I shall leave the soil in this bed exposed during winter, and purpose next spring to save the soil of the sprayed section and replant it with Sweet Potatoes, in order to learn if the contamination of the copper remains in the upper stratum, or if it is washed downward so deeply as not to be harmful to the growth of the plants. These analyses of the soil by vegetation are more searching and more practical than those made by the chemist can be.

My Experiment Vineyard, which has been annually subjected to treatment by the copper solutions ever since 1887, affords a good field for investigation. I purpose to examine chemically the soil of this vineyard, in successive strata, to the depth of, say, two feet, to find where the copper is. On this Experiment Vineyard I do not, as yet, see any defect in the growth of the vines. All are thrifty and are peculiarly healthy. My sprayed vines are covered with green foliage and have plenty of well-ripened canes, while a neighboring vineyard, not ten feet distant from mine, has been bare of leaves for the past two weeks, with its canes but poorly ripened. On my vineyard this year I saved the entire crop by spraying with the Bordeaux mixture. The neighboring vineyard, of the same variety of grapes, lost its entire crop by the black rot. So far as the Vine is concerned its testimony is decidedly in favor of the use of the copper remedies. Yet, other plants in this vineyard—weeds and grasses—tell plainly that something in the soil is hostile to their health. The surface-growths in my Experiment Vineyard, which has been longest sprayed with the copper mixtures, contrast in a striking way with those of vineyards untreated. Among untreated Vines the weeds and grasses are knee-deep. In the sprayed vineyard the soil is nearly bare of this sort of vegetation.

These observations suggest that it may be well to be parsimonious in the use of copper solutions on our soils. How they may affect the root-system of the Vine we, as yet, do not know; but for other vegetations it will possibly prove dangerous. At any rate, until we know more on this subject, it will be more safe to economize in the application of copper.

When we first learned of these mixtures from France it was stated that the simple solution of copper sulphate—one pound of the sulphate to twenty-two gallons of water—is effective in preventing diseases of the Vine. We found that this "simple solution" harmed the foliage of the Vine. We then substituted the Bordeaux mixture, six pounds of copper sulphate, four pounds of fresh lime (to neutralize the acid of the sulphate), and twenty-two gallons of water. French professors at Montpelier now advise the use of twice as much sulphate in the mixture. Now, if the "simple solution" of copper be fatal to the fungus, why is the Bordeaux mixture better, with its six times as much copper salts and lime, to neutralize its effect on foliage? My experiments with the copper sulphates have shown that it is the copper only which is the fungicide. Hence, why may not only one pound of it be effective, if it be neutralized in acid by an alkali?

The experiments in prevention of plant-diseases are, as yet, but crude. Many tests must be made before our agricultural pathologists can speak with certainty on many vital points. The fact is fixed, that the copper mixtures are reliable fungicides. We must now further find how to use them safely—that is, without harm to vegetation.

The suspicion of injury to man when he partakes of fruits sprayed with the copper solutions has been suggested by some city boards of health. But this is preposterous.

Vineland, N. J. *A. W. Pearson.*

Work of the Season.

THE preparation of various plants and bulbs for winter-flowering will occupy a prominent place in the routine work of the present time. The more tender subjects, such as Bouvardias, Stevias, Callas, etc., will be safely housed before this date, for to leave them out after October 1st in this latitude is only to invite injury. *Lilium Harrisii*, for early flowering, should have been potted some weeks ago, but if needed for Easter only, there is still time. For the latter purpose *L. longiflorum* is decidedly better, making a much handsomer pot-plant than the Bermuda Lily.

As a potting material for these Lilies there is nothing better than light loam well enriched with good manure, and they do the best when originally set into the pots where they are to bloom. It is bad practice to disturb the roots of a Lily by a shift after the plant has started. In order to secure a good root-growth before the top makes much headway, these Lilies should be placed in a cold frame until sharp frosts are apprehended, when, of course, they must be brought into more protected quarters; and I have secured the strongest growth by covering the frame with slightly shaded sashes instead of covering the pots with a mulching. Free ventilation is needed, both night and day, so long as the weather will permit.

Lily-of-the-Valley crowns, or pips, will also need to be cared for now. It is best to pot the crowns as soon as they arrive, and then store them out-doors until needed. The separate pips may be treated in the same manner, or may be heeled-in in a frame in the original bundles.

Tulips, Hyacinths and Narcissus should also be potted as received and well covered in cold frames, in order to induce a strong growth. From here they may be brought into heat in successive lots as required. Cannas should be lifted as soon as the foliage is injured by frost and may be stored in almost any moderately warm and dry place for the winter. It will be found a good plan to lift a few clumps of the best dwarf varieties before frost and put them in tubs or boxes for conservatory decoration, and also to furnish flowers for cutting during the winter. The handsome foliage and bright flowers of some of these Cannas are very effective when used in large vases.

Carnations recently lifted should be staked and tied as soon as possible, to prevent the flower-shoots from falling about, and if the plants are set out on a bench, the neatest method of staking is by means of wires placed in the same way as would be done for a bench of Roses. But, whatever method is adopted, some care should be given to the tying of Carnations, for, when bunched up too tightly, the foliage in the centre of the plant soon decays from lack of light and air, and not only the appearance, but also the health of the plants is ruined.

Cyclamens will soon be showing flower—in fact, many will do so before this—and among the most necessary precautions for their welfare are free ventilation and plenty of light. It should also be remembered that shapely, sturdy plants cannot be developed unless they are allowed abundant room.

To encourage the bracts of Poinsettias a stimulant in the form of liquid manure should be given about once a week. Pure guano is probably the most effective for this purpose, but it should at all times be used with caution, for an overdose will do considerable injury.

Holmesburg, Pa. *W. H. Taplin.*

Chrysanthemums.

IN the gardens of the amateur growers of Chrysanthemums at this time one observes a great difference in the forwardness of the buds in the various collections—a difference, apparently, in extreme cases, of a week. This is not peculiar to this season, but it may be observed any year. On a comparison of notes the owner of the backward blooms seems to have cultivated his plants judiciously and given them every requisite attention, and it is sometimes rather difficult to account for the slowness of development. It will generally be found, however, that either over-nourishment of the wood, resulting in gross sappy growth, which matures slowly, or else a rather shady position, and, perhaps, a too close tying together of branches has interfered with the ripening of the wood. Perhaps, also, as the season progresses toward the middle of August, the time when the buds may be expected to appear, the owner, a little over-solicitous, has given them liberal supplies of water and manure and kept them moving, whereas, were the plants kept rather dry till the buds appear and then given the proper amount of manure, the buds will quickly show the benefit of the treatment. These notes refer to plants in the open ground, which, in some respects, require different treatment from those in pots. There seems to be a general impression that these plants require great supplies of water, whereas, in the open, few plants are more easily injured by an over-supply. I should say that they require much less water than Roses to keep them in good condition. It has been often observed that vegetative vigor and sexual vigor are not synonymous, and this is true of no plant more than of the Chrysanthemum. A large grossly grown plant is usually a disappointment if good flowers are expected. A judiciously grown plant, with fine-grained wood, will always produce the best flowers.

Now that the October days have come, with keen frosty air, one turns to the Chrysanthemums with something more than cultural interest; a few forerunners there are in bloom, but these are only plain sisters of the splendid array which will flaunt their beauties in early November. The Chrysanthemum grower finds his present excitement in watching the gradual development of the fat buds which, with many changes, will perhaps expand into the longed-for perfect bouncing flowers. If, at the same time, like many amateurs, he flowers his plants in the open air, with temporary protection, he will find plenty of other excitement in guarding his treasures from hard frosts and high winds, which never seem to blow quite so hard as when one has a tent, or some such contrivance, which is a tempting plaything for a robust and festive gale.

Elizabeth, N. J. *J. N. Gerard.*

The Hardy Plant Garden.

QUITE a number of perfectly hardy bulbs succeed best when planted in fall and allowed to remain in the soil all winter. Although not a bulb, strictly speaking, the Lily-of-the-Valley usually should be planted as soon as it is received. There are many gardens that have a shady corner where this plant would be perfectly happy for generations, in places where it is difficult to get grass to thrive, as, for example, under trees and near shrubs that have become bare at the base. All that is necessary in planting is to cover the crowns, or "pips," about three inches deep and mulch annually with well-decayed manure to insure an abundance of these lovely flowers. Another plant, not bulbous, which should be planted now is *Mertensia Virginica*, the "Virginian Cowslip." No garden is complete without this early spring flower, which is far more sought after in England than here. The Mertensia has large fleshy root-stocks that send up shoots in early spring, and these bear flowers of the most intense blue, which last a long time in perfection even when cut. It is at its best here the first week in May. The Dodecatheons, also, should be planted now, as they flower early too, and if they do not flower the first season mark the spot where they are in June when they die down, and another year, when stronger, their pretty Cyclamen-like flowers may be enjoyed. There are several varieties of Dodecatheon, and all are pretty, though there are some forms sold as *D. Meadia*, that have a poor washed-out pink color, which may be improved by the addition of burnt earth or refuse. Collectors tell us that where prairie-fires pass over a locality the Dodecatheon-flowers are always of a much deeper color. If this is so, we have a very simple way of improving a pretty garden-plant.

If every one had courage to chronicle his failures as well as the successes the world would be much wiser to-day. Certain it is that the beautiful Anemones that thrive so well in Britain cannot be made to feel happy here, and after trying various methods we have now transplanted what are left of them to a cold frame, where they may flower in spring. We hope they will, as they are beautiful when cut and last a long time, but it is not wise to speak of them as hardy. I am inclined to think that *Anemone fulgens* is much more hardy than the varieties of *A. coronaria*. We planted them out once in a cold frame and merely protected them with a sash, simply to keep off the rain and snow, and they did better than any I have ever grown in pots. It is very difficult to procure a good strain of *A. fulgens* now; nearly one-half of them are apt to turn out mere abortions, the flowers being a mixture of green and scarlet shred-like petals. There is a form in cultivation known as Græca, which is the best of all, with broad Tulip-like petals. In districts south of Washington *A. fulgens* would be perfectly hardy and a beautiful border-flower when planted in light rich soil.

Calochortus, again, cannot be considered hardy. We tested them several ways last winter, but our only success was with those in cold frames planted in pans. These flowered beautifully in spring, and were very pretty when cut. In the garden now we have *Colchicum autumnale* in flower, a singular plant, which attracts attention always. Colchicums should be procured early, as the flowers often develop before their arrival here from Holland. In any case much must not be expected the first season, but in spring a good growth of foliage may be looked for, and in fall they will flower abundantly. They are often called autumn Crocuses. The winter Aconite is one of the earliest heralds of spring, with yellow flowers borne on a fringe of foliage just above the ground. A clump of this is gladdening to the eye, as the bright flowers open as soon as frost loosens its hold. Botanically the plant is *Eranthis hyemalis*.

Chionodoxa scarcely needs an introduction, so much has been said of it, but it has never yet been over-praised. The bulbs are small, but even if planted a foot deep they will come up and flower just as early. None except those who have tried know how difficult a bulb this is to attempt to dig in quantity; one is sure to leave as many behind as are taken up. The Chionodoxa is charming in any situation for early spring display, and with it comes the deeper blue Siberian Squill. These are both cheap, perfectly hardy, and should be planted about six inches deep. *Iris reticulata*, one of the bulbous Irises that flower early, is not difficult to keep, and is almost as fragrant as a Violet. A little breadth of this Iris is very pretty in early spring, as the flowers open with the Snowdrops. The best Snowdrop is *Galanthus Elwesii*. This seems to do better year after year than *G. nivalis*, the older kind, and flowers much earlier also. But of the time of flowering for spring bulbs very little can be said, as so much depends upon the weather.

South Lancaster, Mass. *E. O. Orpet.*

Anemone Japonica.—The Japanese Wind-flower, as this plant is commonly termed, is perhaps the best of our hardy Anemones, and undoubtedly the best late-flowering perennial known in New England gardens. The flowering season begins early in September, and continues in great brilliancy until frost. The large, dark green, ternate leaves are borne on stout petioles upward of a foot in length. The blade portion of the leaf in its entirety is of cordate outline, and the oblique lateral divisions and ovate central segment have also the cordate character, and are toothed and irregularly lobed. The stems, ascending boldly erect from the thick foliage to a height of from three to four feet, are branched toward the summit, and bear a profusion of spreading rose-purple flowers three and a half inches in diameter. The segments of the outer circle, where sepals are scarcely distinguishable from petals, are very numerous and of oblong form. The bright green, globular, pistillate mass in the centre, surrounded by a broad ray of showy yellow stamens, greatly enhances the beauty of the flower.

There are two quite distinct varieties of *A. Japonica*. The first, *A. Japonica*, var. *alba*, also known as Honorine Joubert, is by far the most popular, and decidedly the best of the three. The flowers of this variety are a trifle smaller than those of the species, and the elliptical or obovate parts of the pure white perianth rarely number more than nine, or about one-third of the number observed in the original form. *A. Japonica*, var. *rosea*, resembles the white-flowered variety in all particulars save the color of its flowers, which are of a delicate rose tint. These varieties are said not to be of seedling origin, but to have been obtained by means of root-sports.

A. Japonica is a native of China and Japan, and the inhabitants of those countries, where it is carefully grown, have long

appreciated its charms. It was introduced to Europe in 1844. The cultivation of the species and its varieties is not difficult. The plants make their best growth, and, consequently, flower most freely, on a moderately dry site which affords a slight measure of shade. A somewhat sandy loam, well enriched with leaf-mold, forms an excellent compost. Massing is the most effective method of planting, and great care should be exercised in the selection of the position for such masses, so that removal of the plants may not soon become a necessity. Disturbance of the roots is almost invariably resented by healthy plants, hence the desirability of using proper judgment in planting. A light annual top-dressing of thoroughly decomposed leaf-mold early in spring will preserve the needed fertility. Propagation may be effected by carefully dividing the roots in spring.

Cambridge, Mass. *M. Barker.*

Musa Ensete.—In a recess here, sheltered from the northwest winds, there stands, untouched by frost in mid-October, a noble group of the Abyssinian Banana. They are now six years old and have been planted in this corner for the last four years, but, as yet, have not fruited. Every autumn, when cut down by frost, they are dug up and stored in sand, free from frost, until some time in January, when, after repotting, they make new roots and a few leaves, and, although much reduced in size, they are in good condition for planting out in June. The set-back received during winter doubtless prevents their fruiting during the succeeding summer, and it is fortunate it is so, since fruiting in this species means death. Many plants of this species have been lost during winter through over-watering. They need very little. An acquaintance of mine threw a small plant into the loft, above a workshop, which was always free from frost. It kept alive all winter and grew well the following season, with nothing about its roots but a piece of bagging.

Wellesley, Mass. *T. D. Hatfield.*

Correspondence.

The Province Lands at Provincetown.

To the Editor of Garden and Forest:

Sir,—During my recent search for public holdings in the shore-towns of Massachusetts, for the Trustees of Public Reservations, I examined the province lands at Provincetown, and traced the course of legislation regarding the title to them. They are undoubtedly the property of the commonwealth, and thus constitute an important and extensive public reservation already in existence. It comprises all that part of Provincetown lying west of the westerly fence of the eastern schoolhouse, and extends southerly from the said fence about eighteen degrees east to the harbor, and from the said fence northerly about eighteen degrees west to the ocean. A large part of the village of Provincetown stands on this land, and besides the tract thus built upon there is an unoccupied area which the town officers estimate at 4,000 acres.

At a very early period in the history of the colony these lands were, by specific action of the Government, reserved as a colonial fishing-ground, and from it the colony obtained a varying revenue. At a later date this territory was set apart as a fishing-right to be held in common by the people of the province. The records of the colony show that it was enacted by the court in 1661 that no stranger or foreigner shall improve—that is, use—our lands or woods at the cape for the making of fish without liberty from the Government, and that all who obtain the privilege shall obey orders and pay sixpence a quintal for the colony's use for all the fish they catch. In 1670 the colonists were required to pay sixpence a barrel for mackerel caught at Cape Cod, and foreigners one shilling and sixpence. After this there is a long succession of grants and regulations for this fishing-ground, which constantly assert the title of the colony to these lands. Some of these grants were made to support schools, some for bounties for soldiers or their widows. In 1690 the court specifically asserts its possession of all the soil and royalties at Cape Cod.

In 1736 three men, as agents for the inhabitants of the Precinct of Cape Cod, presented a petition to the court asking that the precinct be made a town, and the court granted the request, with this condition, "Provided it do not prejudice the right and title of the province to the lands nor obstruct any person in the fishery, which is a privilege in common." The precinct was made a town in 1727, and called Provincetown, and in the act of incorporation the term "province lands" is first used officially. This is the act:

"Be it enacted, etc., That all the lands on said cape—being province lands—be and hereby are constituted a township by the name of Provincetown, and that the inhabitants thereof be invested with the powers, privileges and immunities that any of the inhabitants of any of the towns within the province by law are or ought to be invested with; saving always the right of this province to said land, which is to be in no wise prejudiced. And provided that no person or persons be hindered or obstructed in building such wharves, stages, work-houses and flakes and other things as shall be necessary for the salting, keeping and packing their fish, or in cutting down and taking such trees and other materials growing on said province lands as shall be needful for that purpose, or in any sort of fishing, whaling, or getting of bait at the said cape, but that the same be held as common, as heretofore, with all the privileges thereunto in any wise belonging."

From 1727 to 1854 there is, so far as I can ascertain, no record or indication of any abandonment or modification of the title of the province or commonwealth to these lands, and in 1854 the legislature enacted that

"The title of the commonwealth, as owner in fee to all the province land within the town of Provincetown, is hereby assorted and declared, and no adverse possession or occupation thereof by any individual, company or corporation for any period of time shall be sufficient to defeat or divert the title of the commonwealth thereto."

"The provisions of the 12th section of the Revised Statutes, chapter 119, shall not be held to apply to any of the province lands in said town of Provincetown."

These paragraphs are sections 8 and 9, chapter 261, of the Laws of 1854. The 12th section of chapter 119, here referred to, provides for the acquisition of title to land by undisputed possession or occupation for a prescribed term of years, and these province lands are expressly excepted from its application.

The people living on these lands are merely occupants and holders. They buy and sell the land, and give, receive and record warranty-deeds, but these, though they may be good as against the claims of individuals, are of no force or validity against the right and possession of the commonwealth, which holds by an absolute title, indefeasible by adverse possession or occupancy by any individual, company or corporation for any period of time.

There is no reason to suppose that the state will ever disturb or eject these occupants of the lands belonging to the commonwealth. Nobody, so far as I know, is in favor of any interference with the occupancy of those who have been permitted to appropriate portions of these common lands to their individual use; but a large number of the inhabitants of the town of Provincetown are dwellers on the public domain, and have no title in fee to the land which they occupy.

The most important feature of the matter is the fact that, besides the territory thus used and dwelt upon, there remains an area entirely unoccupied which is estimated at about 4,000 acres, or six square miles. This region embraces and constitutes the extreme end of Cape Cod. About half of the tract is fairly well wooded, being covered by a thick growth of "hard Pine" (*Pinus rigida*), Oak, Maple and other trees, with a dense undergrowth of shrubs and vines. This wooded portion lies nearest the village of Provincetown, and probably contains about 2,000 acres. The part nearest the shore, constituting the point of the cape, appears to be of nearly equal area. It is a region of moving sand, which is blown by the wind into great billows, or irregular ridges, which are every year rolled farther and farther inland toward the village, swallowing and burying the forest as they advance.

I saw Maple-trees more than twenty feet in height which are entirely covered as they stand, except a few sprouts from the highest branches, by which the tree is struggling to raise its lungs above the suffocating sand. It is a painful spectacle to a lover of trees. The whole of this area of 2,000 acres of unstable sand was covered by a Pine-forest when white men first came to the cape. This desert is not natural, but was directly created by human agency. The trees were cut away, and much of the space—perhaps all of it—burned over, thus destroying the soil and the mat of vegetable fibres which held it in place. All the conditions which maintained the stability of the surface being destroyed, the sand of the shore began to move inland before the wind, and it has continued to advance with increasing depth, volume and velocity until now. The stumps of Pine-trees are still visible where the wind blows the sand away down to the original surface.

Much money has been expended in efforts to stay the progress of this ruinous and resistless tide of sand, but nothing has been accomplished except to demonstrate the futility of the methods employed. The planting of beach-grass has been the means chiefly, or wholly, relied upon to bind the shifting

and flowing surface; but it is almost entirely ineffective, owing to the depth and mobility of the sand and the great force of the wind. A ridge or plateau of sand, from ten to twenty feet in depth and several acres in extent, is sometimes removed in a few hours.

I think the whole of the desert area might be reclaimed and rendered stable and productive, and the wooded region defended from further injury; but no effort for these ends can be successful unless the means used are adapted to the essential conditions and requirements of the problem. These have been entirely disregarded hitherto. The work of restoration must, of necessity, begin at the edge of the water, at the place where the wind which moves the sand first exerts its force.

A temporary barrier or wind-break, extending a considerable distance along the shore, would be required. A hedge or wall, formed of several rows of closely planted Cedar-saplings, or something of a similar character, would afford the protection needed, and under the shelter of this hedge could be planted such cuttings and young trees as are thought best adapted to growth in such conditions, some species of Willow and of Poplar, the Pitch Pine and other suitable trees. One species of Poplar grows rapidly and becomes very large along the streets of Provincetown, where it is absurdly called the "Silver Oak."

The hedge of Cedar-saplings would not be planted to grow, but it would last a long while, would catch most of the sand that might be raised by the wind between the hedge and the sea, and would afford shelter for the growth of the cuttings and young trees planted at its foot on the landward side.

Only a narrow strip could be thus defended at first, and, therefore, only a narrow strip could be planted at once with any possibility of success. The planting of a broad area at the beginning of the undertaking would be entirely unscientific and impracticable. After the young trees of the first narrow strip of plantation along the shore have begun to grow, another narrow belt, on the landward side of the first, can be planted, but the requisite shelter for later strips or belts of planting can be supplied only by the growth of the first belt. The essential requirements for the enterprise would be a small beginning, careful attention to details, unremitting watchfulness and fostering of the young plants and the extension of the plantations by successive narrow belts. After a beginning is successfully made, short lateral spurs could probably be extended from the base line of the planting at frequent intervals and at various angles. Much time would be indispensable, and great patience and faithful industry.

This state reservation is under the care of a state agent who is appointed by the governor and council. He is by law empowered to give permits for the cutting of timber and of sods on the state lands. The sods are not of grass, but of the roots of the bushes and shrubs growing on the land, and when these sods are removed all the soil is taken up with them, down to the inert sand, which is then blown away by the wind, thus adding to the area of desert. The sods are much desired and much used by the people of the village for "bulk-heads," terraces, banks, walls and many similar constructions. It is almost the only building material available for the people of the village without cost, but it does not belong to them. It is the property of the state and ought to be protected from spoliation. The removal of the soil is robbery of the most fatal kind.

The state agent is not, in any considerable degree, efficient. He appears to be extremely honest and conscientious in wishing to avoid expense to the state in the administration of his office. He grants very few permits. The fee for each permit is one dollar. All fees are turned over to the public treasury, and the agent is allowed three dollars a day for time actually employed in the duties of his office. He told me that, to save expense to the state, he seldom visits the reservation. I think that, as a matter of fact, he gives it no considerable attention, and scarcely ever sees much of its area. As a consequence, people do not take the trouble to apply for permits to cut wood or sods, but take what they want without permission. The reserve is despoiled of both wood and sods without scruple. Many of the Portuguese laborers in the town obtain fuel for domestic uses from the state lands, carrying home the wood on their backs after the regular labor of the day is over; but the native Yankees also contribute their full share to the spoliation.

The proximity of thousands of acres of wooded land, without apparent ownership or efficient supervision, is a perpetual provocation and inducement to theft, and it would have a similar effect anywhere. I have repeatedly observed about the same state of things on Indian reservations in Dakota and Idaho, and on the public domain in the Coast-range region. While this Massachusetts reservation remains unguarded and uncared for it must continue to exert a demoralizing influence upon the adjacent community.

I think the law relating to the administration of the reserve should be so changed that no cutting of timber for use outside of the limits of the reservation shall be authorized or permitted, and the removal of sods and soil should be entirely prohibited.

The town officers of Provincetown and other leading citizens would be glad to see an efficient supervision of the province lands established and maintained by the state. There is much talk of various schemes of real-estate men for the use and improvement of this state property as a means of attracting summer visitors and revenue to the village, but the first thing for the people of the state to consider is the need of proper care for the property of the commonwealth, and the adoption of an efficient system of treatment for the reclamation of the desert area and the preservation of the extensive wooded region which still remains unburied.

So far as can now be understood or foreseen, the advancing sand will in time, if it is let alone, bury the remaining woodland and destroy the village and harbor.

Boston, Mass. *J. B. Harrison.*

Sawdust for Protecting Plants.

To the Editor of Garden and Forest:

Sir,—In your issue of September 30th Professor Massey writes on the value of sawdust as a protection for plants. I should like to add my testimony as to its merits as a winter covering. It is somewhat difficult in city gardens to procure an annual supply and care for it from year to year. It surpasses, however, every other material I have ever used for the purpose. I have found it very valuable for wintering Carnation-seedlings, as it carries them through without any appreciable loss, and it is worth trying for any plant that suffers from the cold or severe winds of winter. The proper article to use is coarse sawdust from large circular saws used for manufacturing lumber. Of course, this dust should be kept dry by a covering of boards or building-paper or anything else which will shed rain to a reasonable extent.

Milwaukee, Wis. *Charles L. Mann.*

Recent Publications.

Annals of Horticulture in North America for the Year 1890. By L. H. Bailey.

This volume follows closely the methods of the Annals for the year 1889, and the series promises to be of real value as books of reference. Of course it must be admitted that a compendious record of the advance in horticultural science and practice year after year would be a help to all who have any interest in gardening. This would be true if the work did no more than collect and classify facts that have already been published, and arrange them so that they can be conveniently referred to. But, as Professor Bailey says in his preface, it is very difficult to lay out a plan for such a series which shall include what is most essential and exclude all other matter. The author had determined, apart from the Annals proper, to publish in each volume an investigation of some particular branch of American horticulture, as he did, last year, in his Catalogue of American Kitchen Garden Vegetables, which was the most elaborate chapter in the book. This year he had decided to make a census of native North American plants which have been introduced into cultivation, together with their horticultural varieties, but the work was one of such magnitude that it has been postponed.

The first part of the book gives a general view of fruits and vegetables during the year, with statistics of crops and prices and the like. Ornamental plants and ornamental gardening is next treated in the same way, and this is followed by an interesting and valuable sketch of what has been accomplished during the year in the way of treating plant diseases and injurious insects. A list of the sub-titles of the remaining section of Part I. will give the best idea of the character of the subjects treated. They are: "Legal Control of New Varieties," "Nomenclature," "Road Agitation," "The Census," "The New Tariff," "Educational Matters," "American Wild Flower Clubs," "Societies." Part II. is devoted to special annals, including the introductions of the year and the plant portraits, together with a directory of the most important horticultural societies of North America and of persons in charge of horticultural work in the experiment stations, a list of botanic gardens in the world, a title-index to publications of the experiment stations relating to horticulture, and a subject-index of the same sort, the books of the year, a list of the horticultural periodicals and

a short notice of such tools and conveniences for horticultural work as have been invented and brought into use. Of course, no two people will agree as to what such a work should contain, but the matter presented has been carefully prepared, and the book will be gratefully received by the horticulturists of the country.

Notes.

The Chrysanthemum Show of the Massachusetts Horticultural Society has been postponed until November 10th.

The Horticultural Society of Florida has asked for three acres at the Columbian Exposition in which to show an orange grove and make a fruit display.

Visitors from the east are often surprised at the size of the Geraniums growing out-of-doors in California, where they attain a height of from twelve to fourteen feet, and are covered with bright scarlet blossoms.

Steam-pipes are said to have been made in England from the ramie fibre. This material is subjected to tremendous hydraulic pressure, and, having the property of being unaffected by moisture, will neither shrink nor swell, besides being a non-conductor of heat. The pipes are said to have a tensile strength twice that of steel pipes.

The ornamental fruits of some plants are hardly appreciated for decorative work as they deserve. A lasting and extremely tasteful combination seen a few days ago was that of clusters of the scarlet fruits of *Cratægus coccinea*, intermixed with short sprays of the white-berried *Symphoricarpus racemosus*, with a few green leaves, in a wide, shallow vase of dark blue color. It is worthy of remark that both the plants are natives.

In a paper on gardening read before a meeting of the Croydon Gardeners' Association in England Mr. Charles Gibson spoke of steam-power as an agency which has contributed very largely to the enrichment of gardens with plants from all parts of the world. It is the speed with which plants are dispatched on long journeys which renders the loss so much smaller than what it was formerly, and this change has been brought about by steam.

English horticultural journals are loud in their praises of *Clethra alnifolia* and its racemes of sweetly scented blossoms. Of course it is not new in England, but it is spoken of as somewhat rare among foreign shrubs. The fact is that it is too rarely planted even in this country, where it is a native. The Sweet Pepper-bush, which blooms from midsummer well into September, is not excelled by any shrub of its season for the fragrance and beauty of its white flowers.

Mr. Benjamin G. Smith, of Cambridge, Massachusetts, exhibited at the meeting of the Horticultural Society, in Boston, on the 10th of October, thirty-four different varieties of grapes, and received the silver medal of the society for his collection. The grapes were all cut from the vines the day before, and no copper salts or other mixture had been used to prevent fungal diseases. The general excellence of the collection was noteworthy, and it spoke well for the skill of amateurs in growing hardy Grapes in Massachusetts.

According to Downing's *Horticulturist*, the first specimen of *Paulownia imperialis* which bore flowers in this country stood in the famous Parsons nursery at Flushing, Long Island, and flowered in 1847. One of the finest Paulownias we remember to have seen must have been planted at about the same time as Mr. Parsons' tree, as it was of great size, and bloomed profusely at least as far back as the year 1858. It stood on the west side of Fifth Avenue, near Sixteenth Street, in front of a house which was torn down to make way for the present Judge Building.

Mr. H. W. S. Cleveland writes that there are no acorns on the Bur Oaks in Minneapolis and the region thereabout this year. As a rule, the sidewalks in many places in that city at this season are littered with acorns from the old Oaks which were left standing on vacant lots or have been preserved in the yards of private residences. This year not an acorn can be found in the city nor in any of the woods near by. Mr. Cleveland is interested to know how far this failure extends, and since it is a matter of general interest, we should be pleased to hear reports on the acorn-crop from readers in other parts of the country.

A correspondent of the London *Garden* speaks of *Abelia rupestris* as a very valuable shrub for clothing low walls on account of its neat growth, bright foliage and its long flowering season. It is said that while it is hardy in many parts of England, in others it requires the protection of a wall. It seems to flourish well in this country as far north as Philadelphia. In Washington it is one of the most interesting shrubs in autumn. It is planted very largely in the public grounds of that city, and it is covered for months with clusters of pink and fragrant blossoms. It forms a dense bush, and under careful pruning its slender, curving twigs assume a very graceful outline.

An American Carnation Society was organized at Philadelphia October 15th, with a membership of about fifty. The following officers were chosen: Edwin Lonsdale, President; William Swayne, Vice-President; C. W. Ward, East Moriches, New York, Treasurer; C. J. Pennock, Kennett Square, Pennsylvania, Secretary. The meeting adjourned to meet in New York during the Chrysanthemum Show, to be held there next month. The Executive Committee is composed of the officers as elected and three others, namely, Robert Craig, Philadelphia; R. J. Lombard, Wayland, Massachusetts, and James Hancock, Grand Haven, Michigan. The objects of the society are to improve the Carnation, to encourage the production of new and better varieties, and to discourage the dissemination of novelties which have no decided value. The society ought to accomplish a useful work.

Mr. M. A. Thayer, who has demonstrated practically that small-fruit culture can be made profitable in Wisconsin, has just published a report from his fruit farms at Sparta which, from his careful method of keeping accounts and the generous spirit manifested, seems worthy of commendation. Five years ago the question of growing small fruits there was doubtful, and he therefore gives a full account of his outlay and income. The first year he planted eight acres of Blackberries, seven of Raspberries and two of Strawberries, at a total expense of $1,618, with no income. The second year he added eight acres, and his total expenses were $2,462, and his income was $926. The third year he set ten acres more to small fruits; his expenses were $3,394, and his receipts $4,432, or considerably more than $1,000 profit. The fourth year, or 1891, the expenses were $4,500, and the receipts $8,846, with a profit of $4,346. The receipts and expenditures are itemized, and the report concludes with advice to beginners to go slow, doing only as much as can be done well, since nothing but the best production will pay, and it may safely be estimated that, besides the land, every acre of small fruit properly prepared, planted and brought to a bearing age will cost from $125 to $150, or their equivalent in honest work at $1.25 a day. Mr. Thayer's concluding counsel is: "Begin modestly, subscribe liberally to good papers, increase your plantation as experience is gained," and he promises to answer questions on particular points by mail or otherwise, or send short, plain instructions for growing small fruits, free, to any one who will send his name.

"All the world has agreed," said Downing in his *Horticulturist* some forty-five years ago, "that there is nothing more perfect of its kind than the rural architecture of England. The cottages of that country are as widely different in effect from those of any other as the Anglo-Saxon race differs from all else, civilized or barbarous. What this difference consists in there are, perhaps, few who take the trouble to analyze. Many persons suppose it to lie in pointed gables and high roofs. Still, these were not originally English, but were borrowed from Flanders, yet the Flemish cottages have little or none of the peculiar beauty which charms us in those of England. Others have imagined that it is something especially becoming in the features of the English landscape itself. Yet this can hardly be true, since we have seen faithful copies of the English cottage built in this country in equally picturesque scenery without producing upon the mind the same impression as the original edifice. The secret charm of the English cottage lies, we imagine, in its home-expression and its rurality. . . . The English cottage, even of the humblest class, is surrounded by trees, embowered in vines and creepers and hedged about with shrubs to a degree quite unknown in any other country. The love of trees and flowers is a universal passion in that country, and man, woman and child, among the cottagers, take an especial pride in the green adornments of their home. Slips and roots find their way from the pleasure-grounds of the nobleman's mansion to the humble garden of the cottage; and there is a personal and individual care bestowed upon them, even by those who have scarcely any other of the refinements of life, that neither the people of the Continent nor of this country have, as yet, any positive share of. The effect of all this taste is to spread a beautiful drapery about the rural cottages of England that renders what would otherwise be scarcely more than rude cabins little gems of rural and picturesque beauty. Indeed, strip most of the loveliest cottages of England of their sylvan and floral enrichment and they would absolutely lose their whole power of charming."

GARDEN AND FOREST.

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 28, 1891.

TABLE OF CONTENTS.

The Effect of Gardening upon the Mind.

A TASTE for gardening is one of the elemental impulses of humanity. There are individuals without it, as there are people without sight or hearing or a sense of smell; but, on the whole, to dig comes naturally to man, and at some time or other in the course of his existence the desire to own a portion of the earth's surface is apt to seize upon him and demand satisfaction.

This impulse is of maturity rather than of youth, for gardening in its larger sense is a thoughtful pursuit, appealing to the broader qualities of the understanding. It is not merely the desire for healthful exercise which stirs a man, but also the wish to learn the secrets of our common mother, to force her hand, as it were, and compel her to reward his toil. The fable of the giant Antæus, who renewed his strength when he came in contact with the earth, has a subtle meaning, for it is by this contact that many weary souls have found rest and arisen refreshed.

To him who is tired of mankind the solitude and peace of a garden have a rare charm. Many a great statesman has turned from the cares of state to till his fields, or cultivate his flower-beds and trees, his alert brain finding full range for its activity in some scheme of landscape, or some great project for fertilizing a barren waste and rendering it productive.

Gardening gratifies the thoughtful mind, because it does not look for immediate results. It inculcates patience in all its teachings—patience not only with processes, but with results, for disappointments have often to be met; the best of schemes fail of accomplishment; new enemies arise on every hand, visible and hidden. To combat them requires perseverance, fertility in resource, promptness in action.

The gardener's life can never be purely contemplative. However fair his domain, he must perforce keep his eyes open in it, and his mind active. Vigilance must be his attribute, or he will have cause for regret. By watching he learns what to do and what to leave undone, the habits of the plants he tends—their needs, their uses, the different phases of their beauty. Unconsciously he becomes educated, and his mind lays up new stores of facts and deductions for future use.

The planter also grows in unselfish zeal as his plans increase in scope. He prepares for the future race, not alone for his own joy. The trees he disposes for another generation to sit under; he plants timber for the heir to cut; he adds to his broad acres that he may leave them to his children. For himself the toil, for others the fruit of his labors, and thus, setting aside his own recompense, he comes into a larger manhood, into that fullness of life which only belongs to him who has forgotten self and lives for an end he cannot hope to see.

From all this training should result endurance of unavoidable evils, fortitude in disappointment, serenity of mind. Thus the garden shows itself to be a school of the higher virtues, of patience, of tranquillity, of vigilance, of fortitude, of unselfishness and high serenity.

More lessons than these it teaches, therefore small wonder that the groping soul of man, ever seeking higher things, turns to this simplest pursuit as a child to its mother, finding in her arms comfort for his unrest. Unconsciously he seeks this school, which is so great a help to his spirit, and thinks often it is the pure air and exercise alone that have given tone to his nerves, and fresh vigor to his understanding.

But, after all, the best thing the garden does for man is to imbue him with a love for home, to anchor him to that one spot of the earth's surface which he calls his own, and to which he can impart some portion of his own individuality. The acres he has tilled, the garden-plot he has watered, will always be dear to him and to his children, and it is this desire for a home and an inheritance for those who shall come after him, that drives him to the purchase of land and the beginning of agriculture.

