on the dreadful trade of human butchery to a far greater extent. The direct evidence of the manner of death, as derived from the testimony of the accomplices, was that Burke and Hare were fighting together, when the deceased, in attempting to part them, was struck down by Hare to a sitting posture on the floor; that Burke, as soon as he had overpowered his companion and thrust him on the bed, threw himself on the deceased, kept her down by the weight of his body, and covering her mouth and nose with one hand while he applied the other under her chin, held her thus for ten or fifteen minutes till she was dead. The most remarkable appearances presented by the body when examined two days after death, were the following:—joints flaccid; features composed, red, and rather more turgid than natural; lips affected with dark livor; conjunctivæ of the eyes, even in the horizontal position of the body, much injected with blood; a little fluid blood on the left cheek, proceeding apparently from the nostrils; tongue not protruded or torn by the teeth; the scarf skin under the chin much ruffled, and the surface of the true skin dry and brown when denuded, but without blood or surrounding ecchymosis; integuments every where very free of lividity except on the face; no effusion of blood or laceration of the parts around the windpipe; no injury of the cartilages; the os hyoides and the thyroid cartilage farther apart than usual, in consequence of stretching of their interposed ligament: on the inside of the windpipe some tough mucus, not frothy, with a few points of blood between it and the membrane, which last was healthy; organs within the chest perfectly natural; the lungs remarkably so, and unusually free of infiltration; blood in the heart and great vessels, and indeed throughout the whole body, very fluid and black, and accumulated in the right cavities of the heart and great veins. There were some appearances of violence on the limbs and in the spinal canal, unnecessary to notice, as they were the effects of injuries after death, caused by forcibly doubling up the body to enclose it in a box. Upon this case, Dr. Christison (*Edinburgh Med. and Surg. Journal, vol. xxxi. p. 243.*) (from whose admirable and detailed account we have extracted the foregoing) very justly observes: "A conviction has gained ground among the public, and has been encouraged by the sentiments currently expressed in society by some medical men, that the signs of suffocation generally, and as they existed in the body of the woman Campbell in particular, are so obvious and characteristic that they would of themselves, and independently of a knowledge of collateral circumstances, at once attract the attention of a professional person conversant with anatomy, and excite a very strong and well-grounded suspicion of the cause of death. This idea, if erroneous, must have a pernicious tendency in various ways. A sufficient reason for my taking notice of it is, that it may throw medical inspectors off their

guard, by leading them to expect strongly-marked appearances in every case of death by suffocation. That such appearances are very far from being always present, should be distinctly understood by every medical man.

"In the body of the woman Campbell, no person of skill, whose attention was pointedly excited by being told that from general circumstances murder was probable, but the manner of death unknown, could have failed to remark signs that would raise a suspicion of suffocation. But if his attention had not been roused,—if, for example, he had examined it in the anatomical theatre of an hospital, without knowing that suspicions from general circumstances were entertained regarding it, he might have inspected it even minutely, and yet neglected the appearances in question. Nay, a person of skill and experience would have been more likely to do so than another, because every one who is conversant with pathological anatomy must be familiar with such or similar appearances as arising from various natural diseases."

For persons found dead from *noxious inhalations and poisoning*, see the articles *ΑΣΦΥΞΙΑ* and *ΤΟΞΙΚΟΛΟΓΕΥ*.

Persons found Burned.—In cases where bodies are found dead with traces of extensive burning upon them, the medical jurist, to whom the investigation may be committed, has some delicate and interesting questions to solve. This difficulty has been of late years increased, by the admission of the possibility of spontaneous human combustion, and he is now expected to state—1st, whether burning was the cause of death or not, or, in other words, whether the body was burned before or after death; 2d, whether the burning was spontaneous or ordinary combustion. It is much to be feared that a want of information respecting the peculiarities of these different cases, has led, even in times not very remote, to the condemnation of innocent persons. "On a vu dans le courant du dixhuitième siècle, condamné à périr sur l'échafaud, un malheureux habitant de Rheims, accusé d'avoir assassiné sa femme, et de l'avoir ensuite brûlée, afin de se dérober au supplice qui l'attendait; et M. Vigné a jetté des fleurs sur la mémoire de l'infortuné Millet, dont la femme, sujette à l'ivrognerie, fut trouvée le 20 Février 1725, presque entièrement consumée dans sa cuisine, à un pied et demie du foyer." (Fodéré, Méd. Lég. tom. iii. p. 204.) Two cases related by Dr. Christison, (Edin. Med. and Surg. Journ. vol. xxxv. p. 316,) on the authority of the late Dr. Duncan, appear to us of a similar nature. In each the prisoner was accused of having murdered his wife, and burnt the body afterwards to conceal the murder. "The first was the case of a man, Gilchrist, who was condemned and executed at Glasgow. The prisoner and his wife lived on tolerably good terms, but used to take fits of rambling and get drunk for days together. At last, on one of these occasions, after their return home in the evening, the people who lived in the floor above them heard a noise like that of two persons struggling, and soon afterwards a rattling or gurgling and moaning, as of one choking or bleeding to death. They so strongly suspected that all was not right, that they called

down to Gilchrist through the floor that they were afraid he was killing his wife. In no long time they were further alarmed by the smell of fire and the filling of the house with smoke; upon which they went down to Gilchrist's apartment and demanded admission. After some delay he admitted them, and in doing so appeared to have come out of an inner room, where he said he was asleep in bed. On letting them in, he stumbled over the body of his wife, who lay in the outer apartment quite dead, kneeling before a chair and very much burnt. In these circumstances the prisoner was accused of having murdered her and then burnt the body to conceal the manner of death; while, on the contrary, he alleged he had gone to bed tired, and knew nothing of what had befallen her till he was awakened by his neighbours, and that he presumed her clothes had caught fire while she was intoxicated and burnt her to death. The medical gentlemen who had been appointed to examine the body, merely reported that they found the body so much burnt that they could learn nothing from it as to the cause of death. The general evidence was all against the prisoner. He was accordingly condemned, although the precise manner of his wife's death was not proved even presumptively, and the sentence was put in execution; but to the very last he vehemently and solemnly denied that he was guilty." The second case occurred to Dr. Duncan within the same year at Leith. "The general evidence was of the same nature as in the case of Gilchrist, but even stronger against the prisoner. He lived on bad terms with his wife. On the evening of her death she returned home at a late hour with a lighted candle, after getting some whiskey at a neighbour's. At this time the prisoner was in bed; but some time afterwards there was heard a considerable noise, like that of struggling, and of chairs pushed up and down the room; and after this the man was heard in an adjoining bed-room, endeavouring to quiet his child, who was crying. Presently the neighbours were alarmed by a strong smell of fire proceeding from the prisoner's apartments. At last a man forced his way in by breaking the window. On entering he found the room full of smoke, and observed something burning red in a corner, over which he instantly threw a pitcher of water, and which proved to be the body of the woman burning on the hearth." Dr. Duncan was present at the examination of the body under the sheriff's warrant, and reports as follows: "We found some parts of the body, especially the belly, burnt to a cinder. We then examined the parts on which the fire had acted more moderately, namely, the face and extremities, and here there was every mark of vital re-action; some spots were merely red and inflamed; others scorched to a hard transparent crust, but surrounded with distinct redness, and a great many blisters filled with lymph perfectly different from those produced on the dead body, which are not filled with a fluid, but with air or vapour. In short, we found appearances exactly similar to those of fire on a living body, and therefore we reported as our unanimous opinion, that the deceased was burnt to death." As there was no proof of the prisoner's having set fire to her, he was not found guilty,

but the jury returned the intermediate verdict of *not proven*.

It is worthy of remark, that although the possibility of spontaneous combustion was not mooted at the time of these occurrences, yet the acute mind of Dr. Duncan led him to perceive something extraordinary in the phenomena which presented themselves; and he particularly comments upon the violent and destructive action of the fire, compared with the small quantity of combustible matter consumed. In neither case was there any trace of burning in the house or furniture, and in the last the woman was found on the hearth with part of her clothes unburnt, and a chair from which she had fallen quite entire. She was dead when the neighbours entered, and in the dark the body was discovered by a red light issuing from it.

Upon reviewing these cases, particularly the last, we cannot avoid agreeing with Dr. Christison, that the body was in that singular state in which it is apt to undergo spontaneous combustion; it being difficult to explain otherwise the great extent of injury inflicted. It is not our intention at present to enter into a discussion of the theory of spontaneous human combustion, that subject having been already most fully and ably treated of in a former article, (see COMBUSTION, SPONTANEOUS); but we wish to direct the attention of practitioners to that interesting phenomenon, in order that they may be prepared to detect it when it occurs; and we have mentioned the instances just quoted as examples in which a knowledge of this peculiarly morbid condition of body might possibly have saved the lives of innocent persons.

Was the body burnt before or after death?—This question can only be solved by a reference to the phenomena which are known to occur on the application of a burning heat to a living and a dead body, and by observing those indications of vital reaction which are peculiar to the former, and remain visible after life is extinct. We are indebted to Dr. Christison (Edin. Med. and Surg. Journ. vol. xxxv. p. 321,) for some interesting experiments and observations made for the purpose of arriving at a more certain knowledge of these phenomena; particularly with a view of ascertaining whether the effects of a burn on a living body can be imitated immediately after death by the application of heat. It appears that the most immediate effect of the application of heat to a living body is a blush of redness to a considerable extent round the burnt part, removable by gentle pressure, disappearing in no long time, and not permanent after death. Next to this in order (according to the author quoted), and occurring most generally at the very same time, is a narrow line of deep redness, separated from the burnt part by a stripe of dead whiteness, bounded towards the white stripe by an abrupt line of demarcation, passing at its outer edge by insensible degrees into the diffuse blush already described, but not capable of being removed like it by moderate pressure. In every instance in which Dr. Christison watched the effects of the actual cautery, as well as in those cases observed for him by others, this deep crimson line appeared in a very few seconds, sometimes in five, generally within fifteen, and once only so late as thirty seconds. Dr. Christison never failed to observe this appear-

ance on the bodies of persons burnt a few hours before death, forming a line on the entire skin near the burn, from a quarter to half an inch in breadth, and about half an inch from the burn. Blistering is the next appearance in point of order, but it is not a very constant consequence of a burn if life be extinguished a few minutes afterwards. When the heat is applied by means of a scalding fluid, blisters usually appear in a very few minutes. Yet sometimes, in very extensive burns of this kind, especially in young children, there is no vesication at all in many hours. "It follows, then, that the only effects of burns which appear immediately after the injury and remain in the dead body, are, first, a narrow line of redness near the burn not removable by pressure, and, secondly, blisters filled with serum; that the former is an invariable effect; but that the latter is not always observable when death follows the burn in a few minutes."

In order to try whether these appearances could be imitated by the application of burning substances after death, Dr. Christison made the following experiments:

1. In a stout young man who had poisoned himself with laudanum, a very hot poker and a stream of boiling water were applied to the skin of the chest and inside of the arm one hour after death.

2. A stout young woman died in ten or twelve days of a low typhoid fever, and at her death was but little attenuated. Ten minutes after death boiling water was poured in a continuous stream on the breast and outside of one of the legs.

3. A very powerful, athletic young man poisoned himself with laudanum. Four hours before death a tin vessel filled with boiling water was closely applied on several parts of the anus, and a hot smoothing-iron was held to the outside of the hip-joint. Half an hour after death a red-hot poker was applied to three places on the inside of the arm. The body was examined in thirty-eight hours. "Some of the spots burnt during life presented a uniform blister filled with serum; on two there was no blister, but the cuticle was gone, and the true skin dried into a reddish translucent membrane, at the edge of which there were drops of serum, and also particles of the same fluid dried by evaporation. Round all these spots there was more or less scarlet redness, particularly round the two spots last mentioned. A bright red border, half an inch wide, surrounded the whole burns; and the redness was not in the slightest degree diminished by firm pressure. The spots burnt *after death* were some of them charred on the surface, and not elevated: two presented vesications, but the blisters were filled with air, the cuticle over them dry and cracked, and the surface of the true skin beneath was also quite dry. On the white parts of the skin there was no adjacent redness." Similar appearances were presented in the two former experiments to those now mentioned as the effects produced after death. Three other experiments were made on amputated limbs immediately after operation, with results of a similar nature. From these experiments it appears that the application of heat to the body, even a few minutes only after death, cannot produce any of the signs of vital re-action formerly

described; and that a line of redness near the burn, not removable by pressure, and likewise the formation of blisters filled with serum, are certain signs of a burn inflicted during life.

Was the burning spontaneous or ordinary combustion? We have already referred to the article *SPONTANEOUS HUMAN COMBUSTION* for an account of this extraordinary phenomenon and its probable causes. It is remarkable that by far the greatest number of victims to this accident are females. Sixteen out of seventeen cases related by Kopp, and all those, amounting to eight, given by Lair, were of this sex. In like manner the four cases mentioned by Dr. Apjohn as having occurred in Ireland, were all old women, and in all the use of spirituous liquors had been carried to a great extent. This kind of combustion penetrates the body with extraordinary rapidity, and the flame which accompanies it is with difficulty extinguished by water: but although it acts so rapidly and extensively on the body, it is observed that objects in the neighbourhood, unless those in actual contact with it, are not attacked. The trunk of the body is the part that suffers most, being generally almost entirely consumed, while the head and extremities are more spared. The rapidity and depth of these combustions, together with the small quantity of other surrounding combustibles consumed, contrast strongly with the slowness observed when bodies are burned on a funeral pile or at the stake, and lead us to understand that similar effects cannot be the work of criminal intention, for when burning is resorted to in order to conceal crime, its operations are infinitely more slow, more imperfect, and extend more to surrounding objects, than in cases of spontaneous combustion.

Persons found Dead from Cold.—Death from this cause is by no means rare in countries where the winter is very severe, as we learn from accounts of travellers in Siberia, Lapland, Switzerland, &c.: and even in these countries, when the winter is unusually severe, cases occur which equally illustrate the destructive effects of cold. If such accidents happen at a distance from inhabited places, in snow and frost, they are generally too strongly marked by circumstances to be mistaken. But they may occur in populous places, and even in large cities, and are then more liable to misconstruction and suspicion. "The degree of cold necessary for the production of its fatal effects varies in a very remarkable degree with the strength and circumstances of the individual to whom it is applied, as well as with the rapidity of the cooling process. In some instances we find man enduring an extreme degree of cold with but little inconvenience, whilst in others we see him perishing in a temperature at which water retains its fluidity." (*Paris and Fonblanque*, Med. Jur. vol. vii. p. 950.) There is a very striking description of the effects of cold in the account of the first voyage of Captain Cook. When the Endeavour was off Terra del Fuego, Sir Joseph, (then Mr.) Banks, Dr. Solander, and some others of the company, wished to make a botanical excursion to a mountain that appeared out a short distance from the shore. They set out, twelve in number, including domestics. An intense cold seized them, which they were en-

couraged to resist by Dr. Solander, who had crossed the mountains separating Sweden and Norway, and knew the fatal effects of yielding to its influence. He assured them that whoever sat down would sleep, and that whoever slept would never waken. Nevertheless, he was himself the first to yield to the desire for sleep, against which he had warned the rest. He begged to be allowed to lie down; he stretched himself, and slept some time upon the ground covered with snow, and it was with great difficulty that his friend Banks could rouse him to go a quarter of a mile to a fire which he had lighted. A black servant of Mr. Banks lay down also, replying to the threats of death held out to him, that he only desired to be allowed to sleep and die. Dr. Solander, when aroused at the end of five minutes, had almost lost the use of his limbs, and his feet were so shrunken that his shoes fell off. It was not possible to waken the negro, and he perished with another negro who had been left for a moment with him to assist him. All the persons in the expedition felt the effects of the cold more or less, but the whites were all saved, even Mr. Buchan, a painter, who had a fit of epilepsy, to which he was subject.

In this example, as well as from more recent observation in the polar seas, it appears that a great degree of cold, particularly when joined with fatigue, produces in the body a stupor and numbness almost insupportable, and that the ardent desire to sleep arising from this stupor is such that it cannot be conquered by the fear of the consequences. We also perceive that men least accustomed to cold are those who most readily sink under its influence, as we find the negroes dying while the whites were saved; and also that strength of mind and body tended much to enable the sufferer to resist, since Sir Joseph Banks, a man endowed with great moral and physical energy, was the one who suffered least of the whole party. The same cause will enable animals to sustain cold with impunity. For instance, among hibernating animals, as the dormouse and marmot, it has been observed, in experiments made to ascertain the cause of their sleep, that the most vigorous are the most susceptible of invigoration by heat; and that they are least readily thrown into a state of slumber by artificial cold during summer. Fodéré, who was a Swiss, says that while inhabiting his native mountains, all the cases of death of this nature whose histories he could discover, were of sickly persons, children, old men, or females. From the experiments of Mr. [Sir B.] Brodie, to ascertain the source of animal heat, it is plain that the temperature of animals is in some way or other dependent upon the integrity of the functions of the nervous system; and hence the power of an animal to resist cold will be determined by his power of generating heat. Now it is found that any cause by which the powers of the nervous system are impaired favours the action of cold upon the body; and for this reason an individual labouring under the effects of a narcotic may be killed by a degree of cold that otherwise would have been quite supportable. It is for this reason, also, that intoxicated persons perish in severe cold more readily than those whose nervous system is not so impaired. Dr. Paris (*loc. cit.*) notices two instances

that occurred in London, a few winters back, of drunken persons being taken to the watch-house, and there not being any charge against them they were dismissed by the constable of the night, and perished in the streets. A military friend of his communicated to him an instance where, out of a great number of troops who were exposed to intense cold, the only one who perished was under the influence of intoxication. This was also exemplified on a large scale in the disastrous retreat of the French troops from Russia; for we learn from La Beaume's account that intoxication seemed to insure death.

Mr. [Sir B.] Brodie is inclined to think that cold probably destroys the principle of vitality equally in every part, and does not exclusively disturb the functions of any particular organ. This opinion is supported by the experiments of Dr. Chassat.

In cases of persons found dead from cold, if the accident be recent, attempts may be made to restore life. The application of heat should be very gradual; and artificial respiration may be tried with a prospect of utility. Internal stimulants should be cautiously administered after signs of returning animation are apparent.

Persons found dead from Hunger.—

Food being necessary to the maintenance of life, it is plain that its deprivation cannot be endured for any length of time without causing death, and those cases of long fasting, or of refraining altogether from food for years, have all turned out to be impositions. It has, however, been ascertained that the want of nourishment is borne differently by different persons, a difference depending on age, health, constitution, sex, &c. Thus, a great number of persons doomed by some calamity at sea or elsewhere to perish by this dreadful death, do not all die at the same time, but some, according to their constitution, have the sad privilege of surviving their companions in misfortune. Young persons bear hunger worse than old, and sooner sink under its influence,—a fact no less correctly than beautifully illustrated by Danté in his description of the sufferings of Count Ugolino and his children, four in number, all enclosed in a dungeon together, and condemned to death by starvation. The father is represented as surviving until the eighth day, having witnessed the death of his sons in the order of their age, beginning with the youngest. We see that in general, of the two sexes, women bear the privation of food more easily than men; thus, in all accounts of long voluntary abstinence, three-fourths or more of the individuals are of the female sex. Women usually do not consume much, and all being equal as to age and health, they require much less nourishment than men. The power of resisting hunger varies also with the total privation or otherwise of water. Redi (*Osservazioni intorno agli Anim. viventi*, No. 3, 4.) made many experiments to discover how long animals could live without food. Of many fowls that he kept without eating or drinking, none passed the ninth day. He gave to one as much water as it chose, of which it drank freely and often during sixteen days, and it did not die until the twentieth. Dogs in like manner lived much longer when allowed water. But it would appear from a number of instances, that the moisture of the atmosphere of

the place in which an individual may be confined may compensate in some degree for the want of drink. Foderé relates an instance where three women in Piedmont were overwhelmed by snow, and shut up in a narrow stable without any provision for thirty-eight days, and at the end of that time were rescued alive; and he thinks it probable that they owed their preservation to the moisture of the place of their confinement; the absorbents of the skin being thus able to derive a certain portion of the fluid for the use of the system. Chaussier reports the case of some workmen who remained fourteen days without eating or drinking, shut up in a deep damp quarry, by the sudden falling in of the roof. They were withdrawn at the end of that time, with a small feeble pulse, scarcely any heat, and just a spark of life remaining, which was with difficulty kindled. The absorption of moisture had sustained them, as it did the women at Bergamotto. A very striking instance of the power of water to prolong life occurred in the case of Luc Antoine Viterbi, who starved himself to death in prison at Corsica. (*Paris and Fonblanque*, Med. Jur. v. ii. p. 69.) From the fifth to the sixth day, to hunger insensibly succeeded the much more grievous suffering of thirst, which became so acute, that on the sixth, without ever deviating from his resolution, he began to moisten his mouth occasionally, and to gargle with a few drops of water to relieve the burning pain in his throat; but he let nothing pass the organs of deglutition, being desirous not to assuage the most insupportable cravings, but to mitigate a pain which might have shaken his resolution. Until the tenth the thirst became more and more intolerable, when, overcome by excess of pain, he seized the jug of water and drank immoderately. On the thirteenth, the unhappy man thinking himself at the point of death, again seized the jug and drank twice. On awakening on the morning of the fourteenth, and finding his powers restored, he fell into a rage with his keepers, protesting that they had deceived him, and then began beating his head against the wall of his prison, and would inevitably have killed himself had he not been prevented. During the nineteenth, the pangs of hunger and thirst appeared more grievous than ever; so insufferable indeed were they, that for the first time Viterbi let a few tears escape him, but his invincible mind instantly spurned this human tribute. On the twentieth, he declared to the gaoler and physician that he would not again moisten his mouth, and feeling the approach of death he stretched himself, asking, as on a former occasion, whether he was well out, and added, 'I am prepared to leave this world.' Death did not this time betray his hopes. On the twenty-first Viterbi was no more. In this interesting case, which we have here abridged, we perceive the effect of a small portion of fluid in producing vigour in a body worn out by abstinence. There can be no doubt Viterbi would have died much earlier if he had not made use of the water. In the examination of bodies dead from hunger, the following characters are usually observed. There is general emaciation of the body, together with an acrid fetid odour. The eyes are open and red, the tongue and throat dry, and the intestinal canal is empty. The gall-

bladder is usually filled with bile, which exudes and tinges the neighbouring viscera. The lungs are shrivelled, and all the other organs healthy. It is thought by Fodéré that some conjecture may be drawn as to whether the person has been totally deprived of water or not; for, according to the experiments of Dumas, the dogs which he killed by thirst had the viscera inflamed, and the blood thick and coagulated—phenomena which did not present themselves in the bodies of those dead from hunger alone.

Persons found dead from Lightning.—Death from this cause is sufficiently common to warrant a consideration of it in this place. Its phenomena may be studied by observing those of common electricity, as it has been sufficiently proved that they are identical. The human body is alike affected by both, and death, whether it be occasioned by the discharge of an electrical battery or by that of a thunder-cloud, exhibits effects precisely analogous. Two theories respecting the manner of death by lightning are extant, the first that of Mr. Hunter, the second of Mr. [Sir B.] Brodie. Mr. Hunter supposed that when death is thus occasioned, there is an instantaneous and total destruction of the vital principle in every part of the body, and that the muscles are therefore relaxed and incapable of contraction; that the limbs do not stiffen as after other forms of death, nor does the blood coagulate, and that putrefaction is rapidly set up. On the other hand, Mr. [Sir B.] Brodie concludes from his experiments, given from his manuscript notes by Dr. Paris, (*Med. Jur.* vol. ii. p. 64.) that an instantaneous extinction of vitality does not take place, but on the contrary the functions of the brain are those on which the electric shock exercises its primary influence. In one of his experiments an electric battery of six jars having been charged with electricity, the shock was made to pass through a guinea-pig in the longitudinal direction from the head to the tail. The animal immediately fell on one side insensible, as if stunned; a convulsive action of the muscles of the extremities was observed, but did not long continue, and the function of respiration was not interrupted. In a few minutes sensibility was restored and the animal recovered. In another experiment a shock from nine jars was passed in the same manner through another guinea-pig. The animal immediately fell on one side, exhibited a convulsive action of the voluntary muscles of the limbs, but uttered no cries, and although attentively watched, no signs of respiration could be discovered after the shock had passed through. Three minutes afterwards Mr. [Sir B.] Brodie opened the chest, and found the heart acting with regularity and vigour about eighty times in the minute, and circulating dark-coloured blood. The peristaltic motions of the intestines were also visible, and the muscles obeyed the galvanic stimulus.

In this experiment it is plain that neither the irritability of the muscular system at large nor that of the heart was destroyed by the shock, but death took place as from a severe injury of the head and destruction of the functions of the brain. In this case Mr. [Sir B.] Brodie remarks, that if the lungs had been artificially inflated, the action of the heart might have been maintained, and the animal probably restored to life.

When a discharge of lightning strikes a human body, it may affect the surface and produce vesications, which most commonly, according to Mayer, pass in the direction of the spine; or it may penetrate a particular part of the body and act locally. The clothes are not unfrequently torn, and buttons, coin, or other metallic substance melted, but occasionally cases are met with where the clothes are uninjured. Death has sometimes occurred when the thunder-cloud has appeared to be at a considerable distance. This is accounted for by supposing it to be a discharge of electricity from the earth to the cloud, which had become negatively electric, constituting what is termed the returning stroke. All discharges of electricity occur in consequence of the approach of two bodies in opposite states of electrical excitement. When a substance excited positively is brought near another in its natural state and insulated, the electric equilibrium of the latter is instantly disturbed, the parts nearest to the former become negative, and the distant ones positive. If the body is not insulated, its electricity passes into the earth, and the whole becomes negatively electric. If, on the contrary, the exciting body be negative, it causes the contiguous parts of a body in its vicinity to become positive. Hence it is established as a law, that an electrified body tends to produce in a contiguous substance an electric state opposite to its own. The electricity developed in this way is said to be induced, or excited by induction. The construction of the Leyden phial is upon this principle; when the inside of the jar is rendered positive by contact with the prime conductor, the outside, if in communication with the earth, parts with electricity and becomes negative; both surfaces are therefore electrified, but in opposite states; and if a communication be established between them by a good conductor, the excess of electricity instantly passes along it, and both sides of the jar return to their natural condition. Now when a negatively electric cloud approaches the earth, all objects in its vicinity are positively excited, and when it comes within striking distance,—that is, so near that the tendency of the electricity to pass from the positive to the negative body overcomes the resistance of the intervening portion of air,—the equilibrium is restored with a report and a flash of light, exactly as in the discharge of the Leyden phial. If a person is found in an open place or under a tree shortly after a thunder-storm, with the ordinary appearances mentioned above, we may attribute his death to lightning, and particularly so if the metallic substances about him are found melted and his clothes torn or burnt, while dissection exhibits no other cause of death.

Persons found dead from Wounds.—On the trial of Count Koningsmark for the murder of Mr. Thynne, Mr. Hobbs, the surgeon, being pressed by counsel to discriminate between the relative mortality of certain wounds found on the body of the deceased, replied, “I believe there never was a wound but it might prove mortal.” This is an opinion in which every one who has had opportunities of witnessing a variety of injuries must coincide, from the extraordinary and unexpected results which sometimes follow. Thus, individuals have been known to recover from wounds

which, from their extent and the importance of the organs implicated, left no room for hope; while others have perished after the infliction of violence so slight, and producing such trivial local effects, as to have almost escaped observation. Such consequences, however, must be considered as exceptions to the usual course observed in similar instances; and taking wounds in general, we must admit that they allow of classification in reference to their mortality. Any such classification can never be made complete or definite, from the exceptions just alluded to, as well as from the impossibility of proving the absolute similarity of two wounds, however they resemble each other, when one individual dies and the other recovers, and also from the endless varieties of constitution in different individuals. It is, therefore, upon their usual or more common effects that such a division can be adopted for our present purpose.

The term wound, in medico-legal phraseology, is much more comprehensive than the same word in surgery. In the latter it means a solution of continuity; but in the former it also comprises injuries of every kind caused by mechanical violence, such as bruises, contusions, fractures, luxations, &c. in which sense it is to be understood in the observations that follow.

[It would appear, that the present rule in England is, that no injury constitutes a wound in law unless the continuity of the skin be broken; so that in a case where blows were inflicted with a hammer or iron instrument sufficient to break the collar-bone, and violently bruise but not break the skin, it was held not to be a wounding within the statute (Archbold.) A man was tried at the Central Criminal Court, in August, 1838, on a charge of cutting and wounding the prosecutor. The prisoner struck the prosecutor a severe blow on the temple with a heavy stone bottle, which was thereby broken to pieces. The prosecutor fell senseless, and it was a long time before he recovered. The medical witnesses underwent a rigid cross-examination by the prisoner's counsel, respecting the meaning of the word "wound." They said that there had been a separation of the cuticle or outer skin of the temples, although there was no absolute wound in the usual acceptance of the word. They farther deposed that the prosecutor had lost the sight of his left eye, and the hearing of his left ear, and he was for a considerable time in a state of great danger, from which he had scarcely recovered. The prisoner's counsel maintained that the injuries were not such as to constitute cutting and wounding in law. The court said, in order that a wound, in contemplation of law, should have been inflicted, it was necessary that the *whole skin*, and not the mere cuticle, should have been separated and divided; and as the evidence did not show distinctly, that there was such a wound, those counts of the indictment could not be sustained. The prisoner was found guilty of an assault. (Taylor, *A Manual of Medical Jurisprudence*, p. 282: Lond. 1844.)]

The chief points to be decided by the medical examiner in the case of a body found dead with wounds, are,—1st, Were they inflicted during life? 2dly, were they the cause of death? and if so, were they the result of suicide or homicide?

In order to settle these points, it will be necessary to consider the classification of wounds just alluded to. They have been divided, for the purpose of medico-legal inquiry, into four classes,—1st, those absolutely mortal; 2d, dangerous; 3d, not mortal; 4th, accidentally mortal. This division of wounds is founded, as has been already stated, upon the usual terminations of such injuries, because it is well known that death sometimes follows those of the slightest description; and that others of the gravest kind terminate in recovery. Metzger (Page 327, and Beck, by Darwall, p. 324) mentions an instance of death from hemorrhage brought on by the slightest scratch of the thumb-nail. Dr. Paris (Paris and Fonblanque, *Med. Jour.* v. ii. p. 116) states he has seen a case in which the extraction of a tooth was followed by death in forty-eight hours; and a similar case is reported by Mr. Blagden, (*Med. Chir. Trans.* vi. viii. p. 224.) An instance occurred lately to the writer of this article, in which a fatal hemorrhage followed a superficial incision made into the upper gum of an infant to liberate one of the incisor teeth. On inquiry, it appeared that another child of the same family had died of hemorrhage from some equally slight cause. Leech-bites have been known to produce death in children; and in the case of Brain (*Cro. Eliz.* 778. Paris and Fonblanque, v. ii. p. 122) tried for the murder of Watts, it was proved that the deceased died instantly from a blow on the calf of his leg. On the other hand, we are not without instances of equally surprising recoveries from injuries of the severest kind. We have seen persons survive extensive fractures of the skull, in whom portions of the brain have protruded. Dr. Male mentions the case of a mendicant in Paris, from whose skull a portion of the bone was detached, large enough to be used by him to receive alms. The celebrated case of Mr. Tipple, (related by Mr. W. Maiden. London, 1812,) whose thorax was transfixed by the shaft of a gig, is a striking illustration of the present subject. Dr. Dunlop (Beck's *Med. Jur.* p. 332) records a case of duel in the West Indies, in which one gentleman hit another in the eye, the ball of which was completely obliterated; and the leaden bullet, passing in through the orbit, came out in front of the external ear; notwithstanding which destruction of the eye as well as injury of the brain, the officer recovered with the same facility as if he had only undergone the infliction of a flesh-wound.

On account of these variations from the usual course, the consideration of injuries from wounds in a medico-legal point of view, is, on the continent, and was formerly in these countries, a matter of much more intricacy than it is at present. A person inflicting a wound on another was held amenable for the consequences during a year and a day; a most inconvenient principle of responsibility, and one particularly calculated to create confusion, by either involving the innocent or suffering the guilty to escape. Chaussier relates a case illustrative of this point. Two men who had had some previous misunderstanding, encountered each other on a public walk, when, after some altercation, one of them struck the other with a light cane and retreated; the other, enraged,

pursued him, but had not advanced many steps when he fell dead. On examination of the body, it was found that he had an aneurism of the aorta, which had burst from the excitement under which he laboured at the moment. Fortunately for the administration of justice in this kingdom, that act of the legislature called the "Ellenborough Act," relieves the medical witness of the present day from those serious embarrassments under which our predecessors must have laboured; as by it, wounding with an attempt to kill is deemed equally criminal whether death be the result or not. This, considering man as an accountable being, is the true and just view to take of the crime. Still, however, the testimony of the medical witness will always be important, as by the nature of the injury, its seat, and direction, the evil intent is often to be inferred.

Of *mortal* wounds those which cause instant death are wounds of the brain, of the heart, and large vessels connected with it, of the spinal marrow on the neck, and blows on the stomach; these are all for the most part followed by immediate death. Wounds of the brain must be considered as less fatal than those of the heart, in consequence of the recoveries which are sometimes observed to take place after them, and even wounds of the heart are not necessarily immediately fatal. The late Duc de Berri lived for eight hours after being stabbed through the left ventricle, and similar cases are on record. Next in order as mortal wounds may be mentioned those which interfere with the function of respiration, such as extensive wounds of the diaphragm, and injuries which lay open both sides of the thorax in a considerable degree, and thus impede the dilatation of the lungs. Among *dangerous* wounds must be ranked those of the pharynx and œsophagus, stomach and chylopoietic viscera, the danger of which will be of course in proportion to the extent of the injury. Also, wounds of the urinary bladder and of large blood-vessels in the head, thorax, and abdomen; severe contusions over any of these cavities; wounds of the extremities implicating the great blood-vessels, or causing compound fractures, or in tendinous situations from the danger of tetanus supervening. In the class of *slight* wounds are included those injuries by which the skin and muscles are bruised or divided, and where no tendon, aponeurosis, large nerve, or blood-vessel is touched, and the system has not received any severe shock; to this class belong simple fractures and luxations. The last class, or *wounds accidentally mortal*, are influenced by different causes, which render this division an arbitrary one, and will be considered when we come to treat of those circumstances which alter the medico-legal character of wounds.

In the article PSEUDO-MORBID APPEARANCES, [and in a previous part of this article,] allusion has been made to the spontaneous lividities which occur on the surface of dead bodies; the nature and causes of which, and the means of distinguishing them from the effects of contusions inflicted before death, are there pointed out. But there is another source of error connected with the examination of the surface, which it is necessary to dwell a little upon before we proceed to consider wounds of particular parts; that is, the

possibility of appearances being caused by violence offered to the body after death, which will resemble those that result from injuries received during life.

That such a resemblance does occur is certain, if the blow be inflicted within a certain time after dissolution, and the power of discriminating between the two is of the utmost moment to the medical jurist. We are indebted to Dr. Christison for the most accurate information we possess upon this subject, (Edin. Med. Surg. Journ. v. xxxi. p. 236.) His attention was forcibly drawn to it on the occasion of the trial of Burke and Hare at Edinburgh for the murder of the woman Campbell for the purpose of selling her body. Before the confession of the accomplice, the whole weight of the case rested on the medical evidence; and one of the questions to be answered was, whether certain bruised marks and subcutaneous extravasations of blood, found on different parts of the body, were indications of injuries received before death. Being unable to find in authors on medical jurisprudence any information precisely applicable to the case, except what rested on physiological speculation, Dr. Christison proceeded to subject the question to the extent of experiment. For this purpose, a large dog being strangled, and the hair on various parts of the head, trunk, and legs, being shaved, heavy blows were inflicted on these spots with a hammer, at intervals of from five minutes to two hours after death; but at the end of twenty-four hours no trace of injury appeared in the seat of any of the blows. The next experiment was made on the body of a female an hour and three-quarters after death. Several heavy blows were inflicted with a stick across both shins, on the fore-part of the thighs, on the breast, and on the side of the neck. In less than ten minutes, deep bluish-black discolorations followed the blows on the breast and neck. Twenty-five hours after death the blows were shown on the thighs, by faint stripes consisting of bluish-black points. On the breast and neck the stripes were as deep in tint as any contusions inflicted during life, but without swelling, the colour corresponding with the prominent part of the stick. A severe blow had been struck over the crest of the ileum twenty-three hours after death, which caused ruffling of the cuticle at the time, but no further appearance of injury. The third experiment was on the body of a man. It was struck with a stick on the left side of the back three hours and a quarter after death. More blows were struck on the right side seventeen hours after death. An examination was made forty-seven hours after death, when the blows first struck were marked by two long narrow stripes of dark lividity, with an intervening colourless stripe corresponding with the prominent part of the stick. The redness was confined in this, as in the former case, to the mere surface of the true skin, the rest being natural. The marks of the latter blows consisted of dryness and brownness of the surface, without effusion. The fourth was on the body of a young man, four hours after dissolution. It was struck with a stick, and on subsequent examination it was found that wherever the cuticle had been comminuted, the mark was dry and brown, but

there was no other discoloration of the skin. The subject of the fifth experiment was a stout young man, on whose back several heavy blows were struck with a mallet two hours after death. The body was inspected five hours afterwards, and presented deep lividities in the seat of the blows, but the substance of the skin was nowhere infiltrated or discoloured. The general conclusions to be drawn from the preceding facts are thus stated by Dr. Christison.

"In respect to *external contusions*, the experiments show that for some hours after death blows will cause appearances, which, in point of colour, do not differ from the effects of blows inflicted recently before death; that the discoloration generally arises, like lividity, from an effusion of the thinnest possible layer of the fluid part of the blood on the outer surface of the true skin; but sometimes also from an effusion of thin blood into a perceptible stratum of the true skin itself; and that dark fluid blood may be even effused in the subcutaneous cellular tissue in the seat of the discolorations, so as to blacken or redden the membranous partitions of the adipose cells, but that this last effusion is never extensive. It can hardly be doubted that the appearances now described will exactly imitate slight contusions inflicted during life; but I conceive that the blows in the latter case must be trivial."

"When a blow inflicted during life is more severe, it may have the following effects, few or none of which, so far as we know, can originate in violence after death. 1. There may be swelling from the amount of the extravasation; this is certainly never caused in the dead body. 2. When the violence has been applied a few days before death, there will be a yellow margin round the black mark, which is another appearance that cannot be formed except during life. 3. There may be clots of blood in the subjacent cellular tissue, either with or without swelling: these appearances I have never seen accompanying contusions caused in the dead body; but it may be doubted whether clots might not be formed if the injury was inflicted very soon after death, and had the effect of lacerating a considerable vessel in the neighbourhood of loose cellular tissue. 4. In the instances in which the blood does not coagulate at all after death, contusions caused during life may be recognised by the extent of the effusion into the cellular tissue. In a part not liable to be infiltrated by its depending position, and not in the vicinity of a large vein, a deep effusion of fluid blood, which fills and distends the cells of the cellular tissue can hardly be produced on the dead body. 5. Perhaps one of the most characteristic signs of a contusion inflicted during life is, incorporation of blood with the whole thickness of the true skin, rendering it black instead of white, and increasing its firmness and resistance. This sign may not be always present, for, as every one knows, a blow may cause extensive extravasation below the skin, without affecting the skin itself. But when present, I am disposed to consider it characteristic, because I have never been able to produce it in the dead body, and it is not easy to conceive how such a change can be wrought in so dense a texture as the skin, without the force and agency of living vessels."

"It is impossible to fix absolutely the limit of the interval beyond which contusions cannot be imitated by violence applied to the dead body. It appears to vary with the state of the blood, and the time which elapses before the body cools, and the joints stiffen. Sometimes the appearance of contusions can hardly be produced two hours after death (*Experiment 5th*); sometimes they may be slightly caused three hours and a quarter after it (*Exp. 3rd*); but I should be inclined to think this period very near the extreme limit. Wherever the warmth of the body and laxity of the muscles were not considerable at the time the injury was inflicted, we may be sure the appearance of contusions cannot be considerable (*Exp. 2d*). It is probably, therefore, only on the trunk that even in the most favourable state of the body, namely, when the blood remains altogether fluid, any material mark of contusion can be produced so late as two hours after death."

With respect to wounds of the head, it is well known that all kinds of violence are more dangerous in some constitutions than in others. In good constitutions, wounds may not be dangerous, which in old, bilious, or serofulous habits, are often attended by death, chiefly in consequence of the erysipelatous inflammation that succeeds them. Fracture of the bones of the cranium may take place without any correspondent injury of the integuments, and the symptoms in such cases are extremely equivocal and deceitful. A mere simple fracture when no more is implied than solution of continuity confined to the bony substance without displacement or injury to the neighbouring parts, is not necessarily an event of great importance. In so simple an occurrence we can hardly suppose bad consequences to arise. Simple cases like these, however, are very rare, and these injuries are almost always complicated with some affection more or less severe of the internal parts. Although fractures may be considered more dangerous when accompanied with depression, yet we cannot ascertain the precise degree of injury sustained by the contents of the cranium from the external wound, nor does it follow that the more extensive it is, the more certain is the danger. In fact, our knowledge of the economy of the brain is very limited, and though injuries of it are generally of a most serious character, yet we find surprising recoveries take place. The effusion of a small quantity of blood or pus upon its surface may, and often does, cause the most alarming symptoms, and terminate in death; while, on the other hand, large portions of the brain itself have been removed, and foreign bodies, as a musket-ball, and portions of the skull have been lodged in it, and recovery has taken place. It is hence exceedingly difficult to define the exact amount of injury to the head necessary to cause death; nevertheless, in case of a body found dead with fracture of the skull, and when no other sufficient cause of death can be ascertained, we are justified in attributing the event to the injury. We come to this conclusion from our knowledge of another effect of violence offered to the head, and which must always accompany the former in a greater or less degree,—namely, concussion or commotion of the brain. By concussion of the brain is meant a violent and

sudden shake of the organ without any apparent wound or mark of injury being left. It may be caused by violence offered directly to the head, or transmitted to it by falls on the feet or nates. A remarkable instance of the former is given in the Transactions of the Royal Academy of Paris. A stout young criminal was condemned to be broken on the wheel, and wishing to escape the execution, ran head foremost against the wall of his dungeon, and instantly fell dead. On opening the head, not the slightest appearance of injury was discoverable in either skull, brain, or spinal marrow, except a very minute separation in the squamous suture of one side.