A man who owns a freehold in his country becomes of account at once; it lifts him from the position of a transient into the dignity of a resident; he gives hostages to fortune; he becomes an established citizen in place of a possible tramp, and is of more value in the community forthwith. The effect upon himself is elevating and composing. It stills his restlessness, allays ennui, turns the current of his mind into new channels, provides him with an amusement for his leisure hours, while giving occasion for healthful exertion, as well as stimulating wholesome thought. It is opposed to morbidness, it forbids subjectivity, it rouses the imagination, and gratifies the love of beauty.

There is that fine largeness of quality in it as an amusement that appeals to the simplest minds, as well as to the most comprehensive. It is this which proves that it is elemental and human to love a garden, to enjoy the soil, to find comfort in watching the development of plants and trees, and joy in their blossom and fruitage.

In America we need just this to give us stay and balance. In the older world, where habits are more established, the taste is strong. Here it is overgrown by many things. In so great a land as ours one portion of the soil seems not enough for the citizen. He wants a ranch in Colorado, an Orange-grove in Florida, a sea-side home on the coast of Maine, in addition to his city dwelling. But as the crowd increases and the nation ages, more and more will men concentrate their energies upon one spot, and the love of home and locality will grow more intense, as it is apt to do in the human being as years bring greater quiet to his spirit, and make rest his choicest blessing.

When we are at last sure that our children will be content to reap what we have sown, to repose under the trees that we have planted, solidity and peace will come to us, and life will grow more simple and more pleasurable to our people. Then will the garden be the true pleasure-ground, and its wise stillness will pervade the character of the men who find its culture a real education, and there

learn the needed lessons of perseverance, and patient waiting for the good the future brings, leading lives without hurry, full of calm interest in their surroundings, and with no wish for change.

Village Improvement Societies.

At the recent annual meeting of the Beverly (Massachusetts) Improvement Society, Professor Goodale, of Harvard University, made a few remarks relative to the work of village improvement societies in general. He said that the range of plants used for decorative purposes in the northern states can be much widened. It is a general principle in vegetable physiology that many plants thrive much better when transferred to climates and soils similar to, but not identical with, those of their nativity. This is illustrated in a striking, but unfortunate, manner by the common plants which have invaded parts of Australasia. The thistles and brambles attain a size and vigor unknown in their former home in the Old World, while one of the Roses, well known as Sweet-brier, runs riot over large areas. It is a familiar fact that all of our troublesome weeds in the northern Atlantic states, with perhaps one or two exceptions like Rudbeckia, or Purple Cone-flower, are intruders from other countries, chiefly Europe and South America. On the other hand, the weeds of German gardens and agricultural lands are said by Professor Drude, of Dresden, to be mostly from the Mediterranean regions, but the invasions in the uncultivated districts are largely from America, such as Œnothera, the Evening Primrose, Mimulus, the Meask-flower, and Rudbeckia, just mentioned. Every one knows how admirably many of the Japanese and Chinese species of flowering plants grow in the Occident. This list of plants can be largely augmented particularly in the direction of arboreous and arborescent vegetation. We who live so near the Arnold Arboretum, at Forest Hills, only an hour's ride from this room, can see, if we choose, the progress of experiments directed toward this end. On those ample grounds, one can see for himself the oriental plants which are proving of worth here, and he can make his own selections of plants for the adornment of the streets of our villages. A little pressure brought to bear upon our enterprising nurserymen would increase the scope of their catalogues, adding thereto plants of promise from the eastern countries, China and Japan. Those which we now have in general use are favorites; the list should be lengthened.

Dr. Goodale spoke also in regard to the desirability of preserving some accessible nooks and corners for our native plants. Such shelters need hardly more than a supply of water to help their guests through the hard times of drought which are sure to come at intervals in our climate, and which are exceedingly destructive to transplanted vegetation. If these sheltered nooks are occasionally cleared from the ever-watchful and aggressive invading weeds they can be made to brighten many a spot which would otherwise be unsightly. Essex County has a high reputation for the attractiveness of its native vegetation. This reputation is very largely due to the fact that the county has long possessed ardent and successful students of botany. From Cutler's time, through that of Oakes and Russell, down to the present, when Robinson and Sears and many others have taken up the agreeable task, the attention paid to the native plants of the county has been remarkable. The results of this attention are partly treasured in the excellent collections of the Peabody Academy, in Salem, and are practically at the command of any citizens of the county. There is no excuse here for not making much of our native plants. Other counties in the Atlantic states ought to emulate the example of this county.

Another of the topics taken up by the speaker was the change which has come over the manner of looking at certain features of plant-life. The relations of the soil to water and air, and to the chemical substances which form the so-called ash-constituents of plants, are among the most interesting subjects in nature. The plant stands midway between inorganic matter and animal life, manufacturing from water and what we may well call "impurities," of various kinds, organic and organized substance, part of which is utilizable by animals as food. Of late years we have come to believe that through the agency of infinitely minute organisms, known as microbes, part of the nitrogen in the air, clinging to soil, may be combined with other elements in such forms as to be available to plants.

Another change which has taken place in our method of looking at plants comes from conclusive evidence that all the living matter in the plant is connected together, even where the cell-walls seem at first to be closed partitions; and thus all portions of the plant are constituents of a community, in the strictest sense of the term. Formerly it was held that the conjoined organs and contiguous cells throughout the organism are parts of a corporate body. This true view is rendered more impressive by the conviction that all the living matter in all parts of the plant makes up a united whole.

Other topics discussed were, the principles which underlie pruning and the healing of wounds, the times for transplanting and similar practical matters.

Dr. Goodale expressed the view that the interest in practical questions like these, which come naturally before a village improvement society, can be much increased by occasional meetings during the winter, when, by a suitable division of labor, the freshest intelligence relative to advance in vegetable physiology and horticulture can be presented by the members and familiarly discussed.

Great Hill: A New American Country-seat.—II.

From the north side of the house at Great Hill we look over the lawn, already described, which is bounded on two sides by woods, and on the third by the sea; and the woods continue, running near the west side of the house, down to the water's edge on the south. Here the main front looks over a still larger lawn, comprising some eight or ten acres, while a narrower expanse of sward lies between the building and the eastern shore. Thus the lawns, taken as a whole, are flanked on two sides by forest and on two by blue water. The whole expanse they now cover was, a few years ago, a tangled mass of bushes and stones and little trees, with here and there a few of larger growth. The labor of clearing was great, but, fortunately, the slopes were naturally beautiful. A straight gravel walk leads from the east door to a stone pier; but on the south the main stretch of lawn is not cut, but encircled by paths, one lying close to the forest on the right and the other not far from the water on the left. All along the water's edge is a low growth of shrubs, vines and flowers, chiefly Sumachs and Golden-rods, which make a beautiful border when autumn approaches. The walk near the water passes at a little distance from the house through an irregular group of trees, small Oaks and tall gnarled old Tupelos, the latter forced by the denser growth that once surrounded them into a shape so unlike that which is typical of the species that it needs a close examination to prove them what they are. Otherwise, the lawns are unbroken, save for a few small Oaks and Pines, left here and there in well-chosen positions, which, with the lapse of time, will become interesting trees. The lawns are not so smooth and velvety as those one finds at Newport or Lenox, but for this very reason are all the better in keeping with their surroundings. They are well covered with thrifty grass, and are visibly lawns and not pastures; and their green is bright enough to form a vivid contrast with the blue of the water beyond and the somewhat dusky tone of the Oaks which chiefly compose their bordering woods. Nothing could be simpler than the scene or its arrangement; but its pronounced simplicity constitutes its striking charm. Seldom does one see such broad stretches of sward contrasted with such simple masses of forest and framed in so beautiful a circle of water, with the long line of the Falmouth shore lying against the horizon. No details attract the eye to the disturbance of the general effect of breadth, dignity and repose, and nothing has been done to alter the essential character of the spot as Nature designed it. One would certainly be at a loss where to look for another country place of anything like this size of which it could be said that not a tree or shrub or flower has ever been planted. But this is true of Great Hill, if we except only a few vines which clamber up the piazzas of the house and some narrow flower-beds close to its foundations. Not a tree is in

sight from the house which any one would call a "good specimen," even of wild growth, yet the groups they form are just what the eye demands; and not a spot of color breaks the quiet greenness except where some wild flower grows at the edge of the forest or the Sumachs burn along the water's edge. There are very few owners, I fear, who would not be tempted to set out trees of other species than those which naturally grow here, and to "enliven" the far-stretching lawns with ornamental plants and flower-beds. But a single innovation of this kind would ruin the beauty which now exists, and I can fancy no worse fate for Great Hill than to fall into the hands of an owner with "a taste for horticulture." Any one with a taste for Nature, a taste for beauty developed and clarified but not modified by art, must be thoroughly content with it as it is. May the day be far distant when a white-blotched Negundo or a scarlet Geranium shall intrude upon its broad simplicity and spoil its thoroughly local character.

From the foot of the main lawn one looks westward along a shore which curves out into successive points, clothed with forest to their tips, until, afar off, Bird Island Light shows white against the sky. For the most part there is only a narrow pebbly beach, although, about a mile away from the house, there is a long and broad beach of snowy sand. But these little beaches are, to my mind, as attractive as anything at Great Hill. The forest comes quite close to them, and, the soil being somewhat swampy, it is composed of larger trees than those through which the entrance drive conducted us. And in front of the trees, coming boldly down to the edge of the sand itself, are the most luxuriant masses of shrubs and creepers, bright at every season with a changing wealth of blossoms. Here one sees Willows, Alders and Black Alders, Roses and Cat-briers and Beach Plums, Blueberries and Sumachs and Grape Vines, Wild Azaleas and Andromedas and a score of things besides, crowding one another close and crowding as closely as they can to the water's edge, while now and then they break away to surround a tiny bit of genuine swamp, covered with Cranberry-vines. If a gardener would like to see how a shrubbery should look, edging an expanse of gravel, he could not do better than come and study these which Nature has planted along the little beaches at Great Hill.

All this large property is not given up to mere beauty; but the cultivated tracts and the various farm-buildings are hidden away among the woods, so that one must seek before seeing them; and the same is true of the water tower, which so often mars the effect of a sea-side estate. For a considerable distance from the shore the woods remain untouched save by the construction of a drive, several miles in length, which follows near the water, rounding the head of Wing's Cove and continuing to the confines of the place. In this third drive we have forest and shore views combined. Now we seem to be in the heart of a broad wood, and the next moment find ourselves between the woods and a wide salt-marsh, or between the woods and the water itself. Some very large Pitch Pines and ancient Tupelos occur in this part of the place, and each tree of the sort was scrupulously respected in laying out the road. As its purpose is merely to show the beauty of the place, not to take us anywhere in particular, directness did not need to be considered. And the same is true of certain little walks which, starting near the house, have also been cut through the woods. A pretty feature, which lies only a few steps away from the main lawn but cannot be discovered by a stranger, so inconspicuous is the "trail" through the tall undergrowth that leads to it, is a "deer-rest," made in imitation of those which the deer themselves used to trample out when the forest was wild indeed. It is simply a small circular space which has been freed from everything but grass, above which the trees nearly meet and around which the shrubs, freed from all restraint, have formed, in a couple of years, a high, impenetrable, odorous green wall. The Inkberry had long seemed to me the most beautiful of our native shrubs, but how beautiful it might be I had never realized till I saw it at Great Hill, in some such spot as this.

I need not speak of the other roads which, for more or less utilitarian purposes, have been cut through the woods at Great Hill, or of the pastures where flocks of sheep are feeding, or of the great meadows grown to hay, except to add that nothing, however utilitarian, has been done without a thought of beauty. There has been no ruthless clearing or cutting. The owner marks every tree that is to be felled, and none is ever felled which has any special claim of size, character or situation to plead in its own behalf. So we see here and there in fields and pastures a large Pine, an ancient Cedar or a particularly symmetrical Maple; and I have even been told of one small tract, surrounded by cultivated fields, which remains uncultivated because in the autumn the Gentians grow there in especial profusion. There are Cranberry-bogs also at Great Hill, and wild Grapes and Beach Plums in a profusion by which the housekeeper profits; but while her claims and those of the farmer are respected, Nature's claims are never for a moment forgotten. It hardly need be added that, though there are many workmen at Great Hill, there is no one who calls himself a gardener.

In praising so highly this place, which I have so often visited with ever-growing delight, I do not, of course, mean to set it up as a model for general imitation. Gardens and gardeners, planted trees and cultivated flowers have their part to play in the world, and it must always be a preponderant part when wild country sites are to be fitted for the summer residence of wealthy people. Yet I do think that it would be well if in sea-shore neighborhoods some such treatment as this which has brought the beauty of this place out of a tangled wilderness was adopted. It is adopted, I know, in many small properties; but Great Hill is remarkable as showing how well fitted it is even to estates of unusual size. Certainly, no other method of treatment could have produced so admirable an effect just here, where the forest already existed with a well-marked character of its own, and where the soil is not very easily persuaded to bear trees of other sorts. The chief beauties of Great Hill are its clear local character and its unity. Whether we are traversing the untouched portions of the woodland, following the lovely shore, or surveying the broad expanses of lawn, relieved, but not disturbed, by their Pines and Oaks and Tupelos, and broadly and simply contrasted with the encircling belt of woods, there is never a feature which mars the harmony or changes the general character of the spot. It is simply a piece of the Marion country beautified, but not essentially altered; and this, I believe, whether the gardener has had a part to play in the result or not, is what every country place in every part of the world ought to be. This owner was lucky in finding a spot which he could make habitable and beautiful without a gardener's aid, partly because the unusual, the unexpected, the unconventional is always attractive, but partly also because, when Nature is in an artistic mood, she can do better work than any other artist. But surely, also, the spot was lucky in finding an owner who appreciated his chance and could make the most of it. This he has done, not by starting out with a definite idea of what he "meant to do with the place," but by contenting himself for a time with roughness and incompleteness, living on the place, loving and studying it, and very gradually deciding what the next step should be. And only thus can any good work of art be produced when the materials used are those which Nature supplies, and, consequently, it is impossible to redeem mistakes once they are perpetrated.

Marion, Mass. *M. G. Van Rensselaer.*

Artificial Coffee-beans.

THE manufacture of artificial coffee-beans has, it appears, assumed some importance in this country, and specimens of the spurious beans have been sent to Kew by Dr. Brown Goode, the Secretary of the Smithsonian Institution. The idea of preparing artificial coffee-beans for the purpose of mixing with the genuine beans is, however, not entirely new. As long ago as 1860 coffee-beans, made from finely powdered chicory, were sent to the Kew Museums. The American beans are supposed to be composed of rye-flour, glucose and water; they are made to resemble, in size and color, a moderately good sample of roasted coffee-beans, and, by the introduction of a few genuine beans, are made to possess the aroma of coffee. The modeling is sufficiently good to deceive the ordinary public, but if the product is at all critically examined it is noticed that the groove on the flat surface is broad and shallow, and that it does not extend into the heart of the bean by a long narrow slit as in the real article; and, also, that there is no trace of the silvery skin at the mouth of the slit.

The introduction of spurious coffee-beans as an article of commerce in the United States is described in the following article from the *New York World*, reproduced in the Kew Bulletin:

"The average bulk of the genuine coffee imported into the United States is 8,000,000 bags, or 180,000,000 pounds, per annum. Experts estimate that fully twenty per cent. of the coffee sold to consumers is bogus, which raises the consumption to 216,000,000 pounds. Taking thirty cents per pound as the average retail price, the people of America pay $65,000,000 every year for this one article of food, of which $13,000,000 is paid for roasted and ground beans, pease, rye, or a manufactured article in no way resembling the Brazilian berry. To this must be added the production and sale

of what are called 'coffee substitutes.' So extensive is this business that it is quite safe to say that consumers pay $12,000,000 for what they believe to be cheap coffee. This raises the total expenditure to $77,000,000, and it represents a sale of 276,000,000 pounds, for the 'substitute coffee' usually sells at twenty cents per pound. It will thus be seen that 96,000,000 pounds of bogus coffee are sold in the United States every year, and some estimates place it at 120,000,000 pounds. Taking the lowest figures, $25,000,000 are received for substances which can be profitably placed on the market at six cents a pound. The manufacturers, therefore, receive $6,000,000 for their goods, while retailers gain a profit of $18,000,000. There are two kinds of bogus coffee, an imitation bean and the ground article. The bean is the most difficult to produce, and it is only recently that actual success in this direction has been attained. The bogus bean must not only look like the genuine berry when raw, but it should be capable of taking a proper color when roasted. A very good specimen is now manufactured in Philadelphia and Trenton, being composed of rye-flour, glucose and water. The soft paste is then moulded and carefully dried. To the eye of an expert the presence of this imitation is easy of detection, and it cannot be used to any great extent among wholesalers. But when coffee goes to the retailer adulteration begins. Sometimes the retailer is deceived, but nine times out of ten he is the one who introduces adulteration. The ground article is very easily produced in the proper color, and an aroma is infused by using strong decotions of coffee-essence.

"When mixed with real coffee even the expert eye and tongue may be deceived, while to the ordinary consumer it seems to be the genuine product. Bogus coffee-beans have only a slight resemblance to the natural berry, for though they possess proper form the cicatrice on the inner face is too smooth. Then, again, the gray color of the raw bean is not quite up to the mark, but when these manufactured beans are roasted with five per cent. of genuine coffee they find a ready sale. These bogus beans can be made at a cost of $30 per 1,000 pounds, and when mixed with fifty pounds of pure coffee the whole 1,050 pounds cost $37.50, or 3¾ cents per pound, so that a profit of nearly 100 per cent. is the result. There are any number of 'coffee substitutes,' the Hillis variety being the most successful. This company is already manufacturing 10,000 pounds per week, it being sold by the barrel to retailers in nearly all of the New England, middle and western states. The profits of this concern are supposed to be $300 per day, and its operations have reached such a scale that the stockholders were recently offered nearly $1,000,000 for their secret and business, but it was declined. No one accustomed to coffee-drinking would imagine that a decoction of this stuff was like either Mocha or Rio, but when mixed with four times its bulk of genuine coffee only an expert could detect the imposition. The manufacturers of these 'coffee substitutes' claim that they are not violating the law of adulteration of food-products, because they do not sell their goods as coffee, but simply as a substitute. While this may be true, it does not apply to the retailer, who mixes the bogus stuff with good coffee, and sells the whole as the genuine article. Though manufactories may be beyond the penalties of the adulteration law, they should be suppressed, for without them coffee adulteration by retailers would be impossible. When it is remembered that American people are compelled to pay $25,000,000 for ingredients that can be manufactured for one-fifth the sum received by coffee-growers, the necessity for the suppression of this nefarious trade is apparent. Oleomargarine cannot be sold as butter, neither should 'coffee substitutes' be made to masquerade under the name of Java, Mocha or Rio."

The production of artificial coffee has also received some attention in Germany, where an imperial decree has been issued forbidding the manufacture and sale of the machines for producing the artificial beans, which certain German newspapers have recently advertised. These artificial German beans are not intended in themselves as a beverage, but are to be used in trade for mixing with the genuine article.

Notes on the Distribution of Some Kansas Trees.—III. The Oaks.

KANSAS is credited with ten species of Oak, five of which are confined to the extreme eastern portion of the state. Only those having a more extended range will be mentioned in this paper. The most widely distributed, as well as the most valuable Oak of the state, is the Bur Oak (*Quercus macrocarpa*). This is found throughout the eastern counties and extends to the north-west as far as Bow Creek, a branch of the Solomon River, in Rooks and Phillips counties. From here the line of its western limit may be traced in a south-easterly direction to the Arkansas Valley, and along that stream out of the state in Sumner County. A noticeable feature in the distribution of this Oak is, that it is found in greatest abundance, and, at its best, developed on small tributaries instead of the main streams, and often the best growth will be well toward the head of a branch where the bends are small and the bottoms narrow. The rich deep soil of these bits of bottom-land seems better suited to its growth than the more sandy rich bottoms of the rivers.

Along the Solomon River five groves of this tree may be seen at the junctions of the most of its tributaries, and further up the valley, where there is little or no Oak-timber to be seen on the river a few miles back in the hills, on some small creek we may find scattering gnarled old trees, with short trunks and rugged, angular limbs, while among them will be thrifty young trees, just the size for good fence-posts, either single cuts or quartered. These young trees the traveler of twenty years ago will remember as only straggling bushes, springing up perennially as the fires burned them down. Others still younger are pushing out on the borders, the product of acorns dropped since the buffalo ceased to cut his sharp paths down the hills to water. Further east the older trees are found to be of better length of trunk and straighter grain, though, like the Cottonwood, the best of them have been hauled to the steam saw-mills years ago.

Occasionally one finds a block of the original growth which has escaped the axe; such a one may be seen on the head of Cedar Creek, a small tributary of the Blue from the east, a few miles from Manhattan. Here in an area of not more than an acre, thickly grown with a variety of hard-wood timber, I measured twenty Bur Oaks which averaged ten feet in girth at two feet from the ground and twenty feet to the first limb. The largest of these was fifteen and a half feet around. At present the home market for such timber is much better than it is for Black Walnut, Oak being in great demand for bridge-planking.

Next in an extent of area as well as in size comes the Chestnut or Chinquapin Oak (*Q. prinoides*). This finds its western limit in the lower valley of the Republican River, in Clay County, and on the Smoky for a short distance above its junction with the Republican. This Oak is more commonly found on high ground, often covering the steep faces of the bluffs fronting the streams, where it becomes dwarfed in habit, sometimes only a mere bush, sprouting from a spreading gnarly crown as often as swept over by the fires. Close to the small streams and in the bottoms, where the soil is rich, it occasionally becomes a stately tree. On the banks of the Blue River opposite Manhattan a group of these trees has been jealously guarded by their owner, who was one of the earliest settlers. Five of them which I measured averaged slightly less than ten feet in circumference at two feet above the ground, the largest being twelve feet and eight inches in girth. The wood of this Oak is tough and heavy, and, though cracking badly as it seasons, it is highly valued for posts and fuel. Occupying as it does the stony land and the narrower draws and ravines, there is not the inducement to clear the land for farming purposes, which causes the slaughter of so much valuable hard-wood timber. As there seems to be no basis upon which to separate the form called *Q. Muhlenbergii* by Dr. Engelmann from the smaller and more shrubby growth of the hill-sides, I have preferred to consider them all under the name given above.

Less widely distributed, but more abundant in its region, is the Black Jack (*Q. nigra*). In the eastern part of the state this is abundant, constituting the greater part of the scrubby growth which covers many miles of broken upland. As a mere bush it often crowns some rocky bluff or dots its steep sides; again, it is a dwarfed tree, growing in almost impenetrable thickets; in the more fertile soil bordering the bottoms it becomes a rugged, knotty tree of sometimes two feet or more in diameter and fifty feet high. Whatever the size, it varies but little in character. Its bright red young leaves make a beautiful picture when they are opening. These, as they develop, become thick and leathery, shining dark green above and russety downy beneath, presenting a handsome appearance throughout the season. While maintaining their general wedge-like form, these leaves are exceedingly variable in the number and depth of their lobes, and trees of the extreme forms might readily be mistaken for distinct species if judged by this characteristic only. These leaves, tan-colored and dead, rustle on the twigs till the buds begin to swell in the spring. The bark of the trunks is black, finely checked and rough, shading off to the smooth iron-gray of the limbs, which are

closely set and stiff. With the numerous dead spines and stubs they promise sure destruction to the clothes of any one rash enough to try to climb them.

The most westerly upland growth of this tree is found covering the hills north of the Kansas River in southern Pottawattomie County. It crosses the Blue and is found in considerable numbers along the deeply cut ravines which enter this stream from the west, but this is the limit. I have found no trace of it on the Kansas or any of its tributaries above the mouth of the Blue. The Black Jack affords a fair article of fuel, but is of little value for mechanical purposes.

Closely associated with this species in distribution are the Black Oak (*Q. tinctoria*) and the Red Oak (*Q. rubra*). Of these the Black Oak more nearly resembles the Black Jack in the rough checked appearance of its black bark. It is a larger and better formed tree, and the thinner, deeply lobed leaves will at once distinguish it.

The Red Oak is by far the finer tree, and the iron-gray color and smoother appearance of the trunk, the lofty habit and fine open top, as well as the large acorns with flat shallow cups, and the slightly lobed leaves, readily distinguish it from the others. These three members of the Black Oak family all find their western limit along the west bank of the Blue River in Riley County.

Another member of the Oak family is worthy of mention as occupying about the same limits as the above-named Oaks.

Fig. 79.—Senecio Heritieri.—See page 510.

The *Ostrya Virginica* is found along the Blue and the Kansas and its tributaries to a few miles west of Manhattan. It occurs mostly in secluded rocky ravines along the breaks of the limestone bluffs, and nowhere attains the size to which it grows in the moist woods of Minnesota. Specimens of more than eight inches in diameter and twenty or thirty feet in height are rare in this range.

It is at least a curious coincidence that the field occupied by these last-mentioned trees is nearly identical with that of the glacial drift in north-eastern Kansas. Whether this may have been the cause of their distribution over this limited area only must be purely a matter of speculation, but the fact that these species are so common in Nebraska and Minnesota over the glacial territory would at least be suggestive.

Kansas Agricultural College. *S. C. Mason.*

New or Little-known Plants.

Senecio Heritieri.*

THIS plant was in cultivation at Kew more than a hundred years ago, having been sent thither from Madeira, presumably by the Kew collector, Philip Masson. A figure of it was published by Curtis in the second volume of the *Botanical Magazine*, t. 53 (1787), where it is stated to have been introduced from Africa, but it is now known to be a native only of Madeira and Teneriffe, where it grows in the fissures of rocks. It belongs to the same section of the sub-genus Cineraria as the Madeiran *S. populifolia* and *S. cruenta;* both of which are also in cultivation at Kew, the last-named being the supposed progenitor of the popular garden Cinerarias.

Wild specimens of *S. Heritieri*, as well as the plant represented in the *Botanical Magazine*, are so much smaller and more sparsely flowered than the cultivated examples of it now at Kew that one might almost declare them to belong to different species. And yet Curtis, writing in the *Botanical Magazine*, stated that, "In the beauty of its blossoms, this species of Cineraria, lately introduced from Africa, by far eclipses all the others cultivated in our gardens." The plant represented in our illustration on page 509 is immeasurably superior to anything seen by Curtis, and although we have many beautiful Cinerarias which were not in cultivation a hundred years ago, I question if *C. Heritieri* does not still surpass them all as a greenhouse plant.

It forms a loose many-branched shrub about a yard high, and by a little pinching and staking it may be made to look like a good specimen Chrysanthemum. The branches are zigzag and thickly clothed, as are also the petioles and under surface of the leaves, with a white felt-like tomentum; the upper surface of the leaves is gray-green. The flower-heads are borne in very large panicles on the ends of the strongest shoots, and in smaller clusters on the weaker branches. Each head is an inch and a half across, daisy-like in form, the ray-florets white and rosy crimson, the disk almost purple. They are exceedingly beautiful in color and most graceful in their arrangement upon the plant; moreover, they emit a powerful violet-like odor, and they remain fresh upon the plant two months if kept in a cool greenhouse. I do not think we have any more beautiful greenhouse flowering-plant at Kew than this, and I can imagine its becoming a universal favorite for all sorts of decorative work.

The cultural requirements of this species are not unlike those of the Chrysanthemum, except that it requires a few degrees more warmth, and it does not appear capable of bearing frost. At Kew it has been grown from cuttings struck in summer and potted in good loamy soil, the final shift being into an eight-inch pot. The plants are kept in a cold house or frame all summer, exposed to plenty of sunlight and watered liberally. They come into bloom in May, and are not out of flower until well on into July. This year a few of the old plants had their shoots shortened back after flowering and were repotted, one being planted in a sunny border. They soon made new growth, and they are in flower again now (September). I am told that in some parts of Italy this Senecio is a favorite summer-flowering plant for borders; I should not be surprised if, in the warmer parts of North America, it proved a good substitute for, or companion to, the Chrysanthemum as a border plant. The group of plants, of which this and *C. cruenta* may be considered the types, are now included in the genus Senecio. To be strictly botanical, therefore, the Cinerarias, which are a feature in almost every greenhouse, should be called Senecios, but I doubt if horticulturists will ever accept this change. If called a Senecio then, *S. Heritieri* would be the correct name for the plant here figured, but if Cineraria is preferred, then it is the *C. lanata* of Lamarck. The true *C. aurita* is a very different plant from this, although the name has somehow got attached to it in the few gardens where it is at present cultivated.

Kew. *W. Watson.*

* *Cineraria lanata, Bot. Mag.*, t. 53. (*C. aurita*, Hort.)

Foreign Correspondence.

London Letter.

Insectivorous Plants.—At a recent meeting of the Royal Horticultural Society an exhibition and lecture on Insectivorous or Meat-eating Plants was the special attraction. The exhibition was not as large or comprehensive as was expected, but the lecture, which had been prepared by Mr. Lindsay, curator of the Royal Botanical Gardens at Edinburgh, was full of interest, both for botanists and cultivators. Apart altogether from the extraordinary carnivorous propensities of Nepenthes, Sarracenias, Droseras, Pinguiculas and Utricularias, to a knowledge of which Hooker and Darwin have contributed practically all we know, they have a powerful claim to the notice of horticulturists in their quaint, and, in most cases, decidedly ornamental leaves, besides, in Sarracenia, Pinguicula and Utricularia, in the beauty of their flowers.

The collections of carnivorous plants at Kew are a never-ending source of interest and wonder to visitors, many of whom have heard or read of the "voracious" habits of these plants. I have been asked for the "Colra plant, which had leaves like a Colra and could swallow rats whole," and found that Darlingtonia was the plant meant; I have also heard many visitors declare that these plants "were so dangerous to children and venturesome people that they had to be kept behind wire screens at Kew." Without trespassing into the region of romance the habits and specialized structure of insectivorous plants are scarcely equaled in the whole vegetable kingdom. It is perfectly true that they entrap and digest insects, that they derive nourishment thereby, and, in this respect, are on an equal footing with the animal kingdom. No botanical garden or teaching garden of any kind ought to be without a collection of these wonderful plants. It scarcely needs to be added that there are no good gardens in which Nepenthes, Sarracenias and Droseras do not find a place.

New Orchids.—*Cattleya intermedia*, var. *alba*, is a beautiful addition to Albinos. The type is one of the best of autumn-flowering Orchids and is very easily cultivated. Mr. Stalter, of Manchester, exhibited a plant in flower of the white variety last week, and it was awarded a first-class certificate. *Grammatophyllum Seegerianum* was shown in flower by Messrs. Seeger and Tropp, who introduced and named this species last year. It belongs to the same set as *G. Measuresianum* and *G. Fenzlianum;* indeed, it is not unlikely that the three will prove to be forms of one species. The plant shown bore spikes four feet high, carrying numerous flowers two and a half inches across, not unlike the flowers of *Ansellia Africana*, the color being greenish, with blotches of chestnut, the lip brown.

Cypripedium Antigone.—This is one of the most beautiful of hybrids. It was raised by Messrs. Veitch & Sons from *C. niveum* and *C. Laurencianum*, and it flowered in 1890. It has since passed into the hands of Baron Schroeder, who exhibited it in bloom last Tuesday, when it was awarded a

first-class certificate. The flower is large, well-balanced, and is white, suffused with rose. The flower produced this year is far superior to that of last year.

C. Polletianum.—I noted this last year as a beautiful hybrid which Messrs. Sander & Co. had raised from *C. calophyllum* and *C. œnanthum superbum*. The last-named is one of the choicest of hybrid Cypripediums, but its offspring is generally voted to be a better plant. The flower is very large, with the form of *C. Laurencianum*, the dorsal sepal deep purplish crimson, margined with white and spotted with chestnut. The petals and lip are even darker in color than the dorsal sepal, while the whole flower shines as if varnished.

Kew. *W. Watson.*

Bermuda Potatoes.

THE Bermuda potatoes are all grown in the winter months. The Early Rose and Prolific are used for early planting, and any kind of red Potatoes for the later planting. Of the red kind more Garnets than others are planted.

Red has become by unwritten law the Bermuda trademark, and dealers in New York City do not care to touch a late Bermuda Potato without it be red. Their customers, the grocerymen, say the public do not believe a potato is from Bermuda unless it is red—"that the red soil colors it!"

Many farmers are now, October 15th, planting Early Rose, which will be harvested in from eighty to ninety days after the planting, or about New Year's. When these fields are harvested, the farmer immediately puts in late Onions, and gets two crops in one season.

From now on up to February 15th the farmer will plant potatoes as seems best or convenient, and the harvesting from these successive plantings is kept up to about June 1st. No doubt a northern farmer would be delighted if he could have four months of the year for planting and a corresponding four or five months for harvesting. No one plants after February 15th, as plantings after that date run to enormous tops—sometimes six feet long—but not a tuber will set.

Our potatoes for planting all come from the north, as potatoes grown in Bermuda, and with great care kept over the summer, are almost worthless for planting. Arrangements are made with farmers in Maine, the Adirondack region, Nova Scotia and New Brunswick to grow our red potatoes for planting. Our Early Rose come from New York.

We have great trouble to make these seed potatoes sprout, as potatoes which have gone to sleep in a northern climate, not contemplating an awakening until April or May following, do not readily arouse; they are more inclined to rot than sprout, and it will not answer to put them into the ground until they have sprouted. Probably the most successful way to sprout them is to spread them upon a dry floor for a few days until they are thoroughly dried off from the steamship sweat. Those inclined to rot should be picked out, and the others put back into barrels and kept in a dry warm place. As soon as the eyes begin to show signs of starting the potatoes are cut into pieces with two or three eyes and directly planted in the ground.

The method of planting, after the ground is thoroughly prepared with manure or an artificial fertilizer, is as follows: A garden line is stretched across the field, and a man, following this line, takes each piece of potato and pushes it into the ground some three or four inches. These rows are from eighteen to twenty inches apart, and the potatoes from four to six inches in the row. This is a slow, laborious process, but it is much the best way, as the growth of the Potato here is somewhat different than in the north. There each Potato-plant sends out roots in different directions four or five inches long, and on the end of these rootlets the potato is formed, frequently making a large hill full of potatoes. Here the potato "snugs up" close to the plant, only forming from one to three good marketable potatoes to each stalk. By no known method can the potato be induced to stray away from the stalk, so we strive to have as many stalks or plants to the acre as is possible. After the rows can be seen through the field, men are put in with spading forks, spading carefully between each row, the rows being so close together that a horse cannot be used. A week or ten days afterward the potatoes are hilled up (or, as we say, moulded) by hoe, and nothing more is done with them until harvesting, as the potatoes soon cover in the ground and no weeds can grow.

We do not speak of so many bushels raised to the acre, but so many barrels raised from a barrel of seed. The amount raised is usually from three to six barrels from one barrel planted, though eight and ten are not infrequent. The yield per acre is probably from one hundred to two hundred bushels. If we did not get large prices there would be no profit in this crop.

I give below a statement of account with 115 rods of land (120 rods would be three-quarters of an acre) which I planted in the winter of 1889-90. The planting was at different times, from December 1st to January 5th, and I harvested them from March 27th to April 24th. These were Garnet's late potatoes, and the season was well adapted for potatoes. I bought all the manure and seed and did not do any work myself, and, of course, the workmen did not work hard enough to hurt themselves. I dare say if they had been working on their own crop they would have performed the labor at half the cost. A good Yankee farmer, leading his own workmen, would have realized a large profit from these 115 rods, but in this land of shiftless ways, with a seeming effort to do all things in the slowest way it is possible to find, I made only a fair profit.

An account with 115 rods of land for potatoes in Bermuda Island:

1890.	SALES.		
March 27th.—20 barrels potatoes		$6.72	$134.40
April 10th.—16 " "		6.00	96.00
April 24th.—17 " "		5.28	89.76
May 6th.— 5 " "	second size,	3.00	15.00
			$335.16

	COST.		
20 loads seaweed (36c.)	$7.20		
63 loads (1 horse) manure ($1.20)	75 60		
		$82.80	
38 bushels seed (96c.)		36.48	
58 empty barrels		11.76	
Labor to grow and harvest		84.98	
			$216.02
Net profit on 115 rods			$119.14

We have our trials from disease in the shape of a fungus-growth, which only attacks the plant-leaves when the potatoes are about half-grown and stops their growth. The disease may start in on one side of the field to-day and in two or three days' time it sweeps over the field, and the tops look as though a killing frost had prevailed. Nothing has yet been found to arrest this disease, so we meekly succumb, hoping for a north-east dry wind to come, which usually delays, but does not wholly stop its progress. We have another pest in the shape of the broken-tailed snail, which eats off the stalk at the base when tender; after the stalk becomes harder no harm is done. The Colorado potato-bug is not known here.

We shipped to American ports in the winter of 1890–1891 80,000 bushels, and we paid into the United States Treasury, in custom tax, the sum of $20,000, which the Bermudian feels to be infamous. We are looking forward with fear and trembling to the results of this winter crop. Under the McKinley law we have to pay into the United States Treasury twenty-five cents custom tax on every bushel we place in the New York market before we can come in competition with the United States farmer, and we fear this will so handicap us that our balance-sheet will show a loss.

Hamilton, Bermuda. *Russell Hastings.*

Cultural Department.

Adaptation to Locality.

NOTHING more important, I think, was brought before the American Pomological Society at Washington than Mr. Garfield's remarks upon the adaptation of fruits to locality. The necessity for this is comparatively but little appreciated, and many men, even those of long experience as fruit-growers, but feebly realize the immense importance to the commercial orchardist of a full understanding of this part of his business. A great number of failures are due to lack of knowledge on this point. In a recent issue of the *Stockman and Farmer*, Mr. R. J. Black, of Bremen, Ohio, illustrated the matter clearly in some remarks about the King of Tompkins County Apple, the Tompkins King of the revised nomenclature. Mr. Black says: "The excellence of this apple in Tompkins County, New York—latitude nearly forty-three degrees—is undoubted, but for planting in the central west it cannot be recommended. In this section it is only a moderate bearer; the fruit is generally imperfect, and it does not keep." Exactly this statement can be made of the Baldwin, as regards limitation of usefulness when grown west and south of New York. It then becomes a fall apple, does not hang well to the

tree, and the quality of the fruit—not high at its best—is much impaired. West and south of the Baldwin's limit the Ben Davis is at home. This apple is unquestionably of wide range, but, although it is hardy farther north than the Baldwin, the season is too short there, and it attains neither the size nor color normal to it in the Ohio and Missouri valleys. In quality this apple, when well grown, is barely good, but out of its range, northward, it is almost worthless. Among long-keeping apples, I know of none having so wide a range as Ben Davis.