Certain injuries done to the face belong to this division of wounds. When these are confined to the face alone, the most serious consequence may be no more than deformity; but mortal wounds have been inflicted through the face on the contents of the cranium. The most common of these is where a sharp-pointed instrument is struck into the eye, and pierces the orbital plate of the frontal bone. The celebrated comedian Charles Macklin was tried in the year 1753 for the murder of a brother-player, whom he struck accidentally in the eye with a cane, in some altercation that took place in the green-room. (State Trials.) Thomas Hallum, the sufferer, died the next day, and it was found that the point of the cane had passed through the orbital plate, and wounded the brain. A case occurred some years ago in Dublin of a similar nature. A gentleman received a thrust of a watchman's pike in the eye, in some drunken broil in the street: the immediate effects were so trifling, and the external wound so slight, that he took no notice of it until he was attacked with inflammation of the brain, which killed him in a few days. Mr. Colles, under whose care he was, opened the head, and found a small round hole in the orbital plate of the frontal bone, in the neighbourhood of which there was a large collection of pus. The part is preserved in the museum of the College of Surgeons of Dublin. In like manner, blows upon the nose have not only crushed that organ, but also driven the ethmoid bone up into the brain; and sharp-pointed instruments have sometimes penetrated the brain through this organ, and proved fatal. Such instances as these show how necessary it is to investigate with the greatest accuracy all cases of sudden death; for without the greatest care and attention, cases of this description must elude discovery. We make this observation in order to induce medical examiners to bestow more pains on the highly important trust they undertake, for it must be confessed that in investigations of this sort, we fall far short of the diligence of our Continental brethren.

As connected with wounds of the head, we may observe that children, either before or after birth, may be, and have been, destroyed by fine sharp-pointed instruments passed through one of the fontanelles. A Parisian midwife was executed some years ago on its being discovered that she was in the habit of procuring still-born children for those who desired it, by piercing the brain of the infant before its birth with a fine wire. A wound of this description leaves very little mark, and would of course escape superficial observation.

The neck comprises many important parts, a wound of which is necessarily followed by death. Wounds of the integuments and muscles of the neck may be considered simple wounds, although they are sometimes difficult to heal in consequence of the mobility of the parts; but wounds of the carotid arteries, jugular veins, and spinal marrow, are for the most part immediately fatal. Lacerated wounds of the carotid artery, however, may not be quickly followed by death, an instance of which came within our knowledge some years ago. The artery was torn by the horn of a cow, and the bleeding from the wound, although considerable, was not sufficient to destroy the patient, who survived long enough to have the artery tied, and subsequently recovered. It has been said that a complete division of the trachea is mortal; but the danger attending a wound of this sort arises from the injury usually inflicted upon the great vessels and nerves in its neighbourhood at the same time, more than from the wound of the air-tube itself, for we know that mere division of this part is not necessarily fatal, although it may be very difficult to heal from the great mobility of the part, and the constant passage of the air through it. Wounds of the pharynx and œsophagus are much to be dreaded, as well on account of the other important parts which must be wounded along with them, as from the circumstance that through this channel the nourishment of the body is conveyed, and that the act of deglutition is directly opposed to a speedy adhesion of the parts. The following case gives a good picture of the dangers and difficulties attending wounds of these parts. (Edin. Med. Surg. Jour. v. xvi. p. 353.) A few years ago a prisoner in Edinburgh jail cut his throat transversely, dividing the larynx quite across at the upper end of the cricoid cartilage, and the separated extremities receded from each other to the distance of three inches; the great vessels and nerves escaped injury from the cut being so high. The professional gentlemen who saw him were satisfied that the œsophagus was also cut entirely across. Several attempts must have been made, as another opening was afterwards discovered in the windpipe. In this state a junction of the parts was found to be impracticable, and the ligatures that had been applied with the view of making the best possible approach were separated by his incessant exertions in passing water through the mouth, and out at the wound, in which way he used several buckets full in the course of one day. He was supported in the first instance by nutritious enemata, and afterwards by means of a tube conveyed through the wound into the œsophagus and stomach. After much trouble to the practitioners, and considerable risk to the patient, the functions of breathing and ingestion were carried on through a tube in each passage introduced by the wound, the tracheal tube being removed when it was necessary to apply the other. The man was afterwards tried, acquitted, and liberated from jail, and continued to live under the disadvantages mentioned. Besides the parts just alluded to, the neck gives passage to the par vagum and the great sympathetic nerve, injuries of which, even partial or at but one side, must be considered of the most dangerous kinds, as from them princi-

pally the cardiac and pulmonary plexuses are formed. Injuries to the spinal marrow, either by fracture or dislocation of the vertebræ, or by a wound penetrating between two of the vertebræ, are absolutely fatal. Fracture or dislocation is generally the result of accident, as a fall, or what coachmen are liable to—striking the head against a low arch-way in driving under it. They also sometimes, though rarely, occur in hanging. But they may happen in consequence of disease; a striking example of which came under the observation of the writer some years ago. A boy, who was under treatment in the Richmond Hospital (Dublin) for some disease of the leg, was one morning, during the visit, sitting up in his bed talking to those around him, when his head suddenly fell forward on the breast, and he dropped dead. On examination, it was found that the root of the odontoid process of the second vertebra, and the transverse ligament that binds it in its situation, was ulcerated, and in the motion of the head it had broken off, and compressing the spinal cord, had produced instantaneous death.

A consideration of the important organs contained in the thorax will lead us to estimate the danger arising from wounds which penetrate sufficiently deep to reach them. Wounds of the lungs we know are not necessarily fatal, though for the most part they are exceedingly dangerous, from the size and number of the blood-vessels by which they are traversed. These organs are sometimes seriously injured although no external wound be present. This arises from the fractured portion of a broken rib being driven into their substance, of which injury hemorrhage, emphysema, and inflammation, are the consequences most to be dreaded. Nevertheless, although injuries of these organs are of a very serious nature, and not infrequently terminate fatally, we find occasionally that they support most extensive injury. This is familiar to many military and naval surgeons who during the late war had opportunity of observing the powers of nature in repairing extensive injuries of these organs; and we before alluded to the case of a gentleman who recovered after having both sides of his thorax transfixed by the shaft of a gig. It is quite true that penetrating wounds of the heart are, generally speaking, mortal; but there are so many cases on record of individuals who survived, some of them for days, others entirely, after wounds of this organ, that we cannot agree with those authors who maintain that such injuries are necessarily and instantly mortal. At the battle of Corunna a soldier received a shot in the chest and fell insensible. He was found by a comrade with signs of life, who carried him off the field, and he was immediately embarked with the troops and brought to Plymouth, where he died fourteen days after the receipt of the wound. Mr. Fuge, who records the case, (*Edin. Med. Surg. Jour.* v. xiv. p. 129,) states that, on examining the body, two quarts of blood were found in the left side of the thorax, the lung of that side being compressed towards the spine. A transverse opening an inch long was observed in the right ventricle of the heart near the origin of the pulmonary artery, and the ball was lying in the pericardium. To the same paper is ap-

pended an account of a suicide who lived forty-four hours after discharging a pistol into his breast, and in whom the right ventricle was found wounded, and the ball in the pericardium. Dupuytren, in his "*Leçons Orales*," expresses his opinion that wounds of the heart are oftener cured than is generally imagined. He founds his belief on the instances of animals killed in the chase, in whom balls and the cicatrices of former wounds have been found, and also on similar instances in the human subject. Many individuals have presented all the symptoms of wound of the heart, and yet recovered; and he alludes particularly to the case of a soldier, in whom, six years after the healing of a wound of the chest, a musket-ball was found in the right ventricle of the heart, near its apex. From these circumstances we think we are justified in stating that wounds of all parts of the heart, provided they are narrow, are not necessarily immediately fatal. Acupuncture of this organ has been practised at Warsaw with impunity. If, however, the wound be considerable, some lines for example, death is usually instantaneous, from the great deluge of blood that is poured into the pericardium and chest. Under a wound of less dimensions the individual may survive for some days. Thus, in one of the cases mentioned by Dupuytren, a man thirty-four years of age received two stabs of a knife, one in the belly, the other in the chest, of six and seven lines in length. He lived for eight days, and then died with symptoms of diseased brain, having been affected with tetanic convulsions for two days before his death. The stomach was found perforated, and there were four ounces of blood in the left side of the chest, which had come from one of the intercostal arteries opened by the wounding instrument. In the pericardium was observed a perforation three lines and a half long, and a wound of the same extent in the middle of the left ventricle. In another individual, who died mad, after attempting suicide by amputating the penis, several small wounds of the heart were found, which must have been inflicted several days before with a small round instrument found in his possession. Another man, aged forty years, lived seventy-two hours with three wounds penetrating the left ventricle, inflicted by himself with a sharpened file. In the thesis of M. Sanson numerous instances are mentioned of persons surviving wounds of both ventricles, some of them for twenty days. The late Duc de Berri, whose instance has already been alluded to, lived for eight hours, although stabbed through and through the left ventricle with a long round instrument used by saddlers in piercing leather. All these instances go to prove that wounds of this organ are not necessarily instantaneously fatal,—a very important fact in legal medicine, for it sanctions the possibility of an individual removing to a considerable distance after the receipt of a mortal wound, and being found dead some hours or days after. As an illustration of this fact, involving a question of life or death, we may adduce the following case mentioned by Dr. Dunlop, (*Beck, by Darwall*, p. 335.) as having been tried in Glasgow in the year 1819.

The keeper of a house of bad fame in Greenock, was indicted for the murder of a sailor by shooting

him through the chest. It appeared from the evidence of the medical witnesses, that the auricles and part of the aorta next the heart were shattered to atoms by the slugs and brass nails with which the piece was charged, and in their opinion he must have dropped down dead the moment he received the shot; therefore, as the body was found in the street, and the door of the house was eighteen feet up an entry, it followed that the prisoner must have run after him into the street, and there shot him. For the prisoner, it was urged and proved that he had shot him through the door of his own house, which he was attempting to enter by force. And besides direct testimony to this effect from those within the house, and from a lad who was along with the deceased at the time, it came out in evidence that there was a stream of blood from the door of the house to the spot where the body was found, which could not have run from the body towards the house, as the threshold of the door was on a higher level than the pavement of the street. On this evidence the prisoner was acquitted. In judging of wounds of this organ, the size and shape of the instrument, and the depth and direction of the wound, are to be considered. The extent of the wound, as we have already stated, makes a great difference in the chance of recovery. But there is one circumstance which is not very easily explained, that is, how so large a wound as a musket-ball must make, permits life to be carried on for an instant. It is generally admitted that wounds of the aorta and vena cava are mortal; but this must be taken with limitation, for very small punctured wounds may certainly be inflicted without involving the life of the individual. What the extent of a wound necessary to cause death is, we cannot precisely say; but we can conceive the possibility of these vessels being pierced with an acupuncture needle with impunity.

The thoracic duct, from the important function it performs, can scarcely be wounded without inducing fatal consequences. This arises as well from the extravasation of its contents into the thorax, as from the interruption to the supply of nutriment to the body. Wounds of the diaphragm have been generally divided into those of its tendinous and of its muscular portions; but the distinction is useless, for it is not ascertained that injuries of one portion are less serious than those of the other; and it is certain that both are highly dangerous. There is a source of danger connected with wounds of this muscle, which it is well to bear in mind, and that is, the possibility of some of the abdominal viscera being pushed through the opening, and there being strangulated. Dr. Gordon Smith (*Principles of Forensic Medicine*, p. 279) relates a case of this sort. A sharp-pointed weapon had passed through the diaphragm, notwithstanding which the patient made a rapid and perfect recovery to all appearance. At the end of about three months, he died from strangulated hernia of the stomach, which had passed through the wound of the diaphragm into the thorax.

Wounds of the abdomen, however slight, provided they penetrate its cavity, must be considered dangerous, from the great tendency of its lining membrane to take on inflammatory action, and

the rapidity with which inflammation runs over its surface when once established. Penetrating wounds may also strike one or more of the viscera contained in the abdomen, in which case the danger arises both from the lesion of the organ itself involving derangement of structure and function, and from the effusion of its contents into the abdominal cavity.

Wounds of the stomach are to be deemed highly dangerous, although there has been great diversity of opinion concerning their mortality. Dr. Beck takes notice of the declared opinions of some of the German colleges upon this point. A wound of the stomach was declared only accidentally mortal by the faculty of Giessen, and absolutely mortal by the college at Frankfort; while, in another case, a wound was considered mortal by the faculty at Leipsic, and not so by that of Helmstadt and Wirtenburg. The fact is, that very extraordinary escapes have followed wounds of this viscus. The writer recollects the case of a pauper in the house of industry in Dublin, about the year 1814, who had received a wound of the stomach some years previously, from which he recovered, with a fistulous opening in the side, of considerable size, communicating with the stomach. He kept this plugged with a tent of lint or tow, and, to gratify visitors, he would, for the reward of a few pence, take a large drink of milk or other fluid, and withdrawing the plug, suffer it to flow out through the external opening. This and similar instances tend to show that wounds of the stomach inflicted from without, although highly dangerous, are not absolutely mortal. But we can scarcely say the same of rupture of the stomach caused by a blow or contusion on the part, inasmuch as the contents have then no chance of an external outlet, and must be poured into the peritoneal cavity. While upon this subject, we may remark that rupture of the stomach may take place without external violence, and it then commonly causes death after a train of symptoms that closely resemble the effects of the irritant poisons. This accident usually occurs from the efforts to discharge, by vomiting, the contents of an over-filled stomach. When the organ is in this condition, it is carried forward, and makes an abrupt turn on the lower end of the œsophagus, which acts as a valve, and opposes the exit of the contained matters. A striking case of this kind is related by Dr. Lallemand. (*Inaug. Dis. Paris, 1818. Christison on Poisons, first edition, p. 88.*) A woman convalescent from a long attack of dyspepsia, being desirous to make amends for her long privations as to diet, ate one day to satiety. Ere long she was seized with a sense of weight in the stomach, nausea, and fruitless efforts to vomit. Then she all at once uttered a piercing shriek, and exclaimed that she felt her stomach tearing open; afterwards she ceased to make efforts to vomit, soon became insensible, and in the course of the night she expired. In the fore part of the stomach there was a laceration five inches long, and a great deal of half-digested food had escaped into the cavity of the abdomen. Professor Barzelotti (*Medicina legale, ii. p. 22*) notices a case in which the rupture was caused, not by the accumulation of food, but by the accumulation of gases arising from

depraved digestion, similar to what arises in cows which have eaten largely of clover. In these cases the train of symptoms would lead one to suspect the administration of an irritant poison, but sometimes death is instantaneous. Dr. Christison (*loc. cit.*) mentions the case of a coal-heaver in London, who, while attempting to raise a heavy weight, suddenly cried out, clapped his hands over his stomach, drew two deep sighs, and died on the spot. On dissection, a lacerated hole was found in the stomach, big enough to admit the thumb, and the stomach did not contain any food. These cases show the great danger arising from simple rupture of the stomach; but the danger is still more increased when the laceration is effected by external violence; for then, besides the injury done to the organ itself, the solar plexus and semi-lunar ganglion are implicated in its effects. These parts are so essential to life, that injuries to them are sometimes followed by the most rapid and perfect death, the entire vital power appearing to be at once extinguished.

Persons suffering laceration of the intestines from blows or contusions are likewise exposed to the greatest danger; but perforated wounds do not appear of the same mortal character; and when proper treatment is pursued, very surprising recoveries have taken place. Wounds of the small intestines are said to be more dangerous than those of the larger, in consequence of the more important functions they perform, and of their being supplied with a greater number of nerves; but we cannot perceive the value of this distinction, as the principal dangers, extravasation and inflammation, are not influenced by either of these circumstances.

Individuals may be killed by wounds of the liver; although small superficial wounds, if the sufferer escapes inflammation, may not be attended by serious consequences; but more extensive and deeper injuries may cause a fatal hemorrhage, by opening some of the numerous and large blood-vessels by which that viscus is traversed. Laceration of the liver by falls is not an uncommon occurrence; and when it happens, it most commonly causes the death of the patient. Besides the injury to the liver itself, its great reservoir, the gall-bladder, is exposed to perforation and rupture; and this is an accident of the most fatal character, from the effusion of bile into the peritoneum. This secretion and the urine are the most irritating of all the fluids of the body, and never fail to cause death when suffered to escape into the belly. Wounds of the urinary bladder, therefore, except at the part uncovered by the peritoneum, are of the most fatal kind.

Before we leave this part of our subject, we wish to make some remarks upon a form of accident which has been long known and described, but about which very vague and unphilosophical notions were entertained;—we allude to what have been termed wind-contusions. It is not rare to find upon a field of battle dead bodies preserving their form and the integrity of their surface, and not presenting externally any lesion by which death can be accounted for; but if the body be opened, some of the viscera of the thorax or abdomen are found bruised and ruptured, and an extravasation of black fluid blood or of the con-

tents of the stomach and intestines. When the nature and extent of these internal lesions are considered, it is evident that death must have been instantaneous, and the vital powers so quickly and completely destroyed, that there has not been time sufficient to allow of the infiltration of blood into the cutaneous tissue, so as to produce ecchymosis. As this kind of injury has been observed particularly after battles, it was imagined that death was caused by the wind of cannon-balls, that is, by the compression of the air caused by the passage of the shot in the vicinity of the individual. But when we consider the fluidity and elasticity of the atmosphere, and the little resistance it makes to the passage of bodies through it, we must perceive that this explanation is untenable; for the unconfined air never can be compressed to such a point as to become a mass capable of contusing or even giving a severe shock to our bodies. It is now generally believed that these lesions are caused by the contact of the cannon-shot itself, when towards the close of its trajet. For the first moment of projection, when the force is greatest, it pierces, tears, and carries off all that occurs in the line of its direction; but when it approaches the end of its course, and its velocity is considerably diminished, it loses the power of producing these effects, and as the skin is supple and extensible, and the parietes of the thorax and abdomen are flexible and elastic, and protected by clothing, they yield to the impetus without tearing, and resume their original form as soon as the compressing force ceases to act. But the parts which lie deeper than the parietes, and whose tissue is less flexible, and supported by bone, experience necessarily the whole force of the compression, and are thus contused, bruised, or, in some instances, reduced to a complete pulp. Any doubt of the validity of this explanation is removed by a reference to reports of cases of injuries not dependent on fire-arms, in which the same laceration and contusion of the viscera of the abdomen and thorax have been found without any appearance of external injury. Chaussier relates the case of a strong man, thirty years of age, who, while driving a cart heavily laden with stones, attempted to get on the back of one of the horses, and falling in the endeavour, the wheel passed slowly over his left shoulder, crossing the clavicle near the sternum, and continuing its course obliquely over the entire left side of the thorax. The body was found the following morning on the road, lying on the back with the track of the wheel marked on the clothes by a broad streak of mud. Nevertheless, on stripping the body, there was no appearance on its exterior that could lead to a knowledge of the cause of death. However, after removing the integuments and muscles of the thorax, it was found that the clavicle was torn from the sternum, and all the ribs of the left side were fractured, but there was no ecchymosis under the skin or round the fractures. The first rib was broken in one place near the sternum, but all the rest in two, about three inches apart, which corresponded with the breadth of the wheel. These fractures were not complete, but were limited to the inner surface. On opening the thorax, the pericardium was found distended with coagulated blood, and a large rent was discovered in the left

auricle of the heart. From this it is evident that pressure by the passage of a heavy body may cause bruising or rupture of the internal parts, without leaving any appearance of its action on the exterior; and in like manner those great contusions and sudden deaths, without external mark of violence, observed after actions, are to be ascribed to the size and weight of cannon-shot striking the body with diminished velocity.

We do not deem it necessary to dwell upon wounds of the extremities, as the danger of speedy death in these cases depends upon the escape of blood from some of the great blood-vessels implicated in the injury, a complication which is easily detected by dissection. But there is a form of injury connected with this part of our subject on which it is necessary to make a few observations. We allude to wounds of the external parts of generation in the female, which may prove fatal by excessive hemorrhage; the peculiar structure of the parts, consisting of erectile tissue, which is very vascular, giving rise to a continued, steady, though not very rapid flow of blood. In illustration of this point we may refer to two cases related by Mr. Watson. The first is that of a woman who resided near Edinburgh, whose husband was tried and convicted of having murdered her in the year 1826. "The body," says Mr. Watson, "of this unfortunate person was inspected by Mr. Newbigging and myself. We were informed of her having died suddenly. She seemed to be about fifty years of age, of stout form, of very low rank, having lived in a small, dirty, ill-furnished house, having only some shavings and straw upon the floor, covered with a rug for a bed. The clothes in contact with the private parts were stained with blood. No appearance of injury could be perceived on any part of the body externally; but upon separating the labia pudendi, a wound about an inch and a quarter in length was observed upon the inner side of the right nymphæ. This wound was evidently recent, its surface being covered with coagulated blood. Externally it consisted of a remarkably clean, straight incision parallel with the nymphæ. Internally the finger could be introduced in four different directions to the depth of about two and a quarter inches in each: upwards and backwards towards the division of the iliac artery; backwards towards the tuberosity of the ischium; laterally towards the hip-joint; and upwards towards the mons veneris. In each direction the wound was of nearly the same diameter, which readily admitted the finger, and had distinctly an obtuse termination. By injecting warm water into the large vessels, we found that none of them had been wounded, and the penetrating instrument seemed to have been forced only through the cellular tissue. The weapon had passed up to the peritoneum at the right side of the pelvis, under which there was a considerable effusion of blood, but had not penetrated it. Another very small, but also very clean external incision was observed at the side of that above described. The cavities of the cranium, thorax, and abdomen, were each examined, and their contents found to be quite healthy and natural. The hemorrhage, therefore, which had taken place from the wound was the only cause which we could assign for her death, and this we knew

from the nature and structure (erectile spongy tissue) of the parts cut, must have been profuse." It was proved on the trial that the wound was inflicted by a razor.

The second case is very similar to that first described: it occurred in the person of a woman who lived in Edinburgh, and whose sudden death was occasioned by a wound received on the morning of the 1st of January, 1831. This case was examined by Mr. Mitchelhill and Mr. Watson. They found the body dressed in the ordinary day-clothes, which they removed carefully, and observed no wound or tear on them, but the lower parts were drenched with blood. They then discovered that the hemorrhage had proceeded from a wound of the left labium pudendi, consisting of a very clean incision about three quarters of an inch in length, parallel with the margin of the labium. When the finger was introduced into this wound, it entered a bloody cavity sufficient to have contained a small hen's egg, and from this cavity the finger could be passed upwards towards the symphysis pubis, downwards towards the perineum, and backwards by the side of the vagina and rectum. Its greatest depth at any of these places was between two and three inches. When the internal part of the wound was laid open, the divided orifices of several pretty large arteries and veins were seen, and particularly the divided extremities of the large artery going to the clitoris. By the evidence adduced at the trial of two young men, brothers, for the murder of this woman, it was obvious she had received a wound at the first floor of a common stair, almost immediately after which she was precipitated headlong to the bottom of the stair. In reference to these cases Mr. Watson remarks, "In both, this part of the body seems to have been selected by the murderers to effect their design secretly; for in both, but particularly in the first, the wound was concealed to a superficial observer; and they may have had an idea, from the frequency of flooding in females, that their death might have been supposed to have happened either from this cause or by accidentally injuring themselves by sitting down upon some sharp body. For it is a curious fact that in both cases the probable murderers were the first to go for medical aid to the deceased.

Circumstances affecting the medico-legal character of wounds.—So far we have considered wounds according to the consequences that usually attend them; but the medical jurist should ever bear in mind the fact, that injuries, naturally belonging to the class of slight wounds, may acquire the character of severe, dangerous, or mortal, from the co-operation of circumstances more or less extraneous, and, therefore, relieving the inflictor more or less from responsibility. We have already alluded to the memorable aphorism of Mr. Hobbs, that there never was a wound but it might prove mortal. Let us now inquire into those circumstances that are thus capable of altering the medico-legal character of wounds: these are age, sex, constitutional peculiarities, previous injury or disease, subsequent injury or disease; malum regimen.

Of age, it may be said that adult age is on the whole the most favourable to recovery from injuries: of this we have a very striking example in

the case of burns, the effects of which are much more severely felt by young subjects, and the mortality attending them is greater in this class than in persons who have reached adult age. Fractures may, perhaps, form an exception to this, as it is observed that this species of injury is less fatal in children.

Sex is a circumstance of aggravation in the case of blows on the breast of a female. This organ being in early life endowed with peculiar sensibility, and in later years being prone to take on cancerous action when excited by injury, is naturally a very vulnerable part, and a comparatively trifling blow in this situation, may be followed by the severest effects. In like manner, an injury on the abdomen of a pregnant woman must be regarded as a more dangerous accident than the same force applied under different circumstances.

Constitutional peculiarities do not form a good exculpatory plea unless the wound be slight. They are of two kinds, constitutional infirmities and malformation. Slight wounds may be rendered dangerous, and even mortal, from an extreme irritability of the nervous system. We see this in the different effects produced on different patients by surgical operations, some bearing with fortitude what others unaccountably sink under. The scrofulous diathesis and venereal taint influence the result of wounds, and diseases of the bones and joints have succeeded in such constitutions to injuries which would have been of little consequence in sound ones. The hemorrhagic diathesis is one calculated to increase the danger of slight wounds in a remarkable manner, some striking examples of which have been already mentioned. Original or accidental malformation may likewise contribute to the fatal effects of a slight injury. Thus transposition of the viscera may bring an organ within reach of a wound that might have been otherwise harmless. A very remarkable instance of such malformation is preserved in the museum of the Dublin College of Surgeons. The subject was a woman advanced in life, who died in one of the hospitals of the House of Industry, and who had never given any indication during life of her peculiar formation. On examination of the body after death, all the viscera of the thorax and abdomen were found transposed. The heart was at the right side, the liver at the left, the stomach and spleen at the right, the cæcum in the left iliac fossa, and the sigmoid flexure of the colon in the right, and all the blood-vessels were transposed to correspond. But besides such a general transposition, there may be a partial malposition. Thus, an artery, usually deeply-seated may take a superficial course, and prove a source of danger in case of a slight wound inflicted in that situation. A case in which death occurred in consequence of malposition of an artery, happened in the hands of one of the most experienced surgeons in Dublin some years ago. A fish-bone stuck in the throat of an individual, who applied to the gentleman alluded to for relief. A probang was passed down the œsophagus, when suddenly an immense gush of blood took place from the mouth of the patient, and he dropped dead in his hands. On examining the body to ascertain the cause of this unexpected

fatality, it was found that the arteria innominata, instead of following its usual course in front of the trachea, had dipped down between it and the œsophagus, just at the spot where the fish-bone had lodged, the point of which had been forced by the probang through the œsophagus into the artery, and thus caused the death of the patient. Besides these congenital malformations, there may be accidental displacement of a viscus, as in hernia, by which a blow in certain situations will be made more dangerous.

Previous injury or disease is a plea sometimes set up in extenuation of guilt, but it is a feeble one, and in fact untenable if the injury is of a usually dangerous character, or has manifestly accelerated the death of the individual. It may, however, be used with advantage if the injury was slight; but the degree of weight that should be allowed to it in law is sometimes very difficult of decision. The chief questions on the subject are, 1st, Was the new injury adequate to cause serious mischief in ordinary cases? 2d, Whether did the injury, or the previous disease or accident, occasion death? 3d, Did the alleged previous harm really exist, or was it the consequence of the injury? Chaussier relates the case of a boy who was killed by a very gentle stroke of a switch upon the head, which in ordinary cases would have caused no mischief, but proved fatal in this in consequence of previous absorption of the skull at the particular part struck. An interesting illustration of the second question has already been quoted from the same author, in which death was produced by the bursting of an internal aneurism. Cases that come under our third head are very common; we will content ourselves by quoting one by Dr. Klapp of Philadelphia. (*American Medical Recorder*, v. i. p. 156, and Beck, by Darwall, p. 352.) An individual in that city, who was in habits of intemperance, engaged in a brawl, received an injury, and died thirty-eight hours after the affray. He walked and spoke after receiving the injury, and even drank part of a pint of spirits, but was shortly seized with insensibility, dilated pupils, oppressed breathing, and died without any return of sense. The bone and the brain beneath the injured part were examined and found natural. The mucous membrane of the cardia and the upper part of the stomach were greatly inflamed; the other parts were not diseased. Before the court, Drs. Hartshorn and Klapp gave it as their opinion that the injury to the head had not been the cause of death, and that there was no appearance of a blow on or near the region of the stomach. A verdict of acquittal was the result. But supposing the injury to be of such a kind as would alone prove fatal, then the second question arises, Whether did the injury or the previous disease cause death? There are circumstances which may render this a nice question to answer: thus, for instance, the disease and the injury may cause the same symptoms and appearances, as in the case of apoplexy and extravasation of blood from a blow. In cases of this kind confusion and difficulty are sure to occur, when the investigation is made according to the Continental system; but in these countries the animus with which the injury was inflicted being

the chief object sought after, the medical witness is saved from the nice distinctions laid down in foreign authors.

Subsequent injury or disease may also alter the medico-legal character of injuries. It may happen that a disease totally unconnected with the effects of an injury, may invade a person who has received a wound, and carry him off. This is a case that sometimes creates great difficulty. Thus, a typhous fever may attack an individual labouring under a wound of the head, or spontaneous pleurisy may occur after injury to the chest; in both of which cases it is evident that great obscurity must exist. We recollect the case of a boy who was admitted into the Richmond Hospital, Dublin, labouring under a wound of the head with a small depressed fracture of the right parietal bone. He went on well for some days, when headach came on, flushed countenance, fast and hard pulse, dry and burning skin, and thirst with sickness of stomach. It was at once supposed that inflammation of the brain had set in, and preparations were making for trephining him, when attention was accidentally turned to his right arm, from which he had been bled on the day of his admission, and in it, in the neighbourhood of the puncture and spreading up the arm under the fascia, a large collection of matter was discovered, on the liberation of which, all the bad symptoms gradually disappeared, and the boy recovered well without any operation. This was a case in which a subsequent disease put on the appearance of the worst consequences of the injury, and was at first mistaken for them.

Zacchias relates an instance illustrative of the difficulty that may occur in these cases. During a period in which the plague raged at Rome, a man received a wound on the head, which denuded the bone, but left no fracture. The wound appeared favourable for the first three days; but at the termination of that period a fever came on, accompanied with bilious vomiting and violent inflammation of the wounded part. On the fourth day the wound was gangrenous, petechiæ and buboes occurred, and he died on the sixth. It appeared afterwards that he had been visited during the first two days of his illness by a friend, who had died of the plague on the fourth day after communicating the disease to the wounded person. Tetanus is a consequence of wounds which must occur to every one as likely to alter their medico-legal character. A case occurred a few years ago in England, in which the super-vention of this disease upon a slight injury had a great influence upon the fate of a prisoner. A gentleman fired a gun, loaded with small shot, at a boy whom he found trespassing on his ground. He wounded him slightly in the leg, and the boy appeared going on well until he was attacked with tetanus, of which disease he died. The gentleman was tried, found guilty of murder, and executed. This case forms a good example of what has just been stated respecting the English practice in such cases; for if the wound had been inflicted with a stick or whip, or other implement, it is almost certain that a verdict of murder would not have been returned against the prisoner; but a gun having been used, made it appear that the intent was to do some grievous bodily harm, and

the heaviest penalty of the law was accordingly inflicted.

Malum regimen, or improper treatment, often constitutes a very strong exculpatory plea, as by it the character of wounds may be materially altered for the worse. Accidental or inevitable want of skilful attendance is not a valid plea; but if the omission was intentional or avoidable, it takes off the responsibility of the inflictor in a great degree. If a patient should refuse to submit to proper treatment, or should persevere in the use of forbidden articles of food, or should expose himself to cold or a vitiated atmosphere, it is plain that he must contribute to place himself in a more unfavourable position, the result of which can only be charged on himself. On the part of the medical attendant, misgovernment may arise either from negligence or bad treatment, by either of which the danger of a wounded person may be greatly aggravated. "In general," says Dr. Beck, "when a dissection proves that no wound mortal in its nature has been received, and when none of the circumstances already enumerated can be urged as causing its fatality, the death of the patient should be attributed to the surgical attendant rather than to the author of the wound, provided it can be proved that he neglected the sick person, or maltreated him by leaving foreign bodies in the wound which might have been taken away; by not suppressing hemorrhage; by not evacuating collections of pus when necessary; by employing tents unnecessarily; by neglecting or hurrying operations; or by not causing the proper regimen to be observed." (Med. Jur. by Darwall, p. 327, [or Amer. edit. ii. 235: Philad. 1838.]

In cases where bodies are found dead from wounds or bruises, a very important question arises which the medical jurist is frequently called upon to solve,—that is, are the wounds the result of suicide, of accident, or of murder? In the greater number of cases in which our assistance is required, the circumstances of the case are so well known, or can be so proved by witnesses, that there can be no doubt of the cause of injury or of the true author of it. But there are cases in which, to fulfil the objects of justice, it is necessary to determine whether the wounds inflicted on an individual were by himself or others. The solution of this question is always delicate, often embarrassing, and very difficult. The circumstances to be attended to in this inquiry are,—first, the seat of the wounds; secondly, their direction; thirdly, the probable weapon used. There are few wounds that one person can inflict upon another that may not be accomplished by an individual on himself. Some, however, form an exception on account of their extreme difficulty. For instance, it would be hard to believe that a wound with a sharp-pointed instrument in the spinal marrow was inflicted by the individual himself; and in death from fire-arms, wounds inflicted from behind can scarcely be supposed to have been voluntarily effected. Incised wounds are seldom inflicted except on the throat, for the purpose of suicide; but instances have occurred where individuals have resorted to wounds of the extremities and amputation of the penis for this purpose. A case occurred recently

within our own knowledge, where the suicide, having failed, as often happens, to destroy himself by cutting his throat, deliberately bared his left arm, and cut it across to the bone, above the elbow, dividing the brachial artery, from which he bled to death. The circumstance of fire-arms being discharged in the mouth of an individual is sufficient to warrant the belief that it was not done by the hand of another. Thus, attention to the seat of the wound will often determine whether it is the result of accident, suicide, or homicide, and will throw light upon the evidence of witnesses as to the circumstances under which the injury was inflicted. The direction of the wound will often likewise determine the intent, and the question of suicide or homicide. When a wound does not pass through the body, there will be little difficulty in ascertaining the direction in which it came and in which it passes. In a case of supposed suicide by means of a knife or pistol, the course of the wound should be examined, whether it be upwards or downwards, and the length of the arm should be compared with the situation and direction of the injury. It should be ascertained whether the right or left hand has been used; and as the former is that most commonly employed, the direction should correspond with it; but if the direction corresponds with the left, it should be inquired whether the deceased were left-handed. When a wound is alleged to have been inflicted by accident, we may inquire into the probability of the statement by comparing the stature of the body with that of the inflictor, and the relative position of the two at the moment the wound was received. In fact, a stab given by an individual of small stature to one of greater size is naturally directed from below upwards, and the contrary if it is the larger of the two who has inflicted it. An example of this occurred some years ago at Marseilles, (*Méd. Lég.* t. iii. p. 195,) in two men of different height, who fought a duel with swords on a public walk. The weapon of each of the combatants reached the heart of the other at the same moment, and they fell dead together. Their bodies being examined, it was found that the wound given by the small man was directed from below upwards, and that by the larger from above downwards. The situation and mode in which a wound is inflicted will often point out the intention of the perpetrator. Fodéré (*Méd. Lég.* t. iii. p. 196) relates a case illustrative of this point. A miller was assassinated at his own door by a butcher, who pretended that he had no intention of killing him, but had only threatened him with his knife in consequence of some maltreatment which he had received; that the miller renewed the attack, and in attempting to pursue him, made a false step and had fallen on the weapon. A single external wound, which led downwards to two wounds of the left ventricle of the heart, separated from each other by an interval of two lines, showed that the accused had employed the same method to destroy his victim as that used by butchers in that country to kill cattle; that is, after having driven the knife into the heart, they withdraw it some distance, and replunge it, so as to make a second internal wound. Thus the direction of the wound compared with the respective statures of the two ad-

versaries, (the butcher being much smaller than the miller,) proved that the blow had been inflicted obliquely from above downwards, that is, whilst the miller was sitting at his door, and not by a fall after getting on his feet, in which case the wound must have taken an opposite direction.

In the case of wounds from fire-arms perforating the body, different opinions have been formed as to whether this circumstance should determine the distance at which the shot was fired; and at first we might be led to suppose that if a pistol-bullet passed through, the instrument from which it was discharged must have been very near. But this is found to depend so much upon the strength of the charge, the direction of the ball, and the resistance offered by the parts of the body, that we cannot venture to draw any conclusion from it. It is, however, of importance to be able to discriminate between the entrance and exit wound, as a means of ascertaining the direction of the shot. That made on entering is smaller than the other, and has its edges inverted and depressed, while the latter is much larger, with ragged, everted, and uneven edges,—a circumstance depending upon the direction in which the force is applied to the skin, as well as upon the diminished velocity of the ball. When flat bones are perforated by balls, the same difference in the size and appearance of the two openings is to be observed. A trial, in which the defence rested upon the difference between the wounds, took place a few years ago in Kent, and is recorded by Dr. Gordon Smith. (*Principles of Forensic Medicine*, p. 290.) An officer in the preventive service was indicted for the murder of a man who was shot in the night, under circumstances of a suspicious nature as to his pursuit at the time. There was no doubt that he was in company with a party of smugglers, and came by his death accidentally. He was retreating before the prisoner, who tripped, and in the fall his gun went off. It seems that, on the other hand, several shots were fired on the part of the smugglers in their retreat, and that the deceased was killed by one of them. This appeared from the testimony of a navy surgeon of considerable experience, who examined the body. He found the wound in the upper part of the groin much smaller than that in the lower part of the buttock, which was twice or three times the size of the former, and was ragged and uneven. Fragments of the bone were likewise felt at the hinder opening, but none in the cavity of the pelvis. From these appearances he gave his opinion that the ball had entered in front, and had consequently come from his own party.

The probable weapon with which a wound was inflicted will often assist in disclosing the true nature of the accident. The singularity of shape that some wounds present, and the comparison that may be made between them and that of different instruments, has sometimes served to illuminate obscure cases. Such is the case related by Desgranges, and quoted by Fodéré, of an individual, who, having got drunk in a pot-house, left it to return home at eleven o'clock at night, the ground being covered with snow. He was found dead the following morning, beside a ditch near his own house. Desgranges examined the body,

which at first offered no trace of wound, bruise, or violence; but on turning the head from left to right, an oblique wound was discovered, scarcely three quarters of an inch in extent, under the base of the lower jaw, and about the height of the larynx. The little finger introduced into this wound showed it to be wider and more extensive within than appeared from the external incision. The clothes of the deceased were stained with blood, and there was a large quantity poured out on the snow. It appeared that this wound had been inflicted with an auger, which the deceased had carried out of the pot-house under his arm, with the point foremost, and upon which he, being drunk and hardly able to walk, had fallen. This instrument was found lying beside him covered with dry blood, having been extricated by the deceased from the wound, but not before it had wounded the left carotid artery.

While upon this point, we think it well to insert the declaration of Sir Everard Home, relative to the remarkable case of the death of Sellis, a servant of the Duke of Cumberland, and the simultaneous injury received by his Royal Highness. Sir Everard's declaration seems to indicate that Sellis had committed suicide after attempting the life of the duke. "I visited the duke," he says, "upon his being wounded, and found my way from the great hall to his apartment by the traces of blood which were left on the passage and staircase. I found him on the bed, still bleeding, his shirt deluged with blood, and the drapery above the pillow sprinkled with blood from a wounded artery, which puts on an appearance that cannot be mistaken by those who have seen it. This could not have happened had not the head been lying on the pillow when it was wounded. The night-riband, which was wadded, the cap, scalp, and skull, were obliquely divided, so that the pulsations of the arteries of the brain could be distinguished." "While dressing these wounds, a report came that Sellis was dead. I went to his apartment, found the body lying on its side on the bed, without the coat and neck-cloth, the throat cut so effectually that he could not have survived a minute or two. The length and direction of the wound were such as left no doubt of its being given by his own hand; any struggle would have made it irregular. He had not even changed his position: his hands lay as they do in a person who has fainted. They had no marks of violence upon them. His coat hung upon a chair out of the reach of blood from the bed; the sleeve from the wrist to the shoulder was sprinkled with blood, quite dry, evidently from a wounded artery, and from such kind of sprinkling the assassin of the duke could not escape." (Edin. Ann. Regist. v. vi. pt. ii. p. 19, and Beck by Darwall, p. 308, [or Amer. edit. ii. 93; Philad. 1838.])

Some light may be thrown upon cases of death from fire-arms by attention to collateral circumstances. Thus, in some instances the crime has been brought home to an individual by means of the wadding employed. A case of this kind occurred in France in 1818, and a similar one more recently in England; in both of which the wadding was examined, and discovered to have been torn from paper found in the possession of the

murderer. If the ball is discovered, a comparison of it with the gun or pistol from which it is supposed to have been fired may assist in the inquiry. Thus, in a case of alleged suicide, in which a pistol was found beside the body, on comparing the ball with the barrel of it, it was found too large to have entered it, and so the question of suicide was set at rest, and attention was directed to detect the murderer. If a flint pistol have been employed for the purpose of suicide, it has been imagined that the discoloration of the fingers from the combustion of the priming would confirm the case as one of suicide; but this mark, besides being capable of imitation by a crafty assassin, is becoming every day of less value, in consequence of the general application of detonating locks to all kinds of fire-arms.

[In the Life of Sir Astley Cooper, by his Nephew, (Lond. 1843,) it is mentioned as an evidence of the accuracy of observation of that eminent surgeon, that when called to see a Mr. Blight, of Deptford, who had been mortally wounded by a pistol-shot in the year 1806, he inferred from an examination of the localities that the shot must have been fired by a left-handed man. A friend of the deceased, a Mr. Patch, then unsuspected, was the only left-handed man about the premises. He was afterwards tried and convicted of the crime, and confessed his guilt before execution. (See, on all this subject, the excellent work of Mr. Taylor, entitled *A Manual of Medical Jurisprudence*: Lond. 1844.) The means of identifying spots of blood found on the body itself, on the soil, furniture, or clothes, or on the instrument with which death has been inflicted, have been investigated by MM. Lassaigne, Chevallier, Orfila, Baruel, and others. For the results of these investigations the reader is referred to the works of Devergié, Guy, and Taylor, already cited.]

T. E. BEATTY.

[DEATH, APPARENT.—(SEE DEAD, PERSONS FOUND.)]

DEATH, SUDDEN.—(SEE DEAD, PERSONS FOUND.)

DELIRIUM.—The term delirium has either been employed without design in a vague and indefinite manner, or it has been purposely used in a very comprehensive sense, and made to include every mode and degree of mental disturbance, from the slight and difficultly-traced aberrations of the argumentative and almost rational monomaniac, to the muttering and dreamy stupor of a patient labouring under the delirium of typhoid fever. All the phases and varieties of mental alienation, whether degrees of melancholy or violent madness, the wild ravings of the drunkard and the intense reveries of the opium-eater, as well as the peculiar symptoms resulting from that oppressed and disturbed condition of the sensorium which exists in severe febrile complaints, are alike comprehended under the designation of delirium when thus extensively applied. But there are few common characters belonging to all these phenomena, and for the sake of distinct and accurate description they must be separated. Those which are associated with madness form a particular group, and they may all be set apart under that head. (SEE INSANITY.) Under *delirium* or

febrile delirium we shall here survey the disordered states of the sensorium and intellect which occur principally in fever and inflammatory diseases, and in some disorders affecting primarily the brain itself or its investing membranes; and we shall point out the characters which distinguish these from the other phenomena, frequently though improperly included with them under the same term.

Phenomena. — Delirium supervenes on fever during any part of its course. It occurs in the hot stage of some intermittents, but rarely makes its appearance in typhoid or continued fever until the disease has reached its height, or until the period of strong febrile action is established. It sometimes occurs suddenly, and without any previous sign of disease affecting the head; but much more frequently it is preceded by headach, throbbing of the temples, heat of the scalp, a flushed and oppressed countenance. Occasionally a slight hemorrhage from the nostrils is the harbinger of a severe attack or exacerbation of delirium. The patient is at first delirious during the short and imperfect periods of sleep, or immediately after he is roused, becoming, when fully awakened, more clear and comparatively collected; by degrees this lucid interval is less to be perceived; the individual becomes more and more incapable of reflection and mental exertion, and gradually loses the power of recognizing the persons and objects which surround him.

The phenomena of delirium, as they appear to the observer and are remembered by the patient, are like those of a feverish and incoherent dream. When, in a state of health, all voluntary control over the course of the thoughts is withdrawn and the mind given up to reverie, there is still, during our waking hours, a continual restraint exercised imperceptibly over the wanderings of the fancy by the lively consciousness of external circumstances and relations. This controlling influence is withdrawn in health by sleep, and in disease by the impaired state of the sensitive power which ushers in delirium, and which goes on increasing as that affection advances, until it terminates in coma or complete stupor. Delirium, then, appears to hold a relation to sleep and to the dreaming state which accompanies sleep, or to be itself but a species of dreaming more intense and profound.

Accordingly phenomena are recorded in many cases of delirium, bearing a remarkable analogy to some of the most striking peculiarities of dreams. In dreams the mind is carried back with vivid intensity of feeling to scenes long past, and recalls, with greater accuracy than in the waking moment, minute incidents and circumstances. In delirium, when the sensitive power is nearly obliterated, the memory is occasionally, under certain modifications, surprisingly powerful and active. There are accounts on record, for example, from which it appears that persons labouring under the delirium attendant on fever, or succeeding injuries of the head, have been heard to talk in languages which they had been accustomed to speak in very early childhood, but had for a long course of years disused and totally forgotten. The case of a Welshman has been mentioned, who lay ill for some time in St. Thomas's Hospital, after an in-

jury of the head. During the course of his illness he was heard to talk Welsh very fluently, but could not utter a word of English: when he recovered, it was ascertained that he had been absent from Wales upwards of thirty years, and had entirely forgotten his native dialect, the knowledge of which was thus revived by his disease. This statement, which was first given by Mr. Tupper, has been confirmed to the writer of this article by a personal witness. A parallel case is that of a French countess, born in Brittany, who had learned the Bas Bretagne or Armorican idiom during her infancy; many years after she had forgotten it, during the delirium of a severe fever, she was heard to talk incoherently in a dialect which to the astonishment of everybody, a Welsh servant understood and interpreted. Dr. Rush, of Philadelphia, used to state that some of the old Swedish settlers in Pennsylvania, who, attaining a period of great longevity, had survived till his time, were heard in many instances during their last hours, in the almost incoherent mutterings which preceded dissolution, to talk in their native language, which, during by far the greater portion of their lives, had been entirely disused by them and forgotten.

This restoration of old and effete impressions is accompanied by another phenomenon. When the mind is thus withdrawn within itself, if we may use such an expression, and goes back to the inmost recesses in which are laid up the stores of long-concealed, but, as it seems, never to be obliterated reminiscence, it not only becomes unconscious of external circumstances, or indisposed to the perception of surrounding objects, but even loses the recent impressions of memory. Newly acquired ideas are effaced, like the immediate impressions of sensation. The knowledge of some language but lately acquired has been thus lost. A foreigner, mentioned by Mr. Abernethy, met with an injury of the head when he was twenty-seven years of age. During the delirium which ensued on this accident he could only answer questions in French, though he had previously spoken English perfectly well. He said that he was but sixteen years old, the age at which he left his own country: it is probable that the impressions received during eleven years had been effaced from his mind. After accidents which have occasioned concussion of the brain and consequent delirium, persons have lost all recollection of events which occurred during a certain period antecedent to the injury. Two gentlemen, intimately known to the writer of this article, met with accidents which occasioned to both of them severe injuries of the head. In both, concussion of the brain was followed by stupor, and afterwards by delirium, which continued some weeks. Both of these persons recovered their faculties perfectly, but each of them had permanently lost all recollection of objects and incidents which had occupied his mind for a considerable time previously to the accident.

During the state of unconsciousness as to external impressions, there is, together with excitement of memory, sometimes a considerable degree of mental activity: the mind is exercised even in forming new combinations. Many persons have

been known to compose verses and speeches, and to hold conversations on abstract subjects with individuals whom they imagined to be present.

Persons labouring under delirium are at times capable of being roused by external impressions, and, when once excited, they display unexpected muscular energy, which is followed by exhaustion, but not in every instance by a relapse into delirium. Van Swieten has twice mentioned the case of a man who, under severe delirium, was roused by hearing the noises occasioned by a fire which had broken out in a neighbouring house. His incoherent muttering, which had continued for some days, ceased, and he inquired anxiously into the cause of the alarm: his delirium was cured from that time. A patient lying ill with fever, some years ago, in the Bristol Infirmary, was suddenly roused by a loud peal of thunder. He started from his bed, and in a moment leaped over the beds of the patients who lay in a row opposite to him, and before anybody could lay hands on him, although in the middle of the day, when all were awake, he climbed up to an open window, twelve feet in elevation from the ground of the ward, and almost accomplished his design of throwing himself out of it. He would inevitably have been dashed to pieces if his foot had not providentially fixed upon a projecting ridge below the sill of the window, by which, as well as by one hand grasping the window-frame, he was supported until ladders were placed on the outside of the building, by which he was taken down without injury. This man afterwards recovered.

When delirium terminates fatally, it passes into coma. Sensibility becomes more and more impaired, until all conscious feeling seems to be lost. Inarticulate moaning succeeds to delirious incoherence; the patient loses in a great measure sight and hearing; the pupils become scarcely contractile, and the evacuations escape without consciousness. Patients have recovered after remaining for some time in this state, and this has happened not unfrequently in the case of young subjects. But the symptoms above detailed are more generally followed by others, which are the sure harbingers of death. These are *flocci volitantes*, picking the bed-clothes, convulsions, coma, with *subsulcus tendinum*, the eyes being turned up with a falling lower eye-lid. One of these symptoms alone denotes great danger, but the aggregate announces the speedy approach of dissolution.

Diagnosis.—The diagnosis between delirium and insanity is, in practice, for the most part attended with little or no difficulty. The presence of inflammatory or typhoid fever in the former case, and its absence in the latter, is in general a sufficient indication. Mad persons have many of their functions unimpaired; they walk about, eat, drink, talk. The state of a delirious person is quite different. "The insane," says M. Georget, "have frequently the external senses and the power of voluntary motion in a healthy state; they see, hear, taste; intelligence is in very few abolished; often the mental disorder is confined to a single faculty, or to a limited number of acts dependent on a single faculty; and in those cases in which it appears to be the most extended, in intense maniacal affections for example, the faculties appear to be perverted, or insulated, and with-

out the bond of association, but are yet far from being extinguished: the most irrational maniac talks, reasons, wills, and is not always absurd in his reasonings and actions. In the delirious, on the contrary, all the cerebral functions are severely affected; there are no correct sensations, connected ideas, or passions; no regular voluntary motions; little or no intelligence or recollection: the patient is almost a stranger to every thing that surrounds him as well as to himself." We may on the other hand observe that most insane persons have the digestive or nutritive functions in a sound state, and that they display the external appearances of health, especially after the few first days from the commencement of their insanity, and before they have shown signs of the secondary disease which is destined to bring them to their end: in delirious persons these same functions are always more or less in a state of disorder. We should in fact incur no danger of contradiction from persons who are in the habit of seeing cases of insanity, if we were to venture on the assertion that a great number of lunatics bear infinitely greater resemblance to individuals in perfect health than to patients labouring under febrile delirium.

It is of great importance not to confound these two species of mental disorder. The cerebral affection which is connected with delirium is in general severe and of short duration; it must be combated by a vigorous method of practice in order to prevent a fatal termination: madness is of long duration, and seldom or never attended with danger to existence. The latter disease seems to pursue its victims even after their recovery, by the mistrust which they inspire as well for the present as for the future; a mistrust which even extends itself to their posterity. A patient who recovers from this state is often painfully affected at finding himself in a mad-house. It would be unfortunate, on account of these considerations, to take a patient labouring under delirium for a lunatic; and in doubtful cases the physician should only describe the state of the intellectual faculties by the terms 'delirium' or 'disorder of the brain' until he has clearly recognised and is satisfied of the existence of madness.

The leading criterion between delirium and insanity is afforded by the state of the sensitive power or of the faculties of sensation and perception. Insane persons have the faculty of sensation generally unimpaired; and if they apprehend external objects to be different from what they really are, the error lies not in any disordered state of the perceptive power itself, but in the perverted judgment or false conviction of the understanding, which is so deeply rooted as even to resist the evidence afforded by the senses. An insane woman is convinced that her husband is dead; and when he actually comes to visit her, and to dispossess her of this hallucination, she insists that the devil has assumed the form of her deceased husband in order to impose upon her. A delirious person cannot distinguish one individual from another, and sometimes does not know the nurse who constantly attends him. There are, however, cases of delirium approaching somewhat to mania, in which the sensitive

power is but little impaired, and some of the peculiarities of insanity show themselves. We have witnessed the display of cunning and stratagem by patients slightly delirious; artful plans laid, in order to get rid of annoyances and to gratify inclinations; a strong impression manifested by the patient that he is where he is not; a concealed suspicion that it is intended to carry him off and put him into confinement. We have known instances in which traits of this description have excited great alarm, lest what had been regarded as temporary febrile delirium might prove to be a permanent loss of reason. These fears have proved groundless. The faculties are fully restored after having been obscured under febrile delirium, with very rare exceptions. The restoration to mental vigour is, however, in some instances slow, and occupies several weeks, and even months. Facts, indeed, have occurred within our knowledge which have seemed to indicate that the intellectual faculties have been in some instances even brighter and more vigorous than ever, or at least have been exercised with greater activity, and more displayed after a recovery from febrile delirium; and a parallel observation has been made by some of the older medical writers.

Pathology.—Many practical writers have been led by observation to conclude that there are two different states of the system accompanied by delirium, in one of which the brain is not the actual seat of disease, at least to any great extent, its functions being disturbed in consequence of disease, for the most part of intense degree, existing in some distant organ; while in the other form of delirium the brain or its enveloping membranes is the seat of inflammation. It is very important, in a practical point of view, to distinguish these two affections, which may be termed *sympathetic* and *idiopathic delirium*.

1. The first-mentioned species of delirium was indistinctly described by Dr. G. Fordyce, in his minute detail of the symptoms of fever. Fordyce was of opinion that this form of delirium ought to be treated with slight anodynes and restoratives. M. Dupuytren has given to this species of disease the designation of nervous delirium: he has described it in the "Annuaire Médico-Chirurgical des Hôpitaux." He remarks "that it is frequently observed in highly susceptible or nervous individuals, who have received severe wounds, or have undergone painful operations; in those who have suffered greatly from the apprehension of undergoing operation, and in others who have made efforts beyond their physical strength to display fortitude and courage in bearing pain heroically; and, lastly, in persons who have made an attempt to commit suicide." According to M. Dupuytren's observation, cases of this description are never cured or alleviated by antiphlogistic remedies, but yield easily to the administration of narcotic injections. In the brain no traces of disease have been discovered by M. Dupuytren when he has had opportunities of investigating the morbid appearances in cases of nervous delirium. To this form of delirium, as M. Georget has observed, we must refer the various degrees of mental and sensorial disturbance which occur at the close of chronic, and even of acute diseases. Comparatively few persons die in the full possession of

their faculties. But it may be observed that chronic affections do not in general excite delirium and febrile symptoms without passing into a certain degree of acuteness. May we not refer to the same head, as arising from a cause nearly analogous, the wanderings experienced by patients reduced to an extreme degree of weakness on sitting up or rising from bed, as well as the delirium which ensues on excessive evacuations of blood? Is there not in either case a defect of sanguineous stimulation, giving rise to the disorder in the intellectual processes? If we adopt the opinion of M. Broussais on the frequent existence of gastritis, and on the primitive or secondary causes of febrile action, "the stomach may be the organ which of all others exercises the greatest influence on the brain, and is generally, if not always, the cause of sympathetic delirium: but this opinion cannot be regarded as established."

The opinion that defective vascular action or vascular exinanition is a frequent cause of disorder in the functions of the brain, is a conjecture not peculiar to M. Georget. But the physiology of the brain is not sufficiently known to enable us to follow this conjecture with any thing like a legitimate theory. We only know the fact that long-continued irritation in the system, when the powers of life are giving way, frequently, if not generally, induces, previously to dissolution, more or less of disorder in the sensorial and intellectual functions. This is not the case exclusively in disorders affecting the stomach, or even more frequently than in complaints situated in other organs. Inflammations of the chest, phthisis, chronic ulcerations in the bowels occurring as the sequelæ of fever, and a variety of other disorders, often give rise to the kind of delirium here spoken of.

This species of disease has often been compared to *delirium tremens*. Its phenomena have but little resemblance to the symptoms of that complaint, whatever analogy may subsist between the unknown causes of both. They are alike in one respect, viz., as to the inutility of antiphlogistic remedies. It cannot be said that anodynes are equally serviceable in either; they are, however, in some instances of both diseases to be preferred to all other remedies.

2. Idiopathic delirium is a disease of greater importance than the secondary or sympathetic species, inasmuch as it denotes a specific condition of the brain, which requires a particular class of remedies, and which, unless removed by the timely and vigorous administration of such remedies, will speedily extinguish life. It is more marked in its symptoms, and more readily traced to its exciting causes: there is, therefore, not much difficulty in general in ascertaining its existence. This form of delirium, likewise, sometimes leaves behind it vestiges which may be discovered on dissection. Such are all the various phenomena produced by inflammatory action in the meninges and in some parts of the brain. These morbid changes are, however, seldom of great extent. They consist chiefly in vascular injection of the surface of the brain, increased hardness in its substance, effusion of fluid in the ventricles, injection of the vessels in the pia ma-

ter, serous infiltration of the same membrane: a similar condition of the arachnoid has been, as M. Georget observes, less frequently discovered. More important lesions than these have been traced in cases which combined paralytic or convulsive affections of the muscular system with delirium; but the latter cannot be considered as belonging to the disorder now under consideration.

To the idiopathic form of the disease belong,

a. Delirium following injuries of the head, fractures, concussions, wounds, and lesions of various kinds, which produce inflammation either immediately or after the first effects have subsided.

b. Delirium accompanying inflammation of the brain or its membranes, brought on by exposure to heat or cold. The effects of insolation, and of exposure to heat in furnaces or heated workshops, come under this division.

c. Delirium the result of intoxication, or of excessive doses of opium or other narcotics. We allude here, not to the state of intoxication itself, but to a more severe disease which is often the sequel of intoxication. Of this cases frequently occur in practice. A theatrical performer came home to his wife in a state of intoxication. During the whole night and a part of the next day he was supposed to be merely drunk, and no alarm was taken. As he continued to be delirious on the following day, medical assistance was required. He was still in a state much resembling that of intoxication: his head hot, face flushed, eyes red, mind confused, but without coma or paralysis. His head was shaved, and the jugular veins opened. He expired in the course of the day, and the surface of the brain was found highly injected, the white substance itself presenting abundantly bloody points. A man drank by mistake a poppy-head fomentation. He was seized with violent phrenzy, but speedily relieved and cured by means of bleeding and powerful antiphlogistic remedies.

d. Delirium occurring in erysipelas affecting the head is plainly of this kind. We have repeatedly seen the morbid phenomena denoting inflammation strikingly displayed on opening the head in cases of this description. The metastasis of dropsy, of rheumatism, and of various other diseases, when apoplexy is not the consequence, gives rise to delirium, which may be termed idiopathic, whatever organ had been affected before the disease was transferred to the brain.

e. Delirium attending continued fever is of this kind, when the head is the actual seat of the most intense diseased action. When the fever has been of that kind which some writers have termed *cephalic*, when the ordinary signs of determination to the head, or of increased vascular fulness have preceded and accompanied it, delirium may be considered in cases of fever as an inflammatory complaint. The practical consideration of this subject will be entered upon more fully under the head of FEVER. We now proceed to make some observations on the treatment of delirium.

Treatment.—The treatment of febrile delirium may be reduced to very simple principles, and these are such as are very generally understood.

Shaving the head, the application of cold water, with the admission of free air, are means often adequate to the removal of delirium as it occurs in typhoid fever. We have seen many patients brought from close and foul apartments with typhoid symptoms and labouring under delirium, who, after undergoing these simple remedies, and passing a single night in a cool, well-ventilated ward, have been found on the next morning so much improved, and so collected and free from mental disturbance, as to require no particular remedy directed to the state of the head.

Topical bleedings, viz. either by opening the temporal artery, by cupping on the head, or on the nape of the neck, or by the application of leeches to the head or round the neck, are well known to be among the most important remedies for febrile delirium.

Cold applications, by iced water or merely wetted cloths, by a stream of water passed by means of a funnel over the vertex, by ice pounded and put into a bladder or oiled skin, or by evaporating lotions, are next in point of importance to bleeding.

Blisters to the nape of the neck are often of great service. When the heat of the scalp is not great, or has been reduced, and especially when there is much stupor, or a tendency to coma, blisters are beneficially applied to the vertex.

Incisions in the scalp, made in the direction and over the sagittal suture, are of great service in cases of delirium combined with stupor, whether occurring in the course of fevers, or in affections of the head otherwise brought on. The incision should reach from the vertex to the anterior part of the hairy scalp, and be made down to the pericranium. The effect of this remedy is often an immediate relief by the bleeding which takes place. The subsequent inflammation and suppuration, the incision being kept open, are much more productive of benefit than the ordinary superficial inflammation excited by blisters, or the serous discharge from the surface of the cutis.

The writer of this article has now a patient who is making progress towards recovery, and is already almost convalescent. His improvement appears to have resulted from the means last described. He laboured under severe delirium with stupor, and had occasional fits of convulsion. His disorder was brought on by exposure to heat, his occupation being that of supplying with coal, and attending to the boiling apparatus of a steam-engine.

Purgings is of great benefit in cases of idiopathic delirium, and is often sufficient alone to the removal of the disease. We shall not proceed further at present in the consideration of remedies required for the treatment of delirium. The morbid state of the brain, from which delirium arises, seldom forms a distinct and entire disease. When it occurs in fevers, the remedial treatment belongs to the therapeutics of fever: when it proceeds from injuries of the head, it comes under concussion of the brain, or fracture or wounds of the scalp, &c. To articles on these several subjects in the present work, or to distinct treatises, we must refer our readers for more particular details.

DELIRIUM TREMENS. Amongst the numerous maladies which are the results of vicious indulgence, those of which the foundation is laid in the abuse of ardent spirits, and other diffusible stimuli, form a long and frightful catalogue: inflammation of the brain and its membranes; of the pleura; of the stomach; of the liver; jaundice; dropsy; diabetes; gout; mania; dyspepsia, with its manifold miseries—these are among the diseases induced by habitual intemperance; and several more might be added to the appalling recital.

Place this catalogue before the man who is beginning to acquire a taste for inebriating liquors, and he will feel alarmed; he will probably express his astonishment at the infatuation of the drunkard, and his determination to halt at once in his destructive career. Happy is it for such an one if his conviction of danger be abiding as it is powerful: unfortunately, however, it is in too many instances speedily effaced. Temptation again and again offers itself, and triumphs over repeated sober resolves, till, in the sequel, the victim persuades himself that it is absurd to forego a positive pleasure through fear of remote and contingent evils; of maladies which hundreds, more intemperate than himself, escape altogether; from many of which recovery is not uncommon; and to the visitation of which even the ascetic is liable. For some time, perhaps, he is guilty of excess only on extraordinary occasions; but, by insensible degrees, he slides into the habit of drinking deep in all companies, and, at last, of indulging even in private, and at all hours. From what is termed a pleasant companion, he degenerates into a hard drinker, and ends a complete sot.

Still he is attacked by none of the formidable diseases above enumerated, excepting dyspepsia, which he is very unwilling to ascribe to its true cause; or respecting the real source of which he is perhaps actually deceived, owing to the temporary relief which the application of fresh stimuli constantly affords him. His bane and antidote are one and the same. But he who abandons himself to incessant or immoderate potations should know, that if he escapes those diseases which once created such alarm in his mind, he is yet obnoxious to one not less formidable, which sometimes manifests itself rather suddenly, and speedily destroys the patient; sometimes creeping on by slow and almost imperceptible degrees, though it may not prove immediately fatal, may still leave him in a lamentable state of debility both of body and mind, and materially abridge the term of his existence.

This disease has received a variety of appellations. It has been called *brain fever*, a *peculiar disorder of drunkards*, *delirium et mania e potu*, [*anomania*, *mania e temulentia*, *delirium potatorum*, *d. tremificiens*,] *delirium ebriositatis*, *erethismus ebriosorum*, *encephalopathie crapuleuse*, [*folie des ivrognes*,] *delirium tremens*. The latter designation is here adopted, not as being altogether appropriate, for it is confessedly open to more than one objection. It is not perhaps quite correct to speak of a delirium as *trembling*; and the term is yet more faulty, inasmuch as tremor is not an invariable, though it be a very usual symptom. But the designation first employed by

Dr. Sutton is that under which the disease has been commonly recognized since the publication of his valuable essay. That essay, though it was not the first distinct notice on our present subject, was the first which seemed to attract the attention of the profession in general to a subject previously little known. The earlier labours of Drs. Pearson and Armstrong, important as they certainly were, excited less interest. It has been observed by Dr. Blake, that traces of this affection may be discovered in the writings of ancient authors, even as far back as those of Hippocrates; and it is true that, under the heads of phrenitis, mania, &c. cases are recorded by them of which the symptoms bear an intimate resemblance to those of delirium tremens; but that those cases differed materially from others of true phrenitis or mania, seems not to have entered into the minds of the venerable fathers of medicine. Their successors, from age to age, overlooked the peculiar character of the disease. Not many years ago the most distinguished lecturers offered nothing, or, at all events, nothing precise upon the subject—excepting Dr. William Saunders. (See Sutton's Essay, p. 4—note.) Systematic writers were silent concerning it. The first distinct account of delirium tremens was from the pen of Dr. Pearson, who, it would seem, derived his information from Dr. Young, of Newcastle-upon-Tyne. Dr. Armstrong next published a paper or two upon the subject, and he was followed by Dr. Sutton. Since the appearance of his essay, the disease has again been treated of by Dr. Armstrong, in his lectures, and by several other authors of reputation, both of our own and of foreign countries: it has obtained a place in the works of Good and of Gregory, though unfortunately they differ as to its classification; the former placing it under nervous, the latter under inflammatory affections. It is now fully recognised as a peculiar disease, requiring peculiar treatment, and therefore one which it is of the utmost moment we should be able to distinguish from certain others to which it bears no inconsiderable resemblance, and with which it often has been, and probably often is, confounded, to the great detriment of the patient, as well as to the discredit and mortification of the practitioner.

In describing the phenomena of delirium tremens, we shall adopt Dr. Blake's division of the disease into three stages, not merely as convenient, but as founded upon a philosophic view of the subject. The advantages of considering delirium tremens under separate stages have not been overlooked by other authors; but Dr. Blake's arrangement seems, upon the whole, best calculated to obviate the obscurity and confusion in which its history was formerly involved, and to direct us as to our mode of treatment.

The approach of the first stage is announced by symptoms of general debility; the patient's appearance and manner undergo a certain change; his countenance is dejected and anxious; his spirits are depressed; there is frequent sighing, and oppression of the præcordia. All around him perceive that he is indisposed, though his most intimate friends may be altogether in the dark as to the nature of his malady, or its cause. If the invalid be himself questioned, he will probably maintain that nothing ails him; or, if he admits

that he does not feel quite well, he will not be able to explain what is the matter with him. Upon more particular inquiry it will be discovered that his nights are restless, that his slumbers are short, and disturbed by harassing dreams; that he rises in the morning unrefreshed and languid; that his appetite is impaired, or even that he loathes food; that he is annoyed by nausea and continual vomiting; that he suffers from cramps of the extremities. Vertigo and confusion of ideas are usually present. Pain of head has been reckoned among the symptoms; but it is certainly neither a common nor a leading one. The tongue is sometimes furred, but moist; often, but not in all cases, tremulous. The bowels are generally open. The pulse, according to Dr. Blake, whose opportunities of observing the disease at its commencement have undoubtedly been ample, is invariably slow; and although other writers do not mention this remarkable slowness of pulse, they all concur in representing the pulse as by no means frequent. It is, moreover, soft and compressible; often feeble and unsteady. The temperature of the body generally is not increased, while that of the extremities is considerably below the standard of health. The hands and feet are cold and clammy; the sensation they convey to the touch resembles that observed in persons labouring under enteric inflammation. Tremors of the hands occur in most instances. Such are the principal features of the first stage of delirium tremens, and beyond this stage the disease may not proceed: by timely and judicious treatment its further progress may be arrested, and by subsequent prudence on the part of the patient its recurrence may be prevented.

Generally, however, it is succeeded, after a shorter or longer period, according to the constitution, age, and previous habits of the patient, by the second stage, or that of delirium. In young and robust subjects, whose excesses have not been of long standing, the stage of re-action or excitement will come on much more rapidly than in persons advanced in years, and whose constitutions have been broken down by long intemperance. It is during this stage that the medical attendant is most liable to fall into error. The symptoms, many of them, are so similar to those of inflammation of the brain or its membranes, that, if he is not especially upon his guard, if he allows the pathognomonic signs of the disease to escape him, his diagnosis will be incorrect and his practice unsuccessful. When the second stage is coming on, the vertigo and confusion of head are more marked; there is more decided aberration of mind; the countenance gradually assumes a wild aspect; the patient is incessantly restless; there is apparent an anxiety to perform immediately whatever is desired of him; he even anticipates your wishes, or what he supposes to be your wishes; he is peculiarly sedulous in the performance of his ordinary duties, which he goes about in a hurried immethodical manner; he is very jealous of the least interference, either by advice or otherwise, as to matters pertaining to his vocation, exerting himself painfully to prove he is quite well, yet evidently mistrusting himself. Thus, if his occupation is that of a butler, he will betray a strange solicitude about mere matter of routine; he will be in a perpetual bustle; he will

commit perpetual blunders, at the expense frequently of his master and his guests: his altered countenance, uncertain step, and trembling hands, will sufficiently evince his unfitness for the duties of his situation; yet he will pertinaciously repel the proffered aid of his fellow-servants; his whole manner will much resemble that of a person on the verge of intoxication, who is excessively anxious to appear quite sober. By ordinary observers he will probably be pronounced more than half drunk, and they will recommend his being sent to his bed, under the notion that sleep will effectually restore him. But such a patient cannot sleep off his malady. He is restless; his mind wanders; he rises worse than he was before, with more symptoms of high nervous irritation. By degrees mental alienation is fully established; the patient is in a constant worry about some affairs which he fancies of great importance; some business, *generally private business*, which must be attended to. He makes violent and repeated efforts to liberate himself from restraint, that he may apply himself to these affairs; but he is not, like the decided maniac, or the man labouring under the immediate excitement of an over-dose of strong liquor, disposed to be mischievous; his exertions, though vehement, are not characterized by malignity or ill nature; he quickly forgets what is past, and, if judiciously managed, is, upon the whole, sufficiently tractable. He will generally take the medicines offered him without much difficulty, and, when exhorted to endeavour to keep quiet, will manifest, for a short time, a desire to acquiesce. He will now and then recognize those of his family and friends who are near him, and will return a rational answer to a few questions; but he very speedily relapses into his erroneous train of thought. At this period of the disease the circulation is quickened, the heat of the surface becomes greater, yet still the pulse remains small, and there is a marked difference between the temperature of the extremities and that of the rest of the body, the former continuing damp and cold. If the symptoms above-mentioned be not soon ameliorated, a sweat bursts out, copious and clammy, and occasionally, it is said, of an offensive odour. The mind becomes still more distressed; objects of the most appalling description sometimes present themselves to the patient's imagination; he will be possessed with the idea that he is persecuted by evil spirits, who are upon the point of carrying him away, or are preparing to destroy him; or he may fancy he is surrounded by assassins; and cases are recorded where the unfortunate sufferers actually expired while exerting themselves to the utmost to ward off the violence they supposed was intended them. Catastrophes so lamentable are not, however, of frequent occurrence. Various other hallucinations less frightful, though still very distressing, might be mentioned; it may, however, be sufficient to observe in a general way, that the mental bias is mostly of the melancholic kind. Sometimes the most whimsical notions arise: thus a patient will imagine that rats or mice, or other troublesome vermin are running over him, or near him; that he is employed in drawing ribands from the ends of his fingers, with numberless extravagancies of a similar nature.

When delirium is completely established, there is obstinate pervigilium, and this is a very important, indeed it has been regarded as a pathognomonic symptom of the second stage of the disease. At this period, too, the countenance assumes an aspect of extreme anxiety; the tremor of the hands and tongue is greater; the later is more furred, but still moist; the pulse is not only small but frequent, and also indistinct, partly perhaps in consequence of the tremor and unceasing workings of the tendons of the wrists; the urine is scanty and pale; the bowels are usually confined; the dejections dark coloured; the pupils are contracted, but without intolerance of light. Still there is no indication of local pain, and when the patient is asked how he feels, he will often reply that he is quite well. These symptoms either increase in violence, and others supervening, which very nearly resemble those of the last stage of typhus, the patient dies suddenly in a convulsion; or the long-continued delirium, with subsultus tendinum, picking of the bed-clothes, &c., is succeeded by a short interval of quietude, and he expires without a struggle; or, after two or three days, or it may be a week, yawning and drowsiness come on, and sleep follows, which is generally profound and of long duration, lasting from six to twelve or eighteen hours; the patient wakes collected, and greatly refreshed, and his recovery may be looked upon as almost certain.

Such are the general symptoms of the three stages of delirium tremens, which if they be attentively considered, and viewed as a whole, will enable the medical student to perceive wherein it differs from certain other affections to which it bears a real or an apparent affinity. When he comes to the bedside, he will be in a good measure prepared to discriminate between a case of delirium tremens and one of phrenitis, mania, hypochondriasis, or typhus fever. If he be so fortunate as to be consulted early, during the first stage of the disease, he will scarcely be at a loss as to diagnosis. But it will more often happen that he is not summoned till the second stage is approaching, or until it is fully established; and then there will be more difficulty in recognizing the affection. There may be certain cognate diseases where accuracy of diagnosis is not practically essential, but in very many instances it is of the utmost importance, and on no occasion perhaps more important than when we are consulted in a case of delirium tremens. The previous habits of the patient may be unknown to the medical man; his friends may be imperfectly acquainted with them, or may endeavour to conceal them; to the superficial or the unskilful observer he may appear to be labouring under phrenitis or mania; from himself, of course, no information can be expected. Whenever, therefore, we are called to such a case, we should institute the most careful inquiry into the early symptoms of the complaint, we should endeavour to elicit from the family of the patient what has been his state, both physical and moral, for some time previous to the accession of delirium, and attentively view the previous history, so far as it may be furnished us, in connection with existing phenomena—the pulse, the countenance, the temperature of the skin, especially of the extremities, its dryness or moisture; the appearance of

the tongue; the degree and kind of alienation, whether the delirium be accompanied with pain of the head or any other part, with indications of increased arterial action, or of venous congestion, or otherwise; whether it be characterized by intractable violence, or be of a more mild and manageable nature; whether there be tremors of the hands and tongue, which almost always accompany delirium tremens from the first, and do not indicate extraordinary danger, while in phrenitis they are scarcely ever present until the last stage, and are then of most unfavourable omen.

Having thus detailed the symptoms of the disease, we proceed to say a few words respecting its causes. Now the principal features which mark its first stage so commonly exhibit themselves in intemperate subjects early in the day, when they are in the state of exhaustion which is the usual consequence of a debauch, and have so frequently been observed to arise in soldiers and others, when for a time deprived of their daily quantity of liquor; that the sudden subtraction of accustomed stimuli has been regarded, by respectable authorities, as *invariably* the immediate cause of the disease. The habitual and excessive indulgence in strong liquors, or in other diffusible stimuli, has been considered as the predisposing, and the privation of them as the occasional or exciting cause of the affection.

To a somewhat whimsical theory of M. Leviellé, (*Mémoires de l'Académie Royale de Méd.* tom. i. Sur la Folie des Ivrognes, ou sur la Délire Tremblante,) that delirium tremens consists in exaltation of the vital powers of the brain, excited by alcoholic molecules absorbed from the surface of the stomach and bowels, and carried into the current of the circulation, it is objected by Dr. Blake, that he never saw an individual attacked with delirium tremens so long as he continued to indulge in his accustomed alcoholic potations; but that it invariably came on when old drunkards ceased for a given time (either from the effects of an excessive debauch, or from any other cause whatever, such as a wound, a fracture, or a fever,) to take their usual inebriating draughts. To overthrow M. Leviellé's theory would perhaps cost little labour, but we do not consider that it is in the least degree shaken by the objection just stated; for that delirium tremens may manifest itself in individuals who have never been deprived of their accustomed stimuli, even for an hour, is most certain; as, for example, in publicans, who live in an atmosphere charged with alcohol,—who, though seldom absolutely intoxicated, are always more or less under the influence of intoxicating liquors—who are sipping from morning to night. Instances of well-marked delirium tremens occurring in such persons have fallen under our observation. Interesting cases might be cited, where, upon the patient's being at once removed beyond the sphere of temptation, recovery was rapid and complete; and others might be adduced in evidence that the habitual stimuli being obstinately persisted in, or, after a certain interval of abstinence, foolishly resumed, the disease will proceed to a fatal termination.

The delirium which comes on in persons addicted to hard drinking, several days subsequent to a wound or fracture, the traumatic delirium of

M. Dupuytren, the symptomatic delirium tremens of M. Barkhausen of Bremen, and which is relieved by ardent spirits or strong liquors of one kind or other, though it be doubtless very nearly allied to the affection which is the subject of our present inquiry, does not seem to be identical with it. In such cases the system receives a sudden and violent shock; an individual, previously perhaps in the enjoyment of robust health, accustomed to strong exercise, engaged in a laborious occupation, requiring much support, is at once confined to his bed; his habits are in a moment broken off; and no wonder that, in a few days, he falls into a state greatly resembling that of a patient in typhus—a state which absolutely requires the stimuli to which he used to resort previously to the reception of the injury. But in delirium tremens, unconnected with other disease or injury, we recognise no such immediate and overwhelming shock. The general health is first perceived to fail; it becomes more and more impaired; then come on the characteristic symptoms of the affection; and, if the habitual stimuli be continued, those symptoms progressively increase. From the first the patient passes into the second stage, from that into the third stage of the disease, and he dies. Upon the whole, it would appear that the predisposing cause of the delirium which in intemperate persons supervenes to a wound, a fracture, a fever, &c. is habitual indulgence in strong liquors, or certain other diffusible stimuli, while the sudden abstraction of such stimuli is its immediate cause. But in delirium tremens, unconnected with specific disease or accidental injury, the predisposing cause is to be sought in peculiarity of temperament, combined with other circumstances, such as mental anxiety, great and continued fatigue, &c. while habitual intemperance must be regarded as the immediate or exciting cause.

We have stated that delirium tremens is caused by the intemperate use of strong liquors, or of certain other diffusible stimuli. Of these latter, opium, either alone or in its various combinations, is the chief. The long-continued and free use of opium may certainly induce true delirium tremens. We have known it to be so produced, and this fact is sufficient to overthrow the theory of M. Leveillé, before referred to, which would make the absorption of alcoholic molecules the exciting cause of the disease. It has also been asserted that the poison of lead, that malaria, that long fasting, will produce it; but we think, with Dr. Blake, that where delirium tremens follows emanations from lead, malaria, hunger, &c. it is only in subjects in whose constitutions the *ebriositatic diathesis* has been established by frequent excesses. When delirium from such causes occurs in persons of temperate habits, it will not present the other pathognomonic symptoms of the disease of which we are speaking.

We now arrive at an important question, one which we would gladly dispose of in a satisfactory manner, but which, we fear, must be left in obscurity—What is the pathology of delirium tremens? Dr. Armstrong, in his lectures, fairly confessed he could not satisfactorily answer the question. The affection, he said, appears to depend principally upon some condition of the ner-

vous system with the nature of which we are unacquainted; and so he left the subject. By Dr. Gregory it is dismissed in terms sufficiently expressive of his doubts respecting it. "It appears," he says, "to have for its proximate cause a peculiarly excited state of the nervous system; but the occurrence of such symptoms in cases of extreme inanition would lead to the belief that *exhaustion of nervous power* expresses, perhaps, more accurately its intimate nature." It were easy, in this place, to descant learnedly upon cerebral irritation and disorganization; we might throw additional darkness over what is already obscure; we might pretend to explain what is unknown, by something completely unintelligible. In the absence, however, of just information, either by means of examination after death, or from any other source, we prefer acknowledging that we are very ignorant as to the pathology of delirium tremens: we do not know in what its intimate nature consists; but we do know enough to direct us as to practice; to enable us to state that in delirium tremens, unaccompanied with other serious disease, such as inflammation of some important part, unless circumstances are peculiarly unfavourable, unless the patient's constitution is extremely shattered, or he is very ill-managed, he will recover from the immediate attack. In simple delirium tremens, occurring in a subject neither far advanced in years, nor completely broken down by excess, our prognosis would be favourable.