Even summer and fall apples do not usually give satisfaction over a large territory, either in latitude or longitude. I think there are almost no real exceptions to this rule among our apples from western Europe and their American seedlings. The Early Harvest has been pretty widely distributed because of its earliness, and it has proved productive almost everywhere, but healthy scarcely anywhere. I venture to say that we are likely to find the tree-fruits that will prove valuable over the widest extent of territory in America east of the Rocky Mountains, among those of Russia and northern Asia. According to the American Pomological Society's list, as shown by the starring, the apples of the widest successful distribution within its territory are the Oldenburgh and Red Astrachan. The latter has more stars than any other apple in the list, and is double-starred for twenty-six states and provinces—extending from New Brunswick to Louisiana. Oldenburgh is double-starred for nineteen states, covering the same range. This, it seems to me, is probably so because the apples of western Europe are not so well suited to eastern America as the apples of eastern Europe and Asia. It is true that many of them have been very successful, and that their seedlings have often surpassed their parents. Nearly every popular apple in America (outside of the Russians) is a native seedling ; but excellent as many of them are, nearly every one has a relatively narrow range, both in latitude and longitude.

The Russian tree-fruits are, no doubt, of mixed as well as uncertain origin ; but it is probable that many, if not all of them, are either of home or more eastern nativity. They are mostly early in season, and particularly so when brought to this country and planted ten or fifteen degrees southward of their original habitat. But there is good reason to believe that, by growing seedlings from them, with skillful crossing, long-keepers of merit can be produced, adapted to all sections. Some such seedlings are already known. The Pewaukee, which is becoming popular in Wisconsin and Canada, is such a seedling from crossed Oldenburgh seed, and is a fair keeper. The lately introduced North Star, or Dudley's Winter, is said by its producer to be a pure Oldenburgh seedling, he having no other variety on his place. It is a good keeper in northeastern Maine.

It does not surely follow that because these fall Russian apples have a very wide range of adaptation all their American seedlings will resemble them in that respect. But I submit that, in the experience we already have with them and their seedlings, we have encouragement in thinking them to be a promising race of apples, with very acceptable characteristics ; and that the growing of seedlings from them, either pure or crossed with valuable winter varieties of the old stock, is worth the attention of our agricultural colleges and experimental farms. Heretofore the progress and improvement of our tree-fruits has been dependent almost wholly on chance, and so long as it depends upon individuals it will probably not be different in the future. But the work of the horticultural departments of our agricultural schools can be made continuous, and may be intelligently and perseveringly pursued to effective results. In thirty or forty years they could provide the country with a series of fruits for all seasons and sections, far more valuable than any we now possess.

Newport, Vt. *T. H. Hoskins.*

Vanda Batemanni.

IT is within five years of being half a century since this magnificent species was described by Dr. Lindley in the *Botanical Register* from a specimen which flowered a year earlier in the collection of Mr. Bateman, that being the first to bloom in England. The plant was discovered in the Moluccas by Gandichaud, who gave it the name of *Fieldia lissochiloides*, from a supposed resemblance to some member of the genus Lissochilus. The resemblance was not strong enough for Dr. Lindley, however, so he ignored botanical etiquette, and, after due explanation, named the plant *Vanda Batemanni*, out of regard for the great authority on Orchid matters. The genus Fieldia has been suppressed, and should not be confounded with Cunningham's mono-typic genus of the *Gesneriaceæ* of the same name which is still in existence. Some species of Vanda, including *V. Batemanni*, were separated from that genus by Reichenbach and given the name of Stauropsis, the one now recognized by such authorities as Hooker and Bentham. But this plant is known only as a Vanda to the great majority of gardeners and nurserymen, and it is highly probable that name will survive for many years to come.

These notes on nomenclature are the result of a careful investigation which followed a recent discussion as to the proper name of a plant of *V. Batemanni* now in bloom at the Harvard Botanic Garden. The specimen referred to has been in bloom since July, and gives promise of remaining in that condition several months longer.

Here is Lindley's graphic description of the plant: "It is a very large erect plant, with remarkably thick ærial roots, produced after the custom of its kindred, sword-shaped, two-ranked hard leaves averaging two feet in length, and a still larger spike of some score of flowers, each full two inches and a half across, flat, leathery and long-enduring. But it is not alone for their size that these flowers are so especially worthy of notice; their color is indescribably beautiful. If you look at them in face, they are the richest golden yellow, spotted all over with crimson; but when seen from behind, they are wholly a vivid purple, fading away at the edges into the violet of *Cereus speciosissimus*, so that, regard them which way you will there is nothing but the gayest and richest colors to be seen."

V. Batemanni should be grown in pots, in preference to baskets, on account of its large proportions. These should be filled to two-thirds of their depth with drainage material, upon which the lower roots may rest, filling up the remaining portion with sphagnum, which may be continued and rounded off two or three inches beyond the rim. The plant enjoys abundant light, and should have a position near the glass ; but, notwithstanding this, the fierce sun of an American summer is too much for it, and therefore it should be shaded in bright weather during the warmest months. A high stove temperature and plenty of moisture in the atmosphere and about the roots are indispensable during the greater part of the year. The temperature and atmospheric moisture may be reduced considerably in winter with much advantage, but the sphagnum about the roots should always be kept moist, and it must be replaced by a fresh supply when decay appears.

Cambridge, Mass. *M. Barker.*

Begonia Baumanni was introduced by Messrs. V. Lemoine & Sons, of Nancy, in the fall of 1890, and its flowering has been awaited with much interest, it being the only tuberous Begonia species yet discovered which possesses a distinct, clearly defined perfume. This species is said to have been discovered by Monsieur Sace, of Bolivia, in the central valleys of the Cordilleras and was first described in the *Revue Horticole* in 1886, under the name of *B. de Cochabamba*. The tubers are said to attain the size of a small melon, in some cases weighing twenty-four ounces. In the humid atmosphere of its native valleys the plants assume large dimensions and are in growth and flower about nine months of the year. The small tuber which is now in flower with me scarcely does justice to so vigorous a variety. It rested some six months, breaking in April, and has been grown on the greenhouse bench. It has given one stem, smooth, reddish, and erect about a foot high. The leaves are green, finely seamed and veined, reniform and alternate. The plant bears male and female flowers, carried well above the foliage on long stiff peduncles. The female flower is circular, with five petals. The male is furnished with only four, two of which are only partly developed, as is frequently the case with Begonias making an oval flower. The color is a clear rosy pink of a bluish shade, the female flower bearing a remarkable resemblance to those of *B. Maritani grandiflora*, though when well grown it is said to be three to three and a half inches in diameter.

There seems to be a distinct tendency in the petals to reflex under strong light. Both female and male flowers have a distinct agreeable fragrance, more especially in the morning. The odor is fully as marked as that of *B. odorata* and may be classed as a Tea-rose fragrance. Larger tubers and stronger plants will doubtless give better results, but there can be little doubt that *B. Baumanni* is a valuable acquisition for the Begonia fancier and the hybridizer. Some faint perfume seems to have crept into some strains of hybrid tuberous Begonias lately, but this species will probably add a more distinct odor to its crosses, while its erect habit and stiff peduncles are in the direct line of desired developments.

Elizabeth, N. J. *J. N. Gerard.*

Eulalias.—As single specimens on lawns or used as part of a group of subtropical plants in the summer garden, these

handsome grasses are indispensable. The variety Zebrina, probably the handsomest of all, was once considered doubtfully hardy, but here it stands the winter well, without any protection beyond its own dead leaves, which are burned to the ground in early spring. One of the most effective beds in the English garden at the place of Mr. H. H. Hunnewell is made up of tall-foliaged plants, in which this Eulalia forms part of the group, and it is especially effective in lighting up heavy-foliaged Cannas, Caladiums, and similar plants. The newer *E. univittata*, though not quite so rank a grower as the preceding, is a valuable addition to a not over-large selection of tall grasses. It is quite distinct, and particularly graceful as a lawn specimen. These Eulalias bear handsome plumes late in the autumn, for which alone these plants are cultivated in some parts of the country.

Shrubby Calceolarias.—Though very seldom grown now, as they have been displaced by the showy large-flowered herbaceous varieties, these are, nevertheless, worth a place where handsome pot-plants are required during the early spring months. Though the flowers are smaller, they make up in the quantity produced. They will endure rough treatment, and our plants are shipped to the city during winter, a distance of fifteen miles. Cuttings are struck during the summer, which usually require about two months for the process. These are gradually shifted into eight or ten-inch pots, where they bloom. The flowers vary in color between yellow, red and crimson. Many years ago these were common bedding-plants, but now they are seldom used.

Correspondence.

A New Way to Preserve Fruit.

To the Editor of Garden and Forest:

Sir,—In the progress of my experiments in applying heat to the conversion of food-material into nutritious food by the use of the Aladdin oven I have perhaps discovered a new method of dealing with fruit which may be applied even without the oven, although it can more safely and completely be applied in the oven, for the reason that we have in the oven and lamp combined complete control over the heat. After a little experience in the adjustment of the flame of the lamp and of the size of the oven, we may put the heat at not exceeding 200 degrees, Fahrenheit, and maintain it at that point for any length of time. It is due to this complete control, without attention for a number of hours, that we have been able to do the work which I will now describe:

On the afternoon of the 3d of July a large quantity of currants were stemmed and placed in glass jars of the type known as the Mason butter-jars, a jar which holds about a quart, with a very wide mouth, surmounted by a glass cover resting on a rubber ring, and held down by an outer metallic rim which is screwed upon the lip of the jar. After filling the jar with currants the interstices were then filled up with cold water. Eight jars each were then put into two pans which fitted closely in the inner oven, one above the other. These pans were then one-half filled with cold water. The glass cover was placed loosely upon the jars without the rubber rings. The two jars were placed in the oven in the evening, the oven closed, a lamp of moderate power lighted at nine P. M., which gave, according to a registering thermometer, a heat of 200 degrees, Fahrenheit, a simmering, and not a boiling, heat, which has proved to be sufficient to kill any ferment or spores that might have been in the fruit, in the water or in the air.

There was a slight expansion during the night, with a little overflow from the jars into the pan. The pans were then taken out separately in the morning, and while everything was still hot, and had to be handled with gloves, the covers were quickly removed, the rubber rings put on, and then the metallic ring was screwed down. Everything was then left to cool slowly. The process took but a very few minutes.

These currants are now perfectly sound after passing through the dog-days in the store-closet; they have shrunk a little, but evidently no spores have got in, even though the jars are not completely full. When opened they have a finer flavor and as much freshness as if they had been cooked right from the bushes.

On the same day we put up a few strawberries with a little sugar, which kept well, but were so good that they have long since been consumed. I also put up a considerable quantity of cherries with a little sugar, and a few days later a large lot of blueberries and gooseberries. Later we have put up peaches with a little sugar, and tomatoes in their own juice.

In only one or two instances in eight dozen jars has there been any appearance even of mold. In one jar of cherries a little spot of mold appeared upon the surface, but there had been no fermentation; the contents were perfectly sound.

I was led to these experiments by the success of one of my correspondents in making jellies and jams in practically the same way. The fruit was simmered all night with a little sugar, strained in the morning and put up in the jelly jars without any further work being done on it, thus saving the stirring and the discomfort of doing the work over a hot stove.

We have since then put up a large amount of grape jelly and Beach-plum jelly in the same way in my own household. This process saves a great deal of work, a great deal of time and a great deal of discomfort. By not subjecting the fruit to a high degree of heat the natural flavors are not only retained but even developed to a higher degree than common.

I can conceive that this work may be done in other apparatus than the Aladdin oven, but it may require a little more attention in the process, as there does not seem to be any other cooking apparatus in which the heat can be brought to a given point and there maintained for a long period without close attention.

Two of these ovens have been made especially for surgeons, set at three hundred degrees, Fahrenheit, for the purpose of sterilizing surgical instruments, bandages, etc., for which purpose they serve with complete success.

It is possible that this method of dealing with fruit may enable us to secure from tropical countries some of those fruits, in nearly their natural conditions, which, in their ripe condition, will not bear transportation and cannot be preserved in the ordinary way with sugar. A correspondent in Porto Rico is about to try some experiments in this line. I can conceive that absolutely ripe pine-apples, served in this way, might give us a taste of the pine that we do not ordinarily secure in the specimens that we receive from the tropics.

Boston. *Edward Atkinson.*

The Southern Interstate Exposition.

To the Editor of Garden and Forest:

Sir,—This exposition, now in progress at Raleigh, North Carolina, has some features of special interest to students of Horticulture and Forestry. From a number of states the exhibits of woods are good, North Carolina naturally leading in this respect. Some enormous sections of tree-trunks from the western mountains well illustrate the great wealth of that region in hard woods, while many articles of furniture show the beauty of the Maples, Walnuts, Ashes, Sycamores, Cherry and other woods. Among the exhibits from Florida are many products characteristic of that state. Among these a large number of pine-apples, fruited in pots, attract attention. In the North Carolina Agricultural Department there are shown two products illustrating the wide range of climate in the state. Two Palmetto-trees from Columbus County guard the entrance, and between them stands a Balsam Fir, from one of the high peaks of the west. The Palmettos were, unfortunately, simply cut down with an axe, instead of being dug up entire. They are, however, held in an upright position, and show trunks about eight feet high and a foot in diameter, while the beautiful crowns of leaves on their long stalks make the full height over eighteen feet. One who knows the slow growth of these trees cannot help regretting their destruction for a paltry five dollars each. The Florida people could hardly believe that Palmettos grew to such size in so high a northern latitude. Two of the North Carolina counties exhibited alligator skulls larger than anything in the Florida exhibit.

Northern visitors are attracted by the size and beauty of the apples from the western mountain country. The fact is rapidly becoming recognized that western North Carolina is peculiarly the apple region of the United States, and the time is not far distant when the lands of that beautiful region will be sought after by orchardists from other sections. The Scuppernong grape and other varieties of the Rotundifolia class are well represented at the exposition. Several new seedlings are shown. The fact is curious that seedlings from the Scuppernong, which is a russety green grape, are almost invariably black in color. The two leading seedlings are the James and the Alliance grapes. The James is a large black grape, with a thinner skin than the old Scuppernong, and rather sweeter. It makes larger clusters too, sometimes as many as fifteen berries. The individual berries average over an inch in diameter, many being over an inch and a half. One gentleman reported three bushels from four-year-old vines. Baskets of these grapes look like large Damson plums. The Alliance is shown for the first time. It comes from Wayne

County, and in size is simply immense. In color it is a reddish black, and the individual berries are nearly as large as very large Damson plums.

The exhibit of wines from the Scuppernong and its varieties is very fine. There are two large exhibitors—the Tokay Vineyards, of Craven County, and the Garrett Company, of Halifax County. This last company has an annual output of over 80,000 gallons of wine. The Scuppernong wines are rapidly making a name in the markets. The enormous productiveness of these Grapes, and their capacity for making wines of a high grade, will soon make them the leading feature in the horticulture of eastern North Carolina. The James and the Alliance Grapes are both later than the old Scuppernong, and are not fully ripe until the middle of October.

Just outside the buildings of the Exposition the North Carolina Agricultural Experiment Station has thirty-seven varieties of Figs growing, and still full of fruit. These late fruits are smaller than the early crop, but show the characteristics of the varieties well. So far the best sorts seem to be the White Adriatic and San Pedro, but these plants have been cut so hard for propagation that their full value in fruit has not yet developed.

The Oonshin or Satsuma Oranges at this station, on the hardiness of which we base some hope, have made a fine growth this season. We hoped to have specimens of fruit this year, as one of our trees bloomed in the spring, but a deluge of rain at blossoming time destroyed the flowers. The young trees passed one winter without being injured, and should be in a better condition for supporting another winter. Whether they will pass all of our winters unharmed remains to be seen; but the fact is evident that this Orange is destined to move the Orange-belt a good way north.

Raleigh, N. C. *W. F. Massey.*

Vernon Park, Philadelphia.

To the Editor of Garden and Forest:

Sir,—The city councils of Philadelphia passed finally, last week, an ordinance to take possession of the Wister homestead, in Germantown, as one of its small public parks. This is the third of a series which, under Councilman Meehan's efforts, have been placed on the city plan, and which the city proposes to take from time to time in the future. The city long ago reached the limit of its legal right to incur indebtedness. Unfortunately, its loans were created for long periods, and although there is money enough in the sinking fund to pay half its indebtedness, it is considered legally in debt until the bondholders are paid. Philadelphia, therefore, cannot borrow money for small parks, but has to pay for all these and other large public improvements out of a $1.85 tax-rate, and one or two of these small parks a year is all it can venture on.

The small parks are located under the advice of Councilman Meehan, as chairman of a committee in charge of the subject, and, so far as possible, those localities are selected which have some historical associations. Last year the celebrated Bartram's house and garden were acquired, and now Vernon, the Wister homestead, is added. The mansion-house is a fine specimen of colonial architecture, and the six acres of grounds contain many good specimens of trees collected by early botanists in remote localities of our country, as they were at that time. The first specimen of *Magnolia macrophylla* was brought from North Carolina by Kin, a German botanical collector little known, but of wonderful zeal, and the tree is still growing here. There are also magnificent specimens of Oaks, Pines, Ashes, Kentucky Coffee and other trees. This plot, which will be known as Vernon Park, is in the heart of Germantown, which is the twenty-second ward of the city of Philadelphia, and will be a great boon to that community. It is a district now of nearly 50,000 inhabitants, and yet its only piece of public ground was a little plot of about 150 feet square. There was absolutely no place where even a sick child could be taken for an airing except along the public streets.

It is singular that a city of over a million inhabitants should have miles and miles of brick and mortar with not a solitary open space except the half-dozen small ones plotted by William Penn and his immediate descendants, though its one grand Fairmount Park, of nearly 2,000 acres, is some offset to this surprising negligence. The movement for better things, started by Mr. Meehan in 1883, is now very popular, and councils are overrun with applications for small parks from all parts of its 200 square miles of territory. This is the third park actually acquired out of ten located, and it is believed some four more will be located before the end of the present session of the city councils.

Philadelphia has to pay, by order of state legislature, out of annual taxation, nearly a million dollars a year for the huge pile of marble in the centre of the city, known as the Public Buildings. It is believed this heavy expenditure will end in about five years, and there is little doubt, if the present temper of the citizens continues, Philadelphia will then rapidly retrieve its reprehensible indifference to open spaces, so essential in these days to the good reputation of a progressive city.

Philadelphia. *S. A.*

Begonia Vernon.

To the Editor of Garden and Forest:

Sir,—In No. 185 (September 9th) of Garden and Forest we find a short note on the *Begonia semperflorens atropurpurea*, or *B. Nelsoni*.

We beg to be permitted to remark that that variety having been put upon the market by our firm last year, as you will see by the enclosed novelty list, it is but fair that our right as to its exact name be preserved during the first years at least, and we therefore must protest against the name of *B. Nelsoni* given in the above notes.

If you will please refer to the *Journal of Horticulture*, No. 2219, London, 9th April last, you will find a description of that Begonia, of which we beg to send you enclosed a copy, as also its exact name, which is *Begonia Vernon*, or *semperflorens atropurpurea*.

As regards the statement that the markings have not proved constant with Mr. Gerard, "who is inclined to doubt if they will prove so under your hot sun," we presume that that gentleman has not got the right sort, or has grown the plants under glass or in the shade, in which case they indeed do not show off well their bronzed, purple-tinged foliage.

The latter is seen in the best of conditions under our climate when the plants are grown in the full sun—that is, in situations where the sun shines upon them during the greatest part of the day.

Many American florists who saw the plant in our grounds all agreed that it was one of the finest bedding plants introduced of late years.

Paris. *Vilmorin-Andrieux & Co.*

[*Begonia Vernon* is the only synonym for *B. semperflorens atropurpurea*, and until attention was called by the above letter I was not aware that it had unconsciously been given another. The correct name was perfectly familiar to me, having had fifty plants labeled *B. Vernon* before me for months, and I am unable to account for the mental twist which led me to write an irrelevant name in my note. My plants were from Messrs. Vilmorin-Andrieux & Co.'s seeds, and, as suggested, have been grown under glass. It would seem a good plan for the introducers of new plants to note any peculiarities in their offerings, as does not seem to have been done in this case. Had Messrs. Vilmorin printed on their seed-packet or in their list the fact that the leaves of this variety only show their true character in the open, the experiment would have been tried, and probably a less disappointing report have been given. So far the result is, as given by me, a fine form of *B. semperflorens rosea*, with no indication of leaf-coloring. In my notes the intention is to report faithfully what I see in my own garden, not what is read or heard. The first hint as to growing this variety in the open came to me too late in the season for trial, from a friend who saw *B. Vernon* in Paris this summer, and reports it as fully bearing out all claims made for it.—*J. N. Gerard.*]

Periodical Literature.

The fifth number in a series of articles now being published in the *New Review* under the collective title "A Model City; or, Reformed London," is written by Professor H. Marshall Ward, and called "Trees and Flowers." The main question which the author considers is, "Are cities and towns like London, Birmingham, Manchester, Liverpool, etc., so polluted with gases and smoke and so darkened with soot and fog that the existing show of trees and shrubs is the best possible under the circumstances?" and his answer is, that he thinks he can show cause for believing "that the matter has been considerably exaggerated, and that, if the various local authorities were to take into account all the facts, they would come to the conclu-

sion that not only could much more be done, but that it is a national duty to see that much more is done in this matter of increasing the number and variety of trees and flowers in our towns and cities. Very little technical knowledge of the life-processes of plants and the conditions necessary for their welfare is needed to show that different species differ immensely in the degrees of susceptibility to injury by means of small quantities of acid fumes, such as exist in a diluted condition in the smoke passing off from the tall chimneys of a busy manufacturing centre; nevertheless, no tree will withstand the worst of the conditions found in centres of industry which daily give off small quantities of chlorine, hydrochloric acid or sulphurous acid; but then it must not be forgotten that these worst conditions are out of all proportion to the conditions met with in a city like London. Yet it is surprising to see how gallant a struggle for life is kept up by trees like the Balsam Poplar, the Black Poplar, the Alder, Sycamore, and some other trees even in the worst cases referred to." Coniferous trees, the writer continues, are not nearly so well able to stand these conditions, nor can the Oak, the Beech or the Birch long and successfully continue the struggle, though even these put up with more hardships than is popularly supposed. The chief point he wishes to make plain is that, at all events, in the smaller and more open English towns, many more varieties of trees will grow than have yet been tried, and that here, at any rate, "every effort ought to be made to plant some of the many beautiful North American and other foreign trees that can now be obtained and are known to be capable of easy cultivation in such localities. Moreover, there can be no doubt that much is to be done in this direction in London and other large cities in spite of crowded dwellings and periodical fogs."

Professor Ward then points out some causes for the frequent failure of town trees which do not lie in the unsuitability of atmospheric conditions, and his words show that municipal authorities often work in England pretty much as they do in America. Town trees are "fixed, when young, in a hole, probably filled with good soil, and this is carefully covered in, the young trees suitably staked and protected, possibly the soil round the base of the stem covered with a grating, and the result is—failure! True, it often takes several years to accomplish this striking result, but its inevitableness is none the less assured. While the tree is young, and its root-system is reveling in the pocket of good soil, provided with the overhead grating which ensures a supply of rain-water and air, and it may be of manure also, all goes well, and the head of foliage above is able to make the most of what sunshine there is and to manufacture the substances which supply the wood, new buds, new roots, and, possibly, even flowers. But the time comes when the pocket of soil is exhausted by the roots and they put out spreading thread-like rootlets to explore the soil around. And now comes the critical period; these young rootlets are covered with myriads of extremely fine hairs, and these delicate root-hairs are the only organs which absorb the water containing small quantities of substances such as salts of potash, lime, nitrogen, phosphorus, etc., in solution, and they are utterly incapable of performing this work of absorption in the absence of oxygen. Now, what are the usual conditions of affairs in the streets of a town? Even supposing these new spreading rootlets have good soil around them, and soil which is porous and deep, the rule is, that a practically hermetically sealed layer of flag-stones or asphalt lies above them, and their only chances of obtaining water and oxygen are through the grating and soil close to the stem. No doubt, the most is made of this, and the tree goes on for several years, doing better than it would if the flags or asphalt came up close to the stem. How often does it happen, however, that the new rootlets have nothing better to spread in than old brick rubbish or barren gravel; or, far worse, a soil which is saturated with the poison from leaking gas-pipes?"

Even sanitary appliances have an adverse effect upon town trees, for "the neighboring sewers may be taking off, as fast as they can, the water from soil round the roots, or the case may be otherwise, and the stagnant water, standing too long at the roots of the tree, deprives them of the oxygen necessary for their life and lowers the temperature beyond a minimum they could temporarily withstand. What has been stated so far is enough to show that the wonder is not that trees so often fail in the streets of our cities and large towns, but that the interminable and dreary rows of Planes, Elms and Limes that are planted ever come to anything at all." The author then notes the injuries which may come to town trees through the impact of vehicles, the gnawing of dogs and horses and the pranks of boys, and the danger of selecting, for street-planting, trees which send out long, straggling, superficial roots, running just under the pavement or road, because, as these roots thicken with increasing age, they lift up the flag-stones or other pavement, and, becoming a source of damage and danger to the street, are likely to be injured themselves by passing feet and wheels. The comparative brittleness of the limbs of different trees should also be considered before planting; and, after planting, proper methods of pruning or otherwise treating a tree which is in delicate health or has suffered external injury should be determined.

Although, says Professor Ward, for one reason or another, "the Oak, Ash, Birch, Beech and some others of our forest-trees are unsuitable for town-planting, this is no sufficient reason for flooding London with Planes, and Planes only, as if no such trees as Robinias, Laburnums and American Oaks, Ashes, Walnuts, Maples, etc., existed. Moreover, there is every reason to predict success for trees as yet undreamt of as town ornaments. Let those in authority try some of the hardy Magnolias—say *M. acuminata*, probably one of the best town trees—and extend their experiments to such as the Robinia, the Laburnum, the Tulip-tree, the Mulberry, Fig, Catalpa, and the beautiful Maiden-hair tree of Japan. The list might also include the Almond, Black Walnut, and various species of Sophora, Kolreuteria, Cercis, Gymnocladus, Acer, Rhus, Tilia, Liquidambar, etc. Some judgment would have to be exercised in the matter, of course, but probably all of the trees here mentioned would succeed if properly planted. . . . As regards Poplars, Ashes, Alders, Pavias, Limes, Gleditsia, Horse-chestnuts, Thorns, etc. . . . I will simply remark that these and many more can be placed in the list of trees and shrubs fit to be planted in large towns and cities; some, of course, are more fit for our cleaner and less smoky country towns, but many would resist the evil influences of a London atmosphere if properly planted and cared for." We have omitted the lists of shrubs, climbers and smaller plants which Professor Ward also gives, but may cite his mention of the fact that there was, a year or two ago, a fine specimen of *Ptelea trifoliata* flourishing in the heart of the city of London on the premises of the *Times* newspaper. "Surely," he says, "after this we need not despair, and it behooves all those who are concerned in furnishing towns with those 'lungs' so necessary for prosperity in the true sense, to bestir themselves and look through the lists of likely plants." It may interest Professor Ward to know that some of the American trees he recommends flourish well in the streets of American towns.

Notes.

Messrs. Pitcher & Manda announce an exhibition of Chrysanthemums, Palms, Ferns and Orchids at the United States Nurseries, Short Hills, New Jersey, to continue during this week.

During the famine which has recently afflicted the Volga regions, in Russia, the peasants have found their chief source of subsistence in bread made from a Chenopodium, the common way-side weed which we will call Goosefoot.

Professor N. S. Shaler, of Harvard University, whose excellent book on the "Aspects of the Earth" we reviewed a year or two ago, is about to publish another, called "Nature and Man in America," which will explain in a popular form the influence that environment exerts upon man.

A correspondent deplores the popular taste which makes it possible for a boy made of Roses, Immortelles and Carnations, and trousers made of Roses and Pinks, to be among the constructions spoken of as "beautiful and numerous floral tributes" at the opening of a business house lately.

The study of plants first existed as a branch of medical knowledge. When Hippocrates, "the father of medicine," compiled a list of all medicinal plants known to him only 300 were named. In the time of Theophrastus, the famous pupil of Aristotle, some 500 species could be described, and in the first Christian century, when Dioscorides wrote, 100 more were known.

Among the new books which should interest lovers of nature we notice "Sharp Eyes," a collection of studies of insect, bird and flower-life, by W. Hamilton Gibson; "Japonica," by Sir Edwin Arnold, and "The Warwickshire Avon," by Mr. T. Quiller-Couch, illustrated by Mr. Alfred Parsons. Of the charms of the last-named two we have already spoken during their serial publication in *Scribner's Magazine* and *Harper's Monthly*.

In *Insect Life*, for October, it is stated by way of example of what may be done to mitigate insect attacks, that in the states of North Dakota and Minnesota there has been during the

present year a probable saving, from the ravages of grasshoppers, due directly to the advice of entomologists, of not less than $400,000. This saving was accomplished by fall plowing and the use of "hopper-dozers." An estimate that has been generally accepted is, that about one-tenth of the agricultural products of the United States is annually destroyed by insects.

A recent writer notes the fact that the German botanist, Dillenius, who, early in the eighteenth century, devoted himself to the study of mosses, and was the first to distinguish them from the fungi, found, in the neighborhood of Giessen, where he lived, 200 species of mosses, of which 140 were new to science, and 160 fungi, of which 90 had not previously been known.

In Mr. E. W. Hervey's "Flora of New Bedford and the Shores of Buzzard's Bay," he says of *Gaylussacia resinosa:* "A white variety of this species is occasionally brought from neighboring towns for sale, but in small quantities. A small tract of land in Berkley, about fifty feet square, has borne an annual crop of perhaps a quart of white huckleberries for forty years or more. A few bushes bearing the ordinary black huckleberry are interspersed with those bearing the white variety. The white variety has also been found in East Fairhaven."

In some notes on the Flora of the Lake Superior Region, published in recent numbers of the *Botanical Gazette*, Mr. E. J. Hill says that in Minnesota blue and red flowers are especially bright in color, while white flowers reveal, in a more or less well-marked degree, a tendency to coloration. He thinks that these facts are probably due to the clear bright weather that prevails in Minnesota, as contrasted with those neighboring regions where more moisture exists in the air, and expresses a desire that others may record their observations upon the subject.

In an article in the *Independent*, among the growing industries of Florida, that of bee-keeping is named. The profusion of flowers the year round, and the absence of winter, does away with the necessity of feeding, a matter of great expense in the north. There are now many large apiaries in the state, notably one upon the Appalachicola River, that contains 1,200 stands of Italian bees. This apiary produces about 10,000 gallons of honey per year, which is extracted and sent to market in barrels, bringing about fifty cents per gallon. Put upon the market in attractive shape, the net income might easily be increased fifty per cent.

In an article called "Does our Indigenous Flora give Evidence of a Recent Change of Climate?" published in Bulletin No. 7 of the Natural History Society of New Brunswick, Mr. J. Vroom discusses the question whether the subarctic plants of this country "have lingered here since the glaciers receded, or have once passed on in their northern migrations and been again driven southward to replace less hardy species, and whether a general movement in either direction is now going on." His conclusion appears to be, that within recent geologic times our climate has constantly improved, and that the general tendency of plant migration is steadily northward.

The frequent want of taste we display in the environment of park statues, a theme which was recently discussed at length in our editorial columns, is well illustrated by the present appearance of the Seward statue on Madison Square. The figure itself is a poor one, and rising, as it now does, from a little forest of tall, variegated, foliage plants, its aspect is nothing short of ridiculous. Not a great deal better looks the figure of Washington on the Riverside Drive, for, although here the beds of Coleus and higher plants do not immediately encircle the statue, yet, as one approaches from either direction, it seems to be rising from their midst. A comparison of these effects with that of the Webster statue in the Central Park, partially draped to its top with Japanese Ivy, instantly shows the superiority of vines in such situations.

The credit of originating what is known as the "Landscape Lawn Plan" for rural cemeteries belongs to Adolph Strauch, who was born in Germany in 1822, studied landscape-gardening, chiefly in the famous gardens of Austria, traveled widely and eventually emigrated to this country in 1851. Three years later he took charge of Spring Grove Cemetery, in Cincinnati, and, after encountering much opposition, succeeded in laying it out in accordance with his own new ideas and thereby set a pattern which has been more or less intelligently imitated all over our country, to the unstinted admiration of European visitors. It is interesting to learn, upon the authority of an address republished in one of the reports of the conventions of the American Association of Cemetery Superintendents, that Strauch "was stimulated by the glowing descriptions of Chinese cemeteries in Humboldt's 'Kosmos'" and largely owed to them the idea of introducing kindred effects into American cemeteries.

A correspondent of the New York *Sun*, writing from New Orleans, says that, "under the auspices of the State and the Louisiana Agricultural and Scientific Association, a sugar school has been established in this city, and will go into operation here next month, for the purpose of educating all who desire to take the course in the culture of cane and the manufacture of sugar from it. The school is equipped with a corps of five professors—of sugar agriculture, sugar chemistry, analytical chemistry, sugar mechanics, and sugar-making respectively. It has a plantation attached with a small sugar-house on it, but one thoroughly equipped with the latest and most improved machinery, a library containing all the books and journals on sugar, and everything necessary to teach this industry. The course will be one of two years, at the end of which time the student will be turned out a thorough sugar-maker, a chemist prepared to carry on a sugar-plantation in the most scientific manner."

Mr. J. H. Hale writes to the *Country Gentleman* that, in his opinion, the Excelsior Peach will help to extend the cultivation of Peaches at the far north. In central Connecticut, a hundred miles north of a limit of safe peach-growing on the Atlantic coast, it is possible to struggle against borers, insects, the yellows and other discouragements with fair success, but the serious obstacle in the way of profitable Peach-culture is the killing of the fruit-buds by extreme frosts in winter, so that varieties like Late Crawford give only one full crop and two partial crops in twelve years. Oldmion, Stump, Keyport, White and Smock have given three full crops and as many partial ones in the same time, while Hill's Chili and Pratt have fruited nearly every year. Hill's Chili, however, is unattractive in appearance, and the Pratt rots badly on the tree. Mr. Hale has seen Excelsior fruit in New Hampshire when there was not another Peach in all New England, and he is satisfied that it is a variety which can be trusted to bear every year. The tree is of the Hill's Chili type, although rather more dwarf in growth, but the fruit is much larger, richer and of brighter color, and without the "wool" which is so objectionable in Hill's Chili. It sells as well as the Crawford, and for family use is of better quality.

It would be hard to imagine a more charming garden-scene, or one more artistically portrayed than the Primrose-garden in Surrey, which is the subject of one of the illustrations in a recent issue of *The Garden*, of London. It represents a wood walk lined with a few picturesque Birches, under which are great masses of the Yellow Primrose in bloom; and as this plant, the true English Primrose, is hardy in our northern states, with a little protection, we can endorse the views of *The Garden* when it says that "no flower better deserves a garden to itself than the Primrose. It is so old a favorite, and has been cultivated in so many forms, that any one determined to have a Primrose-garden may choose the kind he likes best and set to work accordingly. There are the single-stalked Primroses, the earliest of all, flowering from the middle of March onward, while some may be had in bloom as soon as the end of February. They range in color from pure white to deep primrose, and from palest pinky lilac, through strong red-purples, to a color nearly approaching blue, and there are also rich reds of many shades. The grand Primroses for garden effect are the large bunch-flowered kinds, white, yellow and orange-colored, red, crimson and rich brown; of infinite variety in form, texture, habit and coloring; easy to raise to any amount by seed, as also by division of the older buds." The garden which our contemporary illustrates was formed a few years ago "by making a cutting, about seventy yards long and varying from ten yards to fifteen yards wide, through a wild copse of young Birch-trees. The natural soil was very poor and sandy so it was prepared by a thorough trenching and a liberal addition of loam and manure, which has to be renewed every year. No formal walks are made, but one main track is trodden down, about two feet wide, about the middle of the space, dividing into two here and there where a broader clearing makes it desirable to have two paths in the width. The whites and yellows are kept at one end of the garden and the reds at the other, the deepest yellows next to the reds. The white stems of the Birches and the tender green of their young leaves help to make a pretty picture, which is at its best when illuminated by evening sunlight."

TABLE OF CONTENTS.

The American Buckeyes.

THE North American forests are comparatively rich in Horse-chestnuts, or Buckeyes, as we are still apt to call them in America. The genus Æsculus, as it is now known, to which these plants belong, only contains thirteen species. Eight of these are American, if we include two little-known shrubs of southern Mexico and of the northern countries of South America, and another shrub of Lower California. Outside of America the genus is represented in south-western Europe, in the tropical forests of India, Assam and Burma, in northern and in central China, and in Japan. The different species fall naturally into two distinct sections. In the first the flowers are furnished with five petals, and the walls of the fruit, or pods, are thick and covered on their outer surface with sharp prickles. The common Horse-chestnut, which is a native of the mountains of Greece and which is now one of the most familiar of all ornamental trees, and the Indian species belong to this section. In the plants of the other, the flowers have only four petals, and the fruit is smooth with thin walls; they are American, Chinese and Japanese, and to them the name of Pavia was formerly given. The two sections are united, however, by one of our American trees, the so-called Ohio Buckeye, which has the flowers of the Pavias and rather thin-walled fruit, which, in its early stages at least, is covered with the prickles of the true Horse-chestnuts. And so it has seemed better to consider the Horse-chestnuts and the Buckeyes generically identical.

Five species grow naturally within the territory of the United States. None of these are so often planted here, however, as the European Horse-chestnut, and none of them, perhaps, are individually as beautiful as that tree, which surpasses all other members of the genus in the massiveness of its port, in the density of its foliage and in the magnificence of its great flower-clusters. But the massiveness and the formality of the head of the Horse-chestnut, while they make it a splendid object in some situations, render it a difficult tree to associate properly with other trees; and it usually looks out of place as an element in a picturesque landscape. Its value, however, for formal plantations, either in city streets or in the avenues of architectural gardens, was recognized in Europe two centuries ago, and no other tree has yet been found which surpassed it for such purposes.

If our American Buckeyes are not equal to their Old World relative in breadth and solidity of head and in floral splendor, they, in their turn, surpass it in grace and in their adaptability to harmonize with the other trees of the forest; and for general planting in this country they are, therefore, more valuable, especially the Sweet Buckeye, the *Æsculus octandra* of botanists, the largest, or, at any rate, the tallest of the American species. It is an inhabitant of the Alleghany region from western Pennsylvania to Georgia and Alabama, and of the Mississippi Valley. When it grows at its best, as on some of the slopes of the high mountains of Carolina and Tennessee, it is a noble tree, sending up a straight shaft two or three feet in diameter, sometimes free of branches for sixty or seventy feet, and often reaching a total height of ninety feet. The head is rather narrow and formal, and the branches are small and often pendulous. The leaves are of ample size, and are dark yellow-green, and rather paler on the lower than on the upper surface. The flowers are peculiar in the unequal size of the petals, the limbs of the upper pair being much smaller than the others and borne on slender claws which much exceed the calyx in length. The fruit is pear-shaped, often two inches long, and is beautiful and conspicuous. There is a variety of this tree found in some parts of the southern Alleghanies and in Texas with red or purple flowers. The yellow and red-flowered varieties are both hardy as far north as New England, and they are both useful ornamental trees, growing rapidly in good soil and harmonizing with the native trees of the north; and, unlike the Old World Horse-chesnut, they are not seriously injured by fungal diseases.

The so-called Ohio, or Fetid, Buckeye, *Æsculus glabra*, is the second of the Horse-chestnuts of eastern America which grows to the size of a tree. It is not as large as the Sweet Buckeye, and it is unusual to find it more than thirty feet in height, although sometimes, under the most favorable conditions, it grows to fully twice that size. The trunk and branches are covered with dark bark which separates readily into thin scales, and these make it easy to recognize the tree at a glance, even in winter and while still very young. The foliage is lustrous, dark yellow-green and rather conspicuous from the yellow midribs and veins of the leaflets. The flowers are of a pale yellow-green color, the petals nearly of the same length, although the lateral pair are much broader than the others. The Ohio Buckeye, which got its name from the fact that it was first known from the banks of the Ohio in Pennsylvania, belongs to the valley of the Mississippi; it is nowhere very common, and is even less common now than it was a hundred years ago. This is due in part, no doubt, to the fact that this tree always selects rich soil near the banks of streams or on river-bottoms, and has had to make way for the crops of the farmer. It is as hardy at the north as the Sweet Buckeye, but, from an ornamental point of view, is a much less desirable tree and hardly worth planting except as a curiosity.

The other Buckeyes of the east are inhabitants of the south, and do not attain to the dignity of trees. The most common of these two plants and the type of the old genus Pavia is the Scarlet Buckeye, or *Æsculus Pavia*. This is sometimes a low shrub, producing its flowers when only a few inches high, and sometimes reaches the height of a dozen feet or more with many slender straggling stems. It is widely distributed and very common in all the coast-region of the southern states, from Virginia to Texas, and west of the Alleghany Mountains, extending as far north as Kentucky and Missouri. The flowers are two or three inches long and bright red; they make a great show therefore, although

individually narrow and placed rather remotely in narrow few-flowered clusters; they appear with the unfolding of the leaves and offer a warm and cheerful welcome to the traveler from the snow and ice of the north as he first reaches the south in early spring. Although this pretty plant cannot withstand the severity of our northern winters, the name is often found in the catalogues of nurserymen who confound it with some of the red-flowered varieties of the Sweet Buckeye.

The fourth species of eastern America is the rarest of all our American Horse-chestnuts, although, strange to say, it is more commonly planted than any of the others, and, therefore, perhaps the best known. It is the *Æsculus parvifolia* or, as it was once called, *Æsculus macrostachya.* It is an inhabitant of the foot-hills of the extreme southern Alleghanies, where the younger Bartram found it, more than a hundred years ago, when he crossed from the sea-board to the head-waters of the Tennessee and saw, before any other educated man, the beauties of that marvelous region, covered then with one great forest, save where the Cherokee had made for himself a home by some swift-flowing river. The Dwarf Horse-chestnut, as the plant which Bartram discovered is now most often called, spreads, in cultivation, into a broad bush of compact habit, sometimes twenty or thirty feet across and six or eight feet tall. From spring to autumn it is a handsome plant as it stands out singly on the lawn, and in early summer it covers itself with long narrow spikes of slender creamy white flowers, made conspicuous by their long exserted stamens and yellow anthers. Although it is a southern species, peculiar to a region whose plants are not, as a rule, hardy at the north, the Dwarf Horse-chestnut flourishes in all parts of New England, where it flowers abundantly, although the season is rarely long enough for the fruit to ripen.

The last of the North American Buckeyes is an inhabitant of California—the *Æsculus Californica* of botanists. It is a low tree, sometimes thirty or forty feet in height, with a short stout trunk, often much enlarged just above the ground, and spreading branches, which form a wide dense head; or more often it is a shrub with stems ten or twelve feet high, forming dense thickets. It is widely distributed in all the foot-hill region of the Coast ranges and of the western slopes of the Sierra Nevada, from the northern almost to the extreme southern part of the state, lining the banks of many streams and the sides of innumerable cañons. The flowers of the California Buckeye are more beautiful than those of the other American species; they are white or pale rose color, an inch or more long, with broad, spreading petals and long conspicuous stamens, and are produced in long, very compact, many-flowered clusters. The fruit, which is pear-shaped and rather larger than that of our other species, is also ornamental. The only drawback to the California Buckeye, as it appears in the valleys of California, is, that the leaves, which appear early and are fully grown when the tree is in flower in May, ripen under the influence of the hot sun very early and often fall by midsummer, thus leaving the branches bare for a considerable part of the year.

An idea of the habit the California Buckeye is capable of assuming when it has grown under the most favorable conditions, and of the profusion of its flowers, can be obtained from the illustration which appears on page 523 of this issue. It represents a tree growing at San Mateo which is thirty-two feet high, with a head sixty feet in diameter and a forked trunk six and a half feet through two feet above the surface of the ground. It is an exceptionally fine specimen, although others nearly as large and symmetrical can be seen in the same region. For the photograph from which our illustration has been made we are indebted to Dr. L. D. Morse, of San Mateo.

The California Buckeye is not very often cultivated, although it was first sent to Europe nearly forty years ago and flowered in England as early as 1858. Unfortunately, it is not hardy in the eastern states, and probably, outside of California, it will never really flourish except in climates similar to that of the Pacific coast. It is well worth planting, however, in all the Mediterranean countries, and, perhaps, in Australia, as an ornamental plant, for it is one of the handsomest of the whole genus, and, when in flower, one of the most beautiful of all North American trees.

The Delayed Frost.

THE charm of a long autumn is very great, but seldom permitted by our capricious climate, which is apt to spoil the garden in September and then make the misfortune the more apparent by a succession of mild October days, when flowers and green leaves would suit the weather.

This year, which has made eccentric shifts of all the months in turn, giving us a dry April and a cold July, bestowed upon us a most enchanting autumn, mild and free from storms, so that vegetation remained perfect till late October, and the harvest-time was most propitious.

No early frost blighted the corn-field or marred the golden pumpkin's fairness. No rain made the apple and pear gathering a disappointment and a sorrow. Late flowers lined the garden-walks in unchilled splendor until mid-October, while the soft September haze and the mellow glow of the succeeding month showed Maples in full green leaf, and Oaks with only a touch of ripened crimson.

When the autumn comes thus slowly to maturity a tinge of russet and gold creeps softly into the landscape. Here and there is the accent of a red leaf or branch like the note of a trumpet in an orchestra. Soft browns steal into the meadows and form a shade on northern slopes. Dead are the Golden-rods and Asters, faded the road-side flowers. The Rose-hips make ruddy gleams in the bushes, and a few belated Barberries cling to their thorny stems in wizened splendor, while other berries, purple and black, cluster by the fences, and the nut-trees hang out their smooth or prickly burrs, promising a harvest of brown fruit.

This is the green old age of the year, cheery and fruitful, bountiful and rich. Gone are the hurry of spring and the burden of summer, the slow harvest has been gathered, and repose has come to the teeming earth. Now must the gardener look forward and plan for the coming season, and set his bulbs for spring blooming, and clear away the rubbish of dead stems from the flower-beds, and transplant perennials that they may blossom freely the following summer.

It is well in planting a garden to arrange for this season, which is so pleasing, by having a profusion of hardy plants that are not easily disheartened by a chill, and make a brave show as the year wanes. This is a care often neglected by public gardeners, who stock their parterres with ephemeral blooms that the first cold breath destroys, leaving but a dreary group of dry sticks behind.

Well mingled with these more delicate plants should be those hardy perennials that lift their gallant little heads and smile in the very teeth of winter. The hardy Chrysanthemum, the Marigold and Calendula are a delight in the late autumn, with their cheery tints. The Salvia, less hardy, is the glory of a September garden, and many another flower, with a little shelter at night, will make a walk gay and cheerful that would otherwise be gloomy with decay and desolation. The Japanese Anemone is a treasure at this season, and those bushes bearing ornamental fruit which hangs on even amid the snows of winter should never be omitted from a border.

Like a happy temper in adversity is a gleam of color in the garden in the late autumn. One draws a lesson of good cheer from a Calendula, so undaunted and gay even when the snows are falling on its golden head. A cluster of red berries on a dry stem give a distinct joy in early winter, and life is made brighter by the aspect of hardy blossoms and hardier fruit when all the trees around are stripped of foliage.

In summer the charm of a garden is in its coolness and shade, in the dark shelter of thick trees and the quiet of a shaded arbor. In the autumn we seek the sunshine and desire color and warmth, wishing to forget the coming cold and the swift fading of leaf and flower.

It is like the natural clinging of man to life which increases as years steal upon him. Youth does not dread death as age shrinks from it. The habit of living becomes stronger as we descend the hill, and the suggestion of interruption seems impertinent. The late scentless flowers are more precious than the summer Roses, for their time will soon be gone. Nature cheats us with her autumn splendor, which beguiles the mind into forgetting that it is the precursor of decay. While we admire the glory of a Maple-grove, we do not realize that the storms of winter are gathering behind the forest. When the mountains are purple in the low sunlight we forget the snows that shall soon whiten their summits, and there is wisdom in this natural instinct that forbids foreboding when joy is at hand, which can rejoice in the present without seeking to lift the curtain of the future.

Let us rejoice, then, in the autumn flowers; in the soft atmosphere that clothes the world with beauty; in the great moon's yellow light; in the round, soft clouds, and the wild skurry of the dun rack that scuds across the heavens when the breeze rises. Full soon will that searching wind scatter the jewel-like leaves, and tear the last petal from the shrinking flowers, while the grass grows brown and sear, and the soft earth stiffens like a body from which life has departed. Too soon will the valiant head of the last Daisy be buried in a mantle of snow, and the leaden sky bend low above a frozen earth. Let us rejoice, then, while we may, for the days shorten, and with them our summer joys and the lives of the autumn flowers.

We are indebted to Miss Graceanna Lewis for the privilege of publishing the following letter from the venerable President of the Delaware County (Pennsylvania) Forestry Association:

Esteemed Friend,—At thy request I visited the trees of which I spoke at the last forestry meeting, and which I knew sixty years ago. I found them looking very much as they did then, and not very perceptibly larger. The first one is on the farm of John Beeson, in Upper Chichester, near the Baltimore & Philadelphia Railroad, and about half a mile west of Ogden Station. It is a Chestnut-tree, and at three feet high its circumference is twenty-seven feet one inch and a half; at six feet high, it is twenty-four feet five inches in circumference, and one foot from the ground it is thirty feet nine inches in circumference. About one-fourth of the body of the tree is dead up to the limbs, which are about twelve feet high. The top is decaying in many places, but it still measures eighty-seven feet from out to out.

The second one is a Cherry-tree on the farm of George Broomall, about a quarter of a mile south-east of the Chestnut-tree. It is fourteen feet and a tenth in circumference at three feet high, and fourteen feet at six feet high. The top measures seventy-one feet and three-tenths from out to out. This tree is in full bearing, having had a large crop of cherries taken from it this year. I found still enough cherries to remind me of the taste of them sixty years ago. The fruit is natural, quite as large as the Bleeding Heart cherry and quite as sweet, and is black in color. I learn that many trees in the neighborhood have been grafted from it, but it is said that the fruit on the grafted trees is not quite as large as that on the original tree.

The third is a Beech-tree in Lower Chichester, on the Naaman's Creek Road, and it is supposed to mark the place where the circular boundary-line between Pennsylvania and Delaware crosses that road. At three feet high it is fifteen feet and eight-tenths in circumference. It is quite a flourishing tree yet, the top being ninety feet from out to out.

The Cherry and the Beech appear to be good for some years to come. The limbs of the Cherry can be reached from the ground, and I recognized those of them by the aid of which I climbed the tree when a boy. The Beech is covered to the height of convenient reaching with the initials of many persons whom I knew in that neighborhood many years ago.

Thy friend, *John M. Broomall.*

Filices Mexicanæ.—III.

WE continue, this week, the enumeration of the Ferns collected in the states of Nuevo Leon, Jalisco, San Louis Potosí and Machoacan, Mexico, during the seasons of 1888, 1889 and 1890, by Mr. C. G. Pringle, of Charlotte, Vermont, together with notes and descriptions of new species and varieties by Mr. George E. Davenport, of Medford, Massachusetts.

Llavia cordifolia, Lagasca (1990). Shaded rocky cañons, Sierra Madre, near Monterey, July, 1888. Mr. Pringle wrote of this Fern that it was "seen chiefly in a broad cañon of the Sierra Madre near Monterey, through which flowed a brook which had brought down from the mountain and strewn along its borders piles of stones of various sizes. Among these stones this plant found favorite conditions, and grew in great clumps two or three feet high."

Lygodium Mexicanum, Presl. (3318). Low forests, Las Palmas; stems twining ten to twelve feet on shrubs; October, 1890.

Nephrolepis cordifolia, Presl. (1835). Wet cliffs near Gaudalajara, December, 1888.

Nothochlæna Aschenborniana, Klotzsch (3297). Shaded ledges, San Jose Pass, October, 1890.

Nothochlæna aurantiaca, D. C. Eaton (1840 and 2587). Dry shaded ledges and cliffs of the Barranca, October and November, 1888–1889.

Nothochlæna brachypus, J. Smith (1787). Damp shaded banks of gullies and ditches near Guadalajara, November, 1888.

Nothochlæna candida, Hooker (2021). Sierra Madre, near Monterey, June, 1888.

Nothochlæna Lemmoni, D. C. Eaton, var. straminea, n. var. (2830). Rocky hills near Guadalajara, December, 1888. A form with yellowish brown, nearly straw-colored, rounder (more nearly terete), and stouter stipites, and rachises less distinctly channeled than in the type; scales of the rhizoma and stipes lighter colored than in the normal form, and with broader, more membranaceous margins; sori also lighter colored, browner. The whole aspect of the plant strikingly different, especially in color, from the normal form, even as collected in Mexico by Dr. Palmer, and appearing to me worthy of recognition as a good variety. Dr. Palmer's 701, from Chapala, 1886, is identical with this, but shows a nearer approach to the normal form than Mr. Pringle's plant, and the deciduous scales have disappeared altogether from the stipites.

Nothochlæna nivea, Desvaux, var. flava, Hooker (2581). Limestone ledges, mountains near Monterey, June, 1888.

Nothochlæna rigida, *n. sp.* (2599). Root-stock rhizomataceous, moderately stout, clothed with dark brownish black opaque scales; stipites stout, rigid, approximate, 3′ to 4′ long, and, as well as the main rachis, terete, dark chestnut-brown, dull-polished, sparsely clothed from the base upward with dark brown opaque scales and a deciduous white powder; laminæ 8′ to 12′, or more, long, 2′ to 3′ broad, only once really pinnate, but appearing as if bipinnate, long-lanceolate, broadest in the middle, with upward of twenty or more pairs of sessile pinnæ; pinnæ acuminate-lanceolate, deeply cut almost to the rachises into 8 to 12 linear, pinnatifid, obtuse divisions on each side, those on the lower side much the longest, lowermost pinnæ gradually reduced; upper surface naked, under thickly coated with white powder; sori light brown; margins slightly recurved.

Habitat: Limestone ledges, Sierra de la Silla, Monterey, May 31st, 1889. This fine new Nothochlæna bears some resemblance to *N. Lemmoni*, and some of the smaller specimens might easily be mistaken for that species; it is, however, a much coarser plant, with more compound fronds and a more rigid habit. Professor Eaton, whose kindly assistance is continually placing me under obligations which I take pleasure in acknowledging, observes, also, that the slightly revolute margins indicate a much closer approach to Cheilanthes than in the case of *N. Lemmoni*, to which I would add that there is about this Fern also, as distinguished from *N. Lemmoni*, that indescribable atmosphere, or feeling, which oftentimes enables one to distinguish one Fern from another by the mere handling. The illustration on page 521 is from a drawing by Mr. C. E. Faxon.

Nothochlæna Schaffneri, Underwood (in litt.), var. Mexicana (*N. Nealleyi*, Seaton, var. *Mexicana*, Davenport, in *Botanical Gazette*, February, 1891). Dry, shaded ledges of the Barranca, November, 1888. No. 1864. Fronds larger, more rigid and more compound than in the type. Dr. Palmer's 555, from the cañon of Rio Blanco, September, 1886, belongs here,

and I suspect Schaffner's 962, from the San Rafael Mountains, does also.

[Note.—Since the publication of my note on Pringle's No. 1864, and *Nothochlæna Nealleyi* in *Botanical Gazette* (l. c.), Professor Underwood has identified the latter Fern as Fournier's *Aleuritopteris Schaffneri*, and having personally examined and compared Schaffner's specimens from his herbarium with the specimens of *N. Nealleyi*, now in my possession from Mr. Seaton, I can vouch for the accuracy of his determination. There can be no question as to the identity, and as Fournier's species was published and described in 1880 (Bull. Bot. Soc. de France, xxvii., p. 328) from specimens collected by Schaffner in the mountains of San Miguel, in September, 1876, it necessarily supersedes and retires Mr. Seaton's *N. Nealleyi*. Schaffner's specimens, as well as those from Mr. Nealley's later collection, show that the species, like nearly all of its congeners, has the stipites, rachises and sori *brownish* as well as *blackish*, and that the frond becomes bipinnate.]

Holiday Notes from Switzerland.—I.

THE latter half of July and the beginning of August of the current year were spent by Mr. Bean, one of my Kew colleagues, and myself in Switzerland, and we remained in the open air by far the greater part of every day. A large number of species was seen by us, and the following notes may be of interest to those readers of Garden and Forest who cultivate some of the beautiful herbaceous and alpine plants we noted, but who may not have had an opportunity of seeing them amid their natural surroundings. We took the steamer at Lucerne for Fluelen—the port of the canton of Uri—and enjoyed to the full the glorious scenery, which, according to many travelers, is unsurpassed in Switzerland, and even in Europe, for magnificence. The beautiful banks are also intimately associated with those historical events and traditions which are so graphically depicted by Schiller, in his William Tell. From Fluelen we took train to Göschenen, and then began our walking tour through Andermatt and Hospenthal to Tiefenbach, thence over the Furka Pass to the Rhone Glacier and afterward down the Rhone Valley to Sierre. From the last-named town we turned up the Val d'Anniviers to Vissoye and then ascended to the Hotel Weisshorn, built at an elevation of about 7,550 feet above sea-level, on the Tetaz-Fayaz, or Sheep's Head. Here we stayed a week, and in that time had not nearly exhausted the district when we were compelled to return to duty.

Shortly after leaving the station at Göschenen (3,640 feet) we entered the sombre rocky defile of the Schöllenen, bounded by lofty and almost perpendicular granite rocks, at the base of which dashes the Reuss. Before arriving at the Devil's Bridge we noticed large sheets of *Astrantia minor* on the flat rocky ledges by the road-side; this is a charming plant; the umbels are about half the size of those of *A. major*, and, like that species, it is thoroughly deserving of a place in any rockery or herbaceous border. Strange to say, however, it is very rare in cultivation in Britain, and might be inquired for in vain in most establishments, even where alpine and herbaceous plants are grown for sale in enormous quantities, both as regards number of species and individuals. In the crevices of steep rocks *Saxifraga Cotyledon*, with its dense rosettes of grayish green leaves surmounted by graceful waving panicles of white flowers, was certainly both conspicuous and beautiful enough to satisfy even the most exacting; in some parts of Switzerland, notably at Locarno, this species is so plentiful that its panicles, together with the flowers of *Lilium bulbiferum*, are used in the decoration of the temporary altars which are erected at the street-corners on the occasion of the feast of Corpus Christi. For this fact, as well as for information as to the distribution of Swiss plants, I am indebted to the classical work of Dr. H. Christ, "La Flore de la Suisse et ses Origines." Let me add, by the way, that botanical and horticultural readers of Garden and Forest who contemplate a Swiss tour should peruse this book before starting, and also take it with them for reference. The Turk's Cap Lily (*L. Martagon*) was also seen growing among the sparse brush-wood on the steep slopes; in several English counties this species is known by the rather droll name, "Turn again Gentleman." Under similar conditions a yellow Foxglove (*Digitalis lutea*) was seen. The three last-named plants, however, were seen after passing the Devil's Bridge, which, by the way, was "ornamented" by a staring advertisement painted in large letters on the surface of the smooth perpendicular rock, and by a rude picture, a conventional representation of his Satanic majesty watching with dismay the first living thing—a hungry dog—which crossed the bridge, just then completed by the pious Abbot Giraldus, of Einsiedel, for the convenience of pilgrims on their way to Rome. Every one is familiar with the way in which the devil was cheated on this occasion, for is not the tradition made use of by Longfellow in his "Golden Legend"?

Before reaching the Urseren Valley a fine Dianthus was collected on hot dry banks; under similar conditions *Cerastium arvense* was seen, forming dense snowy sheets of blossom. Wonderfully differing in aspect from the wild region already traversed is the above-named valley, with its fertile green pastures watered by the Reuss; it is about eight miles long and is surrounded by lofty and barren, partially snow-clad, mountains. Here winter lasts nearly eight months, and fires are often necessary during the short summer. Along the numerous water-courses *Ranunculus aconitifolius* grows in abundance; the double-flowered state of this species—which is so frequently met with in old-fashioned country gardens—is known in England under the pretty name of "Fair Maids of France." The Snake-root, *Polygonum Bistorta*, was seen in such profusion as to color the entire meadows, and this, together with *Campanula rhomboidalis*, produced such color-effects as are, perhaps, not to be seen away from an alpine meadow. The intensely bright sunlight makes up somewhat for the short summer, and the plants bear flowers deeper and richer in color than do the same species under cultivation in Britain. The tuberous roots of the Polygonum are astringent and contain a considerable proportion of starch; they were formerly much used in medicine, and are still highly esteemed by the rustic herbalist; in some countries they are turned to account as food during famine-times. At Andermatt, the principal village of the valley, prevails a curious custom which also obtains in some other parts of Switzerland; the charnel-house attached to the church is adorned with skulls bearing inscriptions, "On the occasional opening of the graves the skulls are conveyed by the relatives of the deceased to the charnel-house, where they are kept in symmetrical piles." Between Andermatt and Hospenthal, in the small patches of rye, *Delphinium consolida*—the parent of some of our races of cultivated annual Larkspurs—occurred as a weed, as well as another fine blue-flowered plant, the Viper's Bugloss (*Echium vulgare*), a biennial which, if cultivated in rich garden ground, increases wonderfully in size and vigor, but, on the other hand, really loses much of its beauty. From Kealp onward many characteristic alpine plants began to be conspicuous in the steep pastures. One of the most charming was *Campanula barbata*, a beautiful Bell-flower, from three to twelve inches in height, with large pendulous bearded corollas, varying in color from white, through pale porcelain blue, to deep blue. *Veratrum album*, the so-called White Hellebore, was perhaps more striking as a foliage plant than by reason of its tall panicles of greenish flowers. *Gentiana purpurea*, about a foot in height, with a terminal cluster of large red-purple flowers, was in full blossom here at an elevation of about 5,500 feet; much later on, about 1,500 feet higher, we only found it in bud.

Royal Gardens, Kew. *George Nicholson.*

New or Little-known Plants.

Dendrobium Phalænopsis.

THIS is the most beautiful of all the Dendrobiums hitherto introduced from northern Queensland and the adjacent islands. It was discovered at Cape York, on the extreme north of Queensland, by a Captain Broomfield, who introduced living plants of it into his garden in Balmain, Queensland. Here it flowered, and was figured by Fitzgerald in his folio work on Australian Orchids. He also sent a description of it to the *Gardeners' Chronicle* for July, 1880. His figure represents a plant with pseudo-bulbs eighteen inches long, terminal, erect racemes, produced from the matured pseudo-bulb, the longest raceme being one and a half feet long and bearing ten flowers and buds. The flowers measure two and a half inches across, and they are described as being lilac in color, with a few small dark calli on the disk of the labellum, and two white glands at the base of the column. There is a family likeness between *D. Phalænopsis* and *D. bigibbum*, *D. superbiens* and *D. Goldiei*, but, as Fitzgerald points out, the first-named is easily distinguished from these three in the form of its flowers and the shape of the labellum. The name *D. Phalænopsis* was given by Fitzgerald from the likeness of its flowers to moths as well as to those of the genus Phalæ-

nopsis. The plant in Captain Broomfield's collection flowered the following April, and produced 300 blooms.

In 1882 Mr. Forbes visited some of the islands north of Queensland on behalf of the Geographical Society of London. He brought back with him several living plants, and among them was a plant of this Dendrobium which he obtained in Timorlant. This plant came to Kew, where it flowered in September, 1884, and a figure of it was published in the *Botanical Magazine*, t. 6817. There is a decided difference between the plant flowered at Kew and that figured and described by Fitzgerald, the scape of the latter being erect, while that borne by the Kew plant was pendent; the lip of the latter was maroon-crimson, whereas Fitzgerald figures and describes his plant with uniformly lilac-purple flowers. However, Sir Joseph Hooker considered and described them as identical. Several plants of *D. Phalænopsis* had been distributed from Kew, and these are now known as the Kew variety to distinguish them from an exceedingly beautiful form of the same species. This was named *D. Phalænopsis*, var. *Schrœderianum*, by Reichenbach in compliment to Baron Schrœder, in whose collection it first flowered at Egham, near Windsor.

Fig. 80.—Nothochlæna rigida, n. sp.—See page 519.

He procured it from Messrs. Veitch & Sons, who had imported several plants of it through the Rev. Mr. Macfarlane, a missionary in north Australia. Mr. Lee, of Leatherhead, also obtained a plant from Veitch, who bought it back again for fifty guineas when Mr. Lee's plants were disposed of by auction. This plant also went into the collection of Baron Schrœder, who is now the sole possessor of the variety. This is certainly a very beautiful Dendrobe. There is a figure of it in *Williams' Orchid Album*, iv., t. 187. It has flowers half as large again as the Kew variety, and the color is much deeper and richer.

Until this week *D. Phalænopsis* was coveted by all who had seen it as exhibited in flower last spring, but Mr. Sander has lately imported a large quantity of what he declares to be the same as Baron Schrœder's variety, and has disposed of nearly a thousand plants by auction sale to-day.

The plants were in very good condition, many of them having young growing shoots. Some of them had pseudo-bulbs over three feet long, one I measured being forty-three inches, and as thick as a man's thumb. Others had thinner and shorter pseudo-bulbs, and were more like what we had hitherto known as *D. Phalænopsis*. Altogether, there was very considerable variation in the length, thickness, shape and color of the pseudo-bulbs on the plants sold to-day. I noticed, too, that the old flower-scapes were nearly all erect; certainly not one was what might be called pendent. If these plants are really *D. Phalænopsis*, then it is a very variable species. Some of the dried scapes exhibited were nearly three feet long, and bore scars of twenty flowers. Dried flowers were also on view, and they were nearly four inches across. Mr. Sander says that there are varieties with white, rose and crimson, as well as purple flowers, among those sold to-day.

Where these plants were collected has not been divulged, but it is probable that their home is not far from New Guinea. Mr. Sander publishes in his sale-catalogue a letter from the collector who sent home the Dendrobiums, which is interesting enough to quote in full. It is headed "The King of Dendrobes." The collector writes:

"With great pleasure I announce to you the fact that I arrived here yesterday with my plants in the finest order, and you will at last get striking novelties from this terrible country. It was the best time to collect the Dendrobe; they had just finished growing, and some were in full bloom. I forgot all my troubles when I saw the first on some rocks, on the

bare limestone between a great number of human skulls and bones. The natives do not bury their dead, but put them in a kind of coffin and then place them on these solitary rocks, which stand scattered about the shore or beach, and which can be reached or got at only at ebb tide. Here in these rocks the plants grow most luxuriantly, exposed to the full sun, and when the weather is rough they often get the spray of the sea-water. At first the natives did not like the idea of collecting the plants; they were afraid the souls of the departed, whose bones were lying there bleaching in the sun, would resent it, but when they saw the gorgeous handkerchiefs, beads, looking-glasses, and brass wire I offered them for the plants, they did not trouble themselves any more about the souls of their ancestors, but boldly went and rooted out every plant to be found. The plants grow chiefly on these solitary, much-honeycombed limestone rocks, always exposed to the sun or getting only very little shade during a part of the day. They also grow on trees in the Ficus-groves more inland, although very sparingly. I found the big specimens on the highest trees in the dense jungle, where they are very rare, and I only saw a few on the very highest trees. I should think in cultivation these plants will require plenty of moisture while growing, and a culture like that of *D. nobile*.

"In size and coloring it varies as much from the ordinary *D. Phalænopsis* as *D. Wardianum* from *D. crassinode;* the largest flowers measured four and a half inches across, none measuring less than three and a half inches. I saw a few plants with branched spikes, but this seems only excess of strength; the spikes are generally from twenty to thirty-five inches long; on some I counted up to twenty-five flowers; the color is very variable, ranging from pure white to dark purple-red, and some are differently colored and variegated, but bright and clear; the flowers last a long time, individually eight weeks. During my stay of three months I saw many plants in flower in April, May and June. A Dutch trader, one of our party, who has been here twice, says that he has seen it in flower in July, August and September. It is, without doubt, the finest Dendrobe in existence, and a gorgeous Orchid."

The sale was a most successful one, the prices fetched by the majority of the plants ranging from twenty to two guineas. Mr. Sander estimated that the seven hundred and odd lots had realized about £2,000.

D. Phalænopsis requires plenty of heat, sunshine and moisture; far more than suffices for *D. nobile*. In this respect it does not differ from its near relatives, *D. superbiens* and *D. bigibbum*. The flowering of the plants of this new importation will be awaited with some interest. At present I am inclined to believe that *D. Phalænopsis* as figured and described by Fitzgerald is not the same species as that figured in the *Botanical Magazine* under the same name, and also that Mr. Sander's plants are likely to include both these, besides, probably, other forms.

Foreign Correspondence.

London Letter.

Conifers, Asters and Sunflowers.—An exhibition and conference devoted to these three classes of plants, and extending over nearly a week, has been the special horticultural feature of the present month. The Royal Horticultural Society had invited growers of these plants in all parts of the United Kingdom to send specimens, photographs and pictures of them to Chiswick for purposes of comparison and observation. The exhibition which resulted might almost have been styled an American one, all the Asters and Sunflowers, and the majority of the conifers shown being introductions from your country. The actual number of specimens, especially of Coniferæ, was so large that the extensive space provided for them was not nearly sufficient to admit of their being set out so as to be seen to proper advantage. From Kew alone specimens of conifers representing over five hundred distinct species and varieties were sent, and the trade dealers in these plants, besides the principal private growers, were equally generous in their contributions of specimens and plants.

Papers were read by scientists specially interested in the plants exhibited, as well as by cultivators, and the amount of valuable information thus brought together was very great. Dr. Masters, Professor Marshall Ward, Mr. G. Nicholson, Mr. Malcolm Dunn, Mr. H. Veitch and several others read papers dealing with Coniferæ in their various aspects. The paper by Dr. Masters was botanical and historical. Professor Ward devoted himself to a popular description and account of the diseases, fungal and other, which attack coniferous plants. This paper, or rather a resumé of it, was listened to with great interest, and its appearance in the journal of the society will be welcomed by all who are concerned in the management of these plants. Mr. Nicholson pointed out some of the most effective kinds for use in landscape-gardening; Mr. Dunn, dealing partly with the same subject and partly with the economic value of some conifers, alluded specially to *Abies Albertiana*, *A. concolor*, *A. Douglasi*, *A. grandis*, *A. magnifica*, *A. Nordmanniana*, *Cupressus macrocarpa*, *C. Lawsoniana*, *C. Nutkænsis*, the Larch and *Thuia gigantea*. These he placed in the first rank as trees likely to prove important in England, either for timber or other valuable uses. Mr. Dunn has charge of the gardens and forests at Dalkeith, in Scotland, where conifers are exceptionally well grown. Mr. Thiselton-Dyer spoke of the beauty and perfection of the large number of these trees cultivated in Scotland, and suggested that their vigorous health, as compared with what is seen further south, is accounted for by the conditions of climate and of atmosphere in the north, which are not to be met with in the southern part of the kingdom.

There is a growing opinion among English landscape-gardeners that conifers are far too lavishly and recklessly used in the making of gardens here. They are supposed to be the right thing and are consequently planted in all kinds of gardens, in many of which the conditions essential to the health of conifers are not possible. A healthy Pine, or Fir, or Cypress is pleasant to look at almost anywhere, but such plants, when in bad health, are the most wretched-looking of all trees. We are apt to overdo the evergreens. No less an authority than Richard Jefferies raised his voice against the "foreign evergreens" being allowed to crowd out almost entirely the native and other deciduous trees. "Let the Cedar and the Laurel," he wrote, "and the whole host of invading evergreens be put aside by themselves, in a separate and detached shrubbery, maintained for the purpose of exhibiting strange growths." It is intended to publish in the journal of the Royal Horticultural Society a list of all the kinds exhibited, with their correct names and synonymy; and, as far as possible, the conditions under which the best examples are grown. The most suitable kinds to plant in the garden, the shrubbery or the park will also be tabulated.

The Asters were exhibited in considerable quantity and formed a striking feature of the show. Papers upon them were contributed by Professor Goodale, of Harvard, and Mr. C. Wolley Dod, the former being devoted to the botanical features and geographical distribution of the genus, with a general review of Professor Asa Gray's latest writings on American Asters. Mr. Dod dealt chiefly with the culture, selection and cross-breeding of Asters, with a view to improving them in habit, size of flower and variety of color.

Asters are features in the gardens at Kew in September and October. They are planted in large beds or singly in shrubberies, and even in the rock-gardens, as well as in the beds devoted to a collection of hardy *Compositæ*. Nothing could be more effective than large masses of such species as *A. amellus*, *A. acris*, *A. Novi-Belgi* and *A. Novæ-Angliæ*. A white-flowered seedling named Harper Crewe is much admired.

The Sunflowers (Helianthus) had two papers devoted to them—one by Mr. D. Dewar, of Kew, who dealt with the botany and history of cultivated Helianthi; the other by Mr. E. H. Jenkins, who discussed their cultivation. Mr. Dewar's paper is so interesting that I will defer my remarks upon it for another occasion. The necessity for replanting frequently and manuring heavily for all the Sunflowers was emphasized by Mr. Jenkins, for, although they will grow in the poorest soil, they amply repay liberal treatment. He stated that it is possible to reduce the height of the tall-growing sorts by cutting back the stems to within about six inches of the soil early in June. In this manner Mr. Jenkins has reduced the height of the tallest to three feet. Those who object to many of these plants in small gardens because of their height should try Mr. Jenkins' plan for lowering them.

Fig. 81.—The California Buckeye (*Æsculus Californica*).—See page 517.

Cultural Department.

The Present Status of Native Plum Culture.

THE dearth of hardy fruits in the north-west is naturally directing attention to the native Plum. In the northern species of this fruit, the *Prunus Americana*, is found a tree that, when properly grown, needs not fear frozen mercury or the brightest summer or winter suns, and that suffers comparatively little from fungal diseases. The pioneers of the north-western states, in common with those of the east, generally regarded the native Plum as of too little value for culture. But when sad experience at length demonstrated that the finer European Plums are unable to endure the severe climatic conditions of these states, the better native Plums were found far preferable to none, and the thickets where this fruit still abounded began to receive protection. Occasionally a specially meritorious tree, or clump of trees—for their suckering tendency often caused the trees to grow in clumps—was honored with a removal to the farmer's yard or garden, and thus the good work of selection was almost unconsciously commenced.

As the real merits of this fruit begun to appear, the more progressive farmers, and especially those whose tastes inclined in the direction of horticulture, begun to espouse its cause in earnest. Mr. J. S. Stickney, of Wauwatosa, Wisconsin, in an address before the Iowa Horticultural Society in 1877, said: "I am dreaming that in these native Plums there is something valuable. Their endurance, productiveness and perfect hardiness should and must be made useful to us, and we have no right to rest or flag in our efforts until we have an orchard of native Plums that shall command in market two to four dollars per bushel, and yield crops as abundant and frequent as the wild ones in our thickets now do. About the possibility of this there is very little doubt." This was written but fourteen years ago, and it seems well to add that this result has already been attained. During a visit to Mr. O. M. Lord, of Minnesota City, Minnesota, early in September last, I saw plums sold from his native plum-orchard at sixty-five cents for the ordinary peach-basket, holding about a peck, while the common native plums, gathered indiscriminately from the wild thickets, were selling at from forty to sixty cents per bushel.