We may now proceed to the treatment of the disease. And here we would once more strongly insist upon the importance of minute attention to its several stages; since, as each stage presents some difference with respect to symptoms, each will require modification as to the plan of treating it. It may be assumed that the disease is one of debility. Bloodletting, as a general remedy, is no longer thought of. In its first stage, of which the symptoms are entirely those of diminished energy, no practitioner would dream of bleeding, either general or topical. In this stage, (we speak, be it remembered, of delirium tremens uncomplicated with other accidental affection,) there is absolutely nothing but what would contra-indicate abstraction of blood. The employment of laxative medicines will however be needed. The bowels may not be, and indeed they usually are not, constipated, yet the stomach and collatitious viscera may fail in the due performance of their respective offices; the alvine evacuations, though not deficient, may be unhealthy. In so disordered a state of the nervous system, as Dr. Gregory observes, the secretions will probably be vitiated. Mild purgatives will commonly suffice; but if, as sometimes happens, the bowels are actually constipated, recourse must be had to more active remedies, and amongst these croton oil perhaps is entitled to especial regard, since, beyond its purgative quality, it appears to exercise a peculiar influence upon the nervous system.

While in this stage of the disease we deprecate bloodletting, and would, under ordinary circumstances, employ only mild laxatives, we would not, on the other hand, advocate a highly stimulant plan of treatment. Under such treatment patients may now and then recover; but, gene-

rally speaking, the liberal exhibition of accustomed stimuli will be likely to render the supervention of the second stage more certain, to induce more violent re-action, and to place the patient in extreme jeopardy. The accustomed stimuli should be withdrawn without hesitation. Neither wine, nor spirits, nor strong malt liquors, should be allowed at all; or at all events they should be administered only in very moderate quantities. Opium should be regarded as our chief remedy; but at this period it is not to be given in full doses, but in small ones, repeated at short intervals. If nausea is present, with disposition to vomiting, or actually vomiting, about ten drops of laudanum, or of Battley's solution, may be given every other hour in an effervescent draught; and anodyne enemata, should the stomach be very irritable, may be employed. If the stomach is retentive, and there be no nausea, the above-mentioned quantity of the opiate, with a few drops of Hoffmann's ether, or (should ether disagree, as it sometimes will, producing a distressing sense of coldness in the stomach,) a few drops of the aromatic spirit ammonia, in camphor mixture or some other grateful vehicle, will be found more advantageous than any of the stimuli to which the patient has been accustomed. The warm bath or tepid affusion should not be neglected. Even cold affusion has been recommended upon highly respectable authority; but, when we reflect upon the train of symptoms which manifest themselves in the first stage of the disease, we should scarcely, even in a young and healthy subject, venture upon the adoption of so bold a practice. Anodyne frictions may be employed to the epigastrium; the head may be shaved, and the scalp stimulated by strong volatile liniment; and a blister be applied to the nape of the neck. Emetics have been recommended by American physicians; but, as they do not appear to recognize the several stages of the affection, they leave us in ignorance as to the exact period when emetics should be given: they can scarcely be deemed applicable during its first stage; and in the second they would seem to be a doubtful remedy.

[By Dr. Joseph Klapp, of Philadelphia, the treatment of delirium tremens was made to consist almost exclusively in the employment of emetics. On them at least the main dependence was placed. When the patient is first seen by the physician, it may be advisable, in many cases, to evacuate the contents of the stomach; and at a subsequent period, the equalizing and revellent action of an emetic may be employed with advantage; but it is very questionable, whether much good can arise from the repeated administration of agents whose action may exhaust; and under such feelings, with the absence of any markedly beneficial results from their use in many cases, they are by no means generally prescribed by practitioners.]

By the judicious employment of the means just pointed out; by the adoption of what may be termed a stimulo-narcotic plan of treatment, modified according to the intensity of the symptoms, and the age, constitution, &c. of the patient; the second stage may be averted; the depressed nervous power being gently raised, the necessity for a great remedial effort of nature, for violent re-ac-

tion, may be superseded; sleep may be induced, and the patient awake free from complaint.

While upon the subject of treatment in this stage of the disease, we have not touched upon diet, and for this plain reason, that the state of the stomach is usually such as not to admit of anything beyond what is essential in the way of medicine. Should, however, this stage be protracted, and the patient seem to require, or express a wish for food, any mild nourishment, such as arrow-root, sago, or broth, may be allowed him.

Should the second stage come on, depletion is, for the most part, still to be avoided; it is a remedy not to be employed but with the utmost caution. In young and vigorous subjects, and where there exists evidence of local determination, a single moderate bleeding from the arm, or the application of leeches to the temples or behind the ears, may prove useful; but the bleeding should never be large, and very seldom will it be proper to repeat it; while, generally speaking, it should be rejected as a practice which has too often done mischief, and has not unfrequently destroyed the patient. Opium is, at this period, our sheet-anchor, opium in full doses; all other remedies are of inferior importance. The object is to get down, and that speedily, what experience has proved to be generally effectual. We would recommend laudanum, say sixty minims, every hour or two; such a quantity of liquid may almost always be given without difficulty, while opium in substance may be refused, or its tincture in combination with other medicines may be obstinately rejected.

The medical attendant should watch by his patient during the exhibition of opium, and steadily persevere for several hours,—not so much regarding quantity, as the effect produced. While, however, we thus strongly insist upon the bold and free employment of opium in the second stage of delirium tremens, we would not be understood as advocating its excessive or indiscriminate exhibition. Should the remedy, after some hours, fail to produce the desired effect, we must proceed with caution, lest by pushing it too far we add to the intellectual disturbance, and to the danger of our patient. The probability, however, is, that in a few hours there will be a remission of symptoms; that tranquillity will succeed gradually to high excitement, and there will be a disposition to sleep. This disposition will sometimes be attended with slight rigors, which may alarm those who are unaware of their nature and consequences. We should then be more sparing in our administration of opiates, and allow some time to intervene between the doses. The inclination to sleep should be promoted by every means in our power; everything calculated to excite, as light, noise, &c., should of course be studiously guarded against. The first slumber may perhaps be interrupted by startings, and the patient may soon awake alarmed and distressed; but a moderate dose of opium, with some warm stimulating drink, and a kind encouraging manner on the part of the attendants, will generally be followed by a sleep more profound and of long duration, from which the patient will awake perfectly collected.

Anxious not to divert the attention of the practitioner, at this so important a period of the dis-

ease, from the one great and principal remedy, we have hitherto said nothing of other curative means; of calomel with the compound ipec. powder, in the proportions of two grains of the former to six of the latter, every two hours, till the system is affected or the disease yields; of the warm bath; of cold applications to the head; of purgatives; among which we may once more notice croton oil, either given internally, or used in the way of friction to the abdomen. These are not to be overlooked: they are valuable auxiliaries; and should opium, after a fair trial, fail us, as it occasionally will, camphor, musk, ether, ammonia, with hyoscyamus, are succedanea not to be neglected. The cautious administration, too, of alcoholic liquors, may, in such cases, be of service.

During this stage we must pay particular attention to the moral management of the patient. We must strive to obtain his confidence, to gain an ascendancy over his mind without having recourse to coercive measures. As patients in delirium tremens are not usually disposed to be mischievous or malignant, physical restraint should be generally avoided: if a man is very uneasy and inquiet in bed, he may be permitted to get up; and if he is very importunate to go over his house, or is possessed with the idea that he must absolutely examine letters or papers, it will be the part of prudence to yield to his wishes, at least to a certain extent, for by so doing we shall be most likely to gain an empire over his mind; and the satisfaction of his desires, when they are not clearly improper, will probably obviate a long and painful scene of impatience and contention, and will favour the return of tranquillity, and the accession of that sleep so much to be wished for. On no account, however, should the patient be left for a moment without an experienced attendant; and it should be remembered, that although the delirium in this disease is not generally characterised by intemperate violence, instances *sometimes* occur where it very closely resembles true mania.* Where the unhappy patient manifests a strong disposition to offer violence to himself, or to those about him, every offensive weapon should be removed, and two male attendants be employed to keep the patient within bounds. We say *two* attendants, because thus the strait-waistcoat may be avoided, which, as Dr. Armstrong has observed, should never be resorted to but at the last extremity.

In one word, the treatment of patients in delirium tremens should be according to Pinel's directions in other cases of mental alienation.

To cut short the disease at this period is beyond our power; our efforts must be steadily directed towards the mitigation of urgent symptoms. Nature is now actively engaged in the work of restoration, and it is the part of the sound physician to be her discreet minister. He may direct her efforts, but he must not pretend to "give them pause." If left to herself, her operations will probably be fearfully energetic: we should endeavour to regulate the efforts she is making towards a good end.

* A medical friend of the writer very nearly lost his life by the violence of a patient labouring under delirium tremens.

It may, however, happen that all our exertions during the second stage of the disease will prove unavailing; that the third stage, that of tranquillity and sleep, will not be induced by any of our remedies; and that all the untoward symptoms formerly enumerated will supervene. How are we then to act? We must persist in the same general mode of treatment. We may shave the head, and apply blisters or antimonial ointment; we may apply blisters, or mustard cataplasms to the extremities; we may employ mercurial frictions; we may give powerful stimulants. It is incumbent upon us not to omit these remedies, though there exists little chance of their proving efficacious. The last symptoms are those of effusion into the ventricles, or on the surface of the brain; and such effusion to any considerable extent is almost always the forerunner of death.

When the event is more fortunate, when the immediate danger is averted, we should support the strength by moderate and frequent supplies of mild nourishment, and the judicious exhibition of diffusible stimuli, gradually diminishing the latter, and after a short time subtracting them wholly.

Having thus far conducted the patient,—having placed him in present safety,—the merely professional duty of the physician may be considered as terminated. Something, however, yet remains for him to do if he would be deemed the *neighbour* of the individual whom he has just succeeded in rescuing from extreme peril. The physician should not lose sight of the convalescent until he has seriously advised him as to future conduct. He should avail himself of the *mollia tempora fandi*;—gratitude, confidence in the talent of his medical attendant, a vivid sense of the danger he has escaped, a present conviction that he has nearly perished through his own folly, will probably incline the patient to listen attentively to counsel earnestly and forcibly urged, yet without the semblance of harshness or the tone of reproach. What the nature of this counsel should be, the medical man need not be informed; the prophylaxis in the disease before us is sufficiently obvious. The complete abandonment of previous habits must be inculcated; but to produce a lasting impression, the adviser must speak from the heart. He must, to adopt the language of one who was truly an ornament to his profession, "evince a genuine love of virtue, accompanied by a sincere interest in the welfare of the person to whom his counsels are addressed." Such honest counsels may be productive of an indelible impression; they may conduct to the happiest results, to moral as well as physical restoration; or should they be offered in vain, the physician will retire with at least the pleasing reflection that he has to the best of his ability fulfilled his duty.

H. W. CARTER.

[The plan of treating delirium tremens pursued by the writer, as stated elsewhere (*Practice of Medicine*, 2d edit. i. 277, Philad. 1844), has been entirely eclectic, and, in many cases, expectant, and the results have been such as to satisfy him. Under the view which he entertains of the nature of the affection,—that the irregularity of nervous action is induced by the withdrawal of an accustomed stimulus, and that the recuperative

powers are, generally, entirely sufficient to bring about the necessary equalization,—he has treated the mass of the cases which have fallen under his care, without either excitants proper, or opiates. In the first instance, an emetic has been given at times, for the reasons above stated; and, afterwards, the patient has been kept in a state of tranquillity in his chamber—the intrusion of too much light and noise being prevented—and, where the stomach would retain it, gently nutritious and easily digestible diet has been prescribed; the bowels have been kept open by gentle cathartics; and this has comprised the essential part of the treatment. In time, the hallucinations have disappeared, sleep has returned, and entire restoration supervened.

Under the idea, so generally prevalent, that the patient will sink unless stimulants or opium are given, if the attack be severe, the physician is apt to become alarmed, and to fly to those agents; but, should he persevere, he will find that his fears are groundless, and he will be encouraged in his course, when he reflects that, by administering either brandy or opium, he cannot infuse fresh vitality into his patient, and can only act on the excitability that is already present in the tissues. In the female lunatic asylum of the Philadelphia Hospital, the course here recommended has been advised, during the author's term of attendance as one of the physicians to the establishment, and where it has been carried out, the general result has been satisfactory, in more respects than one. It has, in the first place, restored the individual to health—not, perhaps, as rapidly as either brandy or opium, but more permanently. The term "restoration to health" is hardly, indeed, applicable to the change effected by the former remedy: the patient is merely placed in the condition in which he was before the stimulus was withdrawn; and, as he was restored by the brandy, he is apt—as before remarked—to regard it as indispensable to his healthy condition. In the "total abstinence" plan, however, the habit of drinking is broken in upon, and even if it should require a short time longer to restore the individual, there is the consolatory reflection, that delay is not useless; as every day's privation of the wonted stimulus diminishes the feeling of necessity, and the desire for it. One evidence of the good effect of the course is, that they who are dismissed cured, rarely, or never, return to the wards. This is an observation that has been made at the Philadelphia Hospital, and as it concerns paupers, it is probable, that the cures are real and permanent, for were it otherwise, they would, on subsequent attacks, be compelled, in their destitution, to seek the wards of the same excellent charity.

Under this eclectic course, it may be advisable, however, in certain cases, to administer both excitants and opiates. Where a person has been accustomed for years to the daily use of large quantities of alcohol, the nutritive functions totter under the irregular innervation, and the recuperative powers seem to be insufficient to restore the balance of nervous action. These cases are, however, uncommon. In like manner, where sleep has not recurred, after a continuance for some days of the plan above devised, a full dose of opium,—two or three grains, in the form of a

soft pill,—frequently forms an excellent adjuvant. There are cases, too, in which the irritability of the stomach is so great, that no food or medicine can be retained, and the patient becomes exhausted by the irritation. A blister, applied over the pit of the stomach, and the blistered surface sprinkled with sulphate or acetate of morphia, (two to four grains at a time,) may allay the vomiting, after which such internal management may be adopted as the case may seem to demand.

Dr. M. Hall remarks, that "it becomes a serious question, whether any stimuli should be allowed" in delirium tremens. Our observation and reflection are, in the main, in favour of the negative; and the remark is applicable to the various excitant antispasmodics that are wholly trusted to by some, because the disease is characterized by tremors. All these "antispasmodics"—*assafoetida*, *castor*, &c.—are, like *capsicum*, mere stimulants. They are not possessed of any specific power over the disease, and are never employed by the writer, unless he is desirous of exciting a new nervous impression on the gustatory nerves, and on the nerves distributed to the lining membrane of the stomach. The same may be said of the cold shower-bath, or *douche*. The shock, or new impression, made by it, is at times salutary, but some discrimination is needed in regard to its application to those whose powers are greatly prostrated.

Admitting, then, that there may be cases which demand something more than the expectant or eclectic treatment, these cases are certainly small in number; and a careful classification, by separating those who are considered to require imperiously the use of stimulants from those who do not, cannot fail to lead to results in the highest degree satisfactory to the philanthropist: first of all, by preventing the indiscriminate treatment by alcohol adopted by many; and secondly,—as a consequence of this,—by leading to a more extensive reformation in the patients themselves. One of the writer's colleagues in the Philadelphia Hospital, Dr. Gerhard, is an energetic supporter of the method of treating the generality of cases by the free exhibition of alcoholic liquors, and, in support of it, cites the results observed in the men's wards under his care, from October 12th, 1839, to October 12th, 1840. Of 162 cases of decided delirium tremens, 87 were admitted in the first stage; 73 in the second; and two in the third: 160 cases recovered, and one remained convalescent, who is since well. "One, only, proved fatal; the patient was admitted in the third stage of the disease, and died in a few hours after his entrance; he had been treated with opium; and a box of pills, which he was taking, was sent to the hospital with him. Of course," adds Dr. Gerhard, "this apparent exception confirms the general conclusion, that the disease terminates favourably in every instance when treated according to the method recommended." Any inference, however, from a single year's observation, may be fallacious; and especially may it be questioned, when the results of a similar treatment adopted by the same observer and by others had been previously less markedly favourable. It is a well-known fact, that in certain seasons and years diseases are more severe than in others; and the

circumstance, that of the 162 cases of delirium tremens, referred to by Dr. Gerhard as having been admitted in the year ending October, 1840, only two are classed in the third stage, sufficiently exhibits, that the disease must have been unusually mild. The writer has now before him a statistical account of the Women's Lunatic Asylum, at the Philadelphia Hospital, for the years 1840 and 1841, which is under the author's charge during the six months, commencing on the first of November, and ending on the first of May; and was, at that time, under his colleague, Dr. Pennoek, for the other part of the year. It may be proper to add, that from November 1st, 1841, to May 1st, 1842, not a drop of alcoholic liquor was used in the treatment of delirium tremens in the Women's Asylum, although some severe cases in the third stage occurred, which, notwithstanding, terminated most satisfactorily.

Patients treated during the years 1840-41.

	Cases admitted.	Cured.	Died.
Intoxication,	44	44	0
Delirium tremens—			
1st stage, 55	55	55	0
2d stage, 19	19	19	0
3d stage, 10	10	9	1

The fatal case was not seen by the author. The patient died the morning after her admission, and had been treated in the city for nearly a week previously. It cannot consequently be considered, that the value of the treatment has been settled "upon a more definite basis than has yet been done." The investigations ought to be continued through a succession of years; the different methods of treatment be compared extensively, and under circumstances as nearly identical as possible, before any such conclusion can be considered established. Moreover, the results obtained by Dr. Gerhard,—successful as they were,—are not more so than those recorded by an observer already cited, who places great reliance on the treatment by emetics. In a report, made by Dr. Klapp, he states, that of 51 cases, all but one were cured without the use of a grain of opium, or a drop of alcoholic drink of any description;—the unsuccessful case died of epilepsy.

ROBLEY DUNGLISON.]

[DENGUE. This singular name for a disease,—according to Dr. Dickson, of Charleston, whose essay (on Dengue, *Bell's Med. Library*, for 1839) has furnished the main material for every thing since written on the subject,—was derived from the English negroes of the Island of St. Thomas, where the disease prevailed, who called it the "Dandy Fever," owing to the stiff, affected gait induced in those labouring under it. When the disease occurred in Cuba, the word "Dandy" was corrupted in Spanish pronunciation into "Dunga," or "Dengue," by which it was known in the southern states. It first made its appearance in the Caribbean Islands in 1827, whence it spread over the West Indies, and in the following year to the southern coast of the United States. It prevailed in New Orleans in May and June; and in July and August affected very severely the inhabitants of Charleston; reaching Savannah in September and October. At the close of the year, it became gradually extinct, and has never since recurred. "In its brief dura-

tion," as remarked by Dr. Dickson, (*op. cit.* p. 6,) "in the suddenness of its appearance, in the rapidity of its spread, and in its total subsequent extinction, offering a striking resemblance to the *Black Death* of the fourteenth century, and the *Sweating Sickness* of the sixteenth, and several other shapes of pestilence, which have at different points of time arisen and died away, scattering among the nations horror and affright." "Happily, however," he adds, "as the record will show, it was much unlike these plagues in proportional mortality; bringing in its train infinitely less of danger and of death than of mere suffering."

Diagnosis.—The disease was generally ushered in by febrile symptoms of an inflammatory character, accompanied by a painful affection of the joints and muscles. On the second or third day, the fever declined, and with it the articular pain,—the attack terminating in a copious perspiration, occasionally attended with a rash or miliary eruption, which was esteemed, however, as only an incidental symptom. On the third or fourth day, the fever having in the meantime intermitted, more or less gastric disorder appeared, and on the fifth or sixth, a cutaneous eruption, which resembled scarlatina more than measles, but was less confluent than either of those affections, and consisted of minute florid red papule, slightly elevated, and distributed in irregularly shaped patches, appearing first upon the face and trunk, and spreading to the extremities. On the full development of the eruption, a second febrile exacerbation, with severe arthritic and muscular pains occurred. After two or three days' duration, the eruption gradually disappeared, with some desquamation of the cuticle. In some cases, the lymphatic ganglions of the neck, groins, and axilla remained swelled for a long period.

Of all the symptoms the affection of the joints was most tenacious and troublesome, adhering for weeks to some, and constituting a sort of permanent lameness. A sore mouth was a frequent symptom, and in one or two instances there was pretty severe glossitis.

In regard to the pathology of Dengue, there has been difference of sentiment. Dr. Dickson, (*op. cit.* p. 8,) classes it among the exanthemata; whilst the union of an eruptive fever with an inflammatory affection of the joints gave occasion to its names, *scarlatina rheumatica*, *exanthematis arthrosia*, and *eruptive articular* or *rheumatic fever*.

Causes.—Opinions have varied on this matter. Dr. Dickson is disposed to regard it as contagious. Drs. Osgood and Lehman, who saw it in Cuba, seem disposed to regard it as the ordinary fever of that region, under certain peculiarities of circumstances not well explained; and Dr. Waring, of Savannah, dwells upon its close analogy with the *break-bone fever* of 1826, and the epidemic bilious remittent fever of 1827 in that city. Still closer, according to Dr. Dickson, (*op. cit.* p. 11,) are the points of similarity which may be found in the history of the *break-bone fever* or remittent described by Dr. Rush as prevailing in Philadelphia, in the summer and autumn of 1780, and the epidemic of Calcutta and Berhampore, portrayed by Dr. Mellis in 1824-5.

The prognosis was exceedingly favourable. Perhaps no form of disease is known, in which the

proportion of deaths was so small compared with the numbers attacked. The aged were most severely handled,—remaining frequently infirm and debilitated, with languor and emaciation. In the intemperate it served to usher in formidable paroxysms of delirium tremens. When it did prove fatal, it appeared to be owing to complications.

Treatment.—The lancet was generally found necessary during the inflammatory period, with cathartics and antiphlogistics. Anodynes were likewise needed to relieve the violence of the pain.

ROBLEY DUNGLISON.]

DENTITION, DISORDERS OF. Under this head we shall endeavour to collect, not all the affections which hereditary errors and popular prejudice have marshalled under it, but such as careful and unbiassed observation has demonstrated to be occasionally induced by the process of cutting the teeth. By adhering to this resolution, a subject, once of interminable length and exaggerated importance, may be brought within comparatively narrow bounds, and if it be curtailed somewhat of its mysterious interest, it will not, we trust, lose in respect of practical utility.

The operations of nature are usually conducted in so skilful and complete a manner as should inspire all reasonable minds with large confidence in her powers, and lead them strongly to doubt all those hypotheses which would make disease a necessary adjunct to the evolution of our corporeal frame. That artificial modes of life, on the other hand, together with injudicious management, an excess of nutriment, with deficient exercise, impure air, and the other causes which tend to derange the general health, must greatly increase the difficulty and danger of the process of dentition, is indubitable; but that the mortality fairly traceable to it should, under any circumstances, have been rated so high as one-tenth and even one-sixth of all the children who undergo it, cannot fail to excite our surprise.

Children, as well as adults, are liable to numerous diseases of the three great cavities; but the difficulty of accurately recognizing them in early infancy too frequently causes their true nature to be overlooked, and disorders which are really idiopathic to be considered merely sympathetic affections depending on the process of teething.

Dentition, though often difficult and painful, is not in itself, properly speaking, a disease; yet the excitement which it produces is favourable to the development of such complaints as there exists a tendency to at this time of life. It is indeed the most critical period of childhood, and the super-vention of any serious disease, as small-pox, measles, &c., during its progress, is, from the increased sensibility of the whole system, attended with more than ordinary danger.

The first Dentition.—The rapidity with which the first set of teeth is developed necessarily causes a considerable determination of blood to the head, a circumstance which assists us in explaining many of the morbid tendencies which at this time occur. The rapid evolution which the brain, also, is at this period undergoing, concurs in a still more powerful degree to heighten the nervous susceptibility. This stage of existence is, indeed, remarkably characterized by a ten-

dency to cerebral affections; and diseases of the chest, abdomen, and other parts, often become complicated with them, or towards their termination merge into them. The irritable constitution and extensive sympathies which distinguish infancy, help us to account for the severity of the symptoms which sometimes occur from teething. As the child grows older, though the local affection may be equally violent, the intensity of the constitutional effects is generally much diminished, and accordingly we find that the cutting of the large double teeth occasionally gives rise to much less disturbance than that of the smaller teeth which preceded them.

Any unusual obstacle to the coming forward of the teeth, such as may be caused by a disproportion between their rate of development and that of the jaw; or even their too rapid progress and the consequent appearance of several of them simultaneously, must greatly augment the disturbance produced by this process.

The rudiments of the teeth are visible in the fœtus about the second or third month. As they increase in size, they are found to consist of a double membranous sac, from the bottom of which rises a pulp composed of a vascular and nervous substance, and surrounded by a colourless fluid of a mucilaginous consistence. This fluid is gradually absorbed as the pulp enlarges, and ossific matter becomes visible on the summit of the latter about the end of the third month. The enamel is subsequently formed, but whether by deposition from the fluid, or by secretion from the inner and vascular membrane of the sac, is a disputed point. The jaw at first presents only a channel along its edge; but by the growth of transverse bony septa, this is subdivided into cells, and the alveoli are thus formed. The germs of most of the permanent teeth are visible even in the fœtus, and are situated behind and below the milk teeth.

At the period of birth the ossification of the teeth is already far advanced, the crowns of the incisors being usually completed, and a considerable part of those of the double teeth formed. The ossification of their roots is a subsequent process, and in proportion as it advances, and as the alveoli become developed, the crown of the tooth is propelled towards the surface of the gum, and by the gradual absorption of this, and of the apex of its own enveloping sac, at length makes its appearance externally. The pressure on the membrane and gums, and the consequent irritation which accompanies this stage of the process, give rise to the painful symptoms of dentition.

The milk teeth are twenty in number: they usually appear in pairs, and those of the lower jaw generally precede the corresponding ones of the upper. They succeed each other commonly in the following order: first, the middle incisors; next, the lateral incisors; then either the canine teeth or the anterior molars,—perhaps more frequently the latter,—(but not invariably so, as M. Serres would have us believe;) and lastly the posterior molars.

The first incisor is generally cut about the sixth or seventh month, although occasionally not for many months later; the canine teeth commonly appear about the fifteenth month; and the poste-

for molars at various periods from the twentieth to the thirtieth. Thus, the whole period occupied by the first dentition may be estimated at from a year and a half to two years.

Such is the usual process of dentition; but it varies considerably in different individuals, both as to its whole duration, and as to the periods and order in which the teeth make their appearance. In scrofulous children, according to Gardien, the first incisors are occasionally cut so early as the third or fourth month; but such teeth are apt to decay and soon drop out. Underwood, on the other hand, has known weakly and rachitic children to be still without a tooth at twenty-two months old; and in such subjects analogy would certainly lead us to expect the ossification of the teeth to be tardy and imperfect. The premature and rapid development of the teeth has occasionally appeared to Guersent to be, not the effect, but the exciting cause of rachitis and tubercles: and, in general, it may be stated that the greater the number of teeth coming forward simultaneously, the greater the danger: those who have them late usually suffer least.

Numerous instances are on record of children who were born with some of their teeth already cut; of which Richard III., Louis XIV., and Mirabeau, were notable examples. In the case of Louis it was brought forward, but fallaciously, as an argument to establish his legitimacy, on which the lateness of his posthumous birth had thrown suspicion. Such premature dentition is neither a proof of protracted pregnancy, nor yet of a strong constitution in the infant, as it has been observed that such children are often unusually small, and most frequently die early. Indubitable instances are mentioned by authors, of individuals who never had any teeth: Borelli knew a woman of sixty years of age in this predicament: certain diseases of the jaw affecting the germs of the teeth may be occasionally the cause of this singular phenomenon. Soëmmering and Fox each saw a case where several of the teeth were consolidated into one mass; and we have met with a similar instance in the Museum at Leipzig, of two incisors grown together by their crowns, whilst the roots are separate.* Such abnormal appearances depend, no doubt, on the deficient evolution of the alveolar septa.

The natural symptoms of dentition in its mild form are an increased flow of saliva, with swelling and heat of the gums, and occasionally flushing of the cheeks. The child frequently thrusts its fingers, or any thing within its grasp, into its mouth. Its thirst seems to be increased, for it takes the breast more frequently, though, from the tender state of the gums, for shorter periods than usual. It is more fretful and restless, and sudden fits of crying and occasional starting from sleep, with a slight tendency to vomiting and diarrhoea, are not uncommon. Many of these symptoms often precede the appearance of the

tooth by several weeks, and indicate an increased activity in the process of ossification and development, or what in common language is called breeding the teeth. In such cases the symptoms subside in a few days, to recur again when the tooth approaches the surface of the gum. In the first period the pressure of corals and other hard substances on the gum seems to be agreeable, by numbing the sensibility and dulling the pain. A better form than that of the ordinary coral is an ivory ring, as it obviates the danger of its being thrust into the eyes or nose. Rousseau, in his *Emilius*, objects to the use of hard substances for this purpose, and refers us to the instinct of the young of other animals, which leads them to exercise their budding teeth, not on bone or stones, but on softer substances, on which they can make some impression. In accordance with this view a stick of marsh-mallows or of liquorice root, a piece of wax-candle or a crust of bread, have been recommended instead of the coral; and in France they often dip them into honey or a sweet decoction of barley, in order to render them more agreeable to the child, and more relaxant to the gums. In some parts of Germany we frequently see infants sucking a small bag containing a mixture of sugar and spices, which is given to them whenever they are fretful or uneasy. It re-acts sufficiently on the gums, and certainly seems a very successful expedient for occupying the child and keeping it quiet: it thus saves the nurse some trouble; but the injury which the constant use of these sweet and stimulant ingredients must do to the stomach, renders their employment very objectionable.

Gentle friction of the gums by the finger of the nurse is pleasing to the infant, and seems to have some effect in allaying irritation and altering the mode of the sensibility.

Pain appears to be the chief cause of all the morbid sympathies accompanying dentition, and is attributable partly to pressure on the membranous sac and on the gum, and partly, or, as some think, principally, to the pressure made by the root of the tooth on the dental nerves.

In feeble and delicate children dentition is usually, as we should naturally expect, more tedious and difficult than in the healthy and robust; but to this there are numerous exceptions; and it is certain that when disorder does occur in the latter, they suffer much more severely, and are more apt to be cut off suddenly by superinduced inflammatory affections, as was long ago remarked by Hippocrates. Puny infants, on the contrary, are more prone to a wasting diarrhoea and marasmus; and those reared in a crowded city generally suffer much more than those who have been brought up in the healthy air of the country. In a word, the two extremes of debility and high health, or rather that appearance of it which is induced by over-feeding, are both exposed, and nearly in an equal degree, to danger;—the former from a low wasting fever and bowel complaints; the latter from acute fever, determination of blood to the head, and convulsions. Those who have asserted that robust children always suffer most, have perhaps been misled by external appearances, forgetting that every the slightest change

* In the same museum, which is very rich in preparations illustrating malformation and diseases of the teeth, there are examples of ankylosis of the teeth with the jaw, occurring in rachitic subjects; and others exemplifying the fragility of these organs in individuals of a similar constitution, and explaining their consequent liability to break in extraction.

of condition in the fat and florid child will be more obvious and striking to the eye, than in one which was already pallid and thin.

The management of infants during teething, when the process is going on in a favourable manner, is very simple, and rarely calls for the interference of the physician. The child should be much in the open air, and well exercised, and the bowels kept free. The employment of the cold-bath or cold sponging daily, followed by gentle friction over the surface of the body, is very useful; and all means should be taken to support the tone of the system at a just medium. The breast should be given to it often, but not long at a time, and thus the attendant thirst will be quenched, and the gums kept moist and relaxed, and their irritation soothed, without the stomach being overloaded. The health and diet of the nurse should at this period be particularly attended to, and all stimulant food and drinks avoided.

Dr. John Clarke, in his Commentaries on the Diseases of Children, ascribes most of the disorders which accompany dentition to over-feeding and consequent plethora; to improper kinds of food, which produce irritation; and to keeping the head too warm. He asserts that coolness of the head, and washing it daily with cold water, renders children much less liable to illness during this period. Spontaneous salivation and moderately lax bowels are always to be considered favourable, as they tend materially to diminish irritation; and when absent, their place should be supplied by gentle aperients, especially in the case of plethoric children, or those with cutaneous eruptions.

[It has been a question, whether, during the irritation of teething, when the child is desirous of conveying everything to the mouth, hard substances should be permitted to press upon the gums. It is a common custom to allow the child the use of a piece of coral, or of sealing-wax, or what is preferable—inasmuch as it cannot be forced into the mouth and injure the soft parts of that cavity—an ivory ring. Some of the French writers discard all such substances, but without much propriety. If the gums be very tender, the child will not use them; and, if pressing the gums upon them should afford relief, there appears to be no good reason why their use should be forbidden, as the pressure cannot fail to aid the absorption of the gum. It has been suggested, as a good plan, to allow the child the use of a small wax candle, a stick of liquorice root, or a crust of bread. The first of these may be unobjectionable; but the liquorice root may load the stomach with mucilaginous saccharine matter, if allowed too freely; and the crust of bread may excite alarm, by the softened portions getting into the glottis, and producing symptoms of strangling. The physician, however, is not often consulted on these points; the whole matter being generally regulated by the parent or nurse. (See the writer's *Practice of Medicine*, 2d edit. i. 41.)]

When dentition is difficult and tedious, the treatment is more complicated, and consists in allaying local irritation, moderating urgent symptomatic affections, and when protracted and productive of much exhaustion, in supporting the general strength. But, in order to treat of this part of our subject more satisfactorily, we shall

divide the phenomena of difficult dentition into the idiopathic or local, and the sympathetic or secondary. These latter might again be divided either according to their nature, into spasmodic and inflammatory; or according to the organ or texture which they affect; as this latter subdivision appears more conducive to accurate diagnosis, we mean to adopt it.

Of the local symptoms, or those occurring in or near the mouth, painful inflammation and swelling of the gum, which is hotter, of a deeper red than natural, and intolerant of the slightest pressure, are the most usual, and the cause of all the rest. There is often great determination of blood to the head, the cheeks being red, hot, and swollen, the eyes irritable and watery, the salivation profuse, and the salivary glands occasionally enlarged and painful. Aphthæ sometimes occupy the mouth and fauces, and abscesses have, in some rare cases, been observed at the root of the tongue. The symptomatic fever is often great, and is remarkable for its sudden rise and declension, intermitting and recurring frequently in the course of a few hours. The thirst is extreme, and the child is at one time restless and irritable, and at another heavy and oppressed. The sleep is broken, and the infant frequently awakens suddenly and in a fright from its short slumbers. The urinary secretion is usually much diminished, though cases do sometimes occur, as has been mentioned by Whytt, when it is increased, and in such the accompanying symptoms will generally be found to be more of a nervous than an inflammatory character.

As all these symptoms are induced by the painful tension of the gum, the most rational mode of attempting their relief is by freely lancing the swollen part. Of the practical utility and perfect safety of this operation, notwithstanding the prejudices which exist against it in some other countries, we have ample proof in its daily performance with impunity, and in the instant relief which it often affords to all the symptoms. To give it a chance of success it must be done effectually, and both the gum and the capsule of the tooth laid fairly open. An assistant holds the head of the infant firm, whilst the operator, with a gum lancet or a narrow bistoury having three-fourths of its blade guarded, separates the jaws, and keeping the tongue and cheek out of the way with the fingers of his left-hand, cuts down firmly in a longitudinal direction on the inflamed and swollen gum; and if it be a double tooth which is coming forward, he should convert the incision into a crucial one. In Paris they often dissect out the flaps, but this seems to be an unnecessary addition to the pain of the operation. The slight bleeding which occurs is highly beneficial, acting as a local depletion, and thus conspiring to take off tension. The fears of an excessive or debilitating loss of blood from this source, may be considered, as to all practical purposes, unfounded and chimerical. We do not usually recommend the performance of this operation till the tooth be already so far advanced that we can be pretty sure of succeeding in laying open the capsule: for slight scarifications of the gum can afford no effectual or permanent relief. Cases may, however, occur, where even the temporary ease which su-

perforical scarifications are capable of affording should not be renounced; but here we must take care to explain to the child's friends the object of their performance, else the speedy return of the symptoms and the non-appearance of the expected tooth may tend to bring the operation of lancing the gums, or our own skill, into disrepute. The old apprehension that the scars which ensue, oppose, by their hardness, the subsequent progress of the tooth, though repeated in one of the latest French works on the diseases of children, is quite groundless; for cicatrices, like all other new-formed parts, are, as Hunter long since pointed out, much more easily absorbed than the original structure. Slight ulcerations of the gum have in some rare instances succeeded to the incisions; but this is a very unusual occurrence, and may be generally prevented by taking care to have our lancets perfectly clean; they are, besides, of very little consequence, as they readily heal under slightly astringent applications. Both Underwood and Hamilton enumerate ulceration of the gums amongst the occasional effects of teething, and the former thinks they occur even more frequently in cases where lancing has not been performed.

When the pain, determination of blood to the head, and fever, persist after the gums have been freely lanced, laxatives, mild diaphoretics, the warm bath, and slightly stimulating pediluvia must be employed, and if these be insufficient, one or two leeches should be applied behind the ears. When by the above means the fever has been in some degree reduced, the bowels continuing free, if the pain be still very severe, the cautious use of anodynes, as a drop or two of tincture of opium, or minute doses of hyoscyamus, may be tried. But perhaps as a general rule, seeing that infants are so very susceptible of the influence of narcotics, their external use, in the form of anodyne frictions to the spine, is preferable. When very restless at night, the infant should be frequently taken up and carried about in an airy room: by the cool air and the nearly erect posture, the feverishness will be alleviated, and the tendency of blood to the head counteracted.

Such are the measures which modern experience has found the most effectual in moderating the pains of dentition. Very different was the practice of our forefathers, who, misled probably by the fanciful doctrine of signatures, were in the habit of applying to the gums specific ointments made of the brains of hares, or of the combs of cocks, which, as old Hartman would have us believe, "cause the production of teeth without difficulty and free from accidents." Whilst we smile at the credulity of former generations, we must not forget that the anodyne necklaces and other charms still in use in our own day are in no wise more trustworthy or less absurd.

With regard to the affections of distant organs occurring during teething, we must not forget that they may originate as primary or idiopathic diseases at this period as well as at any other. Still, after making every allowance on this score, certain disorders manifest themselves so much more frequently during this process, and often subside so rapidly on the appearance of a tooth, as to leave us no doubt with regard to their occasional connection with the business of dentition.

Of the disorders which may be thus called into action by the irritation of teething, very formidable lists have been made out by authors. The following is a specimen of these, and of the confused manner in which symptoms and diseases are often jumbled together: vomiting, anorexia, diarrhoea, cholera, costiveness, increased or diminished urine, urethral or vaginal discharge, with painful micturition; dry cough, dyspnoea, catarrh, pneumonia, spasmodic affections of the face, limbs, glottis, &c.; insomnia, agitation and fright on awaking, epilepsy, somnolence, stertor, coma, transient palsy of the arms and legs; ophthalmia, hydrocephalus, marasmus; eruptions, especially about the head and face, swellings of the hands and feet, enlargement of the cervical, femoral, and mesenteric glands, and other scrofulous affections.

From this enumeration it appears that the chylopoietic and respiratory organs, the brain and nervous system, the skin and the lymphatics, are the chief seats of the sympathetic affections occasionally induced by dentition.

Of these secondary affections, those of the mucous membranes are the most frequent, and they may be either inflammatory or not. Inflammation of the conjunctiva, of the mucous membrane of the air-passages and lungs, or of the stomach and intestines, will be characterized by the usual symptoms, and require the same kind of treatment as idiopathic inflammation of the same parts, though it will rarely be necessary to push it so far. Incision of the inflamed gums should always be premised, and will sometimes, without the employment of almost any other measures, be followed by the speedy resolution of the disease.

Far the greater number, however, of these affections are not truly inflammatory, but depend on a peculiar state of irritation kept up in these remote organs by sympathy with the inflamed gum. Such, usually, is the nature of the accompanying cough, vomiting, or diarrhoea. When the vomiting and purging are not attended with pain on pressure, redness of the tongue, loss of appetite, or great oppression and fever, we have no reason to believe in the existence of inflammation, either in the stomach or intestines. Such symptomatic vomiting may usually be restrained by diminishing the quantity or varying the quality of the child's milk or other food; and if there be evidence of excessive determination of blood to the head, by the application of one or two leeches behind the ears. Should it prove very obstinate, and debility, and loathing of food be induced by it, narcotic frictions and fomentations of the abdomen, and a small blister applied for three or four hours to the epigastrium or to the upper part of the spine, may be requisite.

In severe and protracted diarrhoea interfering with the sleep and nutrition, and accompanied by debility, emaciation, pallid skin, a dull eye, and sunken expression of countenance, in addition to some of the above measures, tonic and alterative aperients are called for, such as rhubarb combined with ipecacuanha or hydrargyrum cum creta. Absorbents will be necessary if there be acidity in the primæ viæ, which is a frequent symptom in the derangement of the digestive organs induced by teething, and is evidenced by griping and by green and sour-smelling stools. If the dis-

charges are of a bad quality, being fetid, blackish, or very pale, an occasional dose of calomel to modify the intestinal secretion should be exhibited. In very obstinate cases the cautious use of Dover's powder, opiates alone, or in combination with minute doses of calomel, and given at short intervals, or opiate enemata may be indispensable. But in the latter mode of exhibiting opium, especially in the case of children, we must never forget that its action is sometimes, as has been pointed out by Dupuytren, even more energetic than when given by the mouth. The diet must be particularly attended to, the nurse changed if her milk seem to disagree, and the strength supported by beef-tea, rice-milk, arrow-root, &c. In many of these cases, quinine in small doses will be found a very useful auxiliary. We are not advocates for the premature use of medicine in this affection: as on the one hand neglected diarrhœa is a frequent cause of death in dentition, and as on the other a lax state of the bowels has a great influence in moderating the dangers of this period, it requires a very nice discrimination on the part of the practitioner to know when to interfere. Perhaps no attempt should be made to check the intestinal secretion so long as the appetite, sleep, and strength continue unaffected. It is certain that bowel complaints, which would be thought very alarming at any other time, are often well borne when they depend merely on the irritation of teething. We should therefore, in most cases, content ourselves with watching their progress as long as they keep within the limits stated above.