What can be said of the quality of the best native plums? This question involves some difficulty, since doubts have been raised regarding the parentage of some of the finer varieties. If the Cheney, Gaylord and Rollingstone plums are pure natives, the gulf between our finest native varieties and the Green Gage or Jefferson is not so great that we need to despair of filling it. It must be confessed that the average wild plum, with its diminutive size and tough acerb skin, would not make a creditable showing by the side of its more cultivated European cousins, but in the Gaylord and Cheney we have size that eclipses the Green Gage, a thin and fairly tender skin, with but the merest trace of acerbity, and with a flesh that for luscious juiciness would suffer little in comparison with the finest European sorts. In the Rollingstone we have a plum of a size equaling the Green Gage, of delicious quality, with a skin which, though rather thick and tough, is without acerbity, and parts readily from the pulp. The fruit has been shipped from Minnesota City to St. Louis and to New Jersey, arriving in excellent condition. The tree is very hardy and productive, and at Minnesota City is said to have missed but two crops in thirty-five years. Some of the finer varieties tend to rot under culture more than in their native state, though I do not know that the tendency to this trouble is greater among the native than the European sorts.

Professor Budd suspects that most of the larger so-called native Plums that have recently been brought to notice in Iowa and Minnesota may be hybrids between *Prunus Americana* and

P. angustifolia, resulting from pits of the latter species having been brought by the Indians from the south or south-westward. If this is true, it would seem that we have discovered a key to the improvement of the former species, for these hybrids, if hybrids they are, manifest a very satisfactory degree of hardiness. The varieties derived from *P. angustifolia* have not thus far proved hardy in Minnesota or Wisconsin.

The soil-requirements of the native Plum appear to vary much with different sorts. Varieties that succeed well on a sandy soil may prove worthless on clay, and vice versa. This often explains the discordant and even contradictory reports so often read regarding the value of certain varieties. The sorts that succeed best at Mr. Lord's place, which is on fine alluvial sand, are not, as a rule, the ones that have proved most successful with Professor Budd at Ames, Iowa, where the soil contains more clay. A few varieties, however, like the De Soto, appear successful in nearly all localities.

The susceptibility of the native Plum to injury from the Plum curculio has been the subject of some dispute. It may be safely said that the native Plums possess no immunity from attack by this destructive insect. It appears, however, that the proportion of larvæ that develop is much smaller in most native varieties than in the varieties of the European Plum. How far this is due to the thicker skin of the native species it is difficult to say. The idea that the native Plum requires no protection against the curculio is erroneous. The proportion of fruit that is destroyed by this insect, even on nearly worthless wild varieties, is often very large. Few precautions seem to be taken at present to hinder the work of the curculio by those who grow native Plums, but I think the time is not far distant when some protection will be regarded as a necessity by the growers of the finer varieties.

It is generally conceded that productiveness in the native Plums is promoted by the intermingling of the trees of different varieties. Certain varieties appear nearly incapable of fertilizing their own flowers, while others, as the De Soto, seem specially adapted to serve as fertilizers. It is possible that much is yet to be learned upon this point, and that the complaint of unproductiveness in the native Plum may often arise from an unfortunate combination of varieties.

The production of the finer native Plums on a commercial scale is as yet in its infancy, but promises rapid development. The planting of some of the recently introduced varieties is now being delayed only by the limits of propagation. The first orchard of native Plums started with reference to selling the product, appears to have been that of Mr. Lord, of Minnesota City, which is now about twenty years old. The number of such orchards at the present time is not large, but is increasing.

Some difficulty is experienced in propagating the native Plum under north-western conditions. The stocks used for the European Plum are not satisfactory, and, so far as fully tested, only the native Plum itself is best adapted for its own stock. The seedlings of pure natives are rather difficult to obtain, the demand for them at present exceeding the supply. The pits are not a commercial commodity, and must be picked up, usually in small lots, and they are not very reliable for germination. Budding in our hot summers is a precarious operation, and the keeping of cions and root-grafts is attended with some difficulty by those who have not yet learned the secret. Even top-grafting in our fickle spring weather is somewhat uncertain. But these difficulties will doubtless disappear before the knowledge developed by careful experiments.

University of Wisconsin. *E. S. Goff.*

Roses.

THE much-dreaded "black-spot" often makes its appearance on Roses under glass the latter part of September or early in October, and while in some instances this disease seems hard to account for, in a majority of cases it is caused by an excess of moisture, either at the roots or in the atmosphere. All syringing or watering should be done early in the day, so that the atmosphere may not be saturated with moisture at night, for if the foliage of the Roses shows beads of moisture in the morning it is evident that the house is too damp or too cold, or both, and as a result a visitation of "black-spot" may be looked for. A solution of sulphate of copper has been used for this fungus by some growers with a certain degree of success; in fact, a bench of La France Roses, on which an experiment with copper solution had been tried, showed a marked difference when compared with an equal portion of the bench on which the plants had not been sprayed.

It may be advisable, when experimenting with this solution, to keep the liquid off the soil as much as possible, as Mr. A. W. Pearson has pointed out in a recent issue of Garden and Forest, for his experiments certainly seem to demonstrate that the copper has an injurious effect on the soil when used out-of-doors. A similar result is quite possible with Roses under glass, though I do not know of any such instance. It is best to remove all decayed leaves, especially if affected with "black-spot" or mildew, and to burn them at once. Cleanliness is essential to the highest cultivation of most plants, and to none more so than to Roses. The first crop is the hardest to manage, and strong, well-ripened plants should be selected and every possible advantage given them.

For early crops of hybrids in pots it is necessary to start plants into growth at once, as at least twelve weeks will be required to bring them into bloom. In the matter of heat much care is needed to secure early hybrid flowers. When given too much heat in the first stages of growth the shoots are likely to prove blind, and though these blind growths sometimes make another start later in the season, and then produce flowers, this hardly repays for the loss of time and space in the first place. The better plan is to start Hybrid Roses with but little heat, and gradually increase the temperature up to fifty-six degrees as the growth advances. A stimulant in the form of liquid manure should be given as the root-action increases, care being taken not to sour the soil by injudicious use of the latter. After the holidays it is much easier to force hybrids into bloom, and while care is at all times essential if fine flowers are desired, the plants are less impatient of any slight omission when the processes of nature are less hurried.

In the selection of early varieties Heinrich Schultheis should not be omitted, this being one of the best early pink Roses, though closely followed in good qualities by the old favorite, Anna de Diesbach, and also by Anna Alexieff. In the same class are the standard sorts, Ulrich Brunner, Mrs. John Laing, Madame Luizet and Magna Charta.

The propagation of Tea Roses for next year's stock will soon demand attention, and where the stock-plants are limited in number it is best to begin the work early in the season by putting in successive lots of cuttings as the wood can be spared. This is not the only consideration in the matter, for there is also a decided advantage in having strong and sturdy plants in readiness for early planting the following summer.

Still another sport from Perle des Jardins has been sent out during the year, and being of Canadian origin has been named Toronto. It is claimed to be superior to its parent in all respects, though of similar type.

Holmesburg, Pa. *W. H. Taplin.*

Pot-plants for Spring Use.

IN addition to the commonly grown *Deutzia gracilis*, *Astilbe Japonica* and a few other shrubs and herbaceous plants which are forced for spring use, and generally put in tubs or pots, and stored in pits until required, there are several which may be added with advantage. The common Foxglove (*Digitalis purpurea*), in purple and white varieties, makes an excellent plant for piazza decoration. Good strong plants, potted now and placed in a cool pit, come along with scarcely any fire heat and bloom by the 1st of May, at which season, in this latitude, it is scarcely safe to expose more valuable forced plants, such as Roses, fancy Pelargoniums, and the like. The common Canterbury Bell is another equally good plant, and is just a little later than the Foxglove. Last year I experimented with quite a number of dwarf-growing hardy plants, with a view to testing their value for early forcing, with poor success. Many were very pretty, but the great objection is their poor lasting qualities. A few, however, were added, which may be considered useful, mainly on account of dwarf habit and unique color. Among these are the Swiss Bugloss (*Ajuga Genevensis*), which produces numerous dense spikes of intense indigo blue flowers, which last a long time. Another is the comparatively new and pretty Mexican Alum-root (*Heuchera sanguinea*). This plant, in addition to handsome foliage, a characteristic of the genus, and for which reason alone many of the species are grown, produces spikes fifteen to eighteen inches long, of fair-sized magenta-red flowers. *Brunella Webbiana*, a very handsome species, has violet-purple flowers of good lasting qualities. The main objection to this is the fact that an inferior, yet bright and free-flowering species is a common weed everywhere.

English hybrid Primroses are becoming as generally grown for market purposes as Violets. They are sure to become popular, and remain so. Their flowers are produced in great abundance during February and March under the same treatment given to Violets, and are of decided colors and fragrant. Clear yellow is the favorite color now, but good crimsons and whites will be in demand. No two more beautiful colors could be associated in a bouquet than Primroses and Forget-me-nots, nor are there two names more full of sentiment. It

can be said of these, as of the Rose, that the name gives more than half the charm.

Every autumn we place on the steps leading to the front entrance, and also in the recesses around the door, a dozen more pot-plants of the Japanese Anemone (*A. Japonica alba* and *A. Japonica hybrida*). No plant has proved so useful, being far superior to the early Chrysanthemums for this purpose. While it is not a Chrysanthemum, it is yet a Japanese plant, and so comes as a natural, and happily chosen, forerunner to the queen of autumn. Although I have before referred to its culture for this purpose, a brief account of the treatment is given here. I usually shake the soil off the old crowns, and if too large reduce them; then repot in good heavy loam Toward the blooming-season a little liquid manure is given. If starting with fresh stock about five crowns should be put in a ten-inch pot; this is a quicker way of producing a specimen than potting singly and waiting for them to grow large enough. We store the plants in a barn cellar, and keep them moderately, but not dust dry until March, when they are brought out and treated as already stated.

The latest blooms picked in the open are from the Perfection Violets. The value of Violets over Pansies is their perpetual blooming habit. We have here only two varieties, but in England, and particularly in Scotland, a specialty is made of them, and many varieties are catalogued, representing several shades of color. They are used for spring bedding, and either in lines or masses are very effective. The severity of the American climate is against their use in the way practiced in Scotland. Here we have to rely almost solely on seed for our stock, and this is against perpetuating any required variety true to color. There the cuttings are taken in late autumn, dibbled in "cradles" in the open, with the protection only of a few leaves or Russian mats in very severe weather, and the rooting is made mostly during the winter.

Another interesting late-blooming plant is *Veronica longifolia*, var. *subsessilis*. I think it would make a good pot-plant, and intend to try it during the coming season. It is a remarkably robust and distinct variety with long spikes of deep blue flowers.

Wellesley, Mass. *T. D. Hatfield.*

Notes from the Harvard Botanic Garden.

Asters in October.—In Garden and Forest, vol. iii., p. 552, attention was called to *A. Shortii*, *A. Tartaricus* and *A. turbinellus*, good late-flowering Asters. These three species have again proved to be effective, reliable and the last to bloom. The group may be extended, however, by the addition of *A. diffusus* and *A. multiflorus*. Both of these plants were still in full flower about the middle of October, and they are valuable in giving a greater range of color to the later representatives of the genus than that afforded by the flowers of the first selection of species. *A. diffusus* attains a height of about four feet, and is very profuse in the production of branches. The leaves are lanceolate; the flowers are small, half an inch in diameter, and exceedingly numerous, and the ray-florets white, with reddish purple disk. These dense masses of flowers are very effective. The plant is of erect, yet graceful habit, and quite common in its wild state. *A. multiflorus* is also common, and from three to four feet high. The stems under cultivation are so top-heavy that support is necessary to keep them in an erect position. The leaves are small, linear, and arranged very closely on the stems and branches. The flowers are white, with yellowish disk; in size somewhat inferior to those of *A. diffusus*, and packed upon the branches in enormous quantity. *A. turbinellus* is undoubtedly the best October Aster, and while *A. Tartaricus* is not so attractive, it is still much to be desired on account of the display it affords in October and November, when all other Asters, and almost all other flowers, are past blooming. The third place in order of merit might be equally divided between *A. Shortii* and *A. diffusus* with perfect justice to each, and admitting that the flowers of the former last the longer. But having already a blue-flowered variety in *A. turbinellus*, *A. Shortii* will be discarded in favor of *A. diffusus* where it is desirable to curtail the number of species.

Bocconia cordata.—To say that this plant is an ally of the Poppy, requires a botanist's knowledge. Its stately growth and insignificant flowers would certainly not convey that information to those who inquire into the mysteries of plant-life no further than is necessary to secure pleasing contrasts in the garden or bring grist to the mill by some of the many ways, direct and indirect, in which plants contribute to the comforts and necessities of mankind. This Poppy, while not like the oriental Poppy, conspicuous at a distance, has attractions which are still worthy of notice. It is a plant of large growth, averaging seven feet in height. The slightly branched stems are erect, well furnished with large cordate and freely lobed leaves (bright green above and glaucous beneath), and terminate with very large panicles of pinkish white flowers. The number of the flowers, arranged closely together in great clusters, rather than their individual beauty, characterize this variety. *B. cordata* is a perfectly hardy herbaceous perennial, and when thoroughly established rapidly forms compact masses of handsome contour. The flowers develop in August and September, and the stems retain all their leaves until hard frost makes its appearance. These qualities render the plant very desirable, as it is most effective in large clumps on the greensward. *B. cordata* is not particular as to soil, but the growth gains strength in proportion with the increase of richness and depth. The plant is a native of China. It was introduced into England by Sir George Staunton in 1795, and is readily propagated by division.

Silphium laciniatum, var.—The common Compass Plant (*S. laciniatum*) is perhaps the most popular and most generally cultivated species of the genus. It is a plant about six feet high, producing its starry yellow blooms on the upper portion of the stems with much freedom during July and August. The radical leaves are of oval outline, flat, parted, laciniate, from one to three feet long, the petiole occupying two-thirds of their length. They form a thick cluster from which proceed the stems, sparingly clothed with much smaller leaves. It is of bold aspect, as are all the species, and suitable for positions requiring massive rather than graceful or pretty subjects. There is one specimen of a supposed variety flourishing here which differs from this species in several important particulars. The leaves are not flat, but somewhat sulcate, and the segments are waved and twisted to a considerable degree. The stems are from eight to ten feet high and are thickly set with small leaves. The flowers measure three inches in diameter, and are of a paler yellow color than those of the species, while they appear only during September and October. This plant has been in cultivation here for many years, but its origin does not appear to be known to any one. There may not be any strongly marked botanical difference between it and the species, as most competent authorities aver; but when viewed from the gardener's standpoint the dissimilarity assumes importance. The difference in the leaves, the height, and, most important of all, the flowering season distinguish it from the type. All other Silphiums are far past their period of brilliancy when this form of *S. laciniatum* expands its first blossoms. This fact in itself will be sufficient to stimulate inquiry relative to the existence of other specimens exhibiting the same characters; and if such plants are to be found, any information that can be gained about them would be interesting, not to say useful. It is hardly likely that any similar variation of the species, which may exist in gardens, can claim the specimen in question as its parent, for it flowers so late in the season that seeds never ripen.

Cambridge, Mass. *M. Barker.*

The Cranberry Scald.—In a recent visit to a large Cranberry-bog it was found that the scald had taken more than one-third of the crop, and from the appearance of the berries in the crates stored in the capacious cellar it seems probable that the second third will decay before the crop finds its way to the Thanksgiving market. There is no doubt that the scald is assuming an alarming form, and should it increase for the next ten years as it has in the past, there will be no profit from the bogs. The first thought is to put some substance upon the vines to ward off the enemy, as Paris green is used to destroy the curculio and the codling moth, and Bordeaux mixture the black rot of the Grape, which, by the way, is not very different from the scald of the Cranberry. There is no question about the Cranberry trouble being caused by a fungus, or that it is in all parts of the plant, leaf, stem and root as well as fruit. It does not come from the outside, as a rule, and that it is due to the scalding effect of the sun has no foundation in demonstrated fact. It is no easy matter to apply a fungicide to a bog so that it will effectively check the scald. An experiment embracing no less than ten substances, all standard fungicides, upon forty plots, during last year, gave only negative results. While, therefore, it may be possible to reach the enemy in this way, success is not probable, and some other method should be looked for. Let it be remembered that the Jersey bogs are largely muck-bogs, especially where the scald is worst. In other states, and where there is no such trouble, the plants are grown in sand.

While the Cranberry-plant is fond of moisture, it does not follow that impure and stagnant water is as beneficial as that coming to it from a clear running stream. The bogs that are

now badly scalded may very likely be improved by getting the roots of the plants into a more healthful stratum. This can be done by covering the bog with a layer of sand so thick that the roots may work up into it, leaving the old portion below. If, in addition to this, more attention could be paid to irrigation and drainage, it is not improbable that bogs now practically unprofitable might be made to pay a large dividend upon the investment. Persons who have sanded a few square rods as an experiment intend to extend the area this winter.

Correspondence.

In the Shore Towns of Massachusetts.—I.

To the Editor of Garden and Forest:

Sir,—Beginning at the New Hampshire line, in my search for public holdings in the shore towns of Massachusetts, I found that Salisbury has no land belonging to the town, no place on the shore to which the public can resort as a matter of right. Salisbury Beach runs the whole length of the town, from the mouth of the Merrimack River to the state line. It formerly belonged to the people in common, and was then regarded as of little value. It now brings important annual revenues to its owners, a corporation, entitled "The Commoners of Salisbury." The members of this body, forty or fifty young and vigorous business men, hold that they are more truly in the legal line of descent and inheritance from the early settlers than the present town itself. The town has so far recognized their title as to tax them on this beach property for the last seventy-five years, but last spring the people voted in town meeting to inquire into the title, and appointed a committee for that purpose. The corporation does not sell land, but leases sites for summer cottages, and there is an almost continuous village of these habitations along a great part of the beach, many of them fairly good houses. Visitors are welcome, for the owners wish to lease cottage sites to more people, but it is all private property, and the public goes there as a matter of sufferance or privilege, and not of right.

The city of Newburyport has a fine system of public parks or open spaces. Some of them have been long in use, and are restful and beautiful, while others are still in process of construction and development. Washington Park consists of about eight acres and has many fine trees. Brown Square, in front of City Hall, is two acres in extent. Kent Street Common, a half-mile away, has five acres in grass and paths. A mile and a half out on High Street is Atkinson Common, ten acres given to the city by Mrs. Eunice Atkinson Currier; this tract is not much improved as yet, as there are few residents in that vicinity, but it will be developed as the increase of population may require. Riverside Park has a front of 125 feet on the river and runs back 500 feet. The Improvement Association is raising money to build a bulk-head here, and thus furnish a public bathing-place. James Parton was much interested in the movement for new public reservations. He told me that for several years he had opened the grounds around his house to the children of the city for a play-ground—over an acre, with sward, flowers and shrubbery. Mr. Parton said the flowers were "almost never touched; not five times in a summer." These children's thought of him is a pleasant fame for this bright-spirited man to leave behind him.

Some of the leading women of Newburyport would like to have "The Captain's Well," which is celebrated in Mr. Whittier's poem of that name, preserved for public use, as the Captain desired, and as a tribute and memorial to the venerable poet. I believe the well is near the road between Newburyport and Amesbury, and it was said to be covered over and not in use, but I did not see it.

Newbury includes nearly all the northern half of Plum Island, with its extensive beaches and shore lands. These all belong to private owners, and ground is leased to summer visitors for cottages, as on Salisbury Beach. Many thousands of people from Massachusetts and New Hampshire towns come down the Merrimack Valley every summer to these beaches. Several crowded steamboats brought excursions the day that I was on this part of the shore. There is no public holding on the beach, but inland there are two small reserves owned by the town, Upper Green and Lower Green, four or five acres each, unfenced, grazed by the neighborhood cows, a few trees, and a school-house on each, with some interesting history in each case, beginning with the first white settlement of the region. The Lower Green was originally the Common of the "Old Town," which was laid out here near the Parker River before Newburyport was thought of. I saw a plat of this most ancient village, with the common much larger than it is now, and the adjacent house-lots all marked with their their owners' names.

The Upper Green was part of a farm owned by a minister in early times. He left this triangle between roads unfenced, and in time the town assumed title, and holds it by undisputed occupancy. Both these small parks have been encroached upon and reduced in area. A little care would make them attractive and valuable to the people of the town, who have no other places of public resort to which they can go as a matter of right.

The public lands and rights owned by Rowley are: 1. Rowley Common, in the nature of a park, in the centre of the village, about four acres, acquired from the Widow Hobsen for a training-field, by exchange of land, about 1670. It was beautified by planting a single row of Elms around it in 1839. 2. Two smaller commons, also in the village, both planted with Elms in 1839. 3. The town landing on Rowley River. 4. About one-fourth of an acre at the stock-yard, so-called, for use as a place for leaving horses when working on the salt-marshes. This has been somewhat encroached upon. 5. A small common in front of Town Hall, set with trees in 1856. There are no known town rights in the beach on Plum Island, nor any shore rights except the one town landing mentioned above, but it is probable that the public has the right of landing on Nelson Island, in Plum Island River, as this landing has always been in use by those who dig clams. Nobody else has any use for it.

This town, perhaps in greater degree than any other in the commonwealth, has remained the same as in earlier times, with people of the same blood living on the same lands, and living much in the same manner; the population is about the same, without much mixture from abroad. There are Bradstreets living to-day, as always, on the farm laid out to Humphrey in 1634, then in Ipswich, now in Rowley by annexation. The same, or nearly the same, may be said of the Mighills and of other families. The general interest in matters of local history is much less than one would expect to find here, but it is an interesting town to the student of civilization and to any observing visitor. Some of the locally historic names get changed or lost, and the errors are perpetuated by the map-makers. Thus a recent map shows the old name Hunsley Hill changed to Huy Slow, which is printed over Bradford Street Hill, leaving the real Hunsley nameless. The old Rowley, with its interesting survivals from a remote past, will not last much longer unchanged. The wayfarer who seeks a summer home by the sea pauses here and there along these quiet roads and notes the attractions of the scenery. "There is a fine view from this point." A new house will rise here, and alien faces will look from its windows across the fields which were first tilled by men whose very graves have been forgotten.

Ipswich has no public holding on the shore. There is a small and pleasant area called Meeting House Green in front of the principal church. This is the only park or public ground. The town contains an eminence with an interesting name—Heartbreak Hill—and I have been trying to find out whose heart was broken there, and why it was broken. I soon met the story of an Indian girl who loved a sailor and climbed to this hill-top to watch for his unreturning sail till she died. This account may be true, but I should like to know how old it is in this case. I am inclined to distrust it because the same story, or nearly the same, is told of so many places, Lovers' Leaps, etc., in all parts of our country. It does not seem that all these Indian girls could have broken their hearts in the same way. Early in this century, perhaps earlier still, the story was told in the Bradstreet family here of a young woman of their own race and name, Hannah Bradstreet, who went up this hill every day to see if her lover's ship was coming up the bay; and it never came. What we need to know about it is the time when the name was first given to the hill, or when it came into popular use, but I fear it is all irrecoverable. I am trying, however, to ascertain when the name was first put on the maps and into the Ipswich town records. Perhaps some reader of this account may be able to give me this information.

Essex has no real sea-shore, as Ipswich and Gloucester meet on the ocean beach, but Essex has all the lower reaches and broad expansions of Essex River, and all this shore is just about the same as sea-shore. It is all private property except the Town Farm and two or three landings. For many years a part of the Town Farm has been devoted to the uses of a public summer resort, the town officers leasing sites four rods by three for cottages, two adjoining lots to one person if desired. There is an area for picnics, clam-bakes, fish-dinners, etc. These grounds are on the bank of the river, and any-

body has a right to go there. The town owns the ground around several of the old landings, in one case two acres or more. Two of these places are now rented to ship-builders. The streams are said to be carefully guarded from defilement. The town has some interesting places connected with the history of a distinguished family, the Choates.

Gloucester, with 25,000 people, has no park or common or public holding of any kind that can be used as a place of resort. A fragment of beach near the Pavilion Hotel belongs to the city, but it is too small to be of much use. I asked some of the leading men where their people go for band-concerts or any out-of-door entertainment, and they said, "the band takes the sidewalk, and the people stand in the street." Next year Gloucester will celebrate her 250th anniversary, and her people have already begun their preparations for the event. They wish to establish an appropriate memorial at that time, and somebody has proposed that they endow a factory, so as to furnish work for laborers now unemployed. I urged the need of a park, common, or open space of some kind for public resort. The effort to establish a memorial of this nature would awaken widespread interest, and would attract the moral support of the Trustees of Public Reservations, of the press of the state, and of all public-spirited citizens. If anybody born in Gloucester has gone away somewhere and got rich, I hope he will remember his native city now, and help her people establish a Memorial Park. There can be no doubt that the higher interests of the city have suffered loss and injury from the want of any place of public resort. The local journalists are earnestly in favor of the park idea, and the farm adjoining the city, on the shore on the lower side, is admirably adapted to the purpose. It is the site of "The Old Stage Fort."

I walked entirely around Eastern Point, and found that the Eastern Point Associates have built a lodge at the entrance to their domain, and swung a gate across the carriage-road, with a notice requiring visitors to obtain permission in the lodge. I went on and was not recalled. The gate is intended chiefly, I suppose, to assert the right of exclusive occupancy, and people enter and pass freely, but a picnic party of country-folk would probably be turned back. There is no public holding along this very attractive shore, and the public has no right whatever even to walk by the sea here. I spent a summer at East Gloucester twenty-five years ago, and where I then passed weeks in solitude on the shore there are now long streets of costly houses. Thus far my quest shows leagues and leagues of shore lands all private holdings, a great population inland hedged away from the beach, and all conditions pointing to a time, not remote, when nobody can walk by the ocean without payment of a fee, as formerly we had to pay for a glimpse of Niagara.

Boston, Mass. *J. B. Harrison.*

Exhibitions.

United States Nurseries, Short Hills, New Jersey.

THE fall exhibition of plants and flowers, held at the United States Nurseries by Messrs. Pitcher & Manda, has become an interesting annual feature, much enjoyed by an increasing number of visitors. Extensions are still going on at this nursery, and north of the range of which the large Palm-house is the centre the sloping ground has been covered with six ranges of greenhouses some 200 feet long. These houses cover a rising slope with a southern exposure, and they form a striking picture; and in them, for the first time, Messrs. Pitcher & Manda are able to exhibit Chrysanthemums with justice to themselves, the former show-house being rather small when such free-growing plants as Chrysanthemums are to be shown.

During the exhibition week, October 26th to October 31st, the upper new range was filled with the new Chrysanthemums which have been selected from the thousands of seedlings of the establishment. Messrs. Pitcher & Manda have adopted the plan of growing their promising seedlings two seasons before offering them to the public for sale, and in the collection shown their best gains were seen, showing probably their fixed character. Their seedlings as thus shown were strikingly robust and well furnished with fine foliage, and mostly of the medium height so much desired by growers. Some single-stem plants were shown which, while taller, were not abnormally high.

Probably the most striking plant shown was W. A. Manda, a yellow hairy kind, well incurved and of a deep rich color. It is a very vigorous grower, but not more so than another seedling, the improved Mrs. Hardy, which in this respect is a contrast to the original. The flower of this variety is of the same character as Mrs. Alpheus Hardy, but is much deeper. Mrs E. D. Adams, a large white flower, with an outer swirl of petals somewhat in style of Madame C. Audiguier, was exhibited last year in poor form, but it has improved, and is a distinct desirable kind. Of other white kinds, George Savage is a grand incurved of the purest white and of fine form. Miss M. Colgate is a white incurved flower with broader petals and of a creamy tint. Other first-rate white flowers were Mrs. W. S. Kimball, reflexed and of fine form, and two as yet unnamed kinds, 169 and 278, differing, but with very broad petals. Of the colored flowers, Harry May, a massive deep incurved flower of bronze, will charm the lover of single blooms. Of a less massive character is Mr. Hicks Arnold, an incurved yellow, flecked with red, of fine form. Mr. D. S. Brown is a pleasing flower, lemon-yellow, with broad petals. Dr. Mandeville is a yellow counterpart to Mrs. E. D. Adams.

Of the less popular, though attractive, colors were Mrs. Mercer, incurved pink, with yellow centre, and an unnamed, No. 343, a bright cherry, Japanese, with gold reflex. Numerous striking varieties yet unnamed were to be seen in the house containing this show of remarkable productions. A lower house was filled with a collection of older varieties, many of which were the former offerings of this house. Still another house was filled with the year's seedlings in countless numbers, and all the varied shapes to be found by the seedling grower. Still another house, closed to the public, was seen to be filled with Chrysanthemums, and probably contained some of Mr. Manda's future surprises. The progress shown here in the successful cultivation of the Chrysanthemum is remarkable.

In the lower house was a glorious bench, some two hundred feet long and three feet wide, of a fine strain of hybrid-tuberous Begonias, both single and double. Few things make a more dazzling display or brighten up a house more than these wonderful flowers, with their pure, clear colors. Here I noted a new *Anemone Japonica-elegans*, darker than the pink type and with narrower, more frequent petals. The large Palm-house at Pitcher & Manda's is always an attractive sight, arranged as it is somewhat on the plan followed in private places. From this house branch off numerous smaller houses filled with small Palms, Anthuriums, Dracænas, Marantas, Billbergias, Nidulariums, and all the various fine greenhouse plants, among which it is a pleasure to loiter.

The famous Cypripediums have overflowed the large house always devoted to them, and now nearly fill the next range. The rage for these attractive flowers is unabated, and the collectors seem destined to have an unending succession of new forms as the new seedlings come into flower. These plants are systematically hybridized here, and a large collection of seedlings in a quiet nook gives promise of some surprises. Among the countless plants in bloom I noted *C. insigne Amesiana*, the rare variety with a broad white margin to the dorsal petal and without spots; *C. Schrœderæ splendens*, *C. Microchilum*, *C. tesselatum porphyreum* and *C. œnanthum superbum*. I noticed some very fine specimens of *C. Spiceri-anum superbum* in great masses, one containing sixty flowers. A mass of Orchids in flower greeted one in the next house, Vandas, Cattleyas, Odontoglossums, Oncidiums, Phalænopsis. A specimen of *Vanda Sanderiana* shown was said to be unique for size of plant, and could not probably be matched anywhere. This specimen had twenty-five flowers on four spikes. A large specimen of *Lælia anceps* was showing fifteen spikes, and a little later will be a grand sight.

A unique plant was *Lycaste Skinneri*, var., with flowers tinted light chocolate. But among so many beautiful and unique things it is vain to particularize. The old show-house contains no flowers, but is packed full on benches and under the roof with some thousands of *Cattleya Trianæ* plants. These have probably interested some visitors more than the bountiful flowers in the other houses, for here is a new lot of unbloomed plants lately sent in by the firm's collector, and there is the pleasure to the plant-lover of looking in anticipation on some novelties. I had a look at the hardy plantation to see if possibly any plants still survived the recent hard weather. There were a few small things in good form, *Stenactis speciosa*, and some new Delphiniums; but the most striking show was made by the white, large daisy-like flowers of *Leucanthemum lacustre*, though *Helianthus Maximiliani* was still in good form in another part of the grounds.

Space will not suffice to dwell further on special plants, but I noticed one exhibit aside from these which will interest exhibitors at flower-shows. This was a complete apparatus for staging single blooms for exhibition and known as Bunyard's Standard Exhibitor; in this flowers are perfectly displayed and held at any height with a very ingenious device for labeling varieties. In the former absence of such a contrivance our

flower-shows have usually presented a makeshift and somewhat unsightly lot of boards. In spite of the distance of Short Hills from the city the exhibition was thronged by interested visitors.

Elizabeth, N. J. *G.*

Notes.

The forests of British Columbia will be represented at the Columbian Exposition in a building composed of every variety of native wood.

Dr. J. H. Mellichamp, of Bluffton, South Carolina, sends us fresh flowers of *Gordonia Lasianthus*, the Loblolly Bay, taken from a tree covered with bloom. It is a young tree, fifteen to twenty feet high, and last year it also produced flowers in the autumn.

Referring to the note in a recent number of Garden and Forest relative to the absence of acorns this year, a correspondent writes from South Lancaster, Massachusetts, that there has not been so large a crop of acorns, chestnuts, shellbarks and butternuts in that vicinity for many years.

The Chrysanthemum Show at Madison Square Garden, in this city, is just opening as we go to press, and promises to excel in richness and variety any exhibition of its kind ever held in this city. Special features for each day will make a constant change and a succession of fresh flowers. The late bright weather has helped to open the blooms, so that nearly all the choice varieties will be seen at their best.

According to the *Kew Bulletin* there has been discovered in the forest of Bonket-Timah, near Singapore, a supply of the most valuable species of Gutta-percha-trees, which had been supposed extinct, ignorant natives having exterminated all the trees of which they knew in their eagerness to meet a demand for this special kind of gutta-percha, which was particularly esteemed for the making of submarine cables. The *Bulletin* deplores the fact that the location of the new find has been made public, and urges the Government to provide for the protection of the trees.

The frontispiece to *Gartenflora* in the issue for October 1st is a colored plate which shows forty-six fine varieties of Hyacinths, Narcissuses and Tulips blossoming at once in the window-garden of Herr Von Pommer Esche, in Berlin. They stand in pots in a slightly projecting glass bay thrown out from an ordinary window facing south-south-east, which opens from the living-room, and is heated only from this, and protected only by a roller-shade of thin slips of wood. The plants had been started in the house and removed to the window as their flowering-time approached.

We have received, through Mr. J. Wilkinson Elliott, of Pittsburg, Pennsylvania, a box of Tuberous Begonia flowers, raised in Mr. T. Tiffin's nursery at Westboro, Long Island, where the plants from which these flowers were taken have been grown in the open air all summer. The flowers are large, several of them measuring five or six inches across, of good substance and brilliant colors—scarlet, yellow and white. They show how well the Tuberous Begonia adapts itself to cultivation in the open ground in this climate, and what a really beautiful and valuable bedding plant it is.

A correspondent of a London paper recently spoke with emphasis of the wonderful development of the Cotton-planting industry in Turkestan. It is but a few years since American cotton was introduced into that country, and exportation began upon a considerable scale only in 1884, when the amount exported did not reach 10,000 poods. Last year 2,700,000 poods were exported, and it is expected that this year the amount will be one-third greater still. Thus far the crops have all been irrigated and cultivated by hand, and the cost of labor has therefore been very large. So it is believed that, with the coming introduction of improved machinery, the industry will increase much more rapidly than during the last ten years.

No more beautiful effect of color could be imagined than that produced during the latter part of October by the creepers which clothe the old reservoir on Fifth Avenue, in this city. The long lower fields of wall were covered two-thirds of the way to the top with thick masses of Wistaria, the still vivid green of which contrasted charmingly with the stretches of gray stone above them and the flat, close garment of Japanese Ivy which covered the three projecting pavilions. On the central pavilion this plant clung so tightly to the stone that the modeling of the doorway and the tablet above it was perfectly distinct. Its color was for the most part a deep warm red, but was flecked with leaves and sprays of a lighter hue, while the terminal shoots were bright pink or still a clear light green. The general tone thus produced was of enchanting richness and softness just because it was nowhere uniform over a single foot of the surface, but produced by varied blended tints.

An illustration in *The Garden*, of London, published on the 17th of October, represents a garden urn, the base surrounded by a bed of Clematis, which has been allowed to cover the pedestal upon which it stands. The effect is charming, and shows how well taken is the point made by our contemporary, that "if some principle of draping with living plants was carefully considered before introducing stone urns, temples, terraces or fountains into rustic scenery fewer of the violent and tasteless anomalies which so often disfigure our gardens and parks, both public and private, would be seen." The French for many years have covered the pedestals of out-door statues and other works of art with Ivy and various climbing plants, and in this way have succeeded in harmonizing such objects with their surroundings of grass, shrubs and trees.

As a result of the memorial recently laid before the President of the United States, asking that certain lands be reserved from settlement, with a view of using them as forest-reserves, the Secretary of the Interior has made the following appointments: Mr. M. J. Haley, of Helena, Montana, to examine the proposed reservation at the head of the Flathead and Marias rivers; Mr. J. F. Majors, of Jadis, Minnesota, to examine the proposed reservation in northern Minnesota; Mr. B. F. Allen, of Los Angeles, California, to examine the proposed reservation on the Tulare River, embracing the forest of Big Trees; Mr. J. S. Stidger, of Santa Fé, New Mexico, to examine the proposed reservation in western Texas at the head-waters of the Pecos River. Friends of the movement to secure these reservations can communicate directly with these agents in case they have any suggestions to offer in the premises.

A correspondent of the *American Architect and Building News* recently described a miniature model, now on exhibition in Chicago, which gives a bird's-eye view of the future aspect of the World's Fair grounds and of the principal buildings thus far determined upon. It has been constructed in the old exposition building, covers a space of 100 x 50 feet, and affords, says the writer, "a better view of the structures in their entirety than very likely will be possible on the exhibition grounds. The relative positions and sizes of the buildings are correct, and the whole lay of the land is carefully imitated. Lake Michigan is indicated by a stretch of running water, being, in fact, a diminutive portion of the lake introduced into the building. Jackson Park, Midway Plaisance, all, are represented by a clayey, paste-like substance painted green. Ground Hemlock is used in the place of the symmetrical Elm, and the whole settlement in the night-scene is illuminated by the smallest-sized electric lamps. When these shine across the turbulent lake or are reflected in the quiet lagoon or shine forth from the doors and windows of the miniature buildings the effect is quite unique."

The October bulletin of the Hatch Experiment Station of the Massachusetts Agricultural College contains a report of the result of experiments during last winter with special fertilizers for plants under glass. For this purpose six plots were arranged in each of two greenhouses, and planted with the same number and kind of Carnations at the same time in September. The soil, temperature, ventilation and all other conditions were kept as nearly alike as possible, and the number of blossoms produced by each plot was recorded. Observations continued during thirty-one weeks showed that the plot fertilized with nitrate of potash gave the best results, sulphate of potash the next, and dissolved bone the poorest result. This result differed from that of the previous winter, when bone-black stood first and sulphate of potash second, and is probably due to the insoluble condition of the bone-black, which in previous tests did not give good results until the latter part of the trial. In five experiments made in this line three have been in favor of bone-black, one of sulphate of ammonia and one of nitrate of potash. Sulphate of potash has stood second in every test. The nitrate of soda and muriate of potash, in every case where the crop has had a tendency to mildew, have given poor results, owing probably to their power of holding moisture near the surface of the soil. In the growth of the Rose, Lettuce and Carnation a moist atmosphere or a very moist soil in contact with the plants, especially at night, must be avoided if success is expected, and, therefore, such fertilizers as nitrate of soda and muriate of potash would aggravate any such condition. The same bulletin contains a chapter on "Experiments in Greenhouse-heating."

TABLE OF CONTENTS.

Public Gardens.

It has been urged in defense of the methods employed in the Boston Public Garden, to which a writer in these columns recently took exception, that this form of gardening is popular with the public. This might also with truth be said of a certain extraordinary construction in a Chicago park, where, for the admiration of the public, is displayed a gigantic vegetable globe, bearing upon its surface a map of the world delineated in Echeverias upon a ground of Sedum. Popular this undoubtedly is, and wonderfully made, the pride and delight of the local gardeners and of the press; it represents a vast amount of labor and care, as well as great expense; but it is bad art all the same, as foreign to the real mission of a public garden as it is obnoxious to cultivated taste. An object distinctly demoralizing to those to whom it is exposed as an object of admiration.

It is not the function of the true gardener to cater to popular taste, but to educate it. As a general thing people do not know just what they ought to like until they are told. There are those unfortunates who prefer the glory of a chromo to the quiet of an etching, a Brussels carpet to an Indian rug, a shilling shocker to a novel by an eminent hand, but it does not follow that these should be the only things provided because they happen to hit the popular fancy; on the contrary, it is the constant effort of the best reviews, the best newspapers and the best public libraries to elevate the taste of the uneducated, to show wherein simplicity and breadth in art excel violence and pettiness, to establish tests of beauty, and to help the world to distinguish the true from the false standard. And this should be equally true of the best gardens.

There is no excuse for uncertain notes from public gardens, for here there is no question of supply and demand. The public have to take what is given them, and they will not absent themselves from their accustomed pleasure-grounds even if their beloved monstrosities are removed, and a quiet and artistic arrangement substituted for one that is artificial and grotesque. A public garden is even more valuable than an art museum as an educator of taste, since it is seen by ten times as many people, and the city which owns one owes it to its inhabitants to instruct them in matters of taste as well as to excite their wonder and curiosity. To do things simply to please them when such things are in themselves violations of good taste, is equivalent to hanging the walls of the Art Museum with chromolithographs as more likely to be "understanded of the people" than the mysteries of Corot or the subtle values of a landscape by Daubigné.

The general public does not know good from bad in gardening, and, therefore, this is the requisite lesson to teach it. Americans are as keen to recognize the good, when once distinctly shown to them, as any people who exist; and a Boston public is especially conscientious and eager to think aright if it can only be taught how.

The instance adduced by our correspondent is a case in point. The Water-lilies were introduced as an experiment into the parks and squares of this city when it was doubted whether the public would care for them, and it was feared they might molest and injure them. On the contrary, they have been appreciated and enjoyed, and have not been disturbed. They are beautiful, they are refined, they have appealed alike to the most delicate and the simplest taste, and have so proved themselves both enjoyable and appropriate decoration. The immense parks in this city and in Brooklyn are great models in landscape-gardening. Are they the less satisfactory to any one on that account? Give the people beauty, both of color and arrangement, and insensibly it impresses itself upon them as a law. Good gardening, skillful grouping of shrubs and flowers, will be quickly imitated in a small way, and a knowledge of propriety in composition will thus be disseminated.

As a nation, the French have fine and discriminating taste, but that taste has been cultivated to its present point of perfection by the constant familiarity of the masses with what is excellent in architecture, painting and the plastic arts, of which they constantly behold excellent specimens. In the galleries of the Louvre and the Luxembourg the traveler is often struck by the delicate appreciation of beauty shown by people in caps and blouses. For generations this sense has been unconsciously trained by the continual observation of beautiful and appropriate forms, and by the knowledge that certain things are admirable, and the consequent effort to understand why they are worthy of esteem. The standard being once set up, insensibly their minds become adapted to it, and their judgment grows secure. It is only thus that the education of any populace can be accomplished. Constant familiarity with the really beautiful cultivates a distaste for what is false and violent. In Japan the very infants have an instinct, which we acquire only by patient study, of that restraint and delicacy and economy of material which is the secret of the best art.

In old times, before exploration and facilities of transportation brought masses of exotic and tropical plants to the gardener's hands, gardening was more beautiful than it is at present, because it was simpler and less confused. The temptation now is to overdecoration, both of public and private gardens, and even the French suffer from an embarrassment of riches which they have not quite learned to grapple with. They show the same tendency to interfere with the breadth of a lovely garden view by the interpolation of great overloaded flower-beds that we do, but in the composition of these beds their trained color-sense shows itself, and they produce a more harmonious composition. Thanks to the inherent German love of nature, and possibly also to the fact that the climate of Berlin is so severe that the number of varieties of delicate plants which can be grown there is very much restricted, the finest city gardens, that is to say the simplest and most natural, are now to be seen in the Prussian capital.

The most general failure in modern gardening arises from the attempt to grow as many things as possible without any reference to the propriety of associating them

together, and every one tries to make a museum or a botanic garden instead of an attractive and restful surrounding to a home. This fault is emphatic in many public gardens, which should be the first to teach a lesson of restraint, of breadth of treatment, of judicious selection and arrangement of a few interesting plants. The most beautiful of all gardens are the old ones, which were limited in the matter of vegetation. The material was scantier then, but the results far better. Where there is much to distract the attention, a multiplicity of detail, it is impossible to derive from a garden that sense of intimate charm which should be its finest characteristic. To be conscious of grace and beauty, of repose and harmony in a pleasure-ground, is impossible when the mind is kept on the alert by endeavoring to take in a hundred new and curious things.

This thirst for photographic detail is the foible of the age; it is thrust upon us at every turn—in pictures, in novels, in current literature, in gardens. The landscape is be-kodaked till fancy and imagination are well-nigh knocked out of the picture. The way of seeing things, the art of composition, is cast aside for the things themselves, heterogeneously thrust upon us. It is the death of the finest art, of repose and dignity and noble simplicity. A delicate suggestion as far outvalues a bald statement as a poet's verse excels a catalogue.

Leave Nature alone and there is never this emphasis of detail. Masses she gives, with here and there an accent, but no overwhelming sense of clutter, of the unimportant and wearisome variety with which man encumbers his landscape. And yet what infinitude the great Artist compresses into comparatively simple expression, but it is as a whole we see her most splendid panoramas, not as a collection of disjointed parts. To learn to express this secret of unity in variety is the lesson of the true gardener, and this it should be his part to teach by vivid and beautiful example.

The guardians of public pleasure-grounds should bear in mind that these resorts are for the education of the public; that they hold their office not to minister to unlearned and vitiated taste, but to appeal to the finer and higher perceptions which may be latent in the most unlikely quarters. The multitude grope in the dark, longing for light. Let that light be true, and not false—a guide, and not a concession; a beacon, not a mirror.

It is wise to show people what can be done with simple and easily accessible material; with perennial plants; with beautiful, but not uncommon, annuals; with shrubbery that can be cultivated in almost any garden; with hardy plants that may be found blooming early and late, when exotics must be housed, and tender things wizen in a chilly wind. Rare things, too, there may be, but let a part of every public ground serve as an example to all who love gardens. There are millions of people, who cannot afford a landscape-gardener, but would be grateful for a hint of how to manage their own little grounds in a way that would be pleasing without being costly, and that would be reasonably permanent. Not until public gardeners realize that they have a mission to perform will they truly merit their high office, for it is a high office to develop taste, to define beauty, and to indicate dignity and grace in the arrangement of trees and shrubs and flowers.

Waste Places.

SCATTERED throughout the eastern states, in fact, on nearly every farm, are untillable places that are almost non-productive, and, being almost worthless, greatly reduce the average acre-value of the farm. Such places are usually wet or rocky, and are pastured, whether profitably or not is for those immediately concerned to decide. But the present depression in the dairying business, together with the increasing value of lumber, has suggested some notice of waste tracts on which timber has been permitted to grow and of which the history is known, in the hope that suggestions may be found that will apply to tracts at present unprofitable. One such lot, which seems characteristic, was found in Warren County, New Jersey, in the Pequest Valley, and is a fair example of what may be expected on muck land that produces only Sedge-grass and wild Rose-bushes when cleared and pastured. Some of the notes of most general interest are here given. The soil is muck, from one to four feet deep. The subsoil is drift redeposited by a post-glacial lake near its eastern shore, and consists of sand and clay irregularly bedded, with some "hard pan." A spring-brook flows through the tract. The surface of the water in the brook is above the surface of most of the subsoil, and supplies the soil with abundant and constant moisture, except during unusual drought.

Prior to 1858 this lot of seven acres had been continuously depleted of tree-growth and burned over. At this date a few defective trees, say twenty, were standing, with about half of the tract in coppice of Maple and Ash, the remainder being occupied by Sedge-grass, Rose-bushes and scattering seedlings. The whole young growth was then cut off, and during the next ten years it was burned over every spring to reduce it to pasture. In spite of the fire and pasturing, the young growth gradually developed into a complete cover. The Maples, starting freely among the Sedge-grass, were at first eaten off by the cattle, but dense clumps and belts of Rose-bushes annoyed the cattle, and, finally, with Blackberry-vines, formed so dense a hedge near the adjacent cultivated land that the cattle seldom penetrated into the young growth of trees.

The last places to be covered were two very wet spots (where the seedlings at last started on decayed logs, sending their roots down a foot or two to the soil, as the logs rotted away), and the higher ground that was never overflowed. The latter was most grazed by the cattle, and was only covered by seedlings after the cattle were hedged out. The trees are thus not all of one age; some are from the seed, others are sprouts from the small stumps left from browsing. The trees near the "fail places," or those places last covered, started up very limby, and are now much shorter than those densely grown from the first. The species found on this lot were Red Maple, Black Ash, Swamp White Oak, Pin Oak, Sycamore, White Birch and White Elm. The Red Maple is throughout the most numerous, and in the parts most subject to overflow is only accompanied by a few Ash and Elm. The oldest of the trees are now about thirty years, and the youngest fifteen years. The greatest space between trees is twenty-five feet, and the average is about seven feet.

The growth on the whole tract is vigorous, and the crown cover is very nearly complete. The trunks of the best trees are free from live limbs to a height of thirty feet above the ground, and are now nearly smooth, though a few dead branches are still adhering near the lowest live limbs. Many inferior trees are dead and sickly from overcrowding, but the remainder will be the better for their death. All the leading trees are vigorous. It is noticed that the White Birch and the Swamp White Oak are rapidly overtopped and killed by the Red Maple. The Elm holds its own with difficulty, while the Ash, in damp spots, where there is more space, seems to equal the Maple, and will eventually overtop it.

An area was selected that seemed to represent fairly the average of the whole tract. The measurements on this acre showed the average to be as follows: Number of trees per acre, 901; height, 48 feet; diameter, 6 inches on stump, and 5 inches breast-high; contents, 4.1 cubic feet per tree, or 3,685 cubic feet per acre; merchantable wood, 3.4 cubic feet per tree, or 30.6 cords per acre.

TABLE OF GROWTH.

No. of Section.	Dist. from Ground.	No. of Rings.	Diameter.
No. 1.....	8″	24	6″
No. 2.....	4′ 8″	22	$4\frac{15}{16}$″
No. 3.....	8′ 8″	20	$4\frac{9}{16}$″
No. 4.....	12′ 8″	19	$4\frac{3}{8}$″
No. 5.....	16′ 8″	16	4″
No. 6.....	20′ 8″	15	$3\frac{5}{8}$″
No. 7.....	24′ 8″	13	$3\frac{1}{4}$″
No. 8.....	28′ 8″	11	3″
No. 9.....	32′ 8″	9	$2\frac{5}{8}$″
No. 10.....	36′ 8″	8	$1\frac{7}{8}$″
No. 11.....	40′ 8″	5	$1\frac{1}{4}$″
No. 12.....	44′ 8″	3	$\frac{5}{8}$″
No. 13.....	48′ 8″	1	$\frac{1}{8}$″

The value of this land at the time attempts at clearing were abandoned in the year 1868 was not more than ten dollars per acre. To-day the market value of the wood-growth alone is $30.00 per acre.

Department of Agriculture, Washington, D. C. *H. B. Ayres.*

Holiday Notes from Switzerland.—II.

BEFORE reaching Tiefenbach, at an elevation of 6,790 feet, we found *Pedicularis tuberosa*, a handsome pale yellow flowered species, in abundance, also the three Vacciniums, the Whortleberry, *V. Myrtillus*, *V. uliginosum* and the Cowberry, *V. Vitis-idæa*. Soldanellas were also seen, but at this elevation they were all long past the flowering stage; toward the close of our holiday, at the very edge of the snow-fields, we found them in flower. The Rosage, or Rose des Alpes, *Rhododendron ferrugineum*, was also out of flower at this elevation. The common Monk's-hood, *Aconitum Napellus*, exhibited its panicles of blue blossoms in a sheltered rocky hollow—only one colony of this species was noted during our first day's tramp. The Crowberry, *Empetrum nigrum*, was common by the roadsides, as was also the Bluebells of Scotland, *Campanula rotundifolia;* in Scotland this species ascends to about 3,500 feet. Here, too, was seen our first living specimen of *Nigritella angustifolia*, a beautiful alpine Orchid with grassy leaves and a dense spike of small blackish purple flowers with a strong vanilla-like fragrance.

The next morning we left Tiefenbach and followed the Furka road, constructed, under many engineering difficulties, principally for military purposes. The road crosses the Tiefentobel, and we leave the fine waterfall formed by the discharge of the Siedeln Glacier on the left; high above this rise the jagged, pointed peaks of the Bielenstock (9,969 feet), and straight before us the Furkahorn. In several places magnificent views are obtained of the Urseren Valley and the pinnacles of the Spitzberge and other mountains. At the Furka Pass, 7,992 feet high, a saddle between the Muttenhörner on the left and the Furkahörner on the right, a glorious panorama unfolds itself, the most imposing object being the snow-clad Finsteraarhorn, the highest of the Bernese Alps, which rises to a height of 14,000 feet. Shortly after crossing the pass, one of the most striking sights we met with, as far as plant-life is concerned, was furnished by an extensive, very steep, slope, thickly studded with *Campanula thyrsoidea*, a remarkable species, about fifteen inches in height, with narrow leaves and a dense, leafy, oblong spike of rather large creamy white flowers. Near trickling rills of water *Silene acaulis* formed compact cushions of the brightest green, thickly set with pretty red flowers. The blue-flowered *Campanula Cervicaria* also occurred, though much less frequently than *C. thyrsoidea*. *Gentiana verna*, one of the most beautiful of all alpine plants, grew in company with the Silene, and its turf-like masses of small dark green leathery leaves were in some cases almost hidden by their wealth of flowers of heaven's own blue. *Cirsium heterophyllum*, a handsome thistle with long-stalked purple flower-heads, was noted here; it is a plant worthy of a place in the herbaceous border. Nigritella, too, was frequent. From the Galenhütten admirable views are obtained of the fantastic ice masses of the Rhone Glacier—resembling a gigantic frozen waterfall—and of the mountains between which it is embedded. Instead of following the road from the Galenhütten we scrambled through the tangle of Alders, Juniper, etc., and in due time reached the base of the glacier. *Alnus viridis*, the Alder just referred to, is a species which nearly marks the highest limit of tree-growth in the Alps, and is generally found in abundance on the sites of old moraines. *Juniperus nana* grew in company with the last-named, and in open places *Epilobium Fleischeri*, a fine Willow-herb, with showy rose-colored flowers. Here, too, we noticed a few clusters of St. Bruno's Lily (*Paradisia Liliastrum*) and St. Bernard's Lily (*Anthericum Liliago*), with their snowy white blossoms still in full beauty. These two species are deservedly popular in British gardens, as they thrive readily and adapt themselves to conditions wonderfully different from those which obtain in their native habitats. *Lilium Martagon* was observed in some plenty, but no color variations were noticed.

A dwarf Achillea (*A. nana*), with white felted pinnate leaves and short stems terminated by almost globular corymbs of inconspicuous flowers, was seen. The neat habit of this plant and the beauty of its white leaves would make it a favorite with the devotees of carpet-bedding—a fashion which all persons of rightly constituted minds are glad to see rapidly declining—if only it would lend itself to cultivation. At the very base of the glacier, where only a few inches of soil and débris covered the solid ice, the Kidney Vetch (*Anthyllis vulneraria*) was covered with its heads of yellow flowers. *Linaria alpina*, too, had but few competitors here, where even grasses and sedges were scarce. The Anthyllis was the prevailing plant, and gave a distinct character to the scene.

A rest of an hour by the infant Rhone, which the ancients poetically describe as "descending from the gates of eternal night at the foot of the pillar of the sun," sufficed to set us up for our further walk of ten miles to Münster. Fine forests of Scotch Fir, Norway Spruce and Larch intermixed, the latter with its branches laden with long masses of Usnea (a lichen called Old Man's Beard in England), occurred on part of our way. The quaint villages of Obergestelen, Oberwald and Ulrichen (a walk of three hours and a half from this place brings us to the Gries Pass, the boundary between Switzerland and Italy), with their very primitive wooden chalets—outside nearly every one of which was a great heap of cow-dung—were passed before we reached the comfortable inn at Münster, the "Goldnes Kreuz."

Royal Gardens, Kew. *George Nicholson.*

Forest-vegetation of the Upper Mississippi.—III.

THE Cottonwood (*Populus monilifera*) grows abundantly along the Mississippi River in bottoms, where both sandy and rich soil seem favorable for its development, and the trees are often of very large size. They are seldom found, however, on the uplands away from the streams, except as recent introductions. The species is now sometimes found in the neighborhood of stone quarries in the loose clay soil. Trembling Aspen (*Populus tremuloides*) is common in the rich black soils of second bottoms, or the humus soil on ridges. Near Dubuque it occurs around rocky ledges. The species grows in groups, sometimes several acres in extent. It is a short-lived tree, and is followed by more useful trees, like the Oak. The Large-toothed Poplar (*P. grandidentata*) is less common than the last. It is found in more or less isolated groups in sandy and clay soils, and its growth is more rapid than that of the Trembling Aspen.

A few trees of the Sycamore (*Platanus occidentalis*) were observed at Turkey River Junction, Iowa. From this point southward it is more frequent in the Mississippi River bottoms.

The Hackberry (*Celtis occidentalis*) occurs in rich soil of the bottoms of Root River and other streams; and not infrequently it is found on the rocky limestone cliffs, as at North McGregor, Iowa. It is a tree which can adapt itself to a variety of soils, and, when cultivated, it does admirably on poor sandy soil.

The Birches are fairly well represented, the most common species being the River Birch (*Betula nigra*). It, with the White Maple, more nearly typifies the timbered region of the Mississippi bottoms than any other tree. The Black Birch diminishes in numbers southward. The Canoe Birch is common about La Crosse and Trempealeau, Wisconsin, where it is usually found on the tops of the limestone bluffs, though also occurring in ravines and ridges as well as in sandy soil. On some of the rocky hills it is almost the only tree. It rarely attains great dimensions, except when growing in rich clay soil. Near Dubuque it is scarce. Yellow, or Gray Birch (*B. lutea*) is found more abundantly along the sandy, rocky cliffs of the Kickapoo. It also occurs on sandstone rocks near a Tamarack-swamp not far from La Crosse. It is not a common tree.

Quite a grove of small Kentucky Coffee-trees occurs south of La Crescent in the Root River bottoms, and on the Wisconsin side there are two or three trees about seven miles below La Crosse. They are from twelve to fifteen feet high. It is much more numerous on steep hillsides near North McGregor, but none of the specimens are large. From this point southward it is more numerous. I noted it at Clayton, Turkey River Junction and Dubuque. It does not occur in the interior of the country east of La Crosse.

The Honey Locust was observed near Turkey River Junction, Iowa; from thence southward it is more numerous.

The Black Locust (*Robinia Pseudacacia*) has established itself near La Crosse and Trempealeau, Wisconsin.

According to Mr. Harris, the Red Mulberry formerly flourished in the Root River bottoms near La Crosse. I have not seen it, however, growing wild. Scattered specimens were found at North McGregor, Iowa, and it is more numerous near Dubuque.

Basswood is largely influenced by moisture. Rich black soil and damp grounds, sloping to the north, are favorable situations for it, and it is commonly found along the rich bottoms of the smaller streams and creeks.

The American Elm is a common tree everywhere along the creeks and streams near springs; occasionally, also, in upland woods in dry soil. The Red Elm (*Ulmus fulva*) is not uncommon on the rocky slopes of hills along the Mississippi. It is absent or rare in the interior of the country. The Cork Elm (*U. racemosa*) is far less common than *U. Americana*.

It occurs near La Crosse, along some of the smaller streams, and I observed it near Turkey River Junction, Iowa.

The White Pine is the most common conifer along the Black River. In the northern part of La Crosse and in the eastern part of Vernon County it is common on the sandy loamy soil. Near the Mississippi River it only occurs on the sandstone ledges. Large trees were once found at La Crescent, Minnesota, and quite a group of these Pines occurs near Clayton, Iowa. Northern Scrub Pine (*Pinus Banksiana*) occurs on sandy prairie soil along the La Crosse and Black rivers, where little else grows besides some tough grasses, Prairie Clover, Lupins and Wild Indigo. Red Pine (*P. resinosa*) occurs in isolated places in the sand bottoms of the Black River and sandy rocky ledges of the Kickapoo River.

Hemlock I have not found along the Mississippi River, nor does it occur near the mouths of the Black, La Crosse and Wisconsin rivers, but near Rockton, on the Kickapoo River, which is a tributary of the Wisconsin, numerous groups occur. The Trailing Arbutus and *Clintonia borealis* flourish under its shade among decaying logs and leaves.

Tamarack grows in the peaty swamps of La Crosse and Trempealeau rivers. During dry years portions of the Tamarack swamps are passable, but during wet years they are for the most part very wet. Owing to frequent overflows, which carry with them much soil from tilled land, these swamps are gradually filling up, and, as a consequence, the Tamarack in these localities is losing ground. I found a small swamp near La Crescent, Minnesota, but in a few years this swamp will be a thing of the past.

Red Cedar (*Juniperus Virginiana*) grows along the Mississippi River, on the sandy out-crops and limestone rocks, and most abundantly in the sandy bottoms of the Black River.

I have indicated, in a measure, the principal forest-trees between Trempealeau, Wisconsin, and Dubuque, Iowa. In the northern portion *Betula papyrifera*, *B. nigra* and *Juglans cinerea* are more numerous than farther southward. *Platanus occidentalis*, *Gleditsia triacanthos*, *Gymnocladus dioicus*, *Juglans nigra*, *Quercus Muhlenbergii* and *Morus rubra* are southern trees which have moved northward along the Mississippi, and, therefore, are found close to the shores.

Agricultural College, Ames, Iowa. *L. H. Pammel.*

New or Little-known Plants.

A New Hybrid Rose.

WE have more than once insisted on the value of the Japanese *Rosa multiflora* as a hardy shrub. A figure illustrating its flowers and foliage was published some time ago in this journal. The picture in the present issue is of a fine specimen in the garden of Mr. John Robinson, of Salem, Massachusetts. It shows the manner of growth of a plant which possesses an individual beauty surpassed by that of few of the plants found in our gardens; and apart from its own merits it seems destined to play an important part in the creation of a new race of hardy climbing Roses.

Mr. Dawson has been hybridizing it at the Arnold Arboretum and has already produced two or three distinct seedlings of very considerable value. We are able to produce on page 533 of this issue a photograph of one of these hybrids obtained by crossing *Rosa multiflora* with the well-known Hybrid Perpetual General Jacqueminot, the latter being the pollen parent. The result is a vigorous and hardy plant with a tendency to climb high. The spines and foliage are those of the pollen parent, but the flowers are clustered like those of *R. multiflora*, sometimes as many as sixty being developed in a single panicle. They are semi-double, rose-colored, an inch across, and exceedingly fragrant.

In *Rosa multiflora* may be found the ancestor more or less direct of the so-called Polyantha or miniature clustered Roses which have become popular of late years in English gardens; but none of these are hardy or very satisfactory with us here in the northern states, probably because they or their parents are of southern origin, and the real interest of the results obtained by Mr. Dawson lies in the fact that by working from an absolutely hardy form of *Rosa multiflora* he has been able to lay the foundation for a race of hybrids of as great or greater beauty than any of the Polyantha race found in gardens, and absolutely hardy.

We intend to figure some of the other hybrids obtained by Mr. Dawson from this cross; among them is one with the habit and foliage of *Rosa multiflora*, with small, semi-double, fragrant, pink flowers, which is, perhaps, even more distinct and beautiful than the one which forms the subject of the illustration in this issue.

New Orchids.

Cymbidium Lowianum, var. concolor, Rolfe.—A very striking variety, in which every trace of red has vanished from the flower, which thus becomes of an almost uniform light greenish yellow, and forms a decided contrast with the ordinary form. It appeared with Mr. C. Eastwood, of Lane House Nursery, Luddenden, Manchester.—*Gardeners' Chronicle*, August 15th, p. 187.

Cypripedium × macrochilum, Hort.—A hybrid raised from *Selenipedium longifolium*, fertilized with the pollen of *Uropedium Lindeni*. It bears much resemblance to *S.* × *grande*, of which it may be considered a variety, with somewhat larger lip and other slight differences. It is a very interesting hybrid, and furnishes another kind of proof that the Uropedium is only an abnormal state of *Selenipedium caudatum*. It was raised by Messrs. James Veitch & Sons, of Chelsea, and was awarded a first-class certificate by the Royal Horticultural Society, on August 11th last.—*Gardeners' Chronicle*, August 15th, pp. 199, 201; September 19th, p. 343, fig. 40.

Oncidium Forbesii, var. Measuresiana, Kränzlin.—A variety with yellow flowers and a very pale border. It appeared in the collection of R. H. Measures, Esq., of The Woodlands, Streatham.—*Gardeners' Chronicle*, August 22d, p. 227.

Catasetum ciliatum, Rodr.—An elegant little species, described some years ago and now appearing in cultivation for the first time in the collection of M. Robinow, Esq., of Didsbury, who received it from the Amazon district, in Brazil. The sepals and petals are greenish white and reflexed, the petals of the same color and erect, and the triangular, acute, concave lip whitish, tipped with deep maroon-purple, with light purple transverse lines on its basal half, and with purple bristle-like hairs, half an inch long, on the sides near the base. The flowers remind one of some peculiar bees on the wing. It is very distinct from *C. roseo-album*, its nearest ally. *Gardeners' Chronicle*, August 29th, p. 242.

Kew. *R. A. Rolfe.*

Plant Notes.

Some Recent Portraits.

The following plants are figured in the October issue of the *Botanical Magazine*:

Yucca filifera (t. 7197): this is the great arborescent species of which portraits appeared in the first volume of Garden and Forest (Figs. 13, 14). The history of the plant from which the figure in the *Botanical Magazine* was made is interesting. The trunk was sent to Kew in October, 1888, by Mr. C. G. Pringle, who collected it at Monterey, in Mexico, as a museum timber specimen. When it arrived at Kew it was apparently quite dead, and the trunk was placed in the museum. Here it remained two years and then put out some rudimentary leaves and an inflorescence, and, being transferred to the temperate house, these developed in September, 1890. The leaves were very short, as compared with those on the wild plant, and the panicle of flowers is less dense, and, curiously enough, is erect, not pendulous.

Cirrhopetalum Collettii (t. 7198): this is an Orchid discovered by Major-General Collett in the southern Shan Hills, and is one of a collection of several hundred species made by him during the late Burmese war, including many plants previously unknown to science. The flower is "remarkable for the extremely long attenuated sepals, which are highly mobile and are wafted about by the slightest

breath of air; and also from being furnished with a number of little streamers or banner-like appendages which, when blown by a breath of wind, wriggle about in a very odd manner." Mr. Hemsley has pointed out a peculiarity in the mode of growth of this species in that the flower-scape is not formed at the base of a fully formed pseudo-bulb, but is developed together with a young leaf, which afterward forms a pseudo-bulb, and is enclosed in the sheaths with it.

Napoleona Miersii (t. 7199): this is the representative of a small genus of west tropical Africa which, in the structure of its flowers, is one of the most curious of flowering plants.

Eucryphia Billardieri, var. *Milligani* (t. 7200), a native of Tasmania and a member of the Rose family, with pale narrow leaves and small solitary white flowers.

Epiphyllum Gærtneri (t. 7201): this is the species so long supposed to be a variety of the well-known *E. Russellianum* now a universal favorite in gardens where greenhouse plants are grown. It differs from that plant in the much larger, broader, thicker crenulate articulations of the stems, broadly truncate at the top, regularly crenate on the sides, with tufts of long hairs both in the crenatures and around the base of the flowers. These present even greater differences in their more brilliant coloring, in the length and narrowness of the petals, in the almost terete

Fig. 82.—A New Hybrid Rose.—See page 532.

(not broadly winged) calyx-tubes, in the very numerous stamens with clustered minute anthers, and in the spreading stigmas.

Foreign Correspondence.

London Letter.

Horticultural Education.—A few weeks ago I mentioned a scheme which was being formulated by the London Worshipful Company of Gardeners and a section of the Royal Horticultural Society which had for its object the establishment of a "School and College of Technical Horticulture and Small Husbandry." The scheme is published to-day in *The Standard*. The aim is "to impart a higher class of education in the principles and practice of the cultivation of fruits, flowers, and vegetables than is at present obtainable in Great Britain." Students will be expected to remain at the school at least two years, during which period they will devote themselves to the manual as well as to the scientific branches of the work. By this it would appear that whatever is not manual in horticulture is scientific, and everything manual is unscientific. Directors of cultivation and qualified lecturers are to superintend and instruct. It is proposed that the gardens of the Royal Horticultural Society at Chiswick should be utilized for this purpose. Beside this scheme we have now actually at work a number of lecturers who have been appointed by several of the county councils in the south to lecture in the towns and villages on the cultivation of the small farm, the garden, and the allotment piece. These lectures, however, are intended for the uninformed in matters horticultural rather than for professional men. It is also proposed to introduce the subject of land culture into the curriculum of schools. At present there appears to be some difficulty in finding qualified men for all these new posts. The value of these several well-intentioned schemes for the propagation of a knowledge of horticulture among the masses remains to be proved. It is questionable if much real or useful knowledge is ever imparted by lectures. The fancy may be tickled or a wish for knowledge may be the outcome of a lecture, but as a direct means of education this popular form of teaching is open to doubt. The schoolroom gardener is not likely to prove superior in cultural skill to the man who has obtained his knowledge of his art by constant practice in the best gardens.

Streptocarpus Galpini, Hook f. (n. s.)—This is a new species of Streptocarpus which is now flowering at Kew. It belongs to the monophyllous group, of which *S. Dunnii*, figured in the last volume of Garden and Forest, is the most remarkable species. The new one has a prostrate fleshy leaf, not so large as that of *S. Dunnii*, the largest at Kew being eight inches long and five inches wide; the nerves are very prominent on the under side and are tinged with purple; the whole leaf is covered with a soft silky pubescence, which gives the upper surface a silvery appearance. The plant now in flower has four erect racemes springing from the base of the midrib of the leaf; they are six inches high, and bear each about twelve flowers, arranged in pairs and opening in slow succession, pedicels one and a half inches long and reddish; calyx formed of five small linear lobes; corolla, with a short broad tube less than half an in h long; lobes spreading, orbicular, the lower one projecting a little and forming a kind of labellum. The flower is nearly one and a half inches across and colored rich lavender-blue, with a clear white throat. The general expression of the flower is not unlike that of *Ramondia Pyrenaica*, but they are larger. Fourteen flowers have been opened together on one plant. I consider this by far the prettiest of all the species of Streptocarpus hitherto introduced. We have no in-door plant which flowers at this time of year that will compare with it. In the shortness of its flowers it differs markedly from all other cultivated plants of this genus. Seeds of this plant were sent from the Transvaal to Kew last year by Mr. E. E. Galpin, of Barberton. A figure of it will shortly be published in the *Botanical Magazine*.

Bordeaux Mixture for Potato Disease.—Experiments have been made in England this year to test the value of Bouillie Bordelaise as a cure for Potato disease. In the *Kew Bulletin* for 1889 there was published some interesting correspondence on the extensive use in France of this substance, which is a mixture of sulphate of copper, slaked lime and water, for the prevention and cure of mildew and other fungoid diseases of the vine. The possibility of its proving equally efficacious with Potatoes induced the Board of Agriculture to arrange for experiments to be made with it in various parts of England. The reports on these experiments so far are not conclusive, some cases showing an improvement in the crop where the Bordeaux mixture was used, others a falling off, and others absolutely no difference. The last published report is from the trial grounds of Messrs. Sutton & Sons, at Reading, from which it would appear that, if anything, the use of this mixture is to be deprecated. Experiments had been made on 278 kinds of Potato, which were planted in 810 rows. Half of each kind was dressed with the mixture, the other half left to take its chance Here is the result:

	Tons.	Cwts.	Qrs.	Lbs.
810 rows, dressed with the mixture, yielded....	4	17	1	1
810 rows, not dressed with the mixture, yielded..	5	8	2	5

Two of the varieties—namely, Sutton's Ringleader and White Beauty of Hebron—were one-third more prolific without the dressing than with it.

By the side of this report from Messrs. Sutton may be placed that from Mr. R. Fenn, well known as a raiser of potatoes, from which it appears that where the dressing was used the crop was about fifty per cent. better than when no mixture was applied. Mr. Fenn attributes the difference between the results he obtained and those obtained by Messrs. Sutton & Sons to his using the mixture in powder form instead of in the liquid, as recommended by the Board of Agriculture, and to his applying the mixture early.

Kew. *W. Watson.*

[Experiments in this country seem to have demonstrated that the Bordeaux mixture is effective against potato rot when the application is made early, and repeated several times. The copper mixtures are preventives, and hence the need of application before the spores of the rot have started into growth.—Ed.]

Cultural Department.

Notes on Small Fruits.

Several promising varieties of Raspberries are being tested at this station. Among them are the following Black Caps:

Lovett's Early is one of the earliest; the plants made a good growth last year, and gave a fine crop of fruit this season. The fruits are quite firm, of good size and appearance. The canes make a very slender growth, but are well branched. This will undoubtedly be a valuable acquisition. Carman has been fruited here two years, and proves the earliest of all Black Caps. The plants make a very vigorous growth, and produce a fair crop of fruits of high flavor and showy appearance, and firm enough to ship. This will, without doubt, become a favorite early variety when better known. A seedling sent out by G. C. Brackett, Secretary Kansas Horticultural Society, under the number 101, has proved itself a valuable variety, being a vigorous grower and productive; its fruits are of the largest size, jet-black and firm; it is in season about with Gregg. Among the older varieties the Hilborn takes the lead, with Smith's Prolific following close in regard to yield. Both of these have fine showy fruit of good quality, and are firm enough to bear shipment. For a late fruit nothing tested here will equal the Ada, a variety of great vigor and productiveness. It is rarely met with, and I fail to find it catalogued, but it should become better known. The Gregg through this section is still the favorite, both for market and canning, but I am of the opinion that either the Holborn or Smith's Prolific will equal it in productiveness, and prove more hardy.

Fig. 83.—Rosa multiflora, trained over a post.—See page 532.

Of the red Raspberries, Quinby's Favorite is one of the best, resembling in a marked degree Cuthbert both in growth of canes and the questionable habit of growing a large number of suckers. The fruits, however, average larger than Cuthbert, are deep red and very firm, but the firmness does not detract from the juiciness, and in flavor it resembles the Cuthbert. Two seedlings from William Parry, of New Jersey, Nos. 1 and 2, are both good, the No. 1 being early, vigorous in habit, fairly productive and of fine flavor; too soft to ship, but a good home berry. The No. 2 begins to ripen fruits in mid-season, and continues to bear for a long period. The berries are of large size, firm and of distinct winy flavor. I think this will prove a valuable variety when known. Stayman's No. 5, originated by Dr. Stayman, of Kansas, is also a very promising variety, throwing up large stools of canes; it is hardy and one of the most productive varieties. The fruits are dark red, large and quite firm. Of the older sorts Cuthbert still leads in productiveness, and, in my opinion, will stand at the head for some time to come. Thompson's Early Pride is a little earlier, and Pomona is larger, but, taking all things into consideration, the berry to supplant it will have to be a decided improvement on any grown at present. Something with the productiveness and hardiness of Schaffer, the size of Clark's or Pomona, and the firmness of Quinby's Favorite would be the ideal berry. Schaffer is the berry par excellence for canning, as its enormous yield enables those growing it to sell at a price below that at which other varieties can be sold, and its great merit to the canners is that it holds its color and shape better than any other.