Vomiting and purging often co-exist, and in their combination frequently constitute a very formidable affection. M. Cruveilhier has described, under the title *Maladie gastro-intestinale des enfans avec desorganization gelatiniforme*, a very violent and fatal disease of the stomach and intestines of this kind, which is characterized by excessive thirst, urgent vomiting, and frequent, very fetid, green stools, like chopped spinach. After repeated vomiting the child becomes cold, and falls occasionally into a state approaching to syncope. The pulse is slow and irregular; the intellectual faculties continue clear to the end. The infant is extremely irritable and cries incessantly, except whilst being carried about in the nurse's arms. A state of drowsiness and oppression supervenes, the face assumes a cadaverous appearance, and the eyes are half closed and turned up. The coldness of the body, and especially of the extremities, goes on rapidly increasing, and in the course of twenty-four or forty-eight hours, a state of extreme prostration and fatal collapse are sometimes induced. By a superficial observer this disease might be mistaken for a cerebral affection, as there is somnolence and screaming, with slowness and inequality of pulse in both; but in the peculiar disorder under consideration the somnolence is interrupted by the slightest touch, the sensibility of the skin is morbidly increased, the intellectual faculties are entire to the last moment, and the respiration is not unequal, as in disease of the brain. On dissection, the mucous membrane of the stomach, and generally that of the small and great intestines, is found in a state of softening, being reduced to a soft and disorganized

pulp, but without any appearance indicative of inflammation. Cruveilhier's treatment consisted in confining the diet entirely to milk, and giving even that in the very smallest quantities, together with baths and fractional doses of opium administered at short intervals, both by the mouth and in enemata. The chief causes of the disease seem to be improper food, premature weaning, and dentition. It may run on for many days, or even weeks, and when it proves fatal, terminates at last either by an acute attack or by gradual sinking. It is evidently closely allied to cholera morbus, and is in no degree an inflammatory affection.

M. Guersent, physician to the Children's Hospital at Paris, has given a description of the above disease, differing in some respects from that of Cruveilhier's. He remarks that this peculiar combination of vomiting and purging occurs only in young infants from three or four months old to the end of the period of dentition, and is most common when they are getting the canine and double teeth. The diarrhœa is extremely abundant, and the stools are sometimes yellow, but oftener green, like flocculi of confervæ floating in a transparent serous fluid. Vomiting is soon superadded, first of a serous fluid, and at a later period of a porraceous matter. A dry cough and irregular febrile exacerbations usually occur in this affection: the prostration of strength and emaciation are extreme. Towards the close, slight convulsive motions are observed, chiefly about the face and eyes. The voice becomes excessively feeble, the features become relaxed, and the child sinks at length either in a state of agitation or of extreme exhaustion, whilst the consciousness to surrounding objects continues unimpaired to the last. There are some varieties of the disease: thus the diarrhœa may precede the vomiting many days; or they may both commence nearly at the same moment, and the child then dies with symptoms of cholera in the space of three or four days, or occasionally even within twenty-four hours. The affection sometimes, however, assumes a more chronic form, lasting thirty or forty days; but here there are frequent suspensions and renewals of the symptoms. On dissection, the mucous membrane of the stomach and intestines has usually been found pale, colourless, and almost transparent, as if it had been macerated in water, and the mucous follicles are in their natural state. In some rare cases slight redness has been evident in the cœcum and colon, but this so seldom, that it could only be considered as a casual complication; and the same may, according to Guersent, who is here at variance with Cruveilhier, be said of the softening of the mucous membrane of the stomach and intestines, which forms no essential or constant part of the disease. The treatment which he has found to succeed best in this peculiar affection, as well as its morbid anatomy, tends to prove that it is much more nearly allied to cholera than to gastro-enteritis: this treatment consisted in the very lowest diet, mucilaginous drinks, emollient injections, fomentations and narcotic cataplasms. Leeches are almost always useless or injurious. As the disease advances, baths and the very cautious use of opiate enemata are proper; and when the prostration is ex

tre, sinapisms and blisters should be applied to the limbs, nucha, or abdomen. Tonics and stimulants have usually seemed to do harm. In the acute or cholera form it mostly proves fatal in spite of all kinds of treatment. It is here from opiates internally that we can alone expect any benefit.

Dr. Parrish, of Philadelphia, has described a spasmodic affection of the intestines, or a species of flatulent colic, which he thinks is often dependent on the irritation of teething. The belly swells up rapidly and becomes extremely tender to the touch, the child cries much, the muscles of the face and limbs are spasmodically contracted, and the stools are suspended. The only thing which gives relief is the expulsion of flatus, and the consequent reduction of the tympanitic state. The appropriate remedies, after lancing the gums, seem to be draughts or enemata, containing a few grains of assafoetida, and two or three drops of laudanum, friction of the abdomen and spine with an anodyne liniment, and the induction of a free state of the bowels by some gentle aperient, or a soap suppository. Mr. Parrish has recommended, as an immediate mode of relief, the extraction of the air from the rectum by means of a syringe.

Having already alluded to disorders of the chest, we shall here only add that a susceptibility to catarrhal, and even peripneumonic affections, seems to be occasionally induced by teething. When the presence of inflammation is indicated by fits of coughing so painful as to make the child cry, and by soreness of the chest, dyspnoea, anorexia, and feverishness, after lancing the gums, repeated purgatives, emetics, and diaphoretics will often afford much relief; but in severe cases leeches and blisters must never be omitted.

The dry nervous cough of irritation is, however, by far the most frequent species, and may occasionally be much alleviated by anodyne frictions of the spine and abdomen, though it often resists all treatment till after the tooth is cut, and then ceases spontaneously. Cough at this period seems sometimes to depend on an intermediate derangement of the digestive organs, as is indicated by the state of the tongue, tension of the abdomen, unnatural stools, and the absence of fever: here emetics and purgatives are the appropriate remedies.

Affections of the brain and nervous system may occur in every degree from a slight and passing determination of blood to those organs, up to the most violent irritation, congestion, or even inflammation. The pain in the gums keeps the nervous system in a state of constant excitement, which is favourable to the development of spasmodic affections.

When there exists considerable plethora and drowsiness, the use of purgatives and leeches, with blisters to the nape of the neck, is indispensable. On the other hand, a state of insomnia is occasionally induced; or the sleep is much interrupted, and the infant often awakes with a start, frightened and crying. This should never be overlooked by the physician, as it indicates a condition in which the occurrence of epilepsy or convulsions is by no means improbable. It seems sometimes to depend on cerebral congestion, and sometimes on derangement of the digestive organs,

though occasionally it is purely nervous; and according to whichever of these may be its cause, it will require the use either of leeches and purgatives, or of antispasmodics and warm baths.

Where much fever accompanies dentition, convulsions often occur, especially if the bowels be in a constipated state. Neither feeble and irritable, nor large and fine infants are exempt from their attacks: but the latter are the most apt to be cut off suddenly by them. It is with the protrusion of the anterior molars, or of the canine teeth, that they most frequently come on; and they are occasionally preceded by grinding of the teeth, trembling of the lips, and other premonitory symptoms. They are not always so dangerous as is commonly imagined, and are least so when confined to spasmodic motions of the eyes, face, and arms. But if, on the other hand, the fits are very general and violent, and succeed each other rapidly, they are then always very alarming. They occasionally terminate in apoplexy or paralysis. As very formidable convulsions have been known to cease immediately on the gums being lanced, this operation should never be neglected where they appear swollen and painful. Tepid baths, leeches, purgatives, narcotics, and antispasmodics, are severally useful in different states of the system. Thus, if pain be the predominant symptom, we should avail ourselves of the soothing influence of tepid baths; if the sleep be lost, the cautious use of narcotics will be justifiable, provided there be no fever; otherwise, and especially if the child be plethoric, purgatives and leeches must be premised. In weakly children, assafoetida and some other medicines of the antispasmodic class have been occasionally found useful. Sprinkling cold water in the child's face while in the bath will often cut short the fit; and when the recurrence of the disease is very frequent, an issue at the back of the neck, or the production of an artificial eruption, is to be recommended. (See CONVULSIONS, INFANTILE.) Underwood speaks of a transient palsy of the arms and legs occurring as each tooth is coming out, and which does not require any particular treatment beyond attention to the gums and to the bowels. The paralysis after convulsions is often permanent and hopeless: leeches and counter-irritation to the spine should, however, have a trial in such cases.

Of the convulsive affections occurring during dentition, one of the most formidable is *spasm of the glottis*, sometimes, but improperly, termed spasmodic or chronic croup. Dr. John Clarke has described it under the title of "*a peculiar Convulsion of Infant Children*;" and it has also been noticed by Dr. Hamilton, of Edinburgh, and Dr. Cheyne, of Dublin. Dr. Monro has alluded to it where he speaks of a peculiar species of hydrocephalus, attended with spasm of the glottis. It has been written on by Mr. Pretty, in the Medical and Physical Journal, under the name of *cerebral croup*, and has been described, in France, by M. Guersent, under the title *Pseudo-croup nerveux*, and still better by Gardien, under that of *Spasme du thorax et de la glotte*; and by Richter, Raimann, Schmalz, Wiemann, &c. in Germany. But the latest, and much the most satisfactory account of this disease is that by Dr. Marsh, in his paper in the Dublin Hospital Re

ports, vol. v. to which, and also to the article *GLOTTIS, SPASM OF*, in the present work, the reader is referred.

A peculiar swelling of the hands and feet has been mentioned by Underwood as an occasional symptom of painful dentition. It was considered by him as in itself, if not decidedly beneficial, like a slight diarrhœa, at least unimportant, as he found it to cease spontaneously when the tooth came up. If any feverishness co-existed, he attributed it not so much to those tumours, as to the casual coincidence of derangement in the bowels or some other organ.

Dr. Kellie, of Leith, who has described this singular affection more at large, asserts that though it be sometimes thus slight and transient, yet in many cases it has appeared to constitute a part of a disease of a more striking and serious nature. The swelling, which is situated on the back of the hand and on the dorsum of the foot, has a considerable degree of roundness and elevation, such as might be produced by a blow. It seems to arise suddenly, and is of a mottled, somewhat livid, or purplish colour, feeling rather cold, and exhibiting no sign of inflammation or increased sensibility. It is firm, and does not pit on pressure. It will occasionally continue for weeks, gradually becoming softer or assuming somewhat of a leucophlegmatic hue, to which occasionally, but very rarely, œdema of the whole limb has been known to supervene. Usually, however, it disappears more suddenly, without passing into the leucophlegmatic stage. It is generally connected with a symptom of a more formidable character than itself, viz., the spastic contraction of the flexors of the thumb and toes. The thumb is rigidly contracted and permanently bent downwards, and laid flat upon the palm of the hand; and in like manner the toes are bent down to the plantar aspect of the foot. The carpus is also sometimes drawn down by its flexors, so as to increase the sphericity of the metacarpal bones. The child is peevish and restless, but does not seem to suffer much pain in the affected parts. In some cases only there is pyrexia towards the evening; the bowels are commonly torpid, and the stools procured by laxatives are fetid, clayey, green, sour, and slimy. Its duration is from a few days to several weeks, and its termination usually favourable. General convulsions have, however, sometimes supervened; in one of Dr. Kellie's cases fever made its appearance, and two others died with what Dr. Armstrong calls symptoms of "hectic teething." It is a disease of the epoch of dentition, and as the symptoms have occasionally ceased immediately after the cutting of a tooth, we may conclude that teething is, at times at least, its exciting cause. The treatment recommended by Dr. Kellie consists in scarifying the gums, removing plethora if it exist, restraining vascular excitement and local determination, and regulating the alvine discharges.

Of the cutaneous eruptions connected with dentition little need be said, as they seem, by their derivative action, like a lax state of the bowels, to be rather useful than otherwise. The principal varieties are, an erythematous efflorescence behind the ears (*intertrigo*); *crusta lactea*; the different varieties of *strophulus* (the red gum or tooth-rash

of the vulgar); small *phlyctenæ*, like those of a burn, and evanescent red spots appearing upon the face and other parts. But as most of these may occur also quite independently of dentition, we can be certain of the connexion in those cases only when they make their appearance, or undergo an exacerbation, just before the cutting of a tooth, and become milder or disappear after it. Should they run to such an extent as to become troublesome, laxatives are the best means of keeping them down. During their existence exposure to cold should always be avoided.

Disease of the lymphatic system is an occasional result of the debility often induced by teething, and is manifested in the enlargement of the cervical, inguinal, and mesenteric glands, &c. In these, as in all other scrofulous affections, our chief attention should be turned towards the improvement of the general health by good air, nutritive food, regular exercise, attention to the digestive organs, and other measures to which we have alluded in a preceding paragraph.

The Second Dentition.—The milk-teeth generally begin to fall out about the seventh year, or somewhat earlier, and are replaced in the course of five or six years by the permanent teeth, which usually come up with little or no pain. Cases do, however, occasionally occur in which there is considerable local irritation, and consequent enlargement of the glands about the jaw and neck, ophthalmia, cutaneous eruptions, &c. The wisdom-teeth, which are cut about the twenty-seventh year, or occasionally much later, are often productive of considerable uneasiness and swelling. The pain being sometimes periodically intermittent, has been mistaken for an aguish or rheumatic affection, and treated with bark and similar medicines. Cases are mentioned where, from the imperfect development of the jaw, there has not been room enough for the *dentis sapientiæ* to come easily forward; and hence much pain and swelling of the face, together with violent headach, inflammation of the eyes, pain in the ear, and abscess near the angle of the jaw, have resulted. Free incision of the gum, or even extraction of a tooth, may, in some of these cases, be necessary, along with leeches, fomentations, and poultices to the external swelling.

The second set of teeth occasionally come up before the first have fallen out, and we have then the singular appearance of a double row of teeth: on the other hand, there are instances on record of individuals who did not begin to get the second set till they were forty or fifty years of age. The cases in which very old persons have cut a third set of teeth (See *Ed. Med. Comment.* vol. iii.) are so extremely rare, that we only allude to them because their development has been sometimes accompanied with excruciating pain and other circumstances, which might be extremely puzzling to the practitioner if not aware of the possibility of such an occurrence.

W. B. Joy.

DERIVATION (from *derivare*). This term may be received in two acceptations: it may apply to an effect produced on any morbid condition of parts by an artificial irritation or determination elsewhere, which removes or diminishes the primary one; or to the removal or diminution of a

morbid condition, consequent on the occurrence of a new irritation or excitation of action *not* artificially produced. Thus when a blister is applied in a case of pneumonia, with relief of the pulmonary disease, we have an example of the first acceptance; and when a disease of the lungs subsides on the occurrence of a cutaneous eruption, or of a diarrhoea, we have an instance of the second. In either case the principal pathological phenomenon is the change of the seat of irritation or excitement.

The term *revulsion* is one better adapted to express this phenomenon, but it matters little which phrase we adopt. The older authors entered into many arguments respecting the difference between *revulsion* and *derivation*, but as their ideas on these subjects were founded on false physiological views, we shall pass them by here.

The circumstances under which *derivation*, as taken in its first acceptance, is observed, may be thus enumerated.

First, the application of agents to the two great surfaces of relation, namely, the skin and mucous membranes, calculated to irritate or merely increase the normal action of these tissues; and secondly, the use of stimulants calculated to excite the secretions of various of the parenchymatous organs. Under these heads may be enumerated all the irritating applications which we make to the skin, such as cantharides, ammonia, tartar emetic, &c., and also the use of friction and heat. When we employ purgatives to cure a dropsy, or a disease of the skin or of parenchymatous organs, when we use diaphoretics to relieve a mucous inflammation, or diuretics to remove serous effusions, we act on the derivative or revulsive system, and the remedies are in all cases derivatives or revulsives. In some of these cases, we cure or alleviate the original disease by the production of a new inflammation in the part acted on, as in the case of blistering; in others, the part acted on is not made the seat of a new inflammation, but its normal secretion is excited and increased, as in the case of warm bathing producing diaphoresis.

The second example of artificial derivation is the production of irritation in tissues deeper seated than the skin, but still exterior to the viscera. Of this, the use of setons and issues is an example.

But, as we have already shown, *derivation* or *revulsion* is often found to occur independently of any artificial excitation, and the consideration of this subject comes to be of the highest interest in medicine. As, however, it is more immediately connected with metastasis, we shall in this place merely sketch the leading physiological facts connected with this species of derivation. One of the most interesting of these is, that this *revulsion* often occurs between analogous tissues; thus, in cases of inflammation of the synovial membranes, the sudden subsidence of the disease is commonly followed by inflammation of some of the serous membranes, such as the pericardium, peritoneum, pleura, or arachnoid. Again, a patient has diarrhoea; this suddenly subsides and is succeeded by violent bronchitis; he has a disease of the skin, which is repressed, and the mucous membranes become engaged, or *vice versa*. But this rule is

by no means so general as to form a law in pathology, for we find very many instances of exception; for example, the occurrence of ascites after suppression of the perspiration, hemorrhage from the kidneys after the desquamation of measles; the alternation of catarrh and hemiplegia; of gout and gastro-enteritis, or bronchitis; of mania and oedema of the lower extremities.

We shall not here examine the relation of cause and effect in these examples of conversion of disease; it may suffice to remark, that in some cases the subsequent or secondary disease appears to arise from the cause so well illustrated by Broussais, namely, the predominance of the sympathetic over the primary irritation; while in others it seems to result from a morbid condition of the whole system, consequent on the subsidence or removal of some local irritation, which, from its chronic duration, has apparently become necessary for the proper balance of the constitution.

Two modes of *revulsion* are used in medicine. In the first, we endeavour to change the seat of irritation or excitement from the viscera to the surface; in the second, we change it from one viscus to another. The first may be called the exterior or peripheral *revulsion*; the second, the interior or visceral. To the first of these we shall in this article principally direct our attention.

The *modus operandi* and therapeutic application of the exterior derivatives are questions of great interest in medicine. In some cases the application of a blister to the surface is followed by great relief of the internal disease, while in others the reverse occurs. To determine the cases in which the favourable or unfavourable results may be reasonably expected, comes to be a great desideratum. Here experience is our chief guide. It has been long known that blisters will relieve local inflammation of the internal parts under three circumstances; *first*, where the disease is of the acute character, but modified in its intensity by active antiphlogistic measures; *secondly*, where it is acute, as respects the time, but occurring in cases where the powers of life are low, as in typhoid inflammations; and, *lastly*, in chronic diseases. In all these cases, the activity of the capillary circulation in the diseased part is weak, and *revulsion* taking place with ease, a rapid removal of the local disease is often the effect of our treatment. On the injurious effects of external revulsives in acute inflammations, before depletion is used, most authors are agreed. Rostan, in his *Clinical Medicine*, says, "Revulsions are generally contra-indicated in the early stage of acute diseases when there is fever and the subject is young and strong." The same author, in another place, says that although a derivative effect is often obtained, yet that in many cases excitation will follow the use of revulsives, and an effect directly contrary to that expected will be produced. Mr. Porter, in his "*Surgical Observations on the Diseases of the Larynx and Trachea*," expresses himself strongly against the use of blisters in acute laryngitis, particularly when applied to the neighbourhood of the part. He says, they cannot be resorted to at an early period without considerable risk of doing mischief. A case is related, where, in acute pneumonia, the application of a blister was followed by an aggravation

of the symptoms and death. On dissection, a portion of the surface of the lung, exactly corresponding to the size and shape of the blister, was found in a more advanced stage of inflammation than the remaining pulmonary tissue. Many other authors might be quoted to the same effect. Our own experience is decidedly in favour of these views. We have often seen a distinct exacerbation follow the application of a blister in the acute pneumonia, bronchitis, or gastro-enteritis of children, in cases where bloodletting was not used; and many medical friends have informed us of similar occurrences in their own practice. Even in a few chronic cases we have observed the same effect where local bleeding has not been premised.

We must, then, admit that external derivatives have two modes of action; the one derivative, the other directly stimulant on the diseased part. We find them, as we stated before, generally useful in three sets of cases, namely, acute inflammations where general and local bloodletting has been premised, typhoid inflammations, and chronic diseases; and it becomes probable that a *part* at least of their utility is owing to the direct stimulus conveyed to the capillaries of the diseased tissue. A state of these vessels, analogous to Andral's *asthenic hyperæmia*, in all probability exists, and we know that stimulation is often the best mode of removing this morbid condition. This will account for the injurious effects of external revulsives in acute cases before depletion has been used, and is not inconsistent with their good effects in cases of a different description. They are all essentially stimulants. If the irritability of the system is great, an increase of fever will be the result of the sympathetic irritation of a blister, and in this way the local inflammation will be aggravated. Whether the increase of the local disease be always owing to this cause, or whether it may occur without the intervention of sympathetic fever, are questions of difficulty, but happily not of great practical importance.

We often find, in cases of intense irritation of internal organs, that blisters will not vesicate the skin, but that, as soon as the disease has been modified, they will produce their usual effect. Can this be explained by supposing, that in consequence of the intense inward determination, the surface has lost a portion of its vitality? In such cases, the vesication of the surface is often not the cause, but the consequence of the diminution of diseased action.

The means generally employed to produce external revulsions are the application of blisters, sinapisms, or the tartar emetic ointment; and the use of setons, issues, the moxa, heat, and friction. In this country the most common mode is the application of blisters, either immediately over the diseased organ, or at some distance from it. Unpleasant consequences often follow even this simple proceeding; of which the principal are the infliction of great pain, the production of a too violent inflammation, and the occurrence of strangury. All these bad effects appear frequently to arise from the practice which commonly prevails of allowing the blister to remain on for twelve or even twenty-four hours; a mode of proceeding totally useless, and constantly injurious.

Dr. Leahy, the learned Professor of the Practice of Medicine in the School of Physic in Ireland, has long inveighed against this practice. His mode is to remove the blister as soon as decided pain is produced, although the part be not vesicated. Simple dressings are then applied; and free vesication subsequently occurs; and in the majority of cases none of the distressing effects alluded to are produced. We can speak from our own experience of the superior efficacy of this mode, and feel strongly disposed to believe that were it more constantly pursued, we would see fewer cases of the aggravation of internal disease from the use of blisters.

These views are also much insisted on by M. Bretonneau, in his *Traité de la Diphtherite*. His mode of using blisters is peculiarly elegant, being founded on the experiments of Robiquet, which show that the vesicating principle is soluble in fatty substances. A piece of extremely thin paper is inserted between the blister and skin, through which of course the oily solution penetrates. Many of the inconveniences of the common mode of blistering are avoided, such as the long-continued irritation that portions of the cantharides produce by sticking to the part; the unsightly marks which blisters leave, &c. &c. and M. Bretonneau states that during six years' practice in his hospital, there did not occur a single case of ischuria after blistering performed in this way.

Some practitioners, particularly on the Continent, prefer applying blisters always at some distance from the seat of disease; in this way, according to their opinion, avoiding the danger of direct stimulation. Facts are still wanting to enable us finally to determine on the relative merits of these two modes of proceeding; but if the use of a blister over a part affected with acute inflammation is avoided until its capillary irritation has been modified by antiphlogistic treatment, we believe that the practice will generally be found safe.

The use of the tartar emetic ointment, as recommended by Jenner, has now become very common. In some cases, however, it is productive of great distress, in consequence of the formation of large and angry pustules; a circumstance in most cases arising from the use of too great a quantity of the salt in forming the ointment. A drachm to the ounce of lard is the usual proportion; but if we employ a diminished quantity, the remedy will act much better, and frequently with little or no distress to the patient. From a scruple to half a drachm of the salt, finely pulverised, is generally sufficient; and in this way an extensive eruption of minute pustules will be produced, from which we have never seen any unpleasant consequences to follow. An extraordinary effect of this mode of counter-irritation has been several times observed, namely, the super-vention of violent irritation about the parts of generation. At first it was supposed that the irritating substance was directly conveyed to the parts by means of the patient's hands; but this opinion is untenable, as the eruption has occurred in cases where the greatest caution was used to prevent any direct conveyance of the ointment to the genitals. This circumstance is noted by Dr. Mackintosh, in his *Practice of Physic* and both

Dr. Graves and the writer of this article have had frequent opportunities of observing it in the Meath Hospital. In a case which occurred in private practice, the inflammation about the genitals in a young female was so severe as to threaten mortification. Another unpleasant result of this mode of counter-irritation is the occurrence of violent and obstinate vomiting, particularly where the ointment has been rubbed over the epigastric region.

We shall now proceed to consider the use of external revulsion in cases of visceral disease. Authors appear to agree as to the impropriety of using revulsives in cases of disease of the brain when it is acute, and particularly where bloodletting has not been premised; thus fully bearing out the doctrine which we have endeavoured to support in this article.

In diseases of the brain and spinal marrow, all the different modes of revulsion have been practised with great success. Indeed, with the exception of the first stage of acute irritations, it may be said that revulsives are of the highest utility in all cerebral diseases, whether functional or organic: where coma supervenes, and in chronic affections, the best results often follow this practice. Thus in all the forms of paralysis depending on disease of the brain and spinal marrow, the various revulsives have long been recognized as among our best remedies; and they may be often employed as prophylactics, as in cases where an apoplectic disposition decidedly exists, and where the life of the patient may be prolonged by the timely use of a seton in the neck.

Dr. Jenner, in his letter on the influence of artificial eruptions, speaks in the highest terms of the utility of the tartar emetic ointment in the cure of insanity, declaring that in all his cases (eighteen in number) this treatment succeeded in removing the disease. Dr. Burrows, however, is by no means so sanguine; but states that in cases where insanity has ensued on the subsidence of a cutaneous eruption, or is connected with gastric irritation, this treatment will ameliorate the symptoms. He prefers the use of the tartar emetic ointment to that of blisters.

In Lallemand's "Lettres sur l'Encéphale," a case is recorded highly illustrative of the effects of powerful revulsion under the most unfavourable circumstance. A patient, upwards of sixty years of age, became affected with symptoms of encephalitis, in consequence of an injury of the head. The prominent symptoms were stupor, paralysis with convulsions of the right arm, embarrassment of speech, and loss of memory. The circumstance of the injury of the head being unknown to his medical attendants, the case was considered as an example of idiopathic fever, until the tenth day, when the patient was seen by M. Lallemand for the first time. The patient had then frequent and long-continued fainting fits; the limbs on the right side were contracted, with complete paralysis of sensation; the eyelids closed, the eyes divergent and insensible to light; there was complete loss of hearing and intelligence; the body was covered with a cold sweat; the respiration frequent and stertorous; and the pulse imperceptible. In this desperate state, Lallemand applied boiling water to the legs of the patient. The first appli-

cation produced a sudden motion of the whole body; the left arm was agitated, the eyelids were raised, and the pulse became perceptible in the arm. In the course of half an hour the boiling water was applied to the thighs with still more remarkable effects: the face became red, and the pulse full and frequent. Ice was now applied to the head, and in two hours the sensibility was so much restored that the patient frequently attempted to remove the cold application. Under this treatment, with the occasional application of a few leeches to the head, the patient was nearly restored in the course of eight days; and in two months all paralysis had disappeared. The eschars produced by the boiling water were very deep, and suppurated abundantly, seven weeks elapsing before cicatrization took place. Dr. Mackintosh, in his Practice of Physic, details a case of severe cerebral affection in fever, where the best results followed a similar practice. In this case, however, neither paralysis nor coma had taken place.

In the employment of revulsives in diseases of the brain, it appears most proper to select for the place of stimulation some part remote from the cranium. In this way the action of the revulsive can be powerfully assisted by the application of cold to the head, as by the use of ice, or, what is still better, the cold affusion, used in the manner directed by Dr. Abercrombie.

We may here notice the practice of counter-irritation along the spinal column, as proposed by Mr. Teale for the cure of hysteric affections; and which, according to him, has been followed by the best effects. It would appear, however, that as yet a sufficient number of observations has not been made to establish the pathological views on which this practice is founded. Doubtless, cases of spinal irritation do occur where the use of revulsion may be followed by the best results. In veterinary practice we have known good effects obtained, in cases of tetanus, by the use of severe counter-irritation along the spinal column.

In diseases of the respiratory organs, whether of the mucous membrane, parenchyma, or serous investment, revulsions have long been employed by physicians. The same principles which guide us in the use of revulsives in diseases of the brain are found to apply here:—improper in the acute stage, and even dangerous when the irritation has not been reduced by antiphlogistic measures, they are found generally of the highest utility in cases where the lancet has been used, and where the inflammation is of an asthenic or chronic character. In simple acute laryngitis, the best authors agree as to the impropriety of using blisters to the anterior portion of the neck. Guersent and Porter express themselves most strongly on this subject; the former, however, admitting that they may be useful in the *asthenic croup*; but he prefers employing them at a distance from the affected part. Indeed, there are few diseases where so much caution should be used in any mode of treatment which would have a chance of increasing irritation; as we know that a momentary spasm of the glottis may suddenly extinguish life. In an irritable patient, then, we must be extremely cautious in the employment of the revulsive mode. But in chronic laryngitis we find the best effects from counter-irritation in the neighbourhood of the part;

repeated blistering, frictions with the tartar emetic ointment, and the use of the seton, being among our most successful modes of treatment in this obstinate disease.

The good effects of severe counter-irritation in a case of chronic laryngitis of long standing, and which threatened the life of the patient, were strikingly exemplified some time ago in the Meath Hospital. The symptoms were extremely urgent, and were not alleviated by local bleeding. Two blisters, of about two inches wide and five in length, were applied along the course of the sterno-mastoid muscles, and the vesicated surface sprinkled with finely powdered tartar emetic. A most severe counter-irritation was thus produced; the patient suffered extremely; but the laryngitis was completely removed, and we believe the cure was permanent.

In diseases of the lungs we find the same general principles equally to apply. We have seen many instances where the symptoms of acute pneumonia or pleuritis were clearly aggravated by the empirical use of blisters; but in the second state of acute bronchitis, in most of the forms of chronic catarrh, in hooping-cough, in hepatizations, or passive congestions of the lung, and in the advanced stages of pleurisy, the revulsive practice is almost always followed by the best effects. The utility of the same practice in cases of chronic phthisis is so well known that we need not comment on it here.

One of the most distressing circumstances in the progress of a case of hypertrophy of the heart, is the occasional increase of palpitations and præcordial distress: this is frequently relieved by the application of a blister; a circumstance which, combined with our knowledge of the efficacy of local bleeding in similar cases, adds greatly to the probable correctness of Andral's opinion, that in many such cases the cause of these symptoms is an irritation of the internal membrane of the heart.

In the examination of the effect of external revulsion in diseases of the digestive system, we must consider its employment in affections of the mucous and serous membranes. Broussais, in his *Phlegmasies Chroniques*, endeavours to establish that in inflammations of the mucous membrane, both acute and chronic, such practice is always improper, and that those cases of altered function which are relieved by vesication of the surface, are not in reality examples of inflammation of the mucous membrane. This assertion, however, appears too general; both analogy and experience lead to the conclusion that in acute gastro-enteritis the use of revulsives to the surface will be probably followed by bad consequences, but this is far from applying to the chronic affections, where we know that this practice is constantly productive of the best effects. In schirrus of the stomach, in chronic diarrhœa, or dysentery, in tabes mesenterica, the great utility of external revulsives has long been established; so that, as far as the affections of the gastro-intestinal mucous membrane are concerned, the general principle which we have been endeavouring to establish is also borne out. In point of fact, Broussais does not seem to be sufficiently aware of the utility of stimulation in the internal as well as the external chronic inflammations.

The same conclusions are to be drawn in the case of peritonitis. In the violent acute disease, and particularly before general and local bleeding has been freely premised, a blister often aggravates the symptoms; but in the chronic and asthenic forms of the disease, as in the low purperal peritonitis described by Dr. Cusack and Dr. Gooch, it is found that blistering the abdomen is often followed by the happiest results.

We are indebted to Mr. Crampton for the particulars of a remarkable case of chronic abdominal disease, where a powerful and extensive revulsion was followed by the greatest relief of symptoms. A lady, who had laboured under ovarian disease, with severe symptoms of chronic inflammation of the mucous membrane of the intestines, as evinced by diarrhœa, bloody stools, tenderness of the abdomen, and emaciation, was severely burned in consequence of her clothes taking fire; the neck, arms, and throat were the seats of the injury. On recovering from this accident, the greatest improvement became manifest in her general health; the bowels became regular, nutrition went on, the ovarian enlargement subsided greatly, and the patient has since enjoyed a state of good health which could never have been anticipated.

For information on the employment of revulsives in diseases of the urinary organs, and in affections of the generative system, we beg to refer to the articles on these subjects. We shall merely remark that many practitioners avoid the application of a blister to the loins in acute irritations of the kidney, such as nephritis or renal calculus, fearing that strangury would be certainly produced. We believe that this fear is quite unfounded, and that the application of a blister to the loins may be constantly had recourse to with the best effect in these cases. There is no evidence to show that strangury is more liable to be produced by a blister to the loins than to any other part; but it is almost certain that in the majority of cases the strangury is owing to the mismanagement of the blister.

The last class of affections in which we shall examine the utility of revulsives is that of fevers. Louis has investigated this subject with his usual precision, by comparing the effects of blisters in cases of typhoid fever which have proved fatal, and in those where recovery took place. In the first class, he found that the mean duration of the disease was not altered by the practice; that no effect, either upon the temperature of the body, or the state of the circulation, could be connected with the action of the blister; that in two-thirds of the cases the cerebral functions underwent no alteration; and that in the remaining third but a very small proportion presented alleviation of symptoms. The examination of the digestive functions showed the same results, so that he concludes that in his cases the action of blisters produced no effect, either on the duration of the disease or the progress of its symptoms. In those cases where recovery took place, he concludes that blisters had no appreciable effect on the disease, and that they perhaps but slightly retarded the convalescence: so that, in connecting these facts with the inconvenience of blisters, he holds

that they should be banished from the treatment of typhoid fever.

It is to be remarked, however, that in these cases the blisters were applied, not over the splanchnic cavities, but to the extremities; the conclusions therefore only apply to this particular mode, and afford no reason for banishing the use of blisters from the treatment of typhoid fever. We know, indeed, from experience, that in certain cases their utility is most remarkable. In the majority of cases of fever the attention of the physician is principally directed to remove inflammation or congestions in some of the great cavities, and revulsion is often the only mode left to him of accomplishing his object. Thus in certain cases of coma occurring at an advanced stage of the disease, the greatest advantage is derived from the application of a blister to the head. In catarrhal fever, when copious secretion sets in, and the powers of life are low, we have found, in the Meath Hospital, the most striking advantage from free blistering on the chest, and have never seen any unpleasant result. So, also, where pneumonia occurs in the course of a typhoid fever, the application of a blister, after depletory measures have been used, or where the skin is cool and the powers of re-action are slight, has been frequently successful in ameliorating or removing the disease. Our experience in the Meath Hospital leads us to the conclusion that, as far as the utility of blisters in fever is concerned, we may use them for the relief of the secondary inflammations which occur, with great benefit; always, however, acting on the principles which we have maintained in this article. [See the article *COUNTER-IRRITATION* for much information on this subject.]

WILLIAM STOKES.

DERIVATIVES. See DERIVATION.

DIABETES.—Some of the earlier writers on medicine have given different names to the disease which forms the subject of the present article. Thus it has been styled *diarrhœa urinosa*, *hydrops ad matulam*, *hyderus*, *dipsacus*, *morbus sitibundus*, *fluxus urine*, *nimia urine profusio*, *polyuria*.

Owing to the excessive secretion and frequent evacuation of urine in this affection, it has also been named *diabetes*, from the Greek word *διαβαίνω*, which signifies to pass through: and from the circumstance of the urine having generally a smell of honey, and a sweetish taste, the adjective *mellitus* has been employed to denote this character. M. Renaudin, in an able article on diabetes in the *Dictionnaire des Sciences Médicales*, and afterwards Dr. Prout, insist upon defining diabetes to be "a disease in which a saccharine state of the urine is the characteristic symptom," although the etymological import of the word extends to any affection accompanied with an immoderate discharge of the urinary secretion. It is not the best logic, however, to found a definition upon an hypothesis; and as there are several instances on record of patients dying under all the symptoms of diabetes, yet without the slightest indication of sugar in the urine, we cannot fairly dispose of these by assuming its presence in the latent state; for it may be latent in the most incidental case of hysterical enuresis, and then how could Drs.

Renaudin and Prout refuse the name of diabetes to this fortuitous symptom? We make no unfair extension of their hypothesis; and to speak truth, chemists have as yet discovered no good test of either sugar or urea when in small quantities, nor, were they perfect, ought medical men to take their results as defining disease. Diabetes, like every other malady, must not be defined by symptom *a* or symptom *b*, but by the aggregate and concatenation of the leading symptoms. Of these, immoderate excretion of urine and cachectic emaciation seem much more characteristic than sweetness, however general, and which it must be allowed is at times undistinguishable. All the modes of analysis hitherto devised for indicating the vegetable and animal oxides are extremely imperfect, especially when these are intermingled with other oxides; and the most delicate of them seem to consist, not in demonstrating the presence of these oxides themselves, but in generating new bodies, which are supposed to result from the re-union of the primary elements into which the former had been supposed to be reduced by their operation. In every genuine case of diabetes, however, Dr. Prout contends that a careful analysis of the urine will detect more or less saccharine matter, even when the sensible qualities of this fluid fail to point out the least saccharine impregnation; for, as Dr. Watt has observed, sugar may be present, but so covered with other substances that it cannot be at all detected by the taste.

Hippocrates seems to have been altogether ignorant of this affection, for we find no allusion to it in any of his writings; but Celsus, Galen, Aretæus, and Alexander Trallianus, have left us histories of diabetes. The description of it given by Aretæus is particularly clear and minute. These writers, however, looked upon the disease simply as an increased flow of urine, and as proceeding from renal irritation. Galen thought that this affection bore the same relation to the kidneys and bladder as the liliary does to the stomach and intestines. Aretæus considered it a colligation of the flesh and limbs into urine. He has observed, "that it has the usual urinary course, namely, the kidneys and bladder, for the patients never cease voiding their urine, but as from the openings of the water-ducts, the stream is perpetual." Trallianus adopted much the same view of the complaint. No further light seems to have been thrown upon the nature of diabetes until the time of Willis, who first pointed out the saccharine taste of diabetic urine. "The subjects of this affection," that able writer has remarked, "pass more urine than the whole quantity of fluids taken into the body; they have besides a constant thirst, and a slow kind of hectic fever always on them. It is very far from true, as some authors affirm, of the drink being again discharged with little or no alteration, for the urine in all that I have seen, (and I believe it will universally be the case,) differed not only from their drink, and from every other fluid in the animal body, but was like as if it had been mixed with honey or with sugar, and had a wonderfully sweet taste." Willis has ably investigated the principal phenomena of the complaint, and endeavoured to point out its seat; but he confesses his ignorance of

its causes and true nature. He has enumerated a variety of remedies adapted to the removal of the disease, but he admits the difficulty of ascertaining what are the true purposes which ought to be kept in view in its cure. At the commencement of the diabetic tendency, he found a cure by no means difficult; but in the advanced stage of the disease, such a result very seldom occurred. This he supposed was owing to the crasis of the blood being only a little loosened, and thus readily brought back again into its former state; but when so much dissolved as to have most of its parts separated from each other, it could seldom, if ever, be restored. The treatise of Willis upon diabetes has been translated by Dr. Latham, and published in his "Facts and Opinions" concerning that affection.

Sydenham, who lived for several years after Willis, and was cotemporary with him, has not alluded to the sweetness of the urine in diabetes, though he has left an extremely accurate description of its causes and the indications of its cure. We shall not attempt to account for this silence of Sydenham, by supposing, with Dr. Latham, that it arose from any other cause than mere inadvertency. Experiment was then but a new branch of science; and the practice of tasting the urine of a diabetic patient was probably first adopted by Willis, of all men, from the beginning of time; nor would the practical mind of Sydenham consider the announcement of more importance than if he had been told that the urine of hydrophobia was bitter; for what, in his time, was to be learnt from either? After Sydenham, we meet with notices of this affection in the writings of Cullen and Heberden; and since their time many attempts have been made to elucidate its real nature, and to establish a successful mode of cure. Dr. Rollo, however, strongly roused the attention of the profession to the subject by the publication and extended circulation of Captain Meredith's case, in which he proposed a new and important plan of treatment. To that author every praise is due for having enabled us to form more correct notions of the nature and cure of this complaint. The names of Cruikshank, Girdlestone, Fothergill, Dobson, Latham, Baillie, Lubbock, Bostock, Wollaston, Warren, Henry, Bardsley, Watt, Satterley, Prout, and Marsh, [Christison, M'Gregor, Bouchardat, Dezeiméris, R. Willis,] may be mentioned as those of valuable contributors to the general fund of information which we now possess concerning this formidable malady.