Either the Caroline or the Golden Queen should always be found in an amateur's collection. Both of these are yellow and about equal in productiveness. The Golden Queen bears the larger and more showy fruits; the habit of plant is identical with Cuthbert, and it makes a dense growth of suckers; it is often killed back one-half in severe weather. The Caroline is extremely hardy, never showing any ill effects from cold weather and withstanding drought. The fruits of both of these varieties are very soft, and, owing to their color, soon look mussy, so that they cannot be shipped; but their superb flavor entitles them to a place in every collection.

Of the Blackberries, Agawam has given the best results thus far; it has proved perfectly hardy, able to resist drought and to mature all its fruits; it throws up a large number of stout canes well supplied with laterals, and while the fruits are not of the largest size, they are of good size and of fine flavor. The Erie is a very fine variety, giving a large yield of enormous berries that, when fully ripe, are as luscious as the old Kittatinny. Its habit of growth is stocky, and heretofore it has proved rust-proof. I think it a good substitute for the Kittatinny in sections where the latter cannot be grown. Last year it did not give very good results, and there were doubts about its value, but since this year's trial I am satisfied it will prove a good berry. The Snyder has not done as well here as elsewhere; while making a very vigorous growth, it has yielded but few fruits in the three seasons it has been under test. Early Harvest, Wilson's Early and Wilson's Junior are three very early varieties, of merit on account of their earliness where they can be grown profitably, but neither of them has given anything more than a small yield here.

Of black currants, Champion Black and Ogden's Black Grape are two of the best, the former being of dwarf upright growth and fairly productive. The fruits, which are of large size, are borne in short clusters. The Ogden's Black Grape is of spreading habit, and is very productive of large jet-black fruits. Both varieties ripen all their fruits at once, and have no green tips to the clusters, as is common with other varieties. The Crandall has proved utterly worthless here, the bushes growing beyond all bounds, but bearing only an occasional fruit, and those of only medium size and no special flavor.

Among red currants, Fay's Cherry and Prince Albert are the leading varieties; the latter is especially valuable on account of its late fruiting. It begins to ripen its fruit when the other varieties are ready to pick, and can be left on the bushes for a long time, as the foliage completely covers the bunches and keeps them from being scalded by the sun. Care should be taken in purchasing this variety, as there is a spurious strain of it in the market; this has the same dark green foliage and habit of growth, but with small fruits in short bunches.

Since we have been able to combat the Gooseberry-mildew successfully, the growing of the large-fruited foreign gooseberries has been revived, and now the only excuse for growing such varieties as the Houghton or Mountain seedling is the ignorance of better kinds. All things considered, I should place Triumph at the head of the list of large-fruiting varieties; but Industry, Wellington's Glory and Whitesmith are also fine, giving a large yield of delicious berries as much superior to our native varieties as a Seek-no-farther apple is to a Baldwin.

Geneva Experiment Station, N. Y. *C. E. Hunn.*

The Hardy Flower Garden.

WHATEVER work remains to be done in this department should be pushed forward with all speed, as the soil is rapidly losing warmth, and the planting of herbaceous plants is dangerous if delayed too long. They do not take root in the cold soil, and are often lifted by the action of frost and killed before one is aware of it. Too much stress cannot be laid on the fact that for a considerable period in fall the soil is much warmer than the atmosphere, as may be easily ascertained by testing the matter with a thermometer, and this condition is very beneficial in establishing fall-planted bulbs and herbaceous plants, and, although herbaceous subjects are planted in larger quantities in spring, it is by no means the best season, as in spring root-action commences as soon as the frost leaves the ground, and it is more or less interrupted by transplanting at that season, however early it may be done.

When Lily-planting is contemplated the present time is the best possible if native-grown bulbs are to be used, but if imported bulbs are desired they cannot be had for several weeks, as the new stock has not arrived, and, in fact, does not arrive until too late for planting in the majority of cases, as, for instance, the Japan varieties, which are more in request than other kinds, and, taken as a class, imported ones are much more satisfactory, with perhaps one or two exceptions, as, for instance, *Lilium auratum*, which no one has taught us as yet how to grow and keep. With the exception of *L. auratum*, home-grown Lilies may be planted now, and better flowers will follow than if later plantings are relied upon. The sooner the bulbs are planted the stronger will be the root-action from the base of the bulb; this is always poor when planting is done in spring, as the bulb has then to depend largely for subsistence upon the roots formed along the stem, and these have plenty to do to nourish properly the stalk and flowers. The depth to plant Lilies must depend largely upon several details which it is well to consider here; but, at the same time, it must be admitted that there never was a truer word spoken than that horticulture is necessarily "empirical." Experience does teach, and it is not all gained in a day, and seldom is Lily-culture fully mastered. I have noticed that some varieties with small bulbs will succeed well with shallow planting, as for example, *L. Wallacei*, *L. callosum*, *L. elegans*, and, emphatically, *L. Philadelphicum*, which always grows near the surface when found wild, while others with small bulbs, as, for example, *L. Columbianum* and *L. tenuifolium*, need deep planting.

A well-known Lily-grower once told me that people thought that because *L. tenuifolium* came from Siberia it would stand any degree of cold; but they forgot about the deep covering of snow by which the bulbs were protected on the approach of winter. Hence the saying that this beautiful Lily is best treated as an annual. *L. tenuifolium*, however, is not nearly as good as *L. pomponium*, which is not so well known, but produces more flowers of the same color, and fragrant, too, and it improves year after year under cultivation, so that we can well spare the Siberian species. *L. Columbianum* comes from the Pacific Coast and succeeds but poorly here in the east. I have only flowered it when planted ten to twelve inches deep, and the same remarks apply to *L. Washingtonianum* and *L. Humboldtii*. They are both beautiful but are seldom seen. Even when once planted in the garden they have a provoking way of lying dormant for eighteen months before trying to flower, and they usually die in the attempt. *L. excelsum* is a very distinct Lily, and is regarded as of hybrid origin as it has never been found growing wild. It should always be tried as it sometimes succeeds as well as *L. candidum*, while the color is unique among Lilies—a light buff. *L. Szovitsianum* is another beautiful Lily seldom seen, though it sometimes succeeds well, but when it does it is not soon forgotten; the flowers are bright lemon-yellow. *L. Martagon* is another difficult Lily to grow, but I believe it needs stony soil, preferably elevated, as on rock-work, to make it comfortable. It is the true Turk's-cap Lily.

While the foregoing may be regarded as the shady side of Lily culture, there is still a bright side and a very sunny one it is. We must thank Japan for it to a great extent, for most of the Japan Lilies are perfectly at home here, and in some cases, as with the Tiger Lilies, we may often see them naturalized as escapes from gardens. *L. speciosum* and varieties, *L. tigrinum* and its varieties, *L. Batemannæ*, *L. Thunbergianum* (or *elegans*), *L. Hansoni*, *L. Japonicum* and its

variety Brownii, with perhaps *L. Leichtlinii*, constitute the majority of Lilies that can be grown outdoors here, and all are of Japanese origin. It is not generally known that the well-known Easter Lily can be grown and flowered in the open border equally as well as in the greenhouse if the bulbs are wintered in a cool cellar and planted out in spring. I refer to *L. longiflorum* and its variety Harrisii. *L. candidum*, the Madonna Lily, is perfectly hardy and needs no commendation. There are still three native Lilies that are worth growing in the garden as they improve so rapidly when given a moist soil and are very ornamental—*L. superbum*, *L. Canadense*, and *L. pardalinum*, the latter a western Lily but perfectly hardy here. As to planting, one cannot do wrong with those noted since they grow well here if they are planted eight or ten inches deep even where the soil is heavy, for this will save the young shoots from injury from frost in the spring; but with those that do not succeed well in all places it is best to try them in all positions available, being assured that when success is attained it will be worth recording.

Andromeda speciosa for Forcing.

THE singular beauty of *Andromeda speciosa* as a dwarf flowering shrub has often been spoken of in Garden and Forest, but it ought to be said in addition that this promises to be one of the very best of shrubs for forcing. It is an Ericaceous plant, a native of our southern states from North Carolina to Florida, where, in the Pine-barrens, it reaches a height of two to four feet. Although not as hardy as many other North Carolina plants, it does fairly well in any sheltered position here. At the Botanic Gardens in Cambridge it has flourished in the same place for twenty years, and probably longer, without any protection; and it will certainly do well in more exposed places if pegged down to the ground and lightly covered with soil. To all lovers of beautiful plants it will repay this slight trouble.

When used for forcing it rivals many of the Heaths with its large white bell-shaped flowers, which are often half an inch across. For forcing purposes the plants do best when lifted early in September, potted firmly and kept in a close frame or greenhouse, and well syringed until established in the flowering pots, which will be in a fortnight or three weeks. They should then be put out-of-doors to harden up until heavy frosts are expected, when they can be placed in a frame or pit until wanted for use. The first lot may be brought into heat about the first of December, and afterward as they are needed. With a temperature of fifty degrees Fahrenheit at night and from ten to fifteen degrees higher during the day they will begin to flower in a month or six weeks. As soon as the flower-buds begin to show, several good waterings of liquid manure should be given, which will make the flowers much more substantial. When the plants have been once forced and are kept in pots during the summer, they will flower much more freely than they do the first season after they are taken from the open ground. This Andromeda is slow to propagate from cuttings. For this purpose forced wood, kept under double glass, is the best. From seed it is as easily raised as Rhododendrons. It grows slowly the first year and begins to flower the third year. The buds are formed in the fall on the terminal shoots in the axils of the leaves. As the plant grows late in moist seasons, this growth is not always well ripened; hence the necessity of covering the plant in exposed places.

Arnold Arboretum. *Jackson Dawson.*

Limnanthemum Indicum.—A charming little aquatic under this name was introduced into this country last year by Mr. E. D. Sturtevant, of Bordentown, New Jersey. The leaves are roundish, heart-shaped, bright green, about three inches across, and float upon the surface of the water. The pure white flowers, with a faint tinge of yellow in the centre, ascend in clusters of several from the petiole, at the point where it joins the blade of the leaf, each borne erect on a slender stalk some two or three inches high. They are rather more than an inch in diameter, and the five radiating petals, of oblong outline, are so densely covered with hair-like material as to present a curious and pleasing woolly appearance on the upper surface. Mr. Sturtevant gives it the common name of Water Snowflake—a name as appropriate as pretty—and speaks of the flowers, from their hirsute decorations, as rivals in miniature of Mrs. Alpheus Hardy Chrysanthemums. I saw several plants of this novelty last September in the gardens of Mrs. H. M. Brooks, at Newport, Rhode Island. They had been planted in four-inch pots and then placed in a tub, a few inches below the surface of the water. The plants were full of flowers, and thriving with great luxuriance in the shade afforded by the vines in a grapery. The gardener, Mr. James Hill, assured me that they had flowered very freely all through the summer. He seemed to be much pleased with the tiny stranger, and said it required little care beyond good soil and an occasional change of water. A rich sandy loam, with a little old manure, is perhaps the best compost that can be devised for this and all similarly delicate water-plants. *L. Indicum* is very variable, and it has several synonyms. *Villarsia Indica*, *Nymphæa ceramica* and *Menyanthes Indica*, all doubtless refer to the same plant. Mr. Sturtevant's plant is most probably a variety of that figured in the *Botanical Magazine* under the latter name. The deep yellow color and somewhat smaller size of the flowers there illustrated are the only perceptible differences in the two plants. *L. Indicum*, in one or more of its numerous forms, occurs in Australia, Asia, and south Africa. A white-flowered variety appears to have been the first cultivated in English gardens; it was introduced from the Cape of Good Hope in 1792. *M. Barker.*

Cambridge, Mass.

Plumbago Larpentæ.—This little plant must be ranked among the best of those that flower late in autumn. It is quite distinct from anything in bloom at that time, and perfectly hardy. The slender stems are from nine to twelve inches in length, and furnished with numerous, rather pale-green, alternate, obovate leaves, which are sessile and taper to the base. The plant soon becomes a dense cluster of stems and leaves, spreading with great rapidity, and is completely covered with a sheet of intense blue during August, September and the greater part of October, lasting, indeed, until frozen. The spreading flowers, three-fourths of an inch in diameter, are borne in compact terminal clusters. *P. Larpentæ* is a charming plant for the rock-garden, and thrives even more satisfactorily in the herbaceous border. The rockery affords the nearest approach to its natural habitation, generally old walls or similarly exposed situations. It is much more vigorous with full exposure to the sun, and appears to better enjoy a deep, rich loam. The roots under such conditions descend to a considerable depth, and are got at with some difficulty when required in early spring for propagation by division, that method being the best. *P. Larpentæ* is somewhat rare in China, of which country it is native. It was first discovered by Mr. Fortune in the vicinity of Shanghai. He failed, however, in his effort to introduce it on behalf of the Horticultural Society of England; but a plant which survived was dispatched soon after, in 1846, by a Mr. Smith to Sir George Larpent. This specimen flowered a year later, and was awarded a prize at a meeting of the Horticultural Society. The plant was afterward described by Dr. Lindley, and named in compliment to Lady Larpent. It was thought, a year or two after its introduction, that *P. Larpentæ* would prove valuable for bedding purposes and speedily become popular, but after more than forty years' acquaintance with its highly meritorious qualities, the plant is still comparatively uncommon. Many of these long-neglected plants are now rapidly coming into favor, and there seems to be no reason why *P. Larpentæ* should not at last receive the attention it so well deserves. *Plumbago Larpentæ* is the name that was first given to the plant, and the one under which it is most generally known. The correct name is *Ceratostigma plumbaginoides*, however, and *Valoradia plumbaginoides* is another synonym.

Montclair, N. J. *S.*

Good Dessert Apples.—Two of our best winter dessert apples are Snow, or Fameuse, and Jonathan, both small in size. There are peculiar advantages in small apples for table use if they are handsome and high-flavored as these are. Few people, either before or after a hearty meal, want large apples, and as a rule do not eat more than half of a Spy or a Baldwin. For cooking the case is different; yet even there it is a mistake to choose very large fruit. The loss from decay of a single Jonathan is very small. Both the fruits named are excellent keepers. The Fameuse is good for October, November and December; the Jonathan will serve finely through January, February and March.

The Wagner is comparatively little known, but it is a remarkable apple both for beauty and quality. The flavor is wild but clear and distinct, and the juice is very refreshing. The Rhode Island Greening is a first-class apple, that is, those specimens are which have a bright golden nut-tint. This color comes in fruit in open lots where the tree gets abundant sunshine. Any apple grown in a close orchard is inferior to those produced in open ground, but this is peculiarly true of the Greening—the contrast is often striking. The Northern Spy is

another example of an apple that may be almost unsurpassed or may be nearly worthless for the table. The flesh of the best is almost a yellow, and the skin finely tinted but not a bright yellow and red. Apple-trees that bear the best fruit are those that stand in pasture lots, or by the fences, or on our lawns as shade trees.

Correspondence.

A Rhode Island Forest.

To the Editor of Garden and Forest:

Sir,—I have lately paid a visit to the plantations of Mr. Henry G. Russell, of East Greenwich, Rhode Island, and as they represent what is the most important experiment in silviculture that has been made in New England in the last twenty years, some account of the results which Mr. Russell has already obtained may be interesting to the tree-loving readers of Garden and Forest.

Mr. Russell's plantations stretch in a rather narrow belt for a distance of two or three miles along the north and north-west shores of Greenwich Harbor, a considerable inlet from Narragansett Bay. The situation is bleak, exposed, and wind-swept; the soil is naturally light and sandy, and what little plant-food the upper layers ever possessed was long ago exhausted by continuous cultivation, first by the Indians who frequented this point to feast on the clams which line its shores and the fish which still abound in the waters which surround it, and then by their white successors. That the soil, in spite of the poverty of the surface, possesses the power to produce good trees is shown by the great Oaks, both White and Black, which are scattered over some parts of Mr. Russell's estate, and by the remarkable growth made by some of the trees in his plantations. The first of these was made in 1878, Mr. Russell having determined to protect his fields by a belt of timber on the shore side. The work has been carried on gradually, the experience gained in one year being used to the advantage of the plantations made the following year. Nearly one hundred and fifty acres in all have now been planted, and the whole coast-line of the estate is lined with trees.

Mr. Russell, like most American planters, made his first attempts with foreign trees, of course with Scotch and Austrian Pines and Norway Spruces. Their worthlessness is already demonstrated, although the largest of the Pines, which are fast dying or blowing over, supply the farm with about all the firewood it consumes. It is interesting to note that large numbers of self-grown seedling Scotch Pines have been springing up in the plantations during the last three or four years from seed scattered from trees now only thirteen years planted.

The European Larch has done better than the other exotic conifers, and has proved one of the best trees planted at East Greenwich. The growth the Larch has made on this sterile soil is remarkable. The writer of this letter was in East Greenwich during the summer of 1878 and pulled up one of the newly planted Larches and wore it in his buttonhole during the day, much to the amusement of some of Mr. Russell's neighbors, who were inclined to look upon his efforts at forest-making with that incredulity with which country-bred New Englanders are apt to regard every innovation in old-time customs. The companions of my boutonnière of thirteen years ago are now stout trees from twenty-five to thirty feet in height, with trunks each thick enough to make two good fence-posts, and the neighbors are not laughing at Mr. Russell as a tree-planter as much as they were, but are themselves planting trees. In 1879 Mr. Russell wanted to try planting the Larch in autumn, and sent to Robert Douglas & Sons, of Waukegan, for one of their dollar packages containing a hundred trees. The package was six or seven inches long and perhaps three inches in diameter; the trees were set on an exposed point, and now they vary from twenty to twenty-seven feet in height. The Larch and the White Pine supply seven-eighths of the material used by Mr. Russell in his plantations. The Larch has grown rather the taller of the two, but the Pines have formed stouter trunks and have probably made more wood, and some of the youngest plantations are composed of White Pines exclusively. They grow with great vigor even in the most exposed situations, but have suffered from the attacks of the Pine louse, and from the Pine weevil which has destroyed the leaders on thousands of trees. Whale-oil soap applied with a syringe has checked, although it has not exterminated the louse. The weevil is a more serious enemy, as its presence is not noticed until the damage is done. The tops of all young trees injured by it are now systematically cut off and at once burned, so that its ravages are likely to decrease. The Douglas Spruce, raised from seed gathered in Colorado, has also proved an exceedingly hardy and valuable tree at East Greenwich, growing almost as rapidly as the White Pine and developing as yet no disease or insect enemy.

Various methods of planting have been tried, it being Mr. Russell's intention to make his place valuable as an object-lesson to the public. Plantings of pure Larch and of pure White Pine have been made and the two trees have been mixed together in different proportions. One of the most promising of the mixed plantations is composed of Larch set four feet apart each way with a White Pine in place of the fourth Larch, so that the Pines stand sixteen feet apart each way. As these have grown the Larches nearest them have been gradually cut away, with the intention of leaving the Pines to occupy eventually the ground.

Two sand-holes, each several acres in extent, near the end of the point, and therefore in an exposed situation, had for years been gradually spreading, and threatened to extend over a large area. It was a difficult and tedious undertaking to cover and fix the surface and so prevent the sand from working inland. This has at last been accomplished by covering the surface with brush and then by planting it thickly with seedling Pines, the Ailanthus, and other trees.

Mr. Russell has found that the best method of planting is to run shallow furrows four feet apart, each way, and then to set three or four-year-old transplanted seedlings at the intersections of the furrows. The land is so poor that weeds do not grow vigorously enough to interfere with the young trees, and they do not require or receive any care or cultivation after planting. For many years Mr. Russell has been planting acorns, principally of the White Oak, among his conifers with a view of securing a succession of forest-growth in case the original trees should be destroyed by fire or other causes. The experiment has been successful, as thousands of young Oaks now bear witness. Some of these, where light has been allowed to reach them by thinning surrounding trees, are five or six feet high and are growing rapidly and vigorously. Acorns were put in with a cane at a trifling expenditure of labor and money, and among the trees which have sprung from them are some which may be expected to flourish for the matter of a century or two after the last of the conifers which now surround and overtop them has disappeared.

The transformation which the plantations have made in the short period of thirteen years is astonishing. Standing now north of the mansion house and looking in the direction of the town of East Greenwich what appears to be an endless forest of waving Pines backed by high hills covered with the slender spires of countless Larches meets the view in place of the ugly, straggling wooden town with its squalid water-front. It is not easy to imagine a greater change or to realize how short has been the time since these trees came into life. At the beginning of the undertaking the plants were brought from the Douglas nursery on the shores of Lake Erie, but of late years Mr. Russell has established home nurseries in which his material is raised, so that the visitor can see here all the operations of tree-planting—beds filled with seedlings, the plantations made last spring (some twenty-five acres) and those of each previous year, and note the condition and rate of growth of the different trees.

Mr. Russell set out to do two things: by planting, to protect his estate from cold winds which were gradually blowing it away; and to show the possibility of making trees grow under what appeared singularly trying and difficult conditions. He has been more than successful in both. The attractiveness and value of his farm is greatly increased by his planting, and he has reared a forest which is more interesting and suggestive than anything of the sort east of the Missouri River. Its value as an object-lesson cannot be overestimated, and Henry G. Russell must stand as one of the foremost educators in rural economy that America has produced. But in doing this he has done something for himself which he, perhaps, never dreamed of twenty years ago—he has created in himself a real and living interest which will last as long as he lives. Among his trees he finds occupation of which he never tires; his greatest pleasure, he tells his visitors, is to go out and "get lost in his woods"; to pass long days among them, studying the trees, marking those which are to be cut, pruning his young Oaks, planning for new plantations, and finding that communion with Nature which is the greatest blessing that can come to any man however great may be his attainments or splendid his possessions.

Providence, R. I. *Davis.*

Exhibitions.

Chrysanthemums in New York.

In one respect the Chrysanthemum show in Madison Square Garden last week was far ahead of any exhibition of flowers which has ever been held in this city. It was a remarkable success financially, and this fact carries with it the promise of the annual recurrence of this festival, with the offer of premiums large enough to reimburse exhibitors for the very considerable expense of preparing and transporting the material for exhibition to the Garden. Last spring a beautiful show was opened to the public at the Lenox Lyceum, but no one went to see it, and heavy bills remained to be met by the local florists' club. This fall the Madison Square Garden Company took the matter in hand through their manager, Mr. Morrissey, who is trained to the business of organizing exhibitions, and by skillful advertising he brought crowds to see the flowers, and Mr. William Plumb, representing the Florists' Club, saw to it that the visitors found something to pay them for their trouble. Good music was furnished every day and evening, the flowers were renewed as they began to fade, and the interest was sustained by novelties up to the close of the week.

It was really a Chrysanthemum show. Orchids were exhibited, it is true, and admirable collections they were for the season, by Siebrecht & Wadley and Pitcher & Manda. Here, too, were large groups of Palms and Ferns from the same exhibitors, and a strikingly beautiful table of Ferns from Mr. Dreer, of Philadelphia. Nor were Roses lacking, and they were of excellent quality, as might have been expected from such growers as F. R. Pierson Co., J. N. May, Ernest Asmus, S. C. Nash and J. H. Taylor. There were Carnations, too, and a special day for Mignonette and Violets, while the mass of French Cannas, by Mr. James Dean was most instructive as suggesting the possibilities of these flowers for winter decoration. But after all, the greater portion of the immense exhibiting space was devoted to Chrysanthemums, and largely to cut flowers, and the exhibition seemed rich and varied in spite of the absence of the neat little Pompons, the Anemone-flowered varieties, and the true incurved or Chinese sorts which were very sparingly shown.

Of specimen plants naturally grown, like those we are accustomed to see at exhibitions in Philadelphia, there were none, if we except a single plant of the variety called Daisy from the collection of Messrs. Pitcher & Manda. This was a well-grown plant completely covered with pure white and almost single flowers which resembled large Ox-eye Daisies. The best-flowered plants in pots were those from Mr. Adolph Ladenburg, who won the first prize for a collection occupying a space of not less than 250 square feet and arranged for effect. These were tall plants, in ten-inch pots, placed close together, each one bearing a few flowers, but so perfectly developed that many of them would have ranked among the best of any class. Indeed, there were no blooms of the variety Lilian Bird exhibited which equaled those on Mr. Ladenburg's plants. The prizes for standard plants were taken by Pitcher & Manda and Mr. Spaulding. A great number of remarkably good plants grown with a single stem were also shown by Mr. Spaulding, but discordant colors were mixed up in such a way that the decorative value of the flowers was obscured. Of course it is impossible in an exhibition like this to arrange plants so as to achieve the best pictorial effect of the display as a whole. It would be a different matter if the plants were contributed for the purpose of decorating the Garden, so that they could all be placed according to some comprehensive artistic design. As it is, the plants come in classes for competition, and this necessitates some stiffness in the details of the arrangement. But, after all, there were flagrant conflicts of color which might have been avoided in several parts of the Garden.

It was owing to some shortcomings of this sort that the visitor on entering the garden experienced a sense of bewilderment and confusion, but after he had become accustomed to the glare and could note the details of the exhibition it was plain that this surpassed all former shows in this vicinity in the great profusion of well-grown flowers. These were to be seen not only on the exhibition boards, but in all directions, and in all available spaces there were splendid flowers with long stems, well furnished with luxuriant foliage. The collection of varieties in vases, a new feature here, was alone sufficient to establish the character of the exhibition. These collections were composed of noble flowers with long stems, each variety loosely arranged in a large tall vase. Almost every group of flowers was a study and fit to decorate a palace. Never before have the capabilities of the Chrysanthemum been so effectively displayed in this city as in this class, where their highest effectiveness was brought out in arrangements of one color. Such a display will do more to popularize the flower than any other form of exhibit which has yet been devised. These flowers were from Peter Henderson & Co., Ernest Asmus, J. N. May, J. Roehrs, Dailldouze Brothers, Flatbush, J. H. Taylor, Bayside, and when it is remembered that the exhibitors are market growers and that the flowers, though their best, were not specially grown for exhibition, it will be understood that the culture of the Chrysanthemum is well understood here. The flowers were deep and full and averaged about six inches in diameter. The varieties which seemed to be most useful to this class of growers, judging from those shown, were the following: White—Mrs. Alpheus Hardy, Jessica, Miss Minnie Wanamaker, Domination, Ivory, Robert Bottomley. Yellow—W. H. Lincoln, Harry Widener, Gloriosum, Rohallion. Pink—Mermaid, Mrs. J. N. Gerard, Excellent, Ada Spaulding, Bride of Roses, J. R. Pitcher, Syringa, and a few darker colors, as Ed. Molyneaux, Mrs. Irving Clark, Moseman, Louis Boehmer, but the whites, yellows and pinks were in the largest numbers. It should be said that the flowers of Mrs. Alpheus Hardy, which somehow have hitherto failed to fulfill the wonderful promise of its introduction, were marvels of beauty as shown in this class, pure in color, refined in texture, perfect in form, but lacking somewhat in strength of stem. They were shown by Peter Henderson & Co.

There were a very few vases with mixed varieties, the most noticeable one, shown by J. Brydon, of Yarmouthport, Massachusetts, containing the best-grown flowers in the entire exhibition, each one being perfect in color, depth and solidity.

On Monday the competition in cut blooms was keen and the classes well filled. The first prize for fifty varieties went to E. A. Wood, West Newton, Massachusetts. These flowers were staged in glasses, with stems a foot long, showing foliage, the latter an innovation which, it was rumored, had influence with the judges. The flowers were good enough, however, to win on their merits. It is worth noting that on the next day the foliage had mostly wilted. The culture of the Chrysanthemum as a greenhouse flower seems to result in making the leaves very susceptible to change of temperature. The first prize for twenty-five flowers, and also for twelve, was taken by Dailldouze Brothers, while the first for twelve Chinese and twelve Anemone-flowered varieties went to William Tricker.

The stand of twelve contained Gloriosum, G. F. Moseman, Viviand Morel, Magicienne, Domination, Jessica, Sunflower, Excellent, Mrs. J. N. Gerard, Ivory, Ed. Molyneaux and Mermaid.

A very good show of twelve, and one of twenty-four were made by an amateur, F. T. Underhill, Oyster Bay, Long Island, who also secured the Havemeyer Cup.

Ernest Asmus captured the first prize for six blooms with Minnie Wanamaker, Mary Wheeler, W. H. Lincoln, Mermaid, Rohallion, Jessica.

The prizes for new seedlings not yet in commerce brought together a large number of promising flowers; a few of exceptional merit and great gains. The Mrs. Herman Oelrichs Cup was awarded to Thomas Griffin, gardener to Mr. A. Ladenburg, for Emily Ladenburg, a fine incurved flower, velvety red, inclining to a mahogany shade, a nearly pure self color, the reflex being very dark. If this seedling holds its present character it will be a great gain. The Mrs. Henry Clews Cup went to J. Brydon, Yarmouthport, Massachusetts, for Miss Mabel Simpkins, an incurved white in the way of Ivory, but more pointed. The Mrs. W. C. Whitney Cup, for a pink variety, was given to Mr. E. G. Hill for Edward Hatch, an extra-large globular flower with wide petals. This was also certificated. The Mrs. Edward Winslow Cup and certificate were given T. H. Spaulding for E. Hitzeroth, a large lemon-yellow flower.

The Mrs. J. F. D. Lanier Cup was taken by Pitcher & Manda with Harry May, a very solid and large bronze incurved flower, which was also certificated. The Mrs. A. Ladenburg Cup was well bestowed on Mr. T. H. Spaulding for H. F. Spaulding, a large incurved apricot variety. Very distinct. The Miss Bird Cup was also taken by Mr. Spaulding with Colonel William B. Smith, a fine yellow flower flecked with red. To Mr. Spaulding also went Mrs. Astor's Cup for the best collection of flowers not yet in commerce.

First-class certificates of merit were awarded Messrs. Pitcher & Manda for Mrs. E. D. Adams; to J. Brydon for Snowflake and Brydon, Jr.; to Robert Craig for Maud Dean, a beautiful pink flower, O. P. Barrett, a mahogany red, C. B. Whitnall and Mrs. Robert Craig. There were numerous other seedlings of more or less merit, the best of which were probably Ruth Cleveland and Lillian Russell, both pink, and well

shown in large vases by Mr. Spaulding. I. Fostermann had a large collection of new and promising varieties.

The most interesting groups of plants were those composed respectively of single masses of Puritan and M. Boyer. Some more ambitious groups emphasized the fact that a casual mixture of colors produces spottiness, and not a pleasing effect.

Table decorations were shown Thursday by Brower Brothers, Siebrecht & Wadley and Charles A. Dards. In each case very large well-grown flowers were used in lavish profusion, and the tables seemed overloaded, so that the effect was rather heavy, though somewhat toned down by artificial light.

One of the most interesting exhibits to the Chrysanthemum-fancier was Mr. T. H. Spaulding's collection of new Continental varieties, including some of S. Delaux's new early varieties, the offering of which was the most important event of the year among Chrysanthemum-fanciers. A glance over these showed many promising things. The serious feature of the introduction of so many new varieties is that so few of them are ever seen at their best or grown after a year or two.

Notes.

In Orange County, California, a single grower this year has sold 115,000 spikes of Pampas-blooms.

The estimated cost of the horticultural building for the World's Fair in Chicago, which will measure 1,000 x 230 feet, is $226,890.

The Danish citizens of Chicago are collecting funds for the erection, in Lincoln Park, of a monument to Hans Christian Andersen.

The 133 free concerts given in the parks of New York during the past summer afforded pleasure to scores of thousands of people whose opportunities for refreshment are few, and cost the city the moderate sum of $14,987.

The care taken to obtain artistic designs for public grounds in Europe is shown by the recent action of the municipality of Breslau, in Silesia, which has offered three premiums, amounting respectively to 1,500, 1,000 and 500 marks, for the best design for a small urban park.

Dr. Wallace writes in *The Garden* that when he first imported Japanese Lilies twenty years ago the bulbs were obtained with difficulty, since they were either gathered wild in the mountains, as was the case with *Lilium auratum*, or picked up one by one in Japanese gardens. Of late years, however, the Japanese have turned their attention to Lilies as an article of commerce, and bulb-farms, like those in Holland, are in successful operation and Lilies are cultivated by tens of thousands. The result of this is that the bulbs which come over are far better individually, and the varieties are greatly improved on account of careful search and selection through the numerous islands of Japan.

Circulars were recently sent by the Department of Agriculture in Victoria, Australia, to all the schools in non-metropolitan districts, asking whether their head-teachers would advocate the teaching of the elements of agriculture and horticulture. The replies showed that eighty-four per cent. of the 1,248 teachers in question were in favor of the idea, and that in thirty-four per cent. of the schools such instruction was already being given. In fifty-two cases the scholars were caring for trees or gardens on the school-grounds, and most of the children in 369 other schools were either assisting their parents in horticultural work at home or caring for garden-plots of their own. In 161 schools the pupils were in the habit of making collections of local plants and insects to be subsequently used as object-lessons in the classes.

A correspondent of the *Evening Post*, of this city, recently wrote that, in spite of the scarcity of true Spruce-gum in Vermont, resulting partly from forest-fires and partly from the increase of saw and pulp-mills, the gum-picker is still a picturesque figure in the remoter districts of the state. "The most famous one is Alonzo K. Bishop, of Woodford. In winter carrying a bag slung over his shoulder, Bishop roams all over the Green Mountains examining Spruce-trees. With a long pole ending in a sharp chisel, he detaches the gum. His journeys often take him many miles from human habitations. When the hills are snow-covered, Bishop still pursues his industry, traversing the country on snow-shoes. He sells the gum for fifty cents to $1.50 a pound, according to quality. The purest gum is transparent, or of a light amber color, filled with minute bubbles of air. Vermonters who have made new homes for themselves in the west consume a great deal of the pure article, which is sent to them by friends through the mails."

Mr. Emory E. Smith, in a paper read before the California horticultural societies, urges the gardeners of that state to give more attention to the improvement of the wild strawberries of the Pacific Coast. He considers them among the most promising of wild fruits there, and little has been done with them in the way of selection or hybridizing. The eastern varieties introduced in California need to be constantly irrigated, and it is believed that improved plants of native parentage would be better adapted to the conditions of the climate. One species, *Fragaria Californica*, often occurs in the driest and most unpromising locations. Besides this, although the eastern strawberries raised under irrigation are very large and finely colored, they are really flat and flavorless, while the native berry in that climate has a delightful sweetness and aroma. The fruiting season of the California native berries is very long. In favorable seasons in the neighborhood of San Francisco *F. Chilensis* gives fruit from January until August, and *F. Californica* in the same section will fruit until the middle of July.

A correspondent of *The Garden*, London, invites attention to *Clematis graveolens*, which he says is rarely met with outside of a botanical garden although it was introduced from Chinese Tartary half a century ago. This plant is not so scarce in American gardens, and yet it is one which should be planted more frequently here than it is. It is quite hardy and will climb to a height of ten or a dozen feet, and its single yellow flowers are an inch across and beautiful, although in no way striking. The heads of fruit, with their long silky tails, are, however, highly ornamental and will cling on the plants until the winter. It is, indeed, a matter of surprise that experimenters who are now hybridizing so many different species of plants have never taken in hand this and some of the other Clematises. With a plant which, like *C. crispa*, gives an abundance of purple flowers all through the summer and autumn months, and another, like *C. graveolens*, which also blooms for a long time, with *C. paniculata* and its abundance of white bloom in September, not to speak of *C. coccinea*, *C. integrifolia* and many more, remarkable results might be reasonably expected.

According to a recent writer in *Gartenflora* the so-called Century-plant (*Agave Americana*) was introduced into Europe during the first century after the discovery of the New World. The blooming of one specimen is recorded as occurring at Avignon in 1599, and of another at Montpelier in 1647, while even as far north as Wurtemberg a specimen was seen in the latter years of the sixteenth century, the flower-stalk of which measured over twenty-four feet in height and more than two feet in diameter. A story is told of one which, in some town of Languedoc, under the eyes of Louis XIII. and Cardinal Richelieu, threw up a flower-stem twenty-eight "hand-lengths" in height during the space of thirty-six hours, so greatly to the astonishment of the king that he decreed the "bewildering stem" should be painted by "some admirable painter." The first illustration of *Agave Americana* was published by Lobelius, who died in the same year as Shakespeare. One does not often realize, perhaps, that in the far-off days of Good Queen Bess American plants were already known in England as well as on the Continent, some of them being almost familiar objects, while as yet there were very few Americans except such as wore red skins.

Catalogues Received.

Dammann & Co., San Giovanni a Teduccio, near Naples, Italy; Wholesale Catalogue of Flower and Vegetable Seeds, Farm Seeds, Seeds of Trees and Shrubs, and Flower Bulbs.—Haage & Schmidt, Erfurt, Germany; Novelties in Flower Seeds for 1892.—Hartman Manufacturing Company, Beaver Falls, Pa.; Hartman Wire Panel Fence, Steel Picket Fence, and Wire Mats.—Harlan P. Kelsey, Linville, North Car.; Wholesale Catalogue of Native Trees, Flowering Shrubs, and Herbaceous Perennial Plants of the Southern Alleghany Mountains and the Southern States.—E. H. Krelage & Son, Haarlem, Holland; Darwin Tulips.—Thomas Meehan & Sons, Germantown, Philadelphia, Pa.; Ornamental Trees, Vines, Shrubs.—William Paul & Sons, Waltham Cross, Herts, England; New Roses.—Richard Pfau, San José de Costa Rica; Trade Catalogue of New and Rare Central American Orchids.—Reasoner Bros., Manatee, Fla.; Tropical and Semi-Tropical Fruit Plants, Economical, Medicinal and Useful Plants, Aquatics, Palms, Orchids, etc.—Frederick Roemer, Quedlinburg, Germany; Novelties in Flower Seeds for 1892.—J. C. Schmidt, Erfurt, Germany; Novelties in Flower and Vegetable Seeds.—William Stahl, Quincy, Ill.; Excelsior Spraying Outfits.—Stark Bros., Louisiana, Mo.; Wholesale Price List of Fruit, Ornamental and Evergreen Trees, Small Fruits, Shrubs and Roses.—W. Thompson, 34 and 36 Tavern Street, Ipswich, England; Flower Seeds.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, NOVEMBER 18, 1891.