It has been supposed that diabetes is a disease of more common occurrence at the present time than formerly, because we meet with so few notices of the complaint in the writings of authors from Willis to Rollo, compared with the numerous authentic records of diabetic cases since the valuable publication of the latter physician. The fact seems to be that the disease is now better understood, and its symptoms are more generally known, so that not a few cases which would formerly have been classed under the head of phlisis or tabes, are now ascertained to be genuine examples of diabetes. Dr. Storer, of Nottingham, states, in a letter to Dr. Rollo, that he had not seen a single instance of diabetes during sixteen years in which he had the care of an infirmary,

containing upon an annual average fifty-two in-patients, and three hundred out-patients. In the Manchester Infirmary, diabetic patients not unfrequently present themselves for admission, and it generally falls to the lot of each of the medical officers of that institution to receive several cases under his care during the year. On inquiry, we have found that the same holds true with other extensive public hospitals. In private practice, too, instances of this disease are by no means uncommon; for we believe there are few medical men who have a fair share of professional employment, to whom cases of diabetes have not somewhat frequently occurred. Diabetes occurs in early as well as in advanced life. Heberden erroneously supposed that it exclusively attacked the aged and infirm. We have witnessed two instances of this disease in children under six years of age; and Dr. Venables has also recorded several marked cases of infantile diabetes. A very distinct example connected with the process of dentition, and in which the urine was sweet, is related by Morton. More than half of the cases seen by Dr. Watt,—and he believed the same observation would hold with regard to all that have been published,—occurred between the ages of thirty and forty-five; and of the other half a greater number were below the former of these ages than above the latter. "Of the whole," he says, "the best marked and most rapid in their progress have occurred in the very prime of life, and when the constitution was supposed to be in its full vigour. There is, perhaps, no period of life completely secure from the disease, though few instances have been recorded under the age of puberty. I have met with one instance in a boy of three years of age. It was most distinctly marked; the urine amounted to six or seven pints daily; the voracious appetite, urgent thirst, and arid skin were very remarkable. He had also phymosis, and afterwards suppression of urine. The disease terminated in a fatal dropsy."

This disease not unfrequently makes its approach insidiously; and it unfortunately happens that the first symptoms are often disregarded, and the complaint is allowed to advance for some time uncontrolled by medicine. The increased flow of urine is merely regarded as the necessary effect of the thirst, and the discovery of the saccharine condition of this fluid is also mostly accidental; but when hectic, emaciation, and debility have supervened, a more strict inquiry into the symptoms is generally instituted, and the real nature of the complaint becomes fully ascertained. The almost constant desire to make water, and the insatiable thirst, particularly during the night, are two most distressing symptoms; the patient being obliged to be supplied with a large quantity of fluid near his bed-side, and having to rise six or seven times or oftener to evacuate the bladder. The urine has a slight straw colour, and sweetish taste, and yields on evaporation a considerable quantity of saccharine extract. The amount of this secretion passed during the twenty-four hours is sometimes very considerable. It has exceeded, in more than one instance, seventy pounds. In the case of Smith, detailed in the writer's "*Hospital Facts and Observations*," thirty-six pints of urine were voided in the course of twenty-four

hours; and in that of Johnson, thirty-two pints. The discharge, generally speaking, is less than the liquid ingesta; but it has been found in one or two cases, that the liquid egesta have considerably exceeded the whole amount both of the solid and liquid ingesta. This fact, though denied by some writers, has been satisfactorily established by Dr. Bardsley, who has shown that the excess of the former cannot be accounted for solely on the supposition of its being derived from a general wasting and diminution of the solid and fluid parts of the system; for in two or three instances during the period in which the register clearly pointed out almost a regular daily excess in the amount of the urine compared with that of the liquids and solids taken, the patients had gained an accession to their weight of many pounds. "To what law or process of the animal economy," the author just named observes, "is the supply of this superabundant quantity of urine to be attributed? Is it derived from cuticular or pulmonary absorption, or from a colliquation of the humours of the body? Each of these modes has been insisted on by different writers." We receive the fact without framing any hypothesis to account for it. The researches of modern physiologists, particularly those of Klapp and Dangerfield, do however render it extremely probable that this superabundant quantity of fluid is absorbed by the lungs from the moisture of the atmosphere. Numerous observations demonstrate that almost every kind of matter in the state of fluid or vapour, introduced into the cells of the lungs, is rapidly absorbed from thence into the circulation, and, generally speaking, presents itself at the kidneys; thus the oil of turpentine manifests itself in the urine within a few minutes; and the amount of these facts goes to prove that there is a free and rapid absorption always taking place on the surface of the lungs. On the other hand absorption through the cuticle, if it exists at all, cannot be demonstrated; while it is admitted by almost every one, that nine-tenths of the copious exhalation of the pulmonary surface, which, according to proportion, must at least be ten times as great as that by the skin, or twenty pounds daily, is constantly in the act of being re-absorbed by the pulmonary surface: and since the avidity of the absorbents is known to be greatly augmented, as in dropsy, by an increased diuresis, while the pulmonary exhalation must be proportionally diminished, it is easy to conceive that the absorption of the fluid excreted from the bronchi will be considerably increased, and thus augment the quantity of fluid egesta above the ingesta. There will, moreover, be absorption of part of the residual air in the lungs, and this will again supply itself from the now moister air brought in from the atmosphere by inspiration, to what extent it is not easy to compute; nor can we reasonably expect that any such computation will correspond very exactly with the weights of the ingesta and body at different times, the means of taking which are often much more fallacious than is generally believed.

The mouth is mostly dry and parched, the taste is perverted, and the secretion of saliva altered. [Mr. McGregor found that it fermented briskly in a diabetic patient, when yeast was added to it,

and complaints are often made of a constant sweet mawkish taste in the mouth, and a feeling as if the teeth were set on edge.] A tough viscid phlegm occupies the fauces; the tongue has a brownish fur on its centre, with florid edges; the gums are soft, spongy, and bleed on the slightest pressure of the tongue against them, being mostly ulcerated about the roots of the teeth; the appetite is usually keen, and sometimes ravenous; uneasiness about the stomach and bowels is experienced, chiefly after eating, and the contents of the former are not unfrequently discharged in an acid and undigested state; the skin is rough, dry, and unperspirable; the bowels are generally costive; there is frequent pain and a constant sense of aching and weakness across the region of the kidneys, particularly on the least exertion; itching and excoriation, with phymosis of the prepuce, occurs in males, and an uneasiness about the meatus urinarius in females; the semen is discharged involuntarily, chiefly after voiding urine; and there is a total loss of the sexual propensities. Headach, impaired hearing, giddiness, and indistinct vision, are mostly present. When these symptoms continue only for a short time, they are followed by serious disturbance in the general health, such as extreme debility, languor, and great emaciation. The pulse, which is at first quicker than natural, becomes slow and feeble. The legs and ankles swell; and a tickling cough, with shooting pains in the chest, mostly harasses the unfortunate patient in the last stage of his disorder. The mind is extremely peevish, irritable, and somewhat suspicious; the spirits are low and depressed.

By attention to the above symptoms, it is not, we conceive, difficult to distinguish diabetes from every other disease. There may be a preternatural discharge of urine in other affections; but *in this only* is a saccharine condition of that secretion present. Most of the more severe symptoms of this disease are attributable to the immense amount of solid matter which is constantly draining off from the body; and indeed some diabetic patients seem to sink merely from the debility occasioned by the continued secretion of an unnatural quantity of urine containing so large a proportion of animal extractive matter. The appetite, though voracious, is inadequate to the supply of nourishment sufficient to balance the immense and rapid waste which is daily taking place. "The loss of so much matter," Dr. Elliotson observes, "from the system, sufficiently explains the hunger, the feeling of emptiness and sinking in the stomach, the emaciation, debility, anaphrodisia, coldness of the legs, pain both of them and of the loins, the depression of spirits, &c. without attributing the disease to the stomach or the kidneys exclusively. The excessive escape of fluid, or when this does not take place, the feverishness, equally explains the thirst and dryness of the skin."

It will be shown, when we come to the consideration of the pathology of diabetes, that it is mostly complicated with disease in some important organs. Dr. Willan observed that he never met with a confirmed case of this disease in which there was not some considerable disorder of the constitution, or a defect in some organ essential

to life. Our experience leads us to hold this remark as not far removed from truth; although it may be said that the constitutional affections are more frequently the effects of the progress of diabetes, than the concomitants of its commencement. Pulmonic affections, we know, not unfrequently precede or accompany diabetes. Dr. Bardsley remarks that he scarcely recollects an instance of the disease where a slight affection of the chest did not more or less prevail. In several instances, too, on record, a connection between phthisis pulmonalis and diabetes is strikingly marked. The phthisical symptoms existing previously to the attack of the latter disorder are often suspended by its influence; but on the partial removal of the diabetic complaint, the tubercles pass rapidly through their several stages, and the patient's sufferings are terminated by death. A similar suspension of the progress of disease in the lungs is sometimes noticed in females who become pregnant whilst labouring under the symptoms of confirmed phthisis. The cough, expectoration, and hectic fever, almost entirely disappear, pregnancy advances, and labour ensues; when in the course of a few weeks (sometimes days) the pulmonary symptoms return with aggravated severity, the strength rapidly declines, and life is soon extinct. In the more confirmed cases of this disease which have fallen under our notice, there has been generally present a teasing tickling cough, sometimes attended with purulent expectoration, and mostly with dyspnoea, and shooting pains in the chest.

The most common exciting causes have been, according to our experience, frequent exposure of the body to sudden alternations of heat and cold, and an indulgence in copious draughts of cold fluid when the system has been over-heated by labour or exercise. In twelve cases that have come under our observation, the patients have attributed their ailment to one of these causes; hence, we have observed this affection chiefly amongst that class of artisans whose occupations expose them to sudden changes of temperature, or who reside in damp and low situations. The intemperate use of spirituous liquors, poor living, and distress of mind, not unfrequently operate, too, in the production of this disorder. It is a curious analogous fact, that dogs and rabbits fed upon rye-meal, or on decoctions of wheaten flour, have a species of diabetes produced; as has been ascertained by the experiments of Dr. Krimer of Hallé. The secretion of urine becomes much increased: the urea and uric acid almost or altogether disappear; the animal becomes emaciated; and in place of sugar, the urine is found loaded with albumen and mucus. The origin of the complaint has been traced by some patients to sleeping out the whole of the night in the open air, in a state of intoxication. The subjects of this disease have been mostly liable to profuse sweating upon any ordinary exertion, and at such times have been accustomed to abate thirst by drinking freely of cold liquids, or by eating immoderately of acid fruits, thus suddenly checking perspiration. The state of the mind seems to have a more intimate connection with this affection than has been generally supposed. In several cases on record, mental anxiety and distress

have been assigned as its chief cause. Indeed, a temporary diabetes insipidus is a very ordinary effect of such a state, and the despondency of mind throughout the disease is distinctly alluded to by Aretæus, and by many other eminent writers.

We have not observed the characteristic odour, compared to that of hay, from the persons of diabetic patients, to which Dr. Latham has particularly alluded. It has been supposed that the phymosis before noticed as a symptom of diabetes, proceeds from the extreme sensibility of the urethra, which subjects it to the general irritation of the system so frequently present in the complaint, and thus renders it morbidly sensible to the stimulus of the urinous fluid.

With respect to the emaciation, it may be remarked that Dr. Lubbock considered it a leading circumstance in this affection: for in his experience it came on slowly, the subject of it not perceiving much deviation from health. "I have at this time," he observes, "two patients who, excepting a slight and very gradual wasting of the body, some increase of thirst, with occasional uneasy sensations about the stomach, to which may be added, febleness of sight at times, and an habitual tendency to phymosis, possess that degree of apparent health and strength that would mislead a common observer." He conceived that the emaciation claimed the first attention of the physician; as without the removal of this symptom, neither the reduction of the urine, the alteration of its quality, nor the appearance of considerable remaining muscular power, could prove that the disease had yielded to any curative process.

Diabetes frequently occurs in the scrofulous habit, but is not confined to it alone. Some authors are of opinion that the disease may be hereditary; thus Dr. Prout observes, he cannot doubt but that a predisposition or tendency to this affection exists in some families, as he has witnessed four distinct instances of such a circumstance. The first was that of a young man whose mother and uncle had died of the disease; the second was that of a lady about fifty years of age, whose brother or sister had sunk under the complaint; the third was that of a girl about ten years of age, whose father two or three years before had died of the same affection; the fourth instance was that of a gentleman, aged fifty-four, who died of this affection, and whose father had laboured under the same disease for several years. Dr. Storer has noticed the occurrence of three cases of diabetes in one family, in the persons of a brother, sister, and her daughter. The father of the two elder died of that affection. In another instance, related by Mr. Leigh Thomas, three brothers in one family laboured under diabetes. Morton has also alluded to the hereditary nature of the disease. We believe that a tendency to it is occasionally inherited; but further experience and a more extended inquiry on this point are necessary, before diabetes can be correctly arranged like scrofula, phthisis, mania, and apoplexy, under the head of *family* diseases; for in not a few instances no hereditary origin can be traced. Yet, it must be observed, that even of these diseases, no two have exactly the same hereditary influence, nor are any two of them modified exactly in the same degree by circumstances

while all of them are seen to spring up every day in cases where no hereditary taint can be suspected: so that, if a comparatively rare disease like diabetes has been found by Dr. Prout hereditary in four times out of twenty, it seems fair to admit, that, as in the case of a great many other diseases, its supervention is often greatly favoured, if not determined, by hereditary conformation; and little more can be said even of scrofula or mania.

Various opinions have been formed concerning the *proximate cause* of diabetes. Thus some authors of eminence, like Mead, have supposed that it depends on a "morbid state of the liver and bile;" some, as Dobson, Home, Cullen, and Rollo, believed that it proceeds from a defect in the assimilatory organs; whilst others, as Dupuytren and Thenard, have attributed the principal phenomena of the disease to a "morbid action of the kidneys." Dr. Baillie also thought it probable that diabetes was owing to a deranged action of the secretory structure of the kidneys, by which the blood there is disposed to new combinations; and that the effect of these combinations was the production of a saccharine matter. He at the same time imagined that the chyle might be so imperfectly formed as to cause the blood to be more readily changed into a saccharine substance by the action of the kidneys. The ingenious author of the *Zoonomia* conceived that diabetes was produced by a retrograde motion of the absorbent vessels, owing to which chyle passed from the lacteals into the lymphatics of the kidneys or bladder. Cawley thought that in this disease the tubuli uriniferi were enlarged or relaxed, by which the chyle escaped into the urine. Willis concluded that diabetes depended upon a dyscrasy or intemperament of the blood, resulting from a morbid action of the assimilating powers. "Thus," he observes, "diabetes is rather and more immediately an affection of the blood than of the kidneys, and it thence has its origin, inasmuch as the mass of blood becomes, as it were, melted down, and is too copiously dissolved into a state of serosity, which indeed is very manifest from the quantity of urine so immensely increased, which cannot arise from any other cause than from this solution and waste of the blood: whence also the blood, which is left in the body, the serum being thus copiously abstracted from it, becomes much thicker and more apt to coagulate, as we may infer from the quick and laborious pulse; for on that account the heart acts with more rapidity, that the blood, which it thus agitates more than is usual, may be preserved from coagulating." The two hypotheses, however, which refer the seat of the disease to a morbid action of the stomach, and a morbid condition of the kidneys, have been most generally adopted. "Were I to give a theory," says Dr. Home, "to explain the nature and symptoms of this wonderful disease, I would say that it arises from a defect of the animal or assimilatory process, by which the aliment is converted into the nature of our body."

Dr. Home considered the excess or defect of this process as the source of many disorders. Rollo, too, observes that the immediate cause of diabetes mellitus is a morbid condition of the sto-

mach, forming or evolving from vegetable substances saccharine matter, which is quickly separated as a foreign body by the kidneys. "But, to be more particular," he continues, "we allege that this disease consists in an increased morbid action of the stomach, with too great a secretion, and an alteration in the quality of the gastric fluid, producing saccharine matter by a decomposition of the vegetable substances taken in with the food, which remains unchanged." It has been urged, and with reason, as a very serious objection to the theory of Dr. Rollo, that no sugar has been detected in the blood of diabetic patients; a fact which we shall shortly show to be established by the interesting experiments of Wollaston, Marcet, Nicholas, Geueudville, Thénard, Bostock, Vauquelin, Segalas, and other able chemists.

In several instances of the disease which have come under our own examination, there certainly has been ample evidence of preceding stomach derangement; but admitting that the stomach is generally in a state of morbid activity, as may be inferred from the increased and almost insatiable appetite which accompanies the disease, still we are ignorant of the particular condition of the *primæ viæ* which leads them to favour the extraction of sugar. Dr. Henry thinks that the theory must be modified by assuming that the blood which reaches the kidneys contains the elements of sugar, and is deficient in those of urea. He supposes, however, that it is necessary to a just pathology of the disease that some morbid condition of the kidneys should be admitted, though of a kind which has not yet been explained by anatomical investigation.

Dr. Mason Good conceived that a morbid and highly irritable state of the kidneys was sufficient to account for every other derangement that marks the progress of the disease. He saw no necessity for supposing an idiopathic affection of any other part, whether the stomach or the nerves, the digestive or the assimilating powers; but decides, from the attention which he has paid to the nature of diabetes, both in theory and practice, that the whole of its phenomena may be traced to renal mischief, and consequently that it is a far less complicated affection than has hitherto been supposed. That the kidneys are frequently in a state of irritation is evident from the pain, heat, and weakness, experienced in those organs, and the augmented urinary secretion.

Dr. Lubbock seems to have noticed the coincidence of the parched and dry skin with the saccharine quality of the urine, from which he was induced to believe that in this affection the want of perspiration or excretion from the surface is connected with sweetness of the urinary fluid; and this belief was supported by an examination of the nature of the perspirable fluids, and of the component parts of saccharine matter. On this view he has formed a theory of diabetes. "It has been proved," he observes, "that sugar is, for the most part, composed of carbon, oxygen, and hydrogen, united in a certain ratio; and it appears, by the experiments of Cruikshank and Abernethy, that, besides the occasional aqueous fluid discharged daily from the surface of the body, about three gallons of carbonic acid are also lost to the system by the perspirable matter. Now

supposing, as happens in diabetes, this perspirable excretion, or carbonic acid, is suppressed and retained in the system, it is probable that the carbon and oxygen of the acid so retained, by entering into a due combination with some portion of the hydrogen of the animal body, may tend to the production of the saccharine matter of the urine; and as the carbonic acid is the general product of the vegetable world, it would follow that its retention in the animal body may produce the phenomena of the defective animalization, characterising diabetes as exhibited in the formation of sugar."

Dr. Latham has broached a very fanciful hypothesis concerning the proximate cause of diabetes, founded chiefly on the dyscrasy of Willis, and the selecting power of the kidney. As it is impossible to condense it, we shall be satisfied with merely mentioning that it is quite as untenable as some of its ancient predecessors. Dr. Ferriar has also given a very vague opinion in explanation of the phenomena of this disease. He supposes that if the extreme vessels should from any cause take on a morbid action, and, instead of supplying nutritious matter, should form a substance which cannot be applied to renew the waste of the system, the diseased secretion must either accumulate in the intermediate passages of the circulation, where it would produce hectic fever, (by absorption,) and subsequently death; or it must be carried off by some of the emunctories, to which its stimulus must cause an increased determination of fluids. This he conceives to be precisely the case in diabetes. He afterwards refers the secretion of saccharine matter in the kidneys to metastasis, and supposes it to arrive there by the circuit of anastomosing branches.

In a reply to some strictures of the reviewer in the Medical and Physical Journal, on a case of diabetes related in the sixth volume of the Edinburgh Medical and Surgical Journal, the editor observes that the discharge in diabetes may be a diversion of a profuse secretion from the skin to the kidneys; that besides being morbidly profuse, it is, like other secretions, susceptible of a change, and may become stimulating even to the skin itself, and consequently much more so to the kidney, where it then most certainly act as a foreign body exciting the organ to extraordinary action; and that in the enlarged and excited state of the vessels of the kidney, time is not allowed for the secretion of urine to be perfect, and that chyle may pass off with it, or it may be called the urine of digestion or of the chyle, which in the healthy state is passed two or three hours after a meal, and cannot be considered a natural secretion. M. Dezémeris supposes that the proximate cause or essence of diabetes consists in irritation of the kidneys; that this irritation is rarely primitive, being mostly the result of chronic gastritis. In the course of the latter affection there is extreme thirst; the patient drinks freely, and the urine is in proportion: this state is prolonged; the activity of the kidneys increases every day at the expense of that of the other excretory organs; they remove from the body those fluids which require constant renewal, and thus again contribute to augment the thirst.

Such are only a few of the hypotheses which have been framed to explain the nature of diabe-

tes; but they are sufficiently numerous to show how little is really known respecting it. One great cause of this diversity of opinion is, as we shall hereafter show, the defective aid afforded by pathological investigation. "Pathological anatomy," as the late celebrated Laennec justly remarked, "is incontestibly the surest guide of the physician, either in the recognition of maladies, or in the cure of those which are susceptible of cure." We have no theory of our own to propose; but from all the attention which we have been able to pay to the subject, and from what we have seen of the disease itself, it appears to us proper to admit that the natural and healthy action of *both the stomach and kidneys* is materially disturbed; the former perhaps primarily, and the latter secondarily; and that the *dry and unper-spirable condition of the skin* is much more intimately connected with its production than is generally supposed: thus diabetes is an affection not proceeding from a morbid action of one particular part, but of several important organs. This statement is sanctioned by facts, and seems to derive confirmation from the symptoms, the remote causes, the effects, and analogy with other diseases. We have used the word *perhaps* in the above allusion to the primary derangement of the stomach, because in several diabetic cases on record the increased secretion of urine preceded every other symptom. So constant is the sympathy between the kidneys and the stomach, that Sydenham himself has declared there is no other mean of distinguishing between nephritis and lumbago than the expression of this sympathy in the former case by vomiting. It is possible that increased action of the kidney may very early, though not primarily, call the stomach into sympathy. In a communication from our friend Dr. Milligan of Edinburgh, he remarks that the famous Peter Petit asks, in his Commentary upon Aretæus, if the excess of sugar is furnished by an error of the digestive process, why does it not pass off by the bowels, the lungs, or the skin, as well as by the kidney? "But this very profound and philosophical question is very easily answered by the practical observation, that we know, as a matter of experience, that any excess of fluid introduced into the circulation does not readily pass off by the skin, lungs, or bowels, but seems naturally and designedly in almost every instance to be carried away by the route of the kidneys and urinary passages; and that, therefore, we have a right to expect that it will be so here. But it does not follow from this that the *first* profusion of urine in diabetes is saccharine, nor yet that the initial steps of the malady are to be traced to errors in the action of the stomach or the skin: may, so great is the number of persons who at all times labour under disease of the two latter organs, that on diabetes commencing we should require very strong proofs that some aggravation of the morbid condition of these parts, unconnected with any suddenly interposed cause, took place at the time, before we admitted that they were instrumental in producing diabetes."

[For some other views on the nature of Diabetes, see page 617.]

We must next allude to the *prognosis* to be generally formed in this malady. It has been

satisfactorily proved that a saccharine condition of the urine may exist during several years without the general health being materially affected, or the powers of the stomach much impaired. Diabetic patients, whose mode of living has been on the whole temperate, have been known, in not a few instances, to reach advanced age. It is in those cases, chiefly, where the constitution has been previously injured by long-continued and frequent irregularities that the disease under consideration proves rapidly fatal. Whilst the digestive organs continue to perform their functions with tolerable vigour, the supply of nutritious matter will be found nearly adequate to balance the waste which is daily taking place from the increased quantity of the urinary secretion. We have at this time two diabetic patients, who, excepting some increase of thirst and urinary discharge, and occasional disturbance of the digestive organs, enjoy a fair share of apparent health and strength, and are fully equal to the various exertions that devolve upon them in the ordinary intercourse of life. The disease, however, ought to be viewed with much concern, for it is too apt to pursue its fatal progress in defiance of all the resources of our art. It is difficult to establish a perfect cure when the characteristic symptoms of the affection have been once fairly developed. We find that even Aretæus alluded to its fatal nature. He has remarked, "that the disease is chronic, and generated by length of time; but short is the life of man when its establishment is fully completed." The perfect recovery of the patient depends upon the removal, not merely of one, but of the whole of the symptoms; for one may be relieved by the aggravation of another. Though there may be a considerable reduction in the quantity of the urine, still if there be no alteration in its quality, and the saccharine impregnation continues, the disease cannot with propriety be said to have yielded to any curative process. It is by close attention to, and an early discovery of the premonitory symptoms that we must hope to prevent a fatal termination. The disease unquestionably may be controlled at its commencement by the employment of the means hereafter to be pointed out; but it unfortunately happens that the malady has in most instances made considerable progress before the patient's attention has been called to its real nature. Rollo, Beddoes, Clegghorn, Watt, Bardsley, and others have related cases of diabetes in which a cure has been effected; but this happy result is by no means of common occurrence. When the disease is complicated with phthisis, scirrhus, or other organic mischief in any important organ, all hope at once disappears.

With regard to the perfect cure of diabetes, it is certainly necessary to speak with much caution; for, like some other formidable diseases, it is for the most part only capable of being relieved, and not of being effectually removed. "Within the last six or seven years," says Dr. Prout, "nearly twenty cases of diabetes have fallen under my observation; and among these, I have never but in *one* instance, and in that *for a very short time only*, seen the urine of a diabetic patient rendered quite natural." Dr. Lubbock, too, never saw this disease yield to any curative measures; the emaciation continued to increase more

and more, until after a lingering and protracted state of suffering, the unhappy subjects of it at last gradually sunk. Of twenty-nine diabetic patients who have been under our care, sixteen have eventually died, strongly evincing the fatality of the disease; eight out of the remaining thirteen have perfectly recovered; and of the other five we have received no account. The chances of restoration to health are frequently diminished by the irregularities of the patients themselves, in deviating from the prescribed modes of treatment, notwithstanding the strongest promises on their part to comply strictly with the wishes of the practitioner.

Previously to enumerating the *morbid changes* which have been observed after death in diabetes, it may be well to inquire what light has been thrown upon the pathology of this disease by chemical analysis of the urine and blood of diabetic patients.

Sensible Properties and Chemical Analysis of the Urine in Diabetes Mellitus.—Several distinguished chemists (amongst whom may be mentioned the highly respectable names of Cruikshank, Fourcroy, Nicolas and Gneudeville, Thénard, Vauquelin and Ségalas, Dalton, Bostock, Henry, and Prout) have sedulously occupied themselves in investigating the properties of diabetic urine, and have performed a variety of interesting experiments, with the view of determining the precise nature of that morbid secretion. The sweet taste of diabetic urine seems, as before observed, to have been first distinctly pointed out by our countryman Dr. Willis. Since his time, the existence of sugar in the fluid has been satisfactorily determined. It is worthy of remark, however, that the saccharine impregnation of diabetic urine is not at all times discoverable by the taste; for that secretion has been found to vary at different intervals during the twenty-four hours. In the case of a young lady, related by Mr. Shirreff, the urine voided at one o'clock was free from sweetness and perfectly insipid; some time after it appeared natural, but two hours after dinner was sweet, and in the evening again perfectly natural. The urine in this disease has, it has been already said, a pale-straw colour. It is mostly clear when first voided, but on standing some time in the vessel, not unfrequently deposits a white flaky precipitate. Its smell at first strongly resembles that of new hay, but in the course of a short time a faintish acid odour may be perceived. It has been stated that the temperature of diabetic urine, when recently voided, is lower than that of the healthy secretion; but this is a point which we have examined with much care, and we have found that no marked difference exists between them. An important circumstance connected with the consideration of the peculiar character of diabetic urine is its *specific gravity*. The profession is under obligations to Dr. Henry for having satisfactorily shown that the specific gravity of the urine in diabetes mellitus is higher than in healthy urine; a circumstance which had been overlooked by some of the most eminent writers on the chemical history of that disease. In ten cases of diabetes where he had an opportunity of determining this property, it never fell short of 1028 nor exceeded 1040;

1000 parts of water at 60° Fahrenheit being taken as the standard; whereas in healthy urine he never found the specific gravity, under any circumstances, to exceed 1020. Dr. Henry has recently informed us that subsequent trials of the specific gravity of the first morning's urine of healthy persons lead him to believe that this is understated, though perhaps a fair average for the whole day. Dr. Henry considers the specific gravity as a most useful test of the existence of diabetes in doubtful cases, and, when taken along with the actual quantity discharged, as furnishing a tolerably correct idea of the degree of morbid action. "It may be objected, perhaps, (he observes,) to the employment of this test, that it requires more familiarity with the method of taking specific gravities than falls to the lot of the greater part of medical practitioners. By means, however, of an hydrometer, which is well known to practical chemists, and which may be readily procured at a small expense, the specific gravity of the urine may be taken in a few moments, and with the greatest accuracy, by a person wholly unaccustomed to experiments of this kind." Deeming it desirable to establish a connection between the quantity of extractive matter and the more certain character of specific gravity, Dr. Henry engaged in a series of carefully-conducted experiments, and from them constructed the following table, which exhibits at one view the quantity of solid matter in diabetic urine of different specific gravities between 1050 and 1020. The scale may be extended, however, by the rule of proportion, to any case in which the urine may be found to have a specific gravity above the former or below the latter of those two numbers. In the experiments which furnished the above data of the table, the urine was evaporated by a steam heat till it ceased to lose weight, and till it left an extract which became quite solid in cooling.

Specific gravity of urine compared with 1000 parts of water at 60°.	Quantity of solid extract in a wine pint, in grains and tenths	Quantity of solid extract in a wine pint, in oz. qr. scr. gr.
1020	382.4	0 6 1 2
1021	401.6	0 6 2 1
1022	420.8	0 7 0 0
1023	440.	0 7 1 0
1024	459.2	0 7 1 19
1025	478.4	0 7 2 18
1026	497.6	1 0 0 17
1027	516.8	1 0 1 16
1028	536.	1 0 2 16
1029	555.2	1 1 0 15
1030	574.4	1 1 1 14
1031	593.6	1 1 2 13
1032	612.8	1 2 0 12
1033	632.	1 2 1 12
1034	651.2	1 2 2 11
1035	670.4	1 3 0 10
1036	689.6	1 3 1 9
1037	708.8	1 3 2 8
1038	728.	1 4 0 8
1039	747.2	1 4 1 7
1040	766.4	1 4 2 6
1042	804.8	1 5 1 4
1044	843.2	1 6 0 3
1046	881.6	1 6 2 1
1048	920.	1 7 1 0
1050	958.4	1 7 2 18

By referring to this table, we can readily ascertain the quantity of solid matter voided by a diabetic patient in a given time. Thus, as Dr. Prout has noticed, suppose ten pints are passed in twenty-four hours, of the average specific gravity 1040, it is evident that this will contain $10 \times 1.4 \dots 6 = 15 \dots 7 \dots 2$, or upwards of a pound and a quarter of solid extract.

The quantity of extractive matter obtained from diabetic urine is liable to considerable variation; but it is for the most part in proportion to the violence and severity of the disease, especially when the patient is not confined to any rules of diet. It has amounted in a few instances to more than two ounces from one pint (wine measure) of the fluid; but the medium quantity in even very aggravated cases of diabetes mellitus may be fairly estimated at not more than ten drachms of solid extract. The specific gravity, too, sometimes changes in a very remarkable manner. In the case of a patient lately under our care, it was reduced in the course of two days from 1033 to 1022, and very shortly afterwards it reached 1042. In another instance, alluded to by Dr. Prout, the specific gravity was reduced in about sixty hours after the patient had commenced with the use of opium, from 1038 to 1.1074. The saccharine matter had apparently disappeared, and was afterwards superseded by urea, the quantity of which had become excessive.

The able author just mentioned has shown that an excess of urea frequently precedes the appearance of saccharine matter in the urine. "Now it is a remarkable fact," he adds, "that in diabetes, in proportion as the saccharine matter diminishes under the above plan, that of urea generally increases; and in such instances the presence of the former principle cannot only be no longer distinguished by the sensible properties of the urine, but scarcely be demonstrated by the utmost skill of the most experienced chemist, though the specific gravity of the urine may at the same time be nearly 1040." Sometimes sugar is wholly wanting in diabetic urine even when the urea has altogether disappeared. Dr. Young met with an instance of this kind. After evaporating the fluid in a gentle heat, a brown substance was dissolved in abundance in alcohol, and afforded a stiff extract, which contained the lactic acid with a little trace of lactate and muriate of ammonia, but consisted almost entirely of the animal extract which accompanied the lactates, was precipitated by tannin, and left after combustion a little muriate of soda, which showed a slight trace of uncombined alkali.

It has been matter of dispute whether urea is contained, in any proportion whatsoever, in diabetic urine. Whilst Cruikshank, Dalton, Fourcroy, Nicolas and Guendeville, Thénard and Bostock contend for the non-existence of urea in the urine of patients labouring under diabetes, Henry and Prout maintain that, although the quantity of that substance be very much diminished, still it is never entirely absent. Dr. Bostock published a highly valuable paper on diabetes in the 6th volume of *Memoirs of the Medical Society of London*, in which he stated that he had procured nitrate of urea in abundance, along with oxalic acid, from the extract of diabetic urine. He was

afterwards induced to repeat his experiments at the request of Dr. Bardsley, who sent to him several pure specimens of saccharine extract for examination, having himself failed in several instances to detect any urea in diabetic extracts. The result was, that Dr. Bostock found his former inference to be erroneous, and with a candour very honourable to himself, acknowledged that we have no evidence of the existence of urea in diabetic extract.

In the experiments of the seven first named chemists, the test employed to detect the presence of urea was the addition of nitric acid to the extract of urine dissolved in a small quantity of water. On treating extracts obtained by slow evaporation from healthy urine in this manner, they found that a copious precipitation of nitrate of urea always ensued; whereas in their trials with diabetic extract they seem to have failed to discover any traces of urea. Dr. Henry, however, has satisfactorily shown by several experiments conducted for the purpose, that the action of nitric acid on the urea may be prevented by its agency on the greater proportional mass of sugar. He has stated that urea cannot be made apparent by nitric acid in the extract from any mixture of diabetic and natural urine, when the former exceeds the latter in a greater proportion than that of six to one; or when the solid urea is less than one-twentieth of the weight of mixed extract. It is on the ammonia which comes over *early* in the distillation of diabetic urine, that Dr. Henry seems disposed chiefly to insist, as establishing the presence of urea, because there is no other animal substance which can give origin to the volatile alkali under such circumstances. "Another proof (Dr. Henry observes) of the existence of some portion of urea in diabetic urine, may, in many instances, be obtained by a careful observation of the phenomena attending its spontaneous decomposition. At a temperature exceeding 60° Fahrenheit, diabetic urine passes rapidly to the acetous state. But if the succession of changes be carefully watched, it will be found that there is a point at which, before it becomes acid, it exhibits, to sufficiently delicate tests, distinctly alkaline properties." "The deficiency of urea in diabetes," he adds, "may be stated as being very considerable. In those cases where I have attempted to estimate it, from the quantity of ammonia evolved by the destructive distillation of the urine, the urea has not appeared to exceed from 1-40th to 1-60th the quantity contained in an equal measure of concocted healthy urine. One specimen of diabetic extract, with which I was favoured by Dr. Bardsley, approached so near to perfect whiteness, that there appeared to me little reason to expect any evidence of its containing urea. Yet even in the product of the distillation of this extract, after being rectified with the addition of potash, ammonia was found. On distilling, also, a portion of the urine itself, the condensed liquor gave manifest traces of carbonate of ammonia. This urine, however, contained a far less proportion of urea than I had ever before ascertained; not exceeding, as nearly as I could estimate, 1-80th of the natural quantity. Making every allowance, then, on account of the increased flow of urine, it will appear that the quantity of urea

discharged by persons labouring under diabetes, in any diurnal interval, falls considerably short of the quantity voided in a state of health." We have repeated these experiments with great care on an extensive scale, and are satisfied with their accuracy. Dr. Prout also considers the absence of urea as by no means characteristic of diabetes. He admits that in this, and some other affections of the urine, very little urea is sometimes present; but the same he shows to hold with respect to the other principles, many of which are deficient in such urine as well as urea. He never met with a specimen in which it was entirely absent. It may in fine be correctly stated that there exists a *deficiency*, though *not a total want of the urea*, in the urine discharged in well-marked cases of diabetes mellitus.

[It would appear, however, from the observations of Messrs. Christison, M'Gregor, and Boncharlat, that urea is generally contained in diabetic urine in larger relative proportion than in health, but that it is masked by the presence of sugar, and cannot be discovered by the addition of nitric acid, except by peculiar management.]

It may be proper to notice the effects produced by certain *re-agents*, and by *evaporation*, on diabetic and healthy urine, according to the experiments of MM. Nicolas and Gueudeville. 1. Tincture of tursool added to diabetic urine received a reddish violet tinge; with healthy urine it assumed a deep red. 2. Nitrate of silver occasioned in diabetic urine a curdy precipitate, of which the colour, at first white, soon changed to violet, and the liquor became limpid with a slight tinge of yellow; it was altogether inodorous. With healthy urine the same re-agent afforded an abundant precipitate of a deeper violet colour, and the liquor preserved a yellowish red colour, and emitted a strong urinous odour. Each precipitate consisted of nitrate and phosphate of silver. 3. Lime-water produced a milkiness in diabetic urine, immediately rendering it turbid, and affording a faint ammoniacal odour. After some time a flocculent precipitate occurred, of which a part remained on the surface of the liquor, which became as limpid as water: this precipitate was phosphate of lime. The same test also rendered healthy urine opaque, and the precipitate was white and extremely buoyant; but the liquid preserved a fine lemon-colour; the precipitate, a phosphate of lime, was also more abundant by one-half. 4. Concentrated sulphuric acid added to diabetic urine afforded a beautiful rose-colour, occasioning at first a slight effervescence. The surface of the fluid became covered with a light froth, which remained for a long time, and there was scarcely any precipitate: the liquor was inodorous. At the instant of mixing sulphuric acid with healthy urine, the effervescence was scarcely perceptible and the foam was slight. The liquor assumed a reddish brown colour, and preserved the odour of urine: at the bottom of the vessel was observed a small quantity of a darkish red precipitate. Dr. Henry has mentioned to us that on adding nitric acid, moderately diluted, to diabetic urine, he has often observed a change of colour to a red, resembling that of a weak acidulated infusion of rose-leaves, and an immediate and very sensible increase of the saccharine odour. 5. Muriate of

barytes rendered diabetic urine somewhat turbid; and in a short time a slight precipitation took place of a white salt, which was sulphate of barytes. The same re-agent produced a like effect upon healthy urine: but the precipitate was rather more abundant, and of a brownish red colour. 6. Oxalic acid afforded with diabetic urine a light rose-coloured flocculent precipitate, of which a considerable part was held in suspension in the liquor. The same acid threw down a precipitate with healthy urine, but it was heavier and of a deeper colour. 7. Sulphate of mercury rendered diabetic urine slightly turbid, and gave it the appearance of a white salt. A precipitate of a reddish tinge gradually occurred, one-half of which remained suspended in the liquor. Treated by the same re-agent, healthy urine assumed a brownish red tinge: the precipitate resembled a lilac-coloured salt, and was wholly deposited at the bottom of the vessel. It was the phosphate of mercury. 8. Pure potass rendered diabetic urine turbid, and afforded a small portion of ammonia; a white precipitate was afterwards procured in small quantity. The precipitate afforded by the same re-agent with healthy urine was on the contrary abundant, and the disengagement of ammonia very considerable. 9. Muriate of lead communicated to morbid urine a milky colour; the precipitate which ensued was that of a white salt, slightly tinged with red; it was a phosphate of lead: the liquor remained transparent. Muriate of lead imparted to healthy urine a violet colour, and produced a red precipitate; the liquor remaining of a brownish red colour. 10. Diabetic urine precipitated nitrate of mercury of a rose colour, and the liquor became as limpid as water. The precipitate of nitrate of mercury by healthy urine was also of a rose colour, but more abundant; and the liquor preserved a brown tinge.

Analysis by Evaporation.—1. After exposure to the air during six weeks, (from 10° to 12° Reaumur, 54° to 59° Fahr.), diabetic urine became turbid within the first six days, and gradually deposited a white flocculent substance, which was found to be albumen. The liquor afterwards became limpid and slightly coloured, having a sour odour and acid taste exactly resembling vinegar made with milk. Healthy urine, after like exposure to the air during the same period, soon exchanged its natural odour for one that was strongly ammoniacal; its colour became brown, and in the end it putrefied, affording a very fetid and offensive smell. The precipitate was pulverulent, and composed of phosphate of lime, soda, and muriate of soda. 2. Diabetic urine became acid, and turned blue vegetable tinctures red; whereas, healthy urine, when putrid, rendered the same tinctures green. 3. This acid urine combined perfectly with carbonate of potass in solution, without marked effervescence; the liquor, after filtration and evaporation, furnished acetate of potash, mixed with a small quantity of phosphate of potash; the precipitate obtained was scanty, of a white colour, and composed of lime and a small portion of magnesia. 4. Four pounds of diabetic urine afforded, on evaporation carefully conducted, four ounces and a half of extract, of the consistence of honey, of a brown colour, like

to treacle, and having the odour of burnt sugar; whereas only three ounces six drachms of an extract of the consistence of honey, of a very brown colour and urinous odour, were obtained from four pounds of healthy urine. 5. Ten parts of diabetic extract were mixed with four of muriate of lead and one of powdered charcoal, and after being dried they were submitted to distillation in a retort. Little or no ammonia was afforded, but carburetted hydrogen and a black fetid oil. The residue in the retort, on being subjected to an intense heat, gave no traces of phosphorus. The extract of healthy urine, treated in the same manner, furnished ammonia and a fetid oil; the residue contained some muriate of ammonia, and when thrown upon ignited charcoal, emitted the odour of phosphorus. 6. One ounce and two drachms of diabetic extract being treated with four ounces of alcohol, at 35° Reaumur, afforded a yellow fluid resembling Spanish wine; the solution of the matter was nearly complete, and the liquor deposited, in the space of twenty-four hours, a light, flocculent, grey substance, which, when washed and dried, weighed only twenty grains; its taste was saline and slightly sweet. Lime-water, added to one portion of the residue, afforded a feeble ammoniacal odour; sulphuric acid, applied to the other portion, changed it to a black colour, and produced the odour of sulphurous acid gas, indicating the presence of albumen. An equal quantity of the extract of healthy urine, treated with alcohol, afforded an abundant precipitate, composed of the phosphates of magnesia, lime, soda, and ammonia, uric acid, benzoic acid, and albumen. Urea and the muriates of ammonia and soda were held in solution in the liquor. In order to obtain these different substances separately, the fluid was evaporated, and the residue being dissolved in water, nitric acid was added to it, which occasioned a copious precipitate. This precipitate was found to be a nitrate of urea. 7. On submitting diabetic extract to distillation with nitric acid, nitrous vapour was disengaged; the residue being dissolved in distilled water afforded, on evaporation, oxalic acid, and a small portion of phosphoric acid. 8. Four ounces and a half of diabetic extract, of the consistence of honey, being dissolved in a pound of distilled water, with half an ounce of yeast added to it, and exposed to a temperature of 15° Reaumur during twenty-four hours, readily fermented, and afforded a considerable quantity of carbonic acid gas. After the fermentation was over, the whole being submitted to distillation yielded ten ounces of a spirituous liquid. Such were the chief methods employed by MM. Nicolas and Gueudeville, with the view of establishing the peculiar nature of diabetic urine. Dr. Bostock also submitted portions of diabetic urine to the action of different re-agents. His experiments, as well as those of Cruikshank, Nicolas, and Gueudeville, satisfactorily prove that the different salts exist in diabetic urine, nearly in the same proportion to each other as in the healthy state of the fluid, but that they amount only to about one-third of the absolute quantity. Sometimes diabetic urine has been found to contain a small portion of blood, (as in the case of Stevenson, related by Dr. Watt,) and occasionally a white milky

like fluid resembling chyle. Having thus noticed the principal circumstances connected with the *urine* in diabetes, it may be proper to allude to the state of the *blood* in that disease.

Analysis of the Blood in Diabetes.—Nicolas and Gueudeville, Wollaston, Marcet, Henry, and some other eminent chemists, have performed many experiments to determine the existence or non-existence of sugar in the blood of persons labouring under diabetes mellitus. Dr. Rollo stated (in the case of Captain Meredith) that the patient was bled, and the blood was kept for several months without undergoing any putrefactive process; while a portion of healthy blood, taken at the same time and placed in the same room, exhibited evident marks of considerable putrefaction in four days, and was obliged to be thrown away on the seventh. Nicolas and Gueudeville ascertained that the blood of diabetic patients afforded some serum, a small quantity of fibrine, and was less animalized than that of persons in good health, but that it contained no saccharine matter. Having satisfied himself how the albuminous part of healthy serum could be most completely coagulated, and by what appearances the presence of sugar that had been added to it would be most easily discerned, Dr. Wollaston added half a drachm of muriatic acid, previously diluted with one drachm and a half of water, to six drachms of serum, and immersed the phial containing them in boiling water during four minutes. In the course of a few hours a drachm or more of water exuded from the serum that had been so coagulated. A drop of this water being evaporated, the salts which it contained were found to crystallize, so that the forms of the crystals could be easily distinguished; they were principally common salt. If any portion of saccharine matter were added to the serum previous to coagulation, the crystallization of the salt was impeded, or wholly prevented, according to the quantity of sugar present. By the addition of ten grains to the ounce, the crystallization of the salts was entirely prevented, and the degree of blackness and disposition to deliquesce was of course more manifest than with smaller quantities. As a further test of the absence or presence of sugar, Dr. Wollaston added a little nitric acid to the salts that remained after crystallization of the drop. He found that when the serum had been successfully coagulated without any addition of sugar, the nitric acid merely converted the muriatic salts into nitrates, and nitrate of soda was seen to crystallize without foam or blackness. But when sugar had been added, a white foam rose round the margin of the drop, and if further heat were applied it became black, in proportion to the quantity of sugar present. On applying the above tests to diabetic blood and serum, Dr. Wollaston failed to detect any traces of sugar. Dr. Henry performed some interesting experiments on diabetic blood, as noticed by Dr. Ferriar, which confirm the results of Dr. Wollaston's analysis. Dr. Prout has also made a comparative examination of the blood of a person labouring under confirmed diabetes, with healthy blood. He states that he was induced to undertake it with the intention principally of determining whether the quantity of azote was the same in each. The diabetic

blood presented the usual appearances of healthy blood. The following were the results of his experiments:—

Specific gravity of the serum of diabetic blood	1029.5
————— of the urine of the same person, voided at the same time.	1044.8
One hundred grains of the diabetic serum, evaporated and dried to the standard formerly mentioned, left ten grains of solid matters, which upon analysis were found to consist of albumen.	8.7
Lactates and animal matters usually existing in the blood6
Salts7

10.

“Which very nearly coincide,” says Dr. Prout, “with the proportions ascertained by Dr. Marcet and Berzelius to exist in the serum of healthy blood. One hundred grains of the diabetic urine, evaporated and dried as before, left 11.7 grains, nearly the whole of which was sugar. Portions of albumen from the serum of this diabetic blood, dried and analysed as before, yielded *precisely the same results* as albumen from the serum of healthy blood.”—“To ascertain,” Dr. Prout continues, “the relative proportions of azote present in the diabetic urinous extract and the extract from healthy urine, portions of them were burnt with the oxide of copper. The results were, that one hundred parts of the diabetic extract (abstracting alkaline and earthy salts) yielded only 6.5 parts of azote, while the same quantity of extract from healthy urine yielded from thirty-five to forty parts of the same principle. To obviate the objection that the saccharine matter of the urine might be formed from the other principles of the blood and not from the serum, comparative experiments were made with the *crur* of healthy and of diabetic blood. The results were precisely similar as to the quantity of azote in both, and at the same time the quantity of azote did not differ much from that found to exist in the serum above mentioned.” From these experiments of Dr. Prout's, it may be safely inferred that the blood of diabetic patients contains an equal quantity of azote with that of healthy persons.

We may observe here, that Dr. Wollaston thought that, in order to account for the presence of sugar in the urine, we must either suppose a power in the kidneys of forming this new product by secretion, or—if we admit that the sugar is formed in the stomach by a process of imperfect assimilation,—must then allow the existence of some channel of conveyance from the stomach to the bladder without passing through the general system of blood-vessels. He conceived, that if prussiate of potass could be taken with safety, its presence would be discerned by a solution of iron in as small a proportion as almost any known chemical test. Finding that a solution of this substance might be taken without the least inconvenience, and that in less than one hour and a half the urine became perceptibly impregnated with it, although the quantity employed had not amounted to more than three grains of the salt,

he administered to a healthy person, about thirty-four years of age, a dose corresponding to three grains and a half of the dry salt, and repeated it every hour to the third time. The urine being examined every half hour, was found in two hours to be tinged, and to afford a deep blue colour at the end of four hours. Blood was then taken from the arm, and the coagulum, after it had formed, was allowed to contract so that the serum might be fully separated. He then endeavoured to ascertain the presence of the prussiate by means of a solution of iron, but without effect. Dr. Marcet also performed several interesting experiments at the request of Dr. Wollaston on this point. In one experiment he administered five grains of prussiate of potash dissolved in water, to a young woman labouring under diabetes mellitus; and the proportion was repeated every hour till she had taken thirteen or fourteen such doses. After the fifth dose, her urine, by the addition of a drop or two of a solution of sulphate of iron, turned blue instantly. At this period of the experiment, a blister was applied to her stomach, and after a few hours, whilst still taking the prussiate of potash, and whilst the urine strongly indicated its presence, the blister was cut and the serum collected. This serous fluid being, in the same manner as the urine, subjected to the action of a solution of sulphate of iron, did not suffer any change of colour in the least indicative of the presence of prussic acid. Yet the urine still remained capable of imparting a blue colour to solution of iron, fifteen hours after taking the last dose of the prussiate of potash. Dr. Marcet afterwards repeated Dr. Wollaston's experiments on the serum itself, and with a similar result. He also found that the susceptibility of the passage by which prussiate of potash is transmitted to the bladder seems to vary in different individuals; for in five trials he failed to discover any vestige of that salt in the urine of persons who had taken it in quantities sufficient to produce its appearance in others.

These experiments, though highly interesting and ingenious, still fail to establish the fact of a direct communication between the digestive organs and the kidneys or bladder, by which sugar may be conveyed from the former to the latter without its entering the general circulation. It is known that other substances are also met with in the urine, such as urea and lithic acid, which have never been detected in the blood or other fluids of the body. We have ourselves also carefully analysed the blood taken from several diabetic patients, but never could detect the existence of sugar in it, nor indeed any marked difference in its chemical composition from blood in the healthy state. Hence, it may be concluded that saccharine matter does not exist ready formed in the serum of diabetic blood; unless, indeed, we suppose with some modern Continental writers, that sugar, like mercury, upon entering the blood, unites itself intimately with the albumen, and constitutes a new compound of unknown properties, and which consequently sets our tests at defiance, although easily decomposed by the glands, of which organs this species of separation seems the natural office. It is not more difficult to conceive how a kidney

strongly excited by a redundant efflux of blood to its tissue, should convert part of the elements of the latter into sugar, than that the mammary glands of a woman should be found to perform the same thing in the sugar of the milk which it secretes upon a similarly sudden determination of blood to it after parturition.

[This negative evidence has been suffered to prevail with the generality of pathologists, although it had been observed that the fluid of transpiration was sweet. Recently, too, as before observed, saccharine matter has been detected in the saliva. It is clear, therefore, that the blood whence these secretions are formed must contain sugar or the elements whence it was formed. Of late, however, respectable chemists have affirmed, that they have unequivocally discovered saccharine matter in the blood. To obtain diabetic sugar, the serum was coagulated by Mr. M'Gregor, and carefully dried by heat. The solid mass being divided as minutely as possible by a pair of scissors, was boiled in water, and the decoction having been filtered through paper was evaporated to a certain extent. The concentrated liquid, on the addition of yeast, fermented strongly for several hours. Not satisfied with these results, and desirous of tracing the presence of saccharine matter still farther back, Mr. M'Gregor instituted several experiments, from which he is led to infer, that the stomach in diabetes, forms a preternatural proportion of sugar, and that the admission of the saccharine matter into the chyloferous vessels, and the consequent presence of a material in the blood, which is foreign to its healthy composition, is the cause of the different morbid phenomena of diabetes;—the kidney merely separating—as the great depuratory organ—the foreign material conveyed to it from the blood.

Pathology of Diabetes.—It is matter of regret, that hitherto the most careful anatomical research has afforded no satisfactory information concerning the origin of this complicated malady. Various morbid changes have been detected on the post-mortem examinations of diabetic patients, but these, in not a few instances, may more properly be considered as the effects than as the causes of the disease. The kidneys are more frequently met with in a morbid state than any of the other abdominal viscera; their size is occasionally much augmented. In four fatal cases under our own observation in immediate succession, these organs were greatly enlarged, and the ureters were considerably dilated. Dr. Duncan has related a case of diabetes in the Edinburgh Clinical Reports, in which the kidneys were much larger than common; and Dr. Rutherford and other pathologists have noticed an unnatural increase of their size. The texture of the kidneys in some instances is firmer, in others more flaccid than usual; their vessels are also occasionally preternaturally enlarged; and their surrounding cellular membrane has more than once been found filled with a gelatinous substance. In the case of Robinson, mentioned by Dr. Rutherford, the kidneys were much augmented in bulk, soft, and their surfaces painted with numerous vessels; the vessels were uncommonly dilated. The emulgent vein of the right side was not under three-fourths

of an inch in diameter, as it appeared distended with blood. The ureters also were considerably dilated; the bladder seemed capacious, its coats thickened, and it was half filled with liquid. In the dissection, too, of Ann Laidlow, given by the same author, the kidneys were found somewhat enlarged, and on cutting into them the tubuli uriniferi were more distinct than usual, and the pelvis of each was also considerably increased; but no other morbid change of structure was perceived. Mr. [Sir B.] Brodie, on examining the kidneys of a patient of Dr. Warren's, who died of diabetes, found them to possess an unusually firm and grisly texture. In order to ascertain the state of the blood-vessels, he injected one of the kidneys with size and vermilion previously to examination; the other was allowed to remain in its natural state. On cutting into the substance of the injected kidney, the cortical part appeared unusually red, and the cryptæ were seen more numerous, larger, and more distinct than ever occurs under circumstances of the most fortunate injection. The blood-vessels of the cortical substance of the kidney which had not been injected were unusually turgid; the ureters, emulgent artery, and vein, were of natural dimensions; the renal capsules were firmer and harder in their texture than usual, and seemed to partake of the grisly structure of the kidneys; the bladder was sound. M. Dezcimeris noticed the increased bulk of the kidneys in three cases of diabetes, which occurred at the Hôtel Dieu in one year. "In all the cases the volume of the kidneys was much enlarged; all their vessels were considerably developed, and their tissue, which was gorged with blood, and of a deep red colour, could be torn with the greatest facility." It appears from an interesting and extremely minute examination of a case of diabetes conducted by Dr. Monro, that all the glands of the absorbent system were either enlarged or morbidly altered in structure. Upon dividing the right kidney into two equal portions by a longitudinal incision, it seemed as if it had been very successfully injected. Many blood-vessels, both in the cortical and medullary part, were filled with florid blood, owing to which the distinction between these parts was not well defined. A transparent yellow-coloured substance was found effused on the outer side of the pelvis and infundibula.

Dr. Beer met with a very remarkable degeneration of both kidneys in the body of a young man, who had for a long time laboured under diabetes. They were extended by hydatids, contained in their interior substance, to such an enormous size that each was one foot long and seven inches broad, and the ureters were of the size of the thumb.

The ureters and bladder are sometimes considerably dilated. In one instance, Dr. Duncan found the bladder capable of containing five pounds of urine, and he states that about that quantity remained in it after death. It had its natural form, and its parietes were rather thinner than usual, although the muscular fasciculi were very well marked. Its inner coat presented a perfectly healthy appearance, and the ureters were about one-fourth of an inch in diameter: the sympathetic and splanchnic nerves were also enlarged

to nearly three or four times their usual size. In the dissection of a diabetic patient of Dr. Pearson's, mentioned in Dr. Rollo's work, the kidneys were found to be in a perfectly sound state, and so were the ureters; but the urinary bladder was much thickened, and the urethra was dilated to three or four times its usual width; in another, related by Dr. Marshall, the kidneys had assumed a chocolate colour, were large, and the texture soft and flaccid, particularly that of the portion comprehending the tubuli uriniferi: the bladder exhibited nothing unusual. In the case of Oliver Ormrod, detailed by Dr. Clark, the ureters were very much dilated, and through their whole course measured full half an inch in diameter. In two cases, we have found the bladder much contracted and thickened. In one instance the capacity of this viscus was so much diminished as not to admit more than a small egg; in the other, the parietes of the bladder were even more thickened.

As post-mortem examinations in cases of death from this disease are always interesting, we shall detail the following one which recently occurred in our own practice. The external cutaneous veins were distended with fluid blood. On detaching the scalp, some ounces of blood issued from the cut surface; the pericranium was redder than usual. The encephalon, and its containing membranes, appeared free from disease. On raising the sternum from the pleura, there were exhibited no traces of recent inflammation, but exudations of coagulable lymph appeared on the surface of the pleura pulmonalis, which had formed pretty strong bands or partial adhesions to the pleura costalis, particularly on the right side. Lungs sound. Nine ounces of fluid were found in the right cavity of the thorax, and eight ounces in the left; the quantity of liquor pericardii was about half an ounce. Gall-bladder distended with bile. Liver larger than usual, and of a firmer consistence. Spleen of natural size, though rather denser than common. The urinary bladder was full. The left kidney had undergone a remarkable diminution in bulk, being not more than one-third of its usual size. After the removal of fat, &c. it weighed ten drachms (troy weight); it was otherwise healthy, with the exception of some small *hydatids* on its surface. The right kidney weighed five ounces six drachms (troy weight); its surface was a little irregular. The stomach was inflamed on its posterior side and next the cardia; the inflammation only affected the inner membrane, which was also slightly corroded by the gastric juice. It contained five ounces of half digested cream-like fluid. In this instance, the diminished size of the left kidney formed the most singular feature in the dissection.

MM. Dupuytren and Thenard, on the examination of a diabetic patient, met with the stomach in a very much enlarged state: its vessels were greatly dilated, and forming upon the internal membrane of the organ a red net-work. It also contained a considerable quantity of uninflamnable gas, and a small portion of a greyish liquid, in which were floating seven or eight small, yellowish, round, fatty substances. The duodenum, and upper part of the jejunum and ileum, were somewhat redder and thicker than natural; no appearance of disease was discoverable in any other part

of the intestinal canal. The liver, spleen, and pancreas were sound. The gall-bladder was moderately filled with healthy bile. The kidneys were at least one-third larger than usual; their structure was soft and of a grey colour, but in every other respect natural. The other organs connected with the urinary apparatus were free from disease, though the bladder was very small. The abdominal lymphatic system, and the thoracic duct, were more than ordinarily developed. The arterial and venous systems had undergone no morbid alteration. The lungs adhered to the sides of the chest by loose cellular tissue. In the right lung there were some small vomicae containing pus; in the left, several cysts completely filled with an elastic fluid. The muscles were pale and flaccid, but otherwise in structure quite healthy.

Dr. Baillie has also left an account of the post-mortem examination of a person who had been long affected with diabetes, and had been a patient under his care in St. George's Hospital. The state of the kidneys is very minutely noticed. "Both were of the ordinary size and shape. When the proper capsule was removed from each, the veins on the surface were much fuller of blood than usual, and had an arborescent appearance. When the substance of both kidneys was cut into, it was observed to be every where much more crowded with blood-vessels than in a natural state, so as in some parts to approach to the appearance of inflammation. Both kidneys had the same degree of firmness to the touch as when healthy, but they were hardly so firm as kidneys usually are the vessels of which are so much filled with blood. A very small quantity of whitish fluid, a good deal resembling pus, was squeezed out from one or two of the infundibula in both kidneys, but there was no appearance of ulceration in either. The artery and vein passing into the cavity of each kidney presented exactly the natural appearance. After separating, a good deal, the cellular membrane which joins together the blood-vessels, was discovered a lymphatic passing from one of the kidneys: it was of the usual size, had the common valvular appearance, and was empty. There were doubtless several others belonging to both kidneys, but they were so small as not to be distinguishable. The nerves of the kidneys were of the usual size, and the ureters of both were perfectly natural. The renal capsules appeared quite healthy. The structure of the liver, stomach, spleen, pancreas, intestines, and urinary bladder, was perfectly natural, but one or two of the mesenteric glands contained a considerable quantity of earthy matter."

Organic changes are sometimes discovered in the internal structure of the kidneys in diabetes. We may state as a pathological fact of some importance, that in three instances of this disease we have detected the peculiar granulated or mottled condition of these organs, so well described by Dr. Bright as occurring in dropsical affections accompanied with albuminous urine. The cortical part had lost all appearance of its natural structure, and presented a tolerably uniform yellowish colour with many yellowish-grey spots. The mesenteric glands in two cases were much enlarged and indurated; and in the other, several vomicae were detected in the right lung. There was no

evidence of organic disease in the liver or in any of the other abdominal viscera in the latter instance.

Besides these morbid conditions of the kidneys and their appendages, a diseased state of the stomach and lungs has also been noticed in this affection. The former organ has been found to exhibit marks of inflammation, and the latter have been studded with tubercles in different stages of their progress. In a fatal case of diabetes, which occurred in the Manchester hospital a few months since, both lungs were tuberculated; and except dilatation of the pelvis of the kidneys and of the ureters, there was no perceptible disease of the urinary organs. The pulmonary affection was subsequent to the diabetes, therefore it cannot be said that this affection was excited by the former. In most of the dissections on record, the mesenteric glands have afforded evidence of structural derangement; and from our own observation we should say, that next to the enlarged and flaccid state of the kidneys, this is the most uniform morbid appearance in diabetes. We not unfrequently meet with similar disease of structure, however, in diseases very different both in their nature and symptoms from the one under consideration; hence, it is not singular that such an infinity of hypotheses should have been advanced to account for the phenomena of this malady. In some examinations of diabetic patients no trace of organic disease has been discoverable. An intelligent practitioner informed us during the last year, that he had recently examined the body of a young man, twenty-one years of age, who had died of this disease, without being able to detect the least deviation from healthy structure in any of the cavities.* The different morbid appearances in the stomach, liver, and lungs, noticed above, are undoubtedly in some instances merely accidental attendants; and indeed the diseased state of the kidneys themselves is, we conceive, mostly the consequence of long-continued morbid action. The ureters, too, become dilated, and the bladder contracted and thickened, from the constant passage of such an increased quantity of urine. From these observations, it is evident that the information regarding the nature of diabetes derived from dissection is very unsatisfactory, and that up to the present period we are ignorant of the *essential pathology* of the disease. With so defective a pathology, the treatment must necessarily be vague, and in a great measure empirical.

The Treatment of diabetes mellitus comes now under consideration. The statements respecting the cure of diabetes furnished by the ancient writers on this disease are altogether unsatisfactory. This cannot be matter of surprise when it is considered that they regarded only the unnatural quantity of the urinary discharge, being entirely ignorant of any morbid alteration in its qualities. As it would answer no useful purpose either to enter into an examination of the comparative value of the whole of the modes of treatment that have been proposed, or to dwell at any length upon the

* In a dissection of a diabetic patient of Dr. Forbes, no morbid lesion could be detected except slight enlargement of the kidneys, and a remarkably hypertrophied state of the duodenum. It was simply hypertrophy, without any mark of inflammation or alteration of tissue.

particular remedies which have been recommended, on various authority, for its removal, we shall first merely notice the four branches of cure, *animal diet, venesection, opium, and astringents*, which of late years have been chiefly adopted; and then point out those principles of treatment which seem to us to be best calculated to arrest the progress and remove the symptoms of the complaint. Dr. Home first suggested the employment of animal diet and alkalies, with a view to their specific operation as septics; but Dr. Rollo is entitled to the high merit of having put into practice the rigid use of an animal regimen as the most effectual mode of curing diabetes. The employment of this plan is founded on the principle of preventing the introduction of the materials of which sugar is formed into the system, and of thus destroying the saccharine impregnation of the urine. Dr. Rollo also combined with an entire abstinence from vegetable food the exhibition of the hepatic ammonia, and the occasional interposition of narcotics and emetics. Dr. Rollo's practice has long since enjoyed a fair trial in the hands of many distinguished practitioners, and consequently sufficient time has been allowed to admit of a correct inference being drawn respecting its real claims to the high character bestowed upon it by so able an advocate. Without particularising individual cases in support of the efficacy of a strict adherence to animal food in removing some of the more formidable symptoms of diabetes, it may be stated that its power of abating thirst, diminishing the unnatural quantity of the urinary secretion and rendering it more animalized, of relaxing the skin, and of increasing the bulk and strength of the body, rests on the incontrovertible evidence of facts and experience. Its influence upon the urine is in general speedy and favourable, and though perhaps when employed *singly* it may prove on some occasions inadequate to the perfect cure of the disease, still, under almost all circumstances, it will be found to act as a powerful auxiliary to venesection, opium, or the other means which may be adopted. Dupuytren and Thénard have contended that diabetes may be as readily subdued by animal diet as an intermittent by the use of the cinchona bark. Dr. Baillie, in alluding to Dr. Rollo's method of practice, observes that it has been much more successful than any other hitherto adopted. Dr. Bardsley has also shown the advantages derived from confining diabetic patients to animal food. Several of his cases strongly exemplify the reduction in the quantity of the urinary secretion, and the disappearance of its saccharine properties, which speedily followed the use of this regimen. Dr. Willan states that this disease has been relieved, and the saccharine quality of the urine removed, by animal diet and the general plan recommended by Dr. Rollo. Were it necessary, other respectable authorities might be adduced in support of the curative value of the same method. We have adopted the animal regimen in several instances with the most marked and unequivocal benefit, and have known patients, who have had sufficient means and resolution to persevere in its use for some length of time, not merely to recover their wonted health, but overcome the tendency to the disease. Owing to the high price of meat, but

few of the poorer classes of persons who have the misfortune to labour under this complaint are capable of a strict compliance with this plan of treatment, for the amount of their daily labour is mostly insufficient to procure such a supply as the appetite demands. This is not the only obstacle to the employment of animal food as a remedy in diabetes; for there is often considerable difficulty in keeping the patients for any length of time exclusively confined to such a regimen; and many failures with this method of treatment may be attributed to a secret indulgence in variety of aliment. In some instances there is an insuperable disgust at the taste, smell, and even sight of animal food. With the ordinary class of hospital patients it is extremely difficult to prevent a deviation from the prescribed plan of diet. Dr. Rollo himself laments that the mode of cure which he proposed is so contrary to the inclinations of the sick. "Though perfectly aware," he observes, "of the efficacy of the regimen, and the impropriety of deviations, they commonly trespass, concealing what they feel as a transgression to themselves. They express a regret that a medicine could not be discovered, however nauseous and distasteful, which would supersede the necessity of any restriction of diet." This aversion, however, to the animal regimen is by no means general, for in some instances it has been adopted with little or no inconvenience, and even been continued by the patients from choice, when a certain allowance of vegetable food has been permitted by the physician. Dr. Marsh rather overrates the loathing of animal food on the part of diabetic patients, when he asserts that the adoption of the animal regimen, during even fourteen days, is, in his opinion, more than questionable. In some of the cases published by Dr. Bardsley, the exclusive use of animal food was continued for more than two months. We occasionally visit a lady who has laboured under diabetic symptoms for more than nine years, and during the greater part of that time she has adhered, with scrupulous exactness, to the use of animal food.

It must be recollected, however, that there is a certain period at which it is necessary to combine vegetable with animal diet. When the more urgent and characteristic symptoms of the disease are subdued, and at the same time the strength and bulk rather diminished than increased, and the appetite is feeble and impaired, it is proper to allow a small proportion of vegetable food. The salutary effects of this change are soon rendered visible in the improvement of the appetite, and the acquisition of flesh, strength, and spirits. It has been remarked, also, that whenever a return to vegetable diet is allowed not only with impunity but advantage, it forms the surest criterion of the restoration of the assimilating powers of the system, and consequently of the removal of the disease. It is necessary, however, to caution patients against indulging too freely at first in the use of vegetable diet after a long and rigid adherence to animal food, as they are apt, from the agreeable nature of the change, to relinquish the latter regimen altogether, and thus favour a reproduction of the disease. At this stage, the state of the digestive organs requires particular attention in order to establish on a firm footing

the benefit obtained; for if the stomach and bowels are permitted to become deranged by irregularities in diet, the danger of a relapse may be apprehended. Bitter tonics, mild aperients, chiefly rhubarb and magnesia, and sea air, prove eminently useful in promoting the tone of the system. It is by no means intended to recommend animal diet as the only mode of subduing this obstinate disease, but to show that no other, without its aid, will have the same influence in arresting the progress of the diabetic symptoms.

Previously to commencing with the sole use of animal food, it is of the first importance to have the stomach and bowels brought into as natural a state as the character of the complaint will allow. Costiveness must be obviated by the regular use of mild aperients, and for this purpose castor oil is preferable to the saline class of purgatives. The first effects of this plan of treatment should be very carefully watched, as there is considerable risk of the sudden occurrence of acute inflammation of the thoracic or abdominal viscera when it is adopted shortly after an entire abstinence from vegetable food. We have more than once been obliged to modify the practice on this account. The liability to inflammation under the animal regimen is strikingly exemplified in the case of James Ridens, aged 26, who was admitted into the Manchester hospital on the 2d of August, 1824, labouring under the ordinary symptoms of diabetes. The quantity of urine passed in the twenty-four hours amounted to nearly two gallons. One pint yielded, on evaporation, 1 oz. 4 drs. and 8 grs. of a thick sweet syrup. He had lost all venereal appetite, and his semen was involuntarily discharged. Animal diet was prescribed, and the nitric acid mixture was ordered for common beverage. His bowels were opened by the aid of castor oil. On the 5th the urine was diminished more than four pints, and the patient said that it was somewhat less sweet to the taste. He had no aversion to animal food. Early on the 8th he was suddenly seized with a severe pain in the epigastric region, which was much aggravated under the pressure of the hand. The stomach rejected every substance received into it. The pulse was small and frequent, and the countenance indicated great uneasiness. Twenty leeches were instantly applied to the epigastrium, sixteen ounces of blood were removed from the arm, and a purgative enema was injected. In the evening the patient seemed somewhat relieved by the bleeding, but the pain of the epigastrium was still present. A copious evacuation followed the enema. The serum of the blood was milky, and the crassamentum firm. Pulse 120, and weak. A vein was again opened, and eighteen ounces of blood were abstracted; twelve leeches were applied to the epigastrium, and a pill with two grains of calomel, and two of extract of hyoscyamus, was directed to be taken every third hour. The pulse after the bleeding was 106. On the morning of the 9th, we found the patient much worse, and evidently sinking very rapidly. He could with difficulty reply to the questions put to him. The pain of epigastrium was diminished, but the pulse was tremulous and intermitting, and his extremities were cold. His bowels had been moved twice during the night. Anodyne fomen-

tations were applied to the epigastrium, weak wine and water was administered, and bottles of hot water were applied to the feet. He expired in the course of the afternoon. His friends, though urged by frequent solicitations, obstinately refused to allow an inspection of the body. From the above reports, however, it is highly probable that Ridens died of inflammation of the stomach, induced by an unlimited use of animal food. At first, it was imagined that the sudden attack which proved fatal might have been owing to over-repletion; but he had retired to rest as well as usual, and even complained of severe pain of epigastrium before breakfast, which was generally with him a very hearty meal. In the case, too, of John M'Lean, related by Dr. Cleghorn, it appears that, although his diabetic symptoms were much relieved by the use of animal food, still the pneumonia which destroyed him was induced by strict adherence to this regimen.

It may be remarked here, that M. Rochoux prescribed urea to a diabetic patient, (whose blood was analyzed by MM. Vauquelin and Ségalas without finding in it any trace of sugar,) and it was continued for several days; but the urine, which was increased in quantity, afforded, on careful chemical examination, no urea.

Very opposite to the above plan of treatment recommended by Dr. Rollo, is that of depletion, by *copious* and *repeated bleedings*. Dr. Watt was first led to try venesection from the circumstance of his patient expectorating blood, and from having in mind the case of Captain Meredith, (related by Dr. Rollo,) who, on the evening after bloodletting, "felt lighter, cooler, and more cheerful, and had less pain about the kidneys." On the following day Dr. Watt's patient seemed much relieved, the quantity of urine had diminished, the crassamentum of the blood was black, and void of tenacity. Finding so much relief from the first bleeding, he resolved on a second, and eighteen ounces were accordingly taken from the arm; an animal diet was enjoined, and carbonate of ammonia prescribed to obviate acidity. By repeated bleedings and a similar diet and medicines, in about four months this patient was restored to health. The following is the statement of Dr. Watt's mode of treatment. "The treatment according to my plan is to reduce the quantity of blood already in the system, to diminish the supply of new materials, and to afford a certain proportion of stimuli. The first is accomplished by venesection; the second, by abstinence; the third, by blistering, mercury, &c. The effect of this treatment on the system is increased re-action, indicated by some degree of fever, and terminating in the restoration of all the secretions." It is to be regretted that the same result has not attended the employment of bleeding in cases of diabetes occurring to other practitioners.

Dr. Watt appears to have tried venesection in one or two instances under the most untoward circumstances, the pulse being slow and feeble, the strength reduced, and the lower extremities œdematous; and still with benefit. Even the first bleeding sometimes produced an evident improvement in the symptoms. In the case of Stevenson, the fifth bleeding acted like a charm. "The recovery after this was instantaneous and

striking. The painful sensation in his bowels left him; the power of virility returned; the gums became sound; the skin soft and perspirable; the saliva, the urine, and the alvine discharge natural; in six days he returned to his work; in two months he was restored to his original health."

Dr. Watt found that the blood first drawn in diabetes was thin and destitute of buffy coat; the coagulum being so soft and weak that it could not support its own weight. As the operation was repeated, the blood assumed more and more an inflammatory character, and often exhibited ultimately a thick buffy coat, and a strong, firm, and tenacious crassamentum. "The improved texture of the blood," he observes, "as venesection was repeated, the increased hilarity of mind, and general renovation of the living functions, warrant the conclusion, that, however weakening it may be in particular circumstances, bloodletting is a most important mean of disburdening the system, and of preparing the way for the final re-establishment of health and vigour." Mr. Murray has also related a case in the eighth volume of the Edinburgh Medical and Surgical Journal, in which the blood improved simultaneously with the health. Some other instances have been recorded, illustrative of the salutary change produced in the constitution of the blood itself by repeated venesections. Dr. Ayre found bleeding useful in one example of this disease. The appearances of the blood strongly resembled those observed by Dr. Watt; and indeed, so close was the relation betwixt the state of the blood and the relief afforded, that the amount of the one was almost determinable by a view of the other. It is mentioned that during the first month the patient lost eighty-eight ounces of blood, and took at least only half the usual food, yet he gained nine pounds in weight, and acquired sufficient strength to follow a laborious employment. The marked good effects of venesection in two cases of diabetes have been ably shown by Dr. Satterly. His experience fully confirms the safety and efficacy of the practice in some species of that complaint.

We are enabled to speak of the *real* value of venesection in diabetes from a careful and fair trial of its influence upon the symptoms on several occasions. It is a remedy of the first importance during the acute stage of the disease, for it has the power of abating the thirst, reducing the quantity of the urinary discharge, and restoring the natural secretion of the skin. Under no other circumstances have we employed venesection with advantage, though blood has been abstracted from the system at regular intervals and to a considerable amount. The practice, indeed, on the contrary, has been attended with a diminution of the patient's strength without relief to the diabetic symptoms. Taking Dr. Watt for our guide, we have followed his plan of treatment with scrupulous exactness, with a view of determining its true claims to confidence, but we have had too often to lament the want of success which has followed its adoption. The experience of the profession at large would seem to confirm the statement just made; for the practice of venesection, so generally employed shortly after Dr. Watt's publication, is now, comparatively speak-

ing, only partially pursued. We venture to recommend the employment of bloodletting during the early stages of the disease in persons of somewhat plethoric habit; and where the strength is not much reduced, and particularly when pulmonary irritation, as indicated by difficulty of breathing, slight cough, and shooting pains in the chest, may be present. The propriety of repeating the operation, and the frequency of the repetition, will be best determined by the effects produced upon the symptoms; for in some instances it may not be prudent to open a vein more than once, whereas in others no such restraint is necessary. There is sometimes an objection on the part of the patients to allow a fair trial of venesection, for feeling great debility and lassitude on the least exertion, they complain more of the want of a supply than of a superabundance of blood, and thus cannot be convinced of the benefit likely to accrue from such practice.

When general bleeding cannot with safety be adopted, the local abstraction of blood may occasionally be substituted with advantage. It has been our uniform custom in cases of this disease, to direct the application of leeches to the loins, when much pain and uneasiness have been experienced in the region of the kidneys, and always with good effect; and we have also found, with Dr. Marsh, that leeches on the epigastrium have been highly useful in removing the feeling of internal heat and tenderness so much complained of in that part. Indeed, patients have requested the repetition of leeches to the epigastrium on more than one occasion, being fully convinced of the benefit derived from them. This local bleeding has not materially reduced the strength, even when employed more than once. It should never be omitted under the circumstances we have pointed out, for though possessed of no curative efficacy, it is valuable in relieving painful and unpleasant symptoms, and is seldom, if ever, attended with harm, which is more than can be truly said of some other remedies proposed in this disease.

In a case of diabetes, under the care of Dr. Forbes, the first application of leeches to the epigastrium was *immediately* followed by a change in the urine to the healthy appearance. It was also much diminished in quantity. But the benefit was temporary, and although the same effect followed subsequent leechings, but in a less degree, the general result did not seem very beneficial.

Cupping is preferable to leeches when it is desirable to fix the precise quantity of blood to be removed, on account of the weakened state of the patient. Great benefit sometimes attends the application of blisters to the loins in cases of this disease. We have preferred the frequent repetition of blisters, to keeping the excoriated surfaces open by means of irritating dressings.

With the view of diminishing the nervous irritability of the system so generally present in this disease, the narcotic power of *opium* has been freely tried, and in many instances much benefit has attended its exhibition. It has also been prescribed with the intention of opening the skin, and exerting an astringent effect upon the kidneys, similar to that which it usually induces on the intestinal canal. Dr. Warren published two cases

of diabetes mellitus treated with opium, in the fourth volume of the Medical Transactions, which afford satisfactory evidence of the influence of that valuable drug in restraining the quantity, and moderating or removing the saccharine quality of the urine. In one of the patients this desirable effect was produced after gradually increasing the proportion of opium to six grains twice a day; the sweetness of the urine returned on the diminution of the dose, but was again removed by increasing it. The other patient died, (although the original disease was subdued,) of phthisis pulmonalis. The dose was gradually augmented to five grains of solid opium four times a day. Dr. Elliotson has since exhibited opium in four cases of diabetes, in which the good effects of this remedy were satisfactorily established. He has administered it in large doses, but it appears more advisable not to push the quantity to any great extent. Dr. Prout also found opium useful in this affection. "All the beneficial effects," he observes, "to be really expected from opium, may in most instances be obtained by moderate doses only; and when thus judiciously exhibited, and when no peculiarity of constitution forbids its use, I believe that it will be found one of the most powerful remedies that we possess in this disease." Dr. Marsh, too, considers, that amongst the remedies hitherto employed, opium in very large doses ranks highest, for it possesses the property of checking and restraining the flow of urine, and depriving it of many of its morbid qualities. Our experience accords with that of the above named authors, but we have rarely found it necessary to administer more than six grains in the day, though on some occasions this proportion has been considerably exceeded; and when continued, during any length of time, in rather large quantities, this drug has produced alarming and pernicious effects. We are decidedly of opinion, that it proves most beneficial in moderate doses. Of late we have given the preference to the acetate of morphia, as it appears to exert an equally powerful influence upon the disease, without occasioning the pain of head and constipation which almost invariably accompany the free exhibition of opium. On the whole, opium is unquestionably entitled to be considered as a remedy of much value in diabetes, for it not merely diminishes the quantity of the urinary secretion, but also proves useful in removing uneasy sensations and calming mental agitation. *Astringents* constitute another line of practice which is very ancient, and is still resorted to by a considerable number of practitioners. They are recommended by Celsus, and from their natural tendency to correct every excess in secretion, have obtained considerable notice in the writings of almost every author since his time. That they prove beneficial by constricting the relaxed extreme vessels through which the urine filters into the papillæ of the kidney in diabetes, is the general opinion; but they may probably act also by an inherent sedative power, on which their astringent virtue seems almost entirely to depend. It is sufficiently proved by observation that they lessen the quantity of urine thrown off by the diabetic patient, up to a certain limit; but this they seldom can be made to pass; and they scarcely ever diminish the saccharine impregnation

of the urine. By acting as tonics, however, and by lessening the sensibility of the stomach, they become useful auxiliaries in several modifications of the disease, and are chiefly objectionable when they are found to increase constipation. Celsus, however, trusted chiefly to a constipating diet, and strong rough wines. Sydenham used the rind of the pomegranate; Morton rhubarb, which was afterwards repeated by Professor Rutherford with advantage. Lime water, decoction of oak bark, infusions of kino and catechu, uva ursi, and *disoma crenata*, with many others, have lately been employed with the same intention as the above: but it may be fairly questioned whether alum, the vitriols, or indeed any astringent that ultimately stimulates, can safely be put in action for the cure of diabetes. Dr. Grahame, of Dalkeith, has lately published an ingenious method of directing the sulphate of zinc to the kidneys, by combining it with turpentine in the form of a pill; but even this mild preparation should be tried with caution.

Thus it appears that each of the four modes of cure mentioned above has strong claims to confidence and adoption, in certain forms and stages of diabetes. Before laying down what appear to be the correct principles of treatment, it may be proper very briefly to enumerate some of the individual remedies that have been employed for the removal of this disease. The phosphoric acid and its salts, as recommended by Dr. Latham, the phosphate of iron as used by Dr. Venables, in doses of one or two grains, gradually increased to a scruple or half a drachm, three or four times a day; the phosphate of soda, on the authority of Dr. Sharkey, who has published two cases of cure attending its exhibition; ammonia; calcined magnesia; tonics, such as the mineral acids, cinchona, myrrh, &c.; various bitters; mercury pushed to the extent of inducing salivation; chalybeates; cold bathing; and the colchicum autumnale, have been severally used in diabetic cases, and with various success. We have been informed by an intelligent medical friend, that he has of late exhibited the meadow saffron in two instances of this disease, and with a highly satisfactory result; but further evidence of its efficacy is required before it can be entitled to rank as a remedy in diabetes. Dr. Ferriar has detailed three cases of confirmed diabetes, in which a cure is said to have been effected by a combination of Peruvian bark, uva ursi, and opium, in the proportion of one scruple of each of the former to half a grain of the latter, administered four times daily, with the use of lime water for common drink. He treated this disease as one of debility. A case has also been related by Dr. Bateman, where the same practice was successfully adopted: but the disease returned after discontinuing the medicine, and did not so speedily yield to a repetition of it. In other hands this treatment has altogether failed. Dr. Shee has published a case, in the progress of which, after the ineffectual administration of astringents and opium, paralysis with convulsions of the whole of the right side supervened. In the course of ten days the patient was restored to health, (the diabetic symptoms yielded first, and afterwards the paralysis and spasm,) by a combination of camphor, kino, and oxide of zinc with tonic infusions. Dr. Alley effected a cure

of diabetes by animal diet and cinchona; and Dr. Fraser mentions an instance in which the urine lost its saccharine property in a month after commencing the use of animal diet and the sulphate of iron.

Of late the aid of iodine has been sought in the treatment of this affection; and it has been stated to us, on highly respectable authority, that it is a remedy of superior efficacy to any of the numerous substances that have been proposed for the removal of the diabetic symptoms. The experience of the profession, however, is as yet required to establish its real remedial virtues in diabetes.

The nitric acid diluted with water, (in the proportion of about three drams of acid to three pints of water,) is generally productive of benefit, mitigating the thirst and heat, and thereby diminishing the quantity of the urinary secretion. In the majority of diabetic cases it may be taken with advantage; but when there is any tendency to diarrhœa it ought to be omitted, as the bowels are apt to be disturbed by its use. Under these circumstances, lime water, or soda water, will be found excellent substitutes, as they are palatable to the taste, and quench the thirst.

The Bristol water was considered by Dr. Baillie as the best kind of drink in diabetic affections; indeed it has long been celebrated in such complaints. Dr. Marsh states that he has known a patient, labouring under confirmed diabetes, drink very largely of the Leamington saline waters without increasing the quantity of his urine, and even apparently with some advantage to his general health.

It has been shown that animal diet, opium, and venesection may be adopted *singly* with advantage in some instances of this disease; but we have found from experience that the *conjoint employment* of the two former remedies, with the occasional aid of the latter, is attended with much greater benefit. Animal diet forms the first and most important part of the treatment; for it possesses by far the most powerful influence upon the urinary secretion; and until the unnatural quantity of that fluid be considerably reduced, it is in vain to hope for any material change or improvement in its quality. Unless the disease be first of all much changed by perseverance in the animal regimen, very little benefit is to be expected from any other remedy whatever. It is proper during its adoption to bear in mind the *probable* occurrence of inflammation in some organ or part of the body, and to be prepared to meet it early by antiphlogistic measures. Opium is also extremely serviceable in allaying nervous irritability, and in restraining the urinary discharge. Indeed, few cases of this disease occur, in which the use of this valuable narcotic is not indicated, or can even be omitted without disadvantage. It does not interfere with the animal regimen, but proves a powerful auxiliary in the removal of the complaint. Venesection, too, when employed with vigour during the early and acute stages of the disease, before the constitution has become seriously affected or much debilitated, occasionally arrests the progress of the diabetic symptoms, and sometimes completely subdues the malady.

Thus it is obviously improper to trust the cure

of diabetes to any one remedy. In the selection of remedies, the symptoms form the safest guide. In obscure diseases, of the known varieties of treatment, that is to be held the best from which most benefit has been obtained; a principle which by no means precludes the trial of new remedies. Having ascertained the individual effects of several, it is often desirable to employ them *together*, as by their combined operation they prove more powerful in promoting restoration to health. Though much advantage often attends the united employment of animal diet, opium, and venesection, still we believe that the warm bath will generally be found more useful than the latter mode of cure. This opinion has been confirmed by the experience of several respectable practitioners. Warm bathing is generally agreeable to the patients themselves, and when aided by flannel clothing proves serviceable in removing the harsh, dry, and shrivelled state of the skin which accompanies almost every genuine case of diabetes. It may be correctly affirmed, that in every instance of this disease it is of the first importance to employ such means as are best calculated to restore the natural functions of the skin. Our experience entirely coincides with that of Dr. Marsh on this part of the treatment. As early as 1765 "a case of incontinency of urine complicated with diabetes" was published in the third volume of the *Medical Observations and Inquiries*, by Dr. A. Fothergill, of Northampton, illustrative of the good effects of antimonial sudorifics assisted by the warm pediluvium. Under this treatment all the symptoms improved; the patient's strength and appetite gradually increased; his skin became moist; and his urine was less in quantity than his drink. His recovery was at length perfect. Dr. Marsh, however, has the merit of having enjoined a more minute attention to the improvement of the state of the skin in diabetes. "Medical assistance," as Dr. Watt has justly remarked, "is seldom required where it is not more or less affected, and we have no security of the disease being removed, though apparently local, till the skin assume a healthy appearance. An excess or deficiency in the cuticular discharge never fails to produce some derangement in the rest of the system." When the functions of the skin are restored, and a free and equable perspiration is re-established, a favourable change in the more urgent symptoms soon becomes manifest; the distressing thirst and sensation of internal heat are mitigated, and the quantity of the urinary discharge rapidly decreases. In diabetes, with the exception of the kidney, there is indeed, (as Dr. Bostock observes,) no obvious exit by which the contents of the stomach can be evacuated; the perspiration is checked, the alvine discharge is in general not increased, and the weight of the body is daily diminishing; hence the necessity of directing remedies to the relaxation of the skin. With a view of producing a more direct action on the skin, Dr. Marsh was induced to employ the vapour bath in a well marked case of diabetes placed under his care, and the impression made upon the disease by the frequent use of this remedy surpassed his expectations. Its salutary effects in promoting diaphoresis were immediately perceptible. He also kept up the perspiration by

means of warm clothing and continued bodily exercise; and with daily improvement to the patient, who was dismissed from the hospital in a convalescent state. "The warm bath has been used," (says the author just named,) "but it has been used only occasionally: it has been employed as a secondary remedy, as one of minor importance, and not as one which, if properly managed, is of itself sufficient to effect a cure. Its daily employment for weeks, nay months, may be requisite to bring about that relaxed and freely perspiring state of the skin, without which, whatever temporary abatement in the symptoms, or diminution in the flow of urine, may have taken place, not one step has in reality been made toward the accomplishment of a cure." We are satisfied, with Dr. Watt, that it is upon the skin the first impression of disease is generally made, and that we have no security of the system being fully restored till it becomes natural in its appearance, and resumes its functions. In the case of Gosling, already before the public, and in two other instances of subsequent occurrence, we have employed the sulphur in preference to the warm bath, as it possesses the power of stimulating the cutaneous vessels more forcibly than the mere vapour of water. The result on each occasion has been the re-establishment of a healthy cutaneous discharge with an amelioration of the symptoms of the complaint. Owing to the great debility and frequent pulmonary irritation present in the disease, much muscular exertion is not practicable, though it is particularly desirable to obtain moderate exercise without inducing fatigue. In conjunction with the warm and sulphur baths, the peditivium, bodily exercise, friction, as recommended by Celsus, and flannel clothing, remedies which act *directly* upon the skin, diaphoretics may be exhibited internally with great advantage. The pulvis ipecacuanhæ compositus, in the proportion of eight grains every five hours, often succeeds in promoting free perspiration, and also proves useful in, allaying nervous irritability. It is certainly entitled to rank very high as a remedy in diabetes. In cases of a chronic kind, and accompanied by much debility and nervous irritation, Dr. Prout says that he has seen the very best effects from a combination of the pulv. ipecac. comp., and full doses of carbonate of iron, exhibited in the form of an electuary made with the albumen ovi. The tartarized antimony, in the dose of a sixth of a grain every three hours, also determines freely to the skin, and at the same time keeps up a slight degree of nausea, which is rather desirable than otherwise. When the salt acts upon the bowels, the proportion must be diminished. Having succeeded by these means in re-producing cutaneous secretion, it is indispensably necessary, in order to insure the good effects of the amendment, to avoid sudden changes of temperature, and to endeavour to maintain healthy perspiration by the aid of warm clothing and daily gentle exercise. We are enabled to speak from our own experience of the efficacy of what may be called the *diaphoretic plan of treatment*. In some instances, where every other means have proved unsuccessful, it has operated in a manner most decidedly beneficial. The patients have regained both flesh and strength, and recovered

their wonted spirits and activity. We have found it most advantageous in the incipient state of the disease; but it has also been of service where the complaint has been long continued, and the patient's constitution much debilitated.

We are led to draw the following inferences from the preceding facts and observations.—1st. That no satisfactory explanation of the real nature of diabetes has, as yet, been presented to the profession; hence, its proximate cause is still involved in obscurity. 2d. That it is probable that in most instances the stomach is primarily deranged, and that the kidneys are rendered morbidly active by the percolation of saccharine matter. 3d. That the employment of an exclusively animal diet proves chiefly useful by cutting off the supply of those materials which lead to the formation of sugar; and thus, if persevered in for a time, a favourable change mostly occurs in the assimilation. 4th. That the *animal regimen*, *opium*, *diaphoretics*, and the *warm bath*, constitute the most effectual means of arresting the progress of the diabetic symptoms, and of effectually removing the complaint; and that cupping and blistering the region of the kidneys, venesection in recent cases of an acute character, lime-water, or nitric acid for common drink, prove useful auxiliaries to the preceding remedies. 5th. That no individual remedy or method of treatment is applicable to every case of the disease: for in some instances an entire abstinence from vegetable food is highly useful; whilst in others, venesection, opium, or diaphoretics are found most beneficial. 6th. In commencing with any plan of treatment in this disease, it is proper to ascertain the quantity of solids and liquids daily taken, in order to be enabled to institute a comparison with the urine and its contents afterwards. A chemical examination of that secretion ought never to be omitted before the trial of any remedial measures, and during the progress of the complaint; as it enables the practitioner to determine with accuracy one most important point, namely, the quantity of saccharine matter it contains, and to ascertain the gradual advances towards recovery. The urine may assume nearly a natural colour, and lose all its diabetic properties to the taste and smell, when, on being evaporated, its residuum is found to afford a saccharine impregnation, showing that the disease is not completely subdued. From inattention to the evaporation and analysis of this fluid, medical men occasionally overlook the real nature of the disease. The specific gravity of the urine ought also to be very carefully ascertained, for it is impossible to pronounce with any degree of accuracy respecting the removal of this disease, or the beneficial change produced by any curative method upon the urinary secretion, without making occasional examination of the specific gravity of that discharge. So long as the specific gravity of the urine remains beyond the natural standard, the cure cannot be considered perfect, although the patient may be capable of resuming the ordinary duties of life.

JAMES L. BARDSLEY.

DIAGNOSIS. This term is derived from $\delta\alpha\upsilon$ and $\gamma\iota\nu\sigma\kappa\omega$, to know, and signifies *distinction* in

general; in medicine it is employed to designate the distinction of diseases.

It is necessary, before giving a detailed view of the diagnostic arrangement of diseases, to enter upon the general consideration of symptoms, as the principal source on which the distinction of diseases depends; and as symptomatology, or the doctrine of symptoms, cannot properly be considered under *diagnosis*, we propose to treat of the symptoms and diagnosis of diseases under the term SYMPTOMATOLOGY.

MARSHALL HALL.

DIAPHORETICS, (*διαφορητικά φάρμακα*, from *διαφορέω*, *differo*, *discutio*, from *εἶα*, *per*, and *φέρω*, *fero*, *porto*;) are medicines that augment the function of perspiration. In order to understand the mode in which they operate, we ought to possess an accurate idea of the manner in which the cuticular function is performed in a state of health.

The importance of perspiration for the preservation of health is well understood, but the laws to which it is subjected are still imperfectly determined. It is a function of the whole of the skin; but whether it is possessed equally by every part of it, has not been ascertained: it is, however, probable that some parts perspire more freely than other parts. The perspiral matter passes off either in the form of a thin, invisible vapour, as *insensible perspiration*; or in a liquid form, as *sweat*. Various attempts have been made to ascertain the quantity of the cuticular discharge. From the time of Sanctorius, who first endeavoured to determine it experimentally, to that of Lavoisier and Séguin, little confidence could be placed on the results of the experiments, as the amount of the pulmonary exhalation was not deducted in calculating the loss which the body sustained in a given time. Lavoisier and Séguin overcame this difficulty, by inclosing the whole body in a silk bag, varnished with caoutchouc, having a small opening carefully cemented round the mouth, which permitted the person to breathe. The quantity of the cuticular discharge was thus determined to be one pound fourteen ounces in twenty-four hours; (*Mémoires de l'Académie des Sciences*, 1790, p. 610,) and, as this was the result of repeated trials, we may regard it as the average quantity in a state of health.

Many circumstances tend to vary the loss by perspiration, not only in different individuals, but in the same person at different times, and under a diversity of circumstances; as, for instance, the vigour of the frame, the nature and quantity of the ingesta, the temperature of the atmosphere, and many external relations. Thus perspiration is diminished immediately after a meal, but augmented during the process of digestion: it is also promoted during sleep; in a dry state of the atmosphere; in a current of air; and under a diminished barometrical pressure. But these circumstances are supposed to promote perspiration independent of vitality; and therefore Dr. Edwards has divided perspiration into that which results from ordinary physical influences, and that which is dependent on vitality or secretion; or into *exhalation* and *secretion*. Both are liable to be affected by external agents. In low tempera-

tures, the loss by evaporation exceeds that by secretion, because cold suppresses secretion more than it impedes evaporation. It may, indeed, be maintained that even in a low temperature the cutaneous capillaries are still stimulated; and, consequently, that the portion of the insensible perspiration, which is the result of vital energy, must still be supplied: but it is in the ratio only of the stimulus which excites the vessels that furnish it: whilst the evaporation is less diminished, because the air being heated by contact with the body, is enabled to hold more moisture in solution than the air farther removed from the body; and thence evaporation is favoured.

One evident intention of perspiration is to prevent the temperature of the body from rising above that degree which a state of health requires, and to operate as a balance to the heating influence of increased arterial action. It also counterbalances other secretions; as for instance that of the kidneys, which is diminished as the perspiration is increased, and augmented when it is checked—a physiological fact of much practical value.

Many experiments have been made to ascertain the chemical nature of the perspired matter. From all that is known, it may be concluded that it consists chiefly of aqueous fluid, containing in solution some free lactic acid, lactate, muriate, and phosphate of soda, and an oleaginous principle: but there is also reason to believe that gaseous fluids are perspired by the skin with bases of nitrogen,* carbon,† and hydrogen;‡ and to the presence of the latter, variously modified by the accession of other constituents, some physiologists attribute the odour of perspiration. This odour, however, seems rather to depend on the secretions of the mucous follicles mingling with the perspiration, than to be a quality of this fluid, as it differs in different parts of the body.

Contemplating the nature of the perspiratory function, we may conclude that it is intended to answer two purposes:—1. to convey caloric from the body, and thereby to moderate and regulate its temperature; 2. to carry off a large quantity of carbon and hydrogen from the circulating mass.

Disease is frequently the consequence of a sudden check to the perspiratory function; means, therefore, have been sought for to restore it; and substances which have the power of effecting this are termed *diaphoretics*. Let us now inquire in what manner they produce their effects.

[The writer has elsewhere attempted to show (*General Therapeutics and Materia Medica*, i. 308: Philad. 1843), that in any mode of viewing the subject, it does not appear that we can ascribe any extensive series of morbid phenomena to simple obstruction of perspiration; and that, consequently, the indication of restoring suppressed perspiration, if it be admitted at all, must exist much less frequently than has been imagined.]

‡ Experiments on Insensible Perspiration, by W. Cruickshanks; Jurine's Experiments, Histoire de la Société Royale de Médecine, tom. x.; and those of Abernethy, detailed in his Surgical and Physiological Essays.

Diaphoretics may operate in two ways:—1st, by stimulating generally, and so augmenting the force of circulation as to propel the blood forcibly through the minute vessels of the *corium*, by which both the secreting power of the skin, and the excretory function of the exhalents, is increased; 2dly, by the absorption of the diaphoretic substances taken into the stomach, and the direct application of these to the cutaneous capillaries.

In the healthy state of the system, perspiration is, probably, always the result of stimulating, either directly or indirectly, the cutaneous exhalents; and sweating follows increased vascular action, whether this arise from muscular exertion, or from substances taken into the stomach. But in disease, when the temperature of the body is augmented, the pulse is often frequent, indicating increased excitement of the general circulation, yet the skin remains dry. In this state there is evidently diminished action of the exhalents, whilst the cutaneous capillaries have their secreting power impeded; and, therefore, this condition must be overcome before diaphoresis can be produced. Those substances which augment the force of the general circulation, whilst at the same time they excite the cutaneous exhalents, will effect this desired change; few substances produce this double effect, alone, but it is readily induced by some combinations.

Those diaphoretics which operate by augmenting the force of the vascular system, increase the frequency and the power of the pulse, and raise the temperature of the body, previous to the flow of perspiration: on the other hand, those which act by stimulating the cutaneous exhalents without augmenting the force of the general circulation, exert a primary influence on the nervous energy of the stomach, and the skin responds by that inexplicable connection to which the term *sympathy* has been applied.

As the primary effect of diaphoretics is the evacuation of a large portion of the aqueous part of the blood, it might be supposed that this vital fluid would in consequence become thicker; but various circumstances concur to prevent such a result. Amongst others, thirst always accompanies sweating; and as this forces us to take fluids into the stomach, the waste of the aqueous matter thrown off by the skin is rapidly supplied. At this time, also, other fluid secretions are diminished, the urine, for instance; so that the watery matters which would be carried off by them are diverted to the surface, and several substances, which naturally find other outlets, are expelled by the skin. This is clearly demonstrated in some diseases. Thus, in cases of *ischuria renalis*, the perspiration has been found to contain uric acid and other traces of urine. Dr. Percival relates a case in which the perspired matter was so saturated with the salts of the reflux urine, as to crystallize on the surface of the body, in the form of a white powder. Such a condition of circumstances is, indeed, not surprising, when we consider that the suppression of one secretion induces an unusual action in the vessels of some other organ, and a changed condition of the secretion.

One unquestionably beneficial effect of diaphoretics is the determination of the blood from the

interior to the surface, thereby relieving congestions, and maintaining that due balance of the circulation which appears to be essential to the preservation of health. Their salutary influence is also displayed in the increased power which they bestow on the absorbents, and in their relaxation of the surface in febrile affections. The relaxing effect of diaphoretics is indeed the most important property they possess as remedial agents, as it is on this power that their utility in inflammatory affections depends. Were it, however, attempted to induce diaphoresis in inflammatory or febrile affections by stimulating diaphoretics, the desired effect would not only be prevented from taking place, but the hazardous symptoms would be aggravated. Several circumstances, therefore, are requisite to be attended to, in the administration of this order of medicines: we shall mention those most important in a practical point of view.

1. Whenever diaphoretics are indicated, the patient should be confined to bed, but not overloaded with bed-clothes. If the pulse be full, hard, and quick, and the skin hot, bloodletting, if not contra-indicated by some peculiar circumstance, should preface the use of the diaphoretics; and the bowels should also be freely opened. It is a correct opinion, that free perspiration is not consonant with a quick, hard pulse, and a temperature of the skin exceeding 102° of Fahrenheit: in this state, if sweating occur, it is generally partial, and rather injurious than salutary. Even after the reduction of the phlogistic diathesis, the diaphoretics to be selected are those which nauseate and relax the surface.

2. The free use of diluents is necessary during the operation of diaphoretics, unless the stomach be in a highly irritable state. If antimonial diaphoretics, however, be employed, acidulated fluids should not be taken soon after the dose of the antimonial, as vomiting would be induced. When the temperature of the surface is high, the diluents should be cold; but when it is moderate, they should be tepid. So important, indeed, is dilution in promoting the action of diaphoretics, that the mere introduction of cold or tepid fluids into the stomach during the hot stage of fever, often produces diaphoresis.

3. During the operation of diaphoretics, it is essential to use bad conductors of caloric as coverings: both the body-clothes and the bed-clothes of the patient should be flannel, which, being of a light spongy texture, not only preserves an uniform temperature, but also absorbs the moisture as the perspiration flows. When linen is employed, the moisture accumulates in it, and aiding its conducting power, carries off the heat too rapidly from the body, and chills the surface. Attention to this circumstance is most essential, if it be requisite to keep up the sweating for ten or twelve hours longer, and especially if sleep become necessary during the continuance of the sweating. The older practitioners invariably resorted to the use of flannel during diaphoresis; a custom which has been too hastily condemned by modern practitioners, who recommend, instead of flannel, frequent changes of well-aired linen, asserting that this is more refreshing to the patient, that, from its comfortable feel, it has a tendency to allay irritation, consequently to aid in subdu-

ing the restlessness and inquietude of fever; and that it is essential for carrying off the fomes of the disease. The last part only of this opinion is well founded; and few practitioners would place a patient labouring under an infectious fever in flannel: indeed, under such circumstances, perspiration to the extent which requires the use of flannel is neither necessary nor desirable.

4. Attention must be paid to the *state of the bowels and kidneys*. If perspiration be requisite in a low stage of fever, purging must be studiously avoided, and should be checked if it occur spontaneously whilst the sweat is flowing; as it is almost certain to stop the sweating and to aggravate the disease, by diverting the blood to the interior, and exposing the patient to cold. The utmost caution, indeed, is requisite to prevent the admission of cold air to the surface; and no cold liquids should be taken into the stomach whilst the sweat is flowing, and for some time after it has ceased. During the administration of diaphoretics, every thing which has a tendency to promote the secretion of the kidneys should be avoided. The avoiding a frequent change of linen is in conformity with this rule, as, in affecting these changes, the surface must be necessarily exposed.

5. The morning, directly after sleep, is the best period of the day for administering diaphoretics, as the system is then easily excited, and the surface is relaxed: experience has demonstrated that many persons in whom perspiration cannot be induced at any other period of the day, may be readily made to sweat at that time. When perspiration accompanies diseases, it generally happens in the morning; there is then, also, a natural decline of febrile excitement; thence it is the most favourable time for the action of diaphoretics: and besides, as the administration of diluents is necessary to maintain the diaphoresis, this is the more convenient period for their administration.

6. When sweating is to be checked, the skin should be dried with soft warm towels; the patient should be carefully moved into dry flannels, and the coverings gradually lessened, allowing the arms to be cautiously exposed to the air. By these means, the injurious consequences, which might follow a sudden revulsion, are avoided.

Before entering upon the examination of those substances and means which are usually employed to promote diaphoresis, it may be proper to state why we arrange them under the two following heads:—

1. Diaphoretics, which cause a copious watery, cutaneous excretion, or flow of *sweat*.

2. Diaphoretics, which only augment the *ordinary perspiration*.

The first set excite the cutaneous capillaries and exhalents to a degree sufficient to increase both the secretory and the excretory functions of the skin beyond that point at which the perspired matter is carried off in the insensible form; thence it appears as sweat, and the substances inducing it ought to be distinguished from other diaphoretics. They are properly termed *sudorifics*. The second set operate in the same manner, but so moderately that they merely augment the ordinary insensible perspiration. It is true that both these results may be obtained by modifying the

dose of the substances employed, and the circumstances under which they are administered; but nevertheless there are substances which, all circumstances being equal, produce a more powerful diaphoretic effect than others; and, therefore, this division is useful.

1. *Sweating* may be produced in two ways: by substances taken into the stomach; and by applications to the surface.

a. The substances capable of producing sweating when taken into the stomach—*sudorifics*—belong both to the *organic* and the *inorganic* kingdom of nature. Among the first, *ipecaeu-anha*, the root of the cephaelis *ipecaeu-anha*, which has been long known as a valuable sudorific, owes its properties to a peculiar alkaline principle, discovered by M. Pelletier, in 1817, named *emetia*.* Separate from the ipecaeu-anha, *emetia* has not yet been introduced into general practice in Great Britain, although it is much employed on the continent. Ipecaeu-anha in moderate doses, one grain or less, is well calculated to produce sudorific effects; but it is seldom administered alone for this purpose, being generally combined with opium, the narcotic influence of which it moderates, whilst its own diaphoretic powers are augmented by the combination. It exists in this state in the compound powder of ipecaeu-anha of the British Pharmacopœia, ten grains of which, a full dose for an adult, contain one grain of ipecaeu-anha and the same quantity of opium. In prescribing this powder, or ipecaeu-anha itself, or its infusion in wine, although it may be advantageously combined with camphor or with nitrate of potassa, yet it ought not to be prescribed in conjunction with astringent decoctions or infusions, as the tannin unites with the *emetia*, forming an insoluble tannate, which is inert. Its sudorific effects, when once begun, should be maintained by copious dilution with tepid fluids; but tepid drink should never be taken immediately after the powder, otherwise it may be rejected by vomiting. It should, also, be recollected that the diluents should not be acidulated, as the combination of vegetable acid with *emetia* is more likely to run off by the bowels than to exert a diaphoretic influence; at the same time, as it is advisable to add something to the tepid water to prevent the nausea extending to vomiting, lemon-peel may be infused in toast-water for that purpose.

Mezereon, the inner bark of the roots of *daphne mezereum*, is also supposed to owe its sudorific property to an alkaline principle, *daphnina*,† which was first procured by Vauquelin from the *daphne alpina*; but this is uncertain. *Mezereon* is a stimulant sudorific, exciting, powerfully, the

* The *emetia*, in its separate state and pure, is white, pulverulent, and unalterable in the air, of a slightly bitter taste, inodorous, sparingly soluble in cold water, but soluble in hot water and in alcohol and ether. It is seldom obtained in this state, but is usually of a reddish-brown colour and deliquescent. One hundred grains of good ipecaeu-anha contain sixteen of *emetia*. MM. Magendie and Pelletier suppose that it is taken into the circulation, and exerts a specific effect on the lungs, and on the mucous membrane of the intestinal canal.

† *Daphnina*, when pure, is a colourless, inodorous alkaline salt, which crystallizes in transparent brilliant crystals, soluble in water, alcohol, and ether. The alkalis, lime water, and barytic water, tinge its solution of a golden hue; nitric acid converts it into oxalic acid.

heart and whole arterial system: it is apt to cause vomiting and purging. It has been found very useful in chronic rheumatism, and, in conjunction with the liquor arsenicalis, in obstinate cases of lepra, and some other chronic cutaneous affections. It is probably to its sudorific property that we are to ascribe its beneficial influence as an ingredient in the compound decoction of sarsaparilla, in secondary syphilis and many chronic diseases. We are aware that Mr. John Pearson states, that he had "very seldom found it possessed of medicinal virtue, either in syphilis or in the sequelæ of that disease, in scrofula or in cutaneous affections.*" Our experience prevents us from according with this opinion. Its sudorific powers may be secured by administering an infusion, made with two drachms of the bark in a quart of hot water, in doses of f.ʒii. every four hours.

Guaiacum, the concrete juice of the *guaiacum officinale*, was known as a diaphoretic so early as 1508, and was used by the natives of St. Domingo as a specific in syphilis; but although, when administered alone, it possesses no influence over lues venerea, yet it is a powerfully stimulant sudorific, and proves useful in impetigo and some other cutaneous eruptions; in oœna, and in scrofulous affections of the membranes and ligaments. Its utility in these cases may depend on its power of augmenting the energy of the absorbents and the cutaneous capillaries, thereby improving the state of the cuticular function. In chronic rheumatism, a solution of *guaiacum* in aromatic spirit of ammonia, the *tinctura guaiaci ammoniata*, given in doses of from f.ʒss. to f.ʒii. at bed-time, and its sudorific powers aided in the morning by copious dilution with tepid fluids, has been productive of much benefit; and it is equally serviceable in atonic gout: but its boasted efficacy as a gout medicine has never been realised; and even in chronic rheumatism the remark of Dr. Ferriar, that although in some forms of the disease it proves serviceable, in others it produces no effect whatsoever, is no doubt correct. Dr. Chapman makes the following remarks on the efficacy of *guaiacum* in a morbid affection of the eye:—"There is a morbid affection of the eye of gastric origin, hitherto not sufficiently noticed, where, although no external inflammation exists, or so slightly as hardly to be perceived, there is great intolerance of light; sometimes very acute lancinating pains through the ball, although more generally the sensation is that of a dull obtuse ache, attended with much heat and aridity of surface, which, whatever may be its nature, is very successfully treated by the *guaiacum*." (Chapman's *Materia Medica*.) Dr. Chapman appeals to his own experience of the efficacy of this medicine, and affirms that he never saw the disease cured by any other—[yet the affection appears to be unknown to every other pathologist and therapist.]

As a sudorific, *guaiacum* acts freely only when the surface is kept warm; otherwise, it excites the urinary discharge. The more minutely the *guaiacum* is divided, the more certain is its sudorific power; and, therefore, the tincture, decom-

posed by water, if the precipitated *guaiacum* be rubbed up with mucilage to suspend it in the liquid vehicle whatever it may be, is the best form in which it can be prescribed. The dose of either of the tinctures is from f.ʒss. to f.ʒiii. The ammoniated tincture is to be preferred in atonic gout.

It is unnecessary to enter into any details respecting those sudorifics which owe their powers to volatile oil. They are all too stimulant to be employed as sudorifics, except in diseases of diminished energy. In the low and sinking stage of typhus, *serpentaria* often proves beneficial; when, although the dry hot skin indicates the necessity of a sudorific, yet the nauseating and relaxing diaphoretics would prove injurious. It has also been found useful in dyspeptic affections accompanied with a dry skin, and is an excellent adjunct to cinchona or its salts in protracted cases of intermittents, and in atonic gout.

The only *inorganic* substances of value as sudorifics are the preparations of *antimony*. All of them may be so managed as to produce sudorific effects, but the most manageable and certain is the tartrate of antimony and potassa; and, in small doses, of from one-sixth to one-fourth of a grain, it seldom fails to procure copious sweating. The experiments of Dr. Elliotson have completely demonstrated the inert character of the *pulvis antimonalis* of the London Pharmacopœia; and the writer of this article has satisfied himself, by an experimental investigation, that it bears no resemblance to the true James's powder, the place of which it is intended to supply. The antimony in James's powder is in the state of a soluble *protoxide*; in the *pulvis antimonalis* it is usually† in that of an insoluble *peroxide*; and as it is undoubted that the more soluble the salts of antimony are, the more certain and powerful is their sudorific influence, it is easy to explain the general inefficacy of the antimonial powder, 130 grains of which have been given, three times a day, without producing even nausea. (London Medical Gazette, December 1831, p. 463.) But, at the same time, it must be admitted that no medicines are so much modified in their effects by idiosyncrasy as antimonials: in one person, small doses of tartar emetic will induce only moderate sweating; in another, the same dose will cause alarming vomiting and purging, extreme depression of bodily strength, and excite a degree of nausea which cannot be allayed.

The influence of antimonials is much augmented by combination with other substances, as camphor, calomel, and opium; but, in prescribing tartar emetic, it should be recollected that it is decomposed by alkaline carbonates, by the medicinal soluble salts of zinc, lead, bismuth, and mercury; and that an insoluble tannate is formed with the protoxide of antimony, when tartar emetic is added to any of the astringent vegetable infusions or decoctions, with the exception of those of oak-bark. The tannate thus formed is inert; on which account decoction of yellow cinchona

* Pearson's Observations on the Effects of various Articles of the *Materia Medica*, in the cure of Lues Venerea, Lond. 1800, p. 49.

† We say usually, because no preparation used as a remedial agent is so variable in its nature. In a few specimens we have found a small proportion of the protoxide; but in far the greater number of the specimens examined, the antimonial is in the state of a peroxide.

is the antidote of tartar emetic. In acute rheumatism and other inflammatory affections, a combination of one grain of calomel, one-fourth of a grain of tartar emetic, and from one to two grains of opium, administered every fourth or fifth hour, produces everything that can be expected from a sudorific: indeed, when the intention is to determine powerfully to the surface, the tartrate of antimony and potassa, in small doses, repeated at proper intervals, and aided by warmth and diluents, is, as we have already said, more manageable and certain in its effects than any other of this order of remedial agents.

b. Those agents which, applied to the surface, produce sweating by directly stimulating the cutaneous capillaries, are warm and hot baths, vapour-baths, hot air-baths, and the cold affusion. For the *modus operandi*, and manner of administering these, we must refer to the article BATHING.

2. The diaphoretics which merely augment the ordinary perspiration produce their effect in three ways:—1. through the medium of the stomach; 2. by entering the circulation, and acting directly on the skin; 3. by application to the surface.

Among the substances of this division of diaphoretics which operate through the medium of the stomach, we think it unnecessary to say anything either of *musk* or of *castor*. With respect to *dulcamara*, (the twigs of the *solanum dulcamara*), which owes its efficacy to a peculiar alkaloid, named *solanina*, either diaphoresis or diuresis may be produced by it, according to the extent of the dose or the manner in which the surface of the body is managed during its administration. It generally produces nausea, and not improbably much of its diaphoretic influence depends on this circumstance; and on this account the dose should be gradually increased during its administration. Two fluidounces of the decoction, made with ℥i. of the bruised twigs boiled in a pint and a half of water down to a pint, given three times a day, seldom fail to induce and maintain a gentle breathing perspiration. *Camphor* certainly produces a tendency to diaphoresis, without increasing the velocity of the pulse; and, therefore, it forms a useful adjunct to more decided diaphoretics; but with respect to *sarsaparilla*, even this is doubtful; and we are disposed to think that the diaphoresis which it is supposed to produce is due to the tepid diluent regimen which is generally prescribed during a course of it.

Among the inorganic substances belonging to this division of diaphoretics, we find the carbonate and citrate of ammonia, citrate of potassa, and acetate of ammonia. The first stimulates the nervous energy, and produces diaphoresis when aided by external warmth and plentiful tepid dilution; it is indicated in the sinking stage of typhoid fevers, and other debilitated conditions in which diaphoresis is still desired; but otherwise its place can be much better supplied by many other substances. In combination with *guaiacum* and opium, considerable advantage has been obtained from it in obstinate cases of chronic rheumatism. To produce its diaphoretic effect the dose should not be less than twelve grains, nor more than twenty: the best vehicle for administering it is the almond emulsion. The *citrate of ammonia*, which is generally prepared at the moment of its

administration by saturating recent lemon-juice with carbonate of ammonia, possesses very moderate diaphoretic powers; but it is less nauseous than the acetate, and forms an excellent vehicle for tincture of opium, when it is desirable to promote its diaphoretic influence. The same remarks apply to the *citrate of potassa*, which is more frequently employed than the former preparation, especially when the stomach is in a highly irritable state. The old method of administering the saline draught—first swallowing the solution of the alkali, and immediately afterwards the lemon-juice, although now seldom recommended, yet had its advantages. The alkaline solution allays the irritability of the stomach, whilst the close application of the carbonic acid, extricated in the stomach, to the nerves of that viscus, affords a certain degree of tone without interfering with the diaphoretic operation of the neutral salt formed by the union of the two bases. The best of the neutral salts, however, for inducing diaphoresis is the *acetate of ammonia* in solution, the old *spiritus Mindereri*. The common solution of this salt, the *liquor ammoniæ acetatis*, is generally very carelessly prepared, and little pains taken to produce a strictly neutral solution: when the alkali predominates, the solution of tartar emetic, occasionally prescribed with it, is decomposed; when the vinegar is in excess, the usual dose of the antimonial excites vomiting. The crystallized salt, formed by saturating strong acetic acid with ammonia, being always neutral, should be employed in solution in preference to the usual preparation. When perfectly neutral, the solution is an excellent vehicle for soluble antimonials and opium, aiding considerably the effect of both on the skin; it is also easily retained on the stomach, and frequently allays the irritability of that organ when administered in doses of ℥ʒiii. to ℥ʒxii. in any bland fluid.

The last of the substances necessary to be noticed in this section of the second division of diaphoretics is *water*. The greater part of the fluid perspired by the skin is water; and if the surface be kept warm, so as to check the action of the kidneys, the proportion is generally in the ratio of the quantity of fluid taken into the stomach. But besides this cause of the diaphoretic influence of water, it is also well known that the sudden impression of a draught of cold water upon the nerves of the stomach acts most forcibly in promoting diaphoresis. A person who awakes in the night with the tongue feverish and parched, a quick pulse, and a dry, hot skin, finds immediate relief from swallowing a large draught of cold water: the cutaneous capillaries immediately consent with the stomach, and copious perspiration often ensues. By imitating this practice in fevers a similar result is occasionally obtained. When water is to be employed as a diaphoretic, much depends on the management of the patient during its administration. If the surface be kept warm, and the body surrounded with bad conductors of caloric, a moderate quantity of water will produce the effect required. Under these circumstances, cold water is to be preferred to warm; but it must be kept in remembrance that in delicate constitutions, even in fever when the excitement is high, a sudden reduction of temperature is hazardous,

and, therefore, tepid drinks are necessary; and small quantities of aromatics may be added to the aqueous fluid to moderate the nausea which tepid water always produces.

Besides being diaphoretic itself, water is the general auxiliary of all other diaphoretics; nor can the influence of the best of them be maintained without ample dilution. In this case the fluid employed should always be tepid, at least of a temperature not under 65° Fahrenheit. The same rule, indeed, is necessary for the administration of diluents as for the external employment of water; when the temperature of the body is under 96°, cold drink should not be ordered. Nature points out the best indications for using water, both as to its administration at first and its continued employment, by the sensation of thirst which accompanies every state of febrile action: when this is present, we cannot err in prescribing water, the temperature being determined by that of the body and the state of the skin.

Among those substances which enter the circulation and operate as diaphoretics by their direct influence on the skin, the first which we have to notice is *sulphur*. When this substance is taken into the stomach, it passes off through the cutaneous exhalents united with hydrogen; a fact demonstrated by silver, worn in the pockets of those taking it, assuming the same dark hue as if it had been exposed to a stream of sulphuretted hydrogen gas; and as it thus passes off, it excites diaphoresis. As a diaphoretic, sulphur is employed in cases of chronic rheumatism and some other skin diseases; and in combination with oil, the oleum sulphuratum of the London Pharmacopœia, in chronic catarrh: but this is an acrid, nauseous preparation, and consequently seldom administered. In combination with potassium, sulphur forms a solid preparation, hepar sulphuris, which by solution in water is converted into a hydro-sulphuret of potassa. Both of these preparations have been employed as diaphoretics in chronic affections of the chest, and in several cutaneous diseases.

The action of the salts of *mercury* upon the capillary system has been long known; and in having the cuticular discharge promoted by them, it is probable that the skin only shares, as a secreting organ, in the general influence which they exert on the glandular system; but although their influence on the cutaneous function is demonstrated by daily experience, yet they are only employed as auxiliaries in promoting diaphoresis. Calomel, the protochloride of mercury, is the preparation usually selected for obtaining the effect of mercury on the cuticular exhalents; and it is generally conjoined with tartar emetic or James's powder, ipecacuanha, guaiacum, or opium; to which it imparts additional sudorific power. In these combinations, calomel is given with advantage in all inflammatory diseases; and, in the form of Plummer's pill, in cutaneous eruptions and in chronic rheumatism. In this pill the antimonial is the antimoniæ sulphuretum præcipitatum of the London College, a preparation possessing more certain sudorific properties than the pulvis antimonalis: whether an influence can be ascribed to the guaiacum, considering its small proportion to the more active ingredients in this

pill, seems doubtful. As a diaphoretic, the dose of calomel should not exceed one grain, frequently repeated.

c. Whether sweating or mere diaphoresis be produced, the cause of both, as far as they are the result of the substances to which we have already referred, is the augmented action of the whole vascular system; but diaphoresis may be procured by the excitement merely of the cutaneous capillaries. The natural insensible perspiration is, indeed, apparently the effect solely of the cuticular system of vessels; and although means exist by which this may be carried to sweating, yet still the cause is confined solely to the cuticular vessels. *Friction* operates in this way, acting on the surface, in a manner equivalent to muscular exertion on the whole habit, in augmenting diaphoresis. The *tepid bath* produces its effects on the same principle, although both the degree and the nature of the stimulus be different. When the tepid bath is employed, it is necessary to continue the application for a considerable time to produce the desired effect. The first result of its application is emollient, the second diaphoretic.

In remarking on the practical employment of diaphoretics, we should say that they must be selected according to the nature of the disease, and the object to be accomplished. Those that operate by augmenting the force of the general circulation are well adapted for relieving internal congestions; those which produce nausea and unload the oppressed capillaries, are adapted for diminishing febrile action, and reducing the morbid temperature of the body.

With respect to the diseases in which diaphoretics are beneficial, we must refer to the various articles which are devoted to their consideration.

[It may, however, be doubted whether we have any internal remedies that are capable of acting as direct diaphoretics,—that is, by virtue of specific properties which they possess over the glandular or diapnogenous apparatus of the skin. In every case in which the skin is hot and dry, and the indication appears to be to establish diaphoresis, the cause of this condition of the cutaneous exhalents must be inquired into, and if possible removed. Hence it is, that the well-instructed practitioner employs *indirect* diaphoretics rather than such as are esteemed *direct*. Thus, diminished sensible exhalation takes place from the skin during the existence of fever or inflammation, but the physician does not have recourse to any reputed diaphoretic, which acts by exciting the sanguiferous system. He adapts his antiphlogistic remedies so as to reduce the already too much excited condition of the blood-vessels, to the healthy standard; and he finds, when he has removed the internal inflammation, the heat and dryness of the skin subside, and diaphoresis satisfactorily established. Under similar circumstances, a full dose of opium is attended with a similar result. Opium in a full dose is a sedative; and hence morphia, in large doses, is often so powerfully diaphoretic. Nauseants are most effective diaphoretics in diseases of excitement; and they are powerful sedatives. On the whole, even in febrile and inflammatory affections, the use of the ordinary internal diaphoretics is uncertain, and generally of no avail; and many of them are de-