TABLE OF CONTENTS.

The Report of the Secretary of Agriculture.

THE current work of the Department of Agriculture during the year that is past has been made the subject of record and comment from time to time in this journal whenever that work related to subjects which are of special interest to its readers, but the annual report of the Secretary, which has just been issued, suggests a rather more comprehensive note. We are not concerned now with the general statistics of crop-values for the year, although it is a matter of congratulation that, in spite of the unusual abundant yields, prices of agricultural products, especially of cereals and animals, have been so well sustained that the increase in the wholesale value of these products when compared with those of last year, at the prices then current, amounts to $700,000,000. The most important way in which this department can aid horticulture in its various branches is through the labors of experts who are employed by it in the various fields of study and experiment. Of course, the department can aid horticultural pursuits on their commercial side in other ways, as, for example, by furnishing accurate statistics as to crops in this and other countries, perhaps by disseminating new varieties of fruit and other plants of economic value, by the suppression of fraudulent substitutes for and the adulteration of agricultural products, and by the actual help in the extermination of plant disease and of insects which are injurious to crops. But, after all, the distribution of information which is of practical value to horticulture is a matter in which we are all primarily interested. In order to ensure work of the highest character in this field it is essential that expert talent of the first order should be employed, and it is gratifying to note that many of the divisions of this department are under the control of men who take rank with the best in the republic of science, and they have exerted an influence which has already been felt in one way or another in almost every farm and garden of the country.

It may be worth while to make brief mention of the kind of work which is being done in the department, omitting such important divisions as the Bureau of Animal Industry, and others which relate more strictly to agriculture. Under the care of the Chemical Division the manufacture of sugar has been the subject of study, and an experimental station for the production of beets of a high saccharine richness has been established in Nebraska. Scientific methods of cultivation have been pursued for the purpose of growing beets of a large sugar-content, for the production of seed, and the establishment of a race of plants which equal or excel in quality the sugar-beets of Europe. Two stations have been established in Kansas—one in order to develop a higher grade of sorghum-cane for sugar-making, and the other to illustrate the possibilities of the alcohol process for producing sugar. The investigation in regard to the adulteration of food, especially of syrups and honey, tea and coffee, has brought to light many fraudulent, and some highly deleterious practices.

In the Division of Entomology, the most interesting work has been the importation of a parasite which infests the Hessian Fly, and of another one to help in the suppression of the Cabbage worm. Both of these attempts, especially the latter one, have been highly successful, and the numbers of destructive insects have been largely reduced by their means. It is no doubt true, also, that the serious damage to the Hop-crop in New York state was prevented by an emergency bulletin distributed through the Hop-growing region, which instructed growers how to fight the Hop-plant louse in the most successful way. In the Botanical Division extensive exploration and survey have been made, especially in the Death Valley of southeastern California, and among the grasses and *Cactaceæ* of Texas, New Mexico, and Arizona; and general herbarium collections have been received from the Indian territory, northern Wisconsin, Minnesota and Florida. An experimental grass and forage station at Garden City, Kansas, has been continuing operations started three years ago for testing grasses and grains adapted to semi-arid districts; these experiments seem to show that there are forage-plants which can produce, with proper management, even under the arid conditions of western Kansas, crops not greatly inferior to those of more eastern and moister regions. The most important work of the Division of Ornithology has been a biological survey of parts of southern California and Nevada under the charge of Dr. Merriam and Mr. T. S. Palmer. The expedition was organized to determine the boundaries of the natural life zone in these regions, and to study the problems which relate to the lines which cover the distribution of life there. The determination of such a line is a matter of consequence, inasmuch as it fixes the northern limit of raisin-production and the cultivation of sub-tropical fruits.

The Division of Vegetable Pathology has been so often mentioned during the year, and its work in the treatment of Grape-diseases and Peach-yellows and the disease which is called Peach-rosette, that it only needs to be added here that a large number of New York nurserymen and fruit-growers requested that an agent from that division should be sent to Geneva to remain on the ground to investigate some diseases of the nursery stock which have grown to such an extent in that vicinity. It shows the general interest and confidence in the work of the division when it is said that about 3,000,000 fruit-trees in nurseries have been treated for leaf-blight and other diseases near Geneva, and it is largely through the aid of investigators in this department that some of the diseases can now be controlled at comparatively little expense.

In the Division of Pomology a monograph on the Wild Grape has been prepared, and a bulletin on Nuts of America is in press. Besides this there have been investigations of fibre, a study of artesian wells and underflow, the continuance of the not very reputable seed division and some comical efforts to coax a fall of rain by means of ex-

plosions. The Secretary states that he has every reason to believe that "the experiments were eminently successful so far as the production of explosion was concerned"; that is, the agents were successful in making a noise, but so far they have not been able to demonstrate that they can make rain to order. Of the Forestry Division we shall make special mention hereafter when we have the full report. It needs only to be said that this division is more efficiently conducted than it has ever been, and commands greater respect and confidence.

We are not among those who believe that the pursuits of agriculture or horticulture will languish unless they are special subjects of fostering attention on the part of the general government, and we do not sympathize with the desire that the administrative functions of the Department of Agriculture should be greatly enlarged. But it is gratifying to know that in the exercise of its legitimate activities the work of the department appears to increase in efficiency from year to year.

In an article on the Central Park, published in *Munsey's Magazine* for October, Mr. J. C. Hamilton says: "The list of statues to be found in Central Park is a long and rather curiously mixed one. Daniel Webster, Alexander Hamilton, Fitz Greene Halleck, S. F. Morse—these names are well worthy to be commemorated. It is not inappropriate that the marble image of Columbus, the discoverer of the New World, should stand in this the chief pleasure-ground of its metropolis. Nor can there be any objection to the ideal figures—that of Commerce, the cleverly modeled Indian Hunter, and the memorial to the soldiers of the Seventh Regiment who fell in the civil war. But, strangely enough, all the other statues in the park are those of foreigners. The German residents of New York presented the busts of Humboldt and Schiller. Citizens of Italian birth erected the bust of Mazzini, while sons of stern Caledonia contributed the statues of Burns and Scott. From South America came the equestrian bronze of Bolivar, and the list of monuments is completed by those of Shakespeare and Beethoven. Great men as all these worthies were, and laudable as is the desire of their fellow-countrymen to do them honor, it is somewhat unfortunate that the erection of a statue in Central Park should have come to be the recognized method of giving expression to this feeling. If the process is continued indefinitely, the park will become so thickly dotted with the monuments of foreigners that the statues of Webster and Hamilton may have to be removed to make room for the images of the deceased poets and scientists of England and France, Finland and Kamtchatka."

We do not agree with Mr. Hamilton in the feeling he expresses. We do not think it unfortunate that our foreign citizens should so often have desired to set up memorials of the great men of their own lands in the most famous pleasure-ground of the land of their adoption. We think, on the contrary, that such gifts should be welcomed as a tribute to America's hospitality, as a sign that those who seek her shores are grateful for the welcome they have received, and, while still loving the nation to which they belong by blood, have learned to love the nation which has granted them wider opportunities for happy existence. In any American city such witnesses to the strength of the tie that binds the foreign-born citizen to the community of which he now forms a part would be appropriate. But in New York, which is pre-eminently the cosmopolitan city of America, they have a double title to exist. There may be reasons why this cosmopolitan character should displease native-born New Yorkers, but its expression through public statues should not be counted among them. If such statues are as yet more numerous than those given by Americans to commemorate Americans, the fault is our own, not that of our adopted brothers.

Nor will the presence of statues of notable foreigners be without its good effect on the public, for surely it is well that Americans should be interested in the great men of other lands as well as of their own. We hope, of course, that in the future the preponderance of foreigners over Americans in the bronze and marble population of our pleasure-grounds will not be maintained. We do not want the great men of Europe alone, though we are willing enough to have these if they be worthily portrayed. Just here is the vital point in the matter. Patriotic citizens need not desire to limit the hospitality of our parks by lines of nationality so long as the works bestowed are paid for by private contribution. But they should insist upon limiting it by the lines which divide good works of art from bad ones. They should object very strongly to the presence of certain statues in the Central Park, not because they portray Burns and Walter Scott and Bolivar, but because they are unworthy, grotesque and hideous productions, distressing to the eye of taste, hurtful to the eye of interested ignorance, and injurious to the effect of the beautiful scenes amid which they stand. What the Park authorities should say to Americans and foreign-born citizens alike is: "Give us all the monuments you choose and of any persons you choose, if these were persons who in any part of the world did helpful service to humanity and were an honor to the name of man. But be sure these monuments are good in themselves and well adapted to such stations as they must occupy. It is our business to preserve the beauty of the Park, to provide for the pleasure and profit of its frequenters, not to honor this man or that, or to 'conciliate' any class of New Yorkers. It is your business, if you want to honor your compatriot and thus to exalt yourselves, to make sure that we can help you without being unfaithful to our important trust."

The Cranberry Bogs of Cape Cod.

EVERYBODY knows that Cape Cod supplies the world with its best Cranberries, and that the business of growing that fruit has transformed many hitherto worthless marshes in that region into land worth a thousand dollars an acre and upward. The word "bog," however, carries with it to few persons any suggestion of rural beauty, and yet the Cranberry Bogs of Cape Cod, apart from their economic value, make pictures of rare attractiveness at all seasons, and particularly at harvest-time. The ridges of rock and sand which form the cape would naturally be considered unpromising places to search for ponds and lakes, but not only do such ponds abound in the higher ground, but many beautiful trout streams wind down from the hills into the bay or the sea. As these streams have comparatively little fall, in the course of ages the booty which they have gathered from the hills has been deposited on either side of them until in time they are bordered by wide, marshy, bottom-lands, in which shrubs and plants and trees which love water grow in tangled luxuriance. Many of the Cranberry Bogs are made on the marshes which border these streams. It is a slow process to cut off the thick swamp-growth and grub out and burn the stumps and roots. In many places it is necessary to "turf" the whole area, as it is called—that is, to peel off one or two feet of the entire surface soil with the living and dead, but undecayed, material which has accumulated there. Then the land has to be drained, because, although the Cranberry is a half-aquatic plant and needs to be flooded with water at certain seasons, yet it must have dry and solid root-hold during the season of growth and fruitage. This means not only that dams are built across the track of the stream at intervals, but deep ditches are cut across and often around the bog to catch the drainage from the bank, so that a series of levels or sections is made, each with its dam and system of ditches, until the bottom-lands are all made ready.

After all this, the beds must be covered with sand from three to five inches deep—a laborious task where a hundred acres are to be dressed, and one which would entail an expense that could not be borne but for the happy circumstance that the material is close at hand in the banks which border the bottoms. When the smooth sanded surface has been prepared at a cost of from $250 to $1,000 an acre, long cuttings of the plants are doubled up and thrust through it at intervals of fifteen inches each way by means of a wooden paddle; these quickly root in the rich soil below. During the first summer the slender vines, which spread out in rays from each cutting, make a beautiful tracery on the white sand,

which helps to hold the warmth, to serve as a mulch, to alleviate extremes of drought and dampness, to smother weeds, to keep the plants from being lifted out by frost in winter, and to check a rampant growth and consequent unproductiveness of the plants. The next year the whole area is covered with a net-work of trailing plants and leaves, and the third year, and for no one knows how long thereafter, the whole field will be covered thickly with short upright fruit-bearing branches so full of berries in autumn that one can hardly run his fingers under them anywhere without pulling out a handful. Very beautiful in summer is this lawn-like expanse of glossy green, and it is still more beautiful as the green or white or red or dark purple fruit appears among the thick leaves. Standing on the high bank which usually borders one of these bogs, and looking across it, the level foreground, with its winding brook, stretches away for ten or a hundred rods, according to the width of the bottom, while the further boundary is usually another steep bluff, at whose base Viburnums and Wild Roses, Bayberries and Sweet Ferns are rioting, and above them are Dwarf Oaks, with a forest of Pitch Pine and Oak on the summit to form a waving sky-line as a fitting finish to the prospect. From some points, looking downward through the valley, glimpses of the sea are caught; again a gray road is seen winding up the opposite slope and finally lost in the woods, and every detail of the picture is charming.

At the harvest-time a new element of interest is added by the pickers, who camp on the bluffs and have a picnic for a month or so. For the actual work of picking, white cords are stretched across the bog about a yard apart at right angles to the straight line of the ditch, where the gathering begins. Each picker gets down on his or her knees and takes the fruit clean between two of the cords, so that the entire force of harvesters move forward, side by side, like an advancing line of battle; and as they are men, women, and children of all nationalities and various costumes, the bright colors of their head-gear and other apparel form a picturesque addition to the scene. A small harvesting party is portrayed in the picture on page 545. Pickers are usually employed in groups of a hundred or more, and as fast as a measure, which holds six quarts, is filled by one, he turns it in and receives a dime for it. It is not an uncommon thing for a superintendent of a bog to receive from Boston by express several thousand dollars in ten-cent pieces to be distributed among the pickers for a day's work. Expert pickers sometimes make five dollars a day, and when they use machines, with which the fruit is stripped off by handfuls, they earn considerably more.

The Cranberry Bogs of Cape Cod furnish a striking example of what may be accomplished by specialization in economic horticulture. It has taken long years of experiment and practice to determine what the Cranberry-plant needed in order to reach its highest possible productiveness, and now, with intelligent preparation and enrichment of the soil, close attention to every cultural detail, constant watchfulness against weeds and insects, frosts and fungi, a yield of 150 barrels of solid, evenly colored berries to the acre is not surprising. How thickly the fruit must hang on the vines which yield such a crop may be imagined, if it is remembered that this means a barrel of berries on every sixteen feet square.

Entomological.

A New Herbarium Pest.

IN the year 1890 a number of small Geometrid larvæ, recalling somewhat in appearance those of the genus Aplodes, were found by the botanist of the Department of Agriculture infesting certain dried plants in the department herbarium, and especially those which had been received from Mexico and lower California from Dr. Edward Palmer. Dr. J. N. Rose first observed it in January, 1890, on plants from La Paz, but it was still more abundant in a collection from the State of Colonna, Mexico, made in the beginning of the present year. Being referred to me for identification, I became much interested in the matter, as it was the first case that had come under my notice of a Geometrid larva feeding upon dried plants. The matter acquired additional interest also because the species was evidently new and there was danger of its being spread through distribution into other parts of the world. I therefore took steps to watch the course of the insect and rear it to the imago state. This was done some time ago, and I have had drawings of the different stages finished for some time, and call attention to the matter now because the trouble has grown in the department herbarium and it is of sufficient importance to put on record. The first moth emerged October 22, 1890, and others were subsequently reared from material received from time to time from the department herbarium. While the larva was first discovered, as stated, on Mexican plants, it has not confined its work to such plants, but has spread to others and is by far the most destructive herbarium pest which the botanists in charge have to deal with. Plants of the genus Coulterella, for example, which were sent by Dr. Rose to Dr. O. Hoffman in Berlin, have been so injured that but one perfect flower remained; yet, according to the observations of Mr. L. H. Dewey, in overhauling the herbarium, the insect's work is still mostly confined to south-western plants. Next to these from Mexico those from California suffer most. In some cases eastern plants have not been attacked, even when associated with western, but in one case, at least, that of *Rhus Toxicodendron*, eastern plants have been extensively infested.

The larvæ feed on the flowers and also to some extent on the leaves. More rarely they feed on the hard fruits and seeds. The following list, prepared by Mr. Dewey, of the plants upon which the larvæ had been found prior to its work on *R. toxicodendron*, will be of interest in this connection:

SPECIES.	LOCALITY.
Ptelea aptera	Southern California.
Ceanothus sorediatus	Southern California.
Dalea Seemanii	Southern California.
Lupinus coccinius	Arizona.
Purshia tridentata	Arizona.
Prunus demissa	Southern California.
Ribes viburnifolia	Southern California.
**Epilobium angustifolium*	Eastern Massachusetts.
Arctostaphyllos oppositifolium	Southern California.
Eriodictyon glutinosa	Southern California.
Cilia Rusbyi	Arizona.
Pentstemon secundiflorus	Arizona.
Audibertia Clevelandii	Southern California.
Dracocephalum parviflorum	Arizona.
Salvia ballotæflora	Arizona.

The eggs are laid upon the plants or on any surrounding object. They are but slightly attached, bluntly ovoid, 0.3mm. wide and 0.4mm. long. They are steel-gray in color, the shell white with faint iridescence when empty, and faintly and irregularly reticulate. The duration of the larval period has not been determined. Growth, however, is very slow, and the period from the egg to the full larval development is variable. The larval life extends in some cases certainly over a period of three months. When full-grown the larvæ attain a length, extended, of 8mm.; contracted when disturbed or at rest of 5 to 6mm. Whenever disturbed they contract

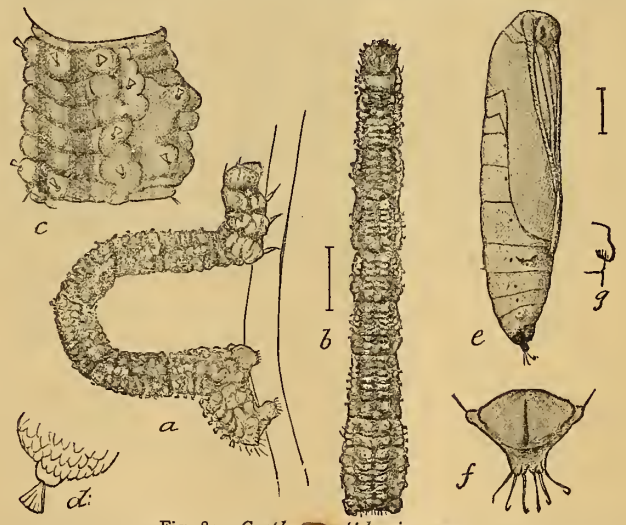

Fig. 84.—*Carphosiara ptelearia*, n. sp.

a, larva, side view; *b*, same, dorsal view—enlarged; *c*, side view of a single segment still more enlarged; *d*, a single tubercle of same—still more enlarged; *e*, pupa; *f*, cremaster of pupa—enlarged.

considerably and become rigid and motionless. The larva is shown in characteristic positions in the accompanying illustration (Fig. 84 *a*). It is dull grayish in color, varying considerably in different specimens. On reaching full growth the larva constructs a cocoon of loose white silk, forming an irregular open net-work, as shown in Fig. 84 *b*. The cocoon is usually placed in a fold of the leaf or is otherwise protected by the plant, and is occasionally partly covered with bits of

* *E. angustifolium* grows in the west, but mostly in northern California and Oregon.

anthers or fragments of leaves. In shape it is irregularly ovoid and is about 6mm. by 3.5mm. The change to pupa takes place about three days after the cocoon is completed, and the moth usually appears eighteen to twenty days after pupation. The pupa is 5mm. in length, somewhat robust, and is slightly yellowish in color, with sutures and tip brownish, the latter being quite dark. A peculiar pad or flap-like projection occurs on the side of the fifth abdominal joint (*e* and *g*). The cremaster is produced, notched at the tip and armed with six long, hooked hairs or spines (Fig. 84 *f*). The adult insect is about 5mm. long, and expands from 13 to 14mm. The general color is grayish yellow, inclining to saffron, the primaries being somewhat darker. The wings are marked (Fig. 85) with transverse bands of dusky shade, and each wing has a discal spot. The head is dark brown, with the antennæ, including a large spot on the vertex, yellowish. The under surface is nearly concolorous, the dark bands being less distinct, and the discal spot more intensified. The fringes are concolorous with the ground color and with black dots beyond the veins.

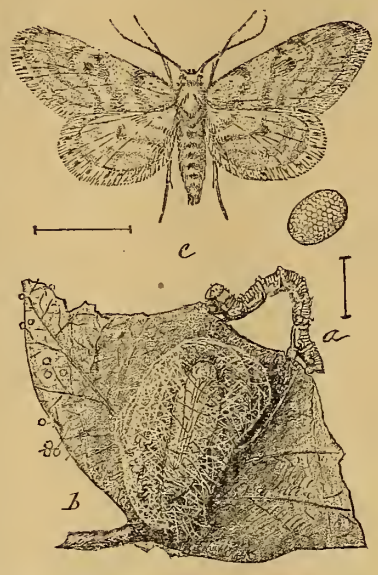

Fig. 85.—*Carphoxera ptelearia*, n. sp. *a*, larva in natural position; *b*, cocoon on dry leaf; *c*, moth, with egg at its lower right-hand corner. All enlarged.

This insect has become a source of positive alarm in the department herbarium on account of its rapid multiplication and the harm it occasions. It behooves botanists to be on the lookout for it and to adopt such measures as will ensure immunity from it, if dry specimens are being received from Mexico and the southwest, or from herbaria in which it is known to occur. The custom of poisoning dried plants with corrosive sublimate to protect them from various enemies, such as book-mites, Psoci, etc., should give immunity from the attacks of this insect if the poison has been thoroughly applied. If to the corrosive sublimate a quantity of arsenic is added the protection will be more effectual. I would also recommend, as very useful in disinfecting herbaria of this and other pests, an air-tight quarantine box of zinc or galvanized iron in which the plants may be temporarily placed and submitted to the fumes of bisulphide of carbon, which are very sure to destroy all insect life. Effective steps have already been taken to prevent the sending out from the department of any infested specimens in future.

The fact that this insect has appeared in dry plants from the comparatively arid western regions may furnish a clue to its original habit. It is presumable that it normally feeds on the dead or dried plants of Mexico and adjacent arid regions, and that it has simply adapted itself to the somewhat similar conditions prevailing in herbaria.

This is the first true Geometrid, so far as I know, recorded as feeding on dry and dead vegetation. In the Pyralidina a number of species are known to be not only truly carnivorous, feeding on other insects, but also to feed upon grass and rejectamenta as well as dead leaves. Some Tineina are also known to have similar habits, while in the Deltoid group of the Noctuids several genera are known to feed on dead leaves.

The illustrations, which have been prepared for *Insect Life*, are used by permission of the Honorable Edwin Willits, Assistant Secretary of Agriculture.

Washington, D. C. *C. V. Riley.*

New or Little-known Plants.

New Orchids.

Catasetum Naso, Lindl.—The female flower of this singular species has now appeared in the Kew collection on a plant which has produced males only in former years. It is about the size of those of the other sex, the color light green, with a narrow purple margin to the lip.—*Gardeners' Chronicle*, August 29th, p. 242.

Lælia-Cattleya × Nysa, Hort.—A hybrid raised in the collection of Messrs. James Veitch & Sons, of Chelsea, between *Cattleya gigas* and *Lælia crispa*. The flower is pale lilac, with the front of the lip deep crimson. It was exhibited at a meeting of the Royal Horticultural Society on August 25th last.—*Gardeners' Chronicle*, August 29th, p. 254.

Neobenthamia gracilis, Rolfe.—A very interesting new genus of Orchids, allied to Bromheadia, which flowered at Kew in February, 1890. The plant is a native of tropical Africa, and was sent from Zanzibar, by Sir John Kirk, in 1884. It is of a peculiar straggling habit, as if it grew among bushes and availed itself of their support. The leaves are distichous, drooping, and about six inches long, and the short racemes are borne at the ends of the branches. The flowers are white, the lip with a yellow midline, and a row of rosy purple spots on either side.—*Gardeners' Chronicle*, September 5th, pp. 272, 273, fig. 33.

Cypripedium × Macfalanei, Kränzlin.—A hybrid raised in the collection of Messrs. F. Sander & Co., of St. Albans, from *C.* × *calophyllum* (itself a hybrid from *C. barbatum* and *C. venustum*), fertilized with the pollen of *C. Spicerianum*. It bears much resemblance to the pollen parent, with some characters derived from the mother plant in the petals and leaf.—*Gardeners' Chronicle*, September 12th, p. 300.

Kew. *R. A. Rolfe.*

Plant Notes.

Some Recent Portraits.

In the *Gardeners' Chronicle* for October 3d the cones and flowers of the noble Himalayan Fir (*Abies Webbiana*) are figured. This tree, which is remarkable for the silvery whiteness of the lower surface of the leaves and for its great dark purple cones, succeeds fairly well in some of the southern counties of England. It seems perfectly at home in many gardens on the shores of the Italian lakes, and there are several flourishing specimens in California. Unfortunately, it will not thrive in the eastern states, although possibly in some parts of Georgia and Carolina it will be able to support our eastern climate.

The October 1st issue of the *Revue Horticole* contains a colored plate of a fruiting branch of *Ficus stipulata*. This is the plant which is found in almost every greenhouse under the name of *F. repens*, where it generally only reaches its juvenile state when it is a vine with small leaves, climbing by rootlets developed from the slender stems. At the end of several years, when it becomes adult, it changes its character entirely and develops robust erect branches, producing large, oval, oblong, obtuse, petioled leaves and violet-colored figs the size of the ordinary edible fig. The fruit is produced sparingly, although it seems that in the south of France, in the open air, it is not an unusual occurrence to find the plant in its adult state, and more or less covered with fruit.

F. stipulata has been known in gardens for more than a hundred years. It is a native of Japan and southern China, extending at least as far south as Hong Kong, and it is probable, therefore, that it will succeed in some parts of the southern states, and certainly in southern California. It is needless to say that in its young state it is one of the very best of all evergreen climbers to cover the back walls and other waste places in greenhouses which it is desirable to clothe with vegetation. The fruit is not edible.

Foreign Correspondence.

London Letter.

Cattleya Warocqueana.—Last year I stated in a letter to Garden and Forest that this Cattleya, which had been introduced by M. Linden, and described by Mr. Rolfe, was a form of *C. Gaskelliana*. This statement produced a protest from M. Lucien Linden, who declared that in the opinion of competent judges there was no difference between his *C. Warocqueana* and the autumn-flowering *C. labiata*. At that time I shared the view of many authorities here with regard to this Cattleya, namely, that while it was

of quite exceptional value as a garden plant, it could not be considered identical with *C. labiata vera*. I was wrong. M. Linden has sent to London this week no less than two hundred plants in flower of his *C. Warocqueana*, to be sold by auction after being exhibited in the rooms of Messrs. Protheroe & Morris, Cheapside. Among them there were many which might have been mistaken for the form of *C. labiata*, previously represented in English collections by less than a dozen plants, all supposed to be from the original plant described by Lindley. There were also among M. Linden's plants some which, while possessing all the characteristics of that species, were even superior to it in size of bloom and depth of color. The plants sold well, realizing from twenty guineas to one guinea each. M. Linden deserves all the credit of being the first to discover the whereabouts and to introduce living plants of Lindley's *C. labiata vera*. It follows from there being so many plants of this Cattleya recently imported, first by M. Linden and again lately by Mr. Sander, that there are now thousands of it in cultivation, and consequently the plants which two years ago were worth fifty guineas are now worth perhaps ten shillings. The Cattleya is, however, a most valuable plant for gardens, as it flowers at a time when flowers of any kind are not too abundant, namely, October and November. One cannot, therefore, very well have too many plants of it.

Cochleoda Noezliana.—Several plants in flower and a large number of newly imported pieces of this new and pretty Orchid were included in the sale at Messrs. Protheroe & Morris' rooms. The flowers are borne on arching spikes, similar in size and form to those of *C.* (*mesospinidium*) *vulcanicum*, but of thicker texture and colored orange, almost the same shade as the flowers of *Ada aurantiaca*. I am told that this little Orchid is very easily grown in a cool, moist house, and that it will flower regularly and profusely.

Cattleya Bowringiana.—This is proving itself a first-rate plant, probably the best of the section to which it belongs. It is freer in the production of flowers and more variable in color than its near ally, *C. Skinneri*. I saw this week in the nursery of Messrs. F. Sander & Co., St. Albans, a large number of plants of this Cattleya in flower. Some of the spikes bore sixteen flowers, and I was told of one plant which had borne three spikes, two bearing seventeen flowers and one with eighteen. The color of some of the flowers is deep rosy mauve, others are lilac, others rosy crimson. This variation in color extends to the labellum, some having a large maroon blotch, others a paler one, others a whitish margin, and others no blotch at all, but wholly white inside the tube. The season of flowering may be made to extend over several months in autumn and early winter. Moreover, the plants grow well in an ordinary greenhouse temperature.

Dendrobium Phalænopsis.—A considerable number of the newly imported plants of this Dendrobe are now flowering at St. Albans. So far every one has proved to be a form of the plant represented in the *Botanical Magazine*, and many of them have large and richly colored flowers.

Fig. 86.—A Cranberry-field on Cape Cod, Massachusetts.—See page 542.

Miltonia vexillaria, var. Sanderiana.—This is a new and well-marked variety which is now in flower at St. Albans. It is by far the handsomest of the many forms of this Miltonia, the flowers being three inches across, of good substance, and colored bright rosy mauve, with a large triangular fretted blotch of rich maroon on the labellum. This blotch is the distinguishing feature of the flower, as it is an inch broad at the base of the labellum and is narrowed to a point at the sinus. Mr. Sander obtained this variety from a native collector in Colombia, to whom he paid fifty guineas for it. Should it prove to be an autumn-flowering one under cultivation its value will be considerably enhanced.

Darwin Tulips.—This is a new and beautiful race of Tulips which has lately been brought into prominent notice by Messrs. Krelage, of Holland. As Darwin Tulips are almost certain to become favorite garden-plants, their

colors being so exquisite and varied, and their forms elegant, a few words with regard to their origin may be interesting to bulb-growers in America. I have seen these Tulips in Messrs. Krelages' nurseries, and have heard from the venerable chief of the firm himself the history of what he considers to be the most beautiful of all races of Tulips. The name of the race has been given by Messrs. Krelage to commemorate the work of Charles Darwin in the elucidation of the subject of variation and cross-breeding in the vegetable kingdom.

It appears that about thirty years ago a Dutch bulb-grower set to work to produce from a selection of the best breeders of Tulips a fixed race which should differ from those then known. The plants he had to operate upon had been in the possession of his family over a century. About six years ago the Messrs. Krelage purchased the whole of this ancient collection and transferred it to their nursery at Haarlem, where the process of selection and propagation of the best varieties was pushed on in earnest. The result is now a magnificent collection of bulbs ready for distribution by the Haarlem firm. There are hundreds of kinds, besides many which have not been named. The cheapest mixed bulbs will be sold at about thirty shillings per hundred, while the choicest named sorts are priced at from five to forty shillings each. At Kew there was a small collection of Darwin Tulips in one of the flower-beds last spring. They flowered well, showed great variety in color, and were much admired. They appear to be strong in constitution and to grow vigorously in ordinary garden-soil.

Autumn Leaves.—An exhibition of the most conspicuous among those deciduous trees and shrubs whose leaves assume bright colors before falling in autumn was a special feature of the last meeting of the Royal Horticultural Society. The plants exhibited, as well as the excellent lecture delivered by Mr. H. Veitch, only emphasized what I said in a letter about this time last year, namely, that beautiful leaf-pictures might be produced by means of autumn tints which would equal in effect the best of pictures produced by flowers. The weather in autumn has considerable influence upon the coloration of leaves, and owing to the absence of frost and prevalence of heavy rains this autumn the leaves are not as bright as usual. Still there are plenty of beautiful leaf-pictures in the garden now. Oaks, Rhus, Vitis, Cratægus, Ribes, Liquidambar Nyssa, Acers and many others are aflame with color. Mr. Veitch drew attention to the beauty of all these, and also pointed out that garden-makers, as a rule, failed almost entirely to take these plants into account. The best of the autumn-colored trees and shrubs in cultivation in England are either of Japanese or North American origin. The rich colors of the leaves of these plants as exhibited invested them with a new interest for those who had previously paid no attention to the subject of autumn-colored foliage available for outdoor effects.

New Chrysanthemums.—The following have received certificates, this week from the Royal Horticultural Society: M. R. Bahaunt—a large incurved variety, broad in petal, full, and of a rich red-brown color; Louis Boehmer—already well known in America. So far as English experience with it goes, this variety is much superior to its older rival, Mrs. A. Hardy, which has proved one of the very worst growers in England; R. Smith—a bright-colored sport from Dr. Sharp, distinct in its larger flowers and bright brown-crimson shade; Mrs. Nisbet—a dwarf reflexed variety scarcely three feet high, with rich claret-crimson flowers, broad petaled and suggesting the flowers of Madame C. Audiguier; William Wells—a bright primrose-colored sport from Madame B. Pigmy.

Aristolochia gigas.—This is the correct name for the plant figured last year in Garden and Forest as *A. grandiflora* and noted this year in almost all the English garden periodicals under the same name. The Kew plant was obtained from Mr. Sturtevant, of Bordentown, New Jersey, last year, and it has been a great attraction here since the beginning of August, having produced altogether about fifty flowers, and there are more to come. The largest measured eighteen inches by twenty-two inches, with a tail three feet long. It appears that Lindley figured and described *A. gigas* in the *Botanical Register* in 1842 from a plant introduced from Guatemala to Chiswick, where it flowered in 1841. In 1848 a second figure of it was published in the *Botanical Magazine* (t. 4368-9) under the name of *A. grandiflora*, made from a plant supposed to have come from Jamaica. Herein lay the mistake. So far as can be made out at Kew now Lindley's *A. gigas* has not been found wild in Jamaica or anywhere in the West Indies, and if Purdie found the plant figured in the *Botanical Magazine* in Jamaica it must have been either cultivated or introduced. The species common in Jamaica and the West Indies is *A. grandiflora* true. This is very similar to if not the same as *A. fœtens*, and has comparatively small flowers, certainly less than a quarter the size of Mr. Sturtevant's plant; it also differs in the length and form of the tube, as well as in other structural characters. *A. gigas*, then, must stand for the Guatemalan plant. But this form of it, for which we are indebted to Mr. Sturtevant, is so very much larger than that figured in the places above referred to, that, for horticultural purposes at any rate, it ought to have a distinctive name. We propose, therefore, to call it *A. gigas*, var. *Sturtevanti*.

Kew. *W. Watson.*

Cultural Department.

About Apples.

A NATURAL fault in most men of limited experience is to dogmatize by assuming that their experience covers the whole ground. But in any art having to do with plant-growth and culture the variation of a few degrees of latitude, or even of longitude, on the American continent at least, will expose facts as hard and unyielding as rocks, and over which a cart-load of theory can easily be upset. I have been a fruit-grower and observer in the south and west, and in the north and east, long enough to learn that an even moderate change of conditions will modify fundamentally the whole situation and demand, often, a complete reversal of practice.

As an illustration of this truth it may be stated that while there is no better locality on this continent for the propagation of the Apple-tree than north-western New York, and while there are no more experienced nurserymen than those of that region in matters of which they have full cognizance, yet there is nothing which excites more bitter scorn among practical orchardists in northern New England and the Canadian provinces than the mention of New York trees. On the other hand, I have never yet met more than one New York nurseryman who did not stand ready to overwhelm the very mention of the iron-clad varieties with impatient ridicule. I have myself, at least temporarily, lost credit at pomological meetings in northern New England by saying that I am as willing to plant New York trees as any, if they are of the right variety. But when I went on to ask exclaiming doubters whether they thought a New York grown Oldenburgh would not stand the winters of northern New England, they were compelled to reflect a little. Some would say that New York trees are grown too fast by high manuring, and the wood is tender and pithy; but when it came to close questions they "did not know but Russians and Crabs grown in New York might do well enough."

Now, in my own experience I have never found that strong-growing trees, well cultivated and attended to on well-enriched land, were any more likely to fail, when properly set out and cultivated, than the gnarled and scrubby trees of local origin. With me, strong, vigorous trees (of the right kinds) reaching the height of four or five feet at three years, and then set out in rich soil and well cared for, have continued to grow on and, contrary to much prophesying, come soon and profusely to bearing, and remain healthy after many years. My orchards have been visited by many experts who can testify to these facts.

There is, at present, a controversy on the subject of grafting the Apple upon what are called "piece-roots"; and a western nursery which claims to make a specialty of whole-root grafts sends me a circular in which very eminent pomologists—in fact I may say the most eminent, since President Berckmans and Vice-President Lyon of our Continental Pomological Society are among them—give unqualified assent to the practice.

So do I, with some qualifications which experience demands. There are certainly no objections to whole-root grafts—if you can get them. So far as I know they are not really made; for although a seedling may be used for each graft it is always more or less trimmed. The question is also complicated as regards the iron-clad varieties, by the fact that these root-grafts must be deeply planted to protect them from winter-killing; and it is widely believed, especially in the north-central states and Canada, that it is better to use a short root and a long cion—the grafts in nursery and the trees in orchard being deeply planted in order to get roots from the cion. That this can be done with the Apple, as it is done with the Pear on Quince roots, is unquestionable; and I should ask those gentlemen who prescribe piece-roots whether they have not seen many vigorous old standard Pear-trees which were originally dwarfs on Quince, but are now on roots of their own. I can point to a whole orchard of such trees, some forty years old, in the city of Gardiner, Maine.

President Berckmans will find no man of experience taking issue with his statement that in nurseries and orchards crown-grafts will, as a rule, take the lead in growth, other things being equal. The more root there is to a root-graft at first (if the work is well done) the more vigorous will be its growth in nursery; and if the tree is properly transplanted this lead in the nursery will be maintained in the orchard. I have grown nearly all the trees in my orchards from the root-graft, and such has been my experience. But it is also my experience that grafts with smaller roots make quite as thrifty trees, and the difference seen in the nursery does not increase in the orchard. I have always, when root-grafting, taken pains to choose stock and cion of equal size, so that there should be a chance for union all around; and I would like to suggest that a poor growth upon a medium or small root is as likely (and indeed much more likely) to be due to a bad fit between root and cion than to the mere size of the root. It should be understood that all the stocks should be carefully assorted at digging and all weaklings rejected. Difference in the size of healthy roots, within limits, is due chiefly to a more or less good chance in the seed-bed. Even with careful thinning this will be true. If all these points have due and careful attention a moderate difference in the size of roots makes no practical difference in the size and productiveness of the orchard tree.

I think there is one fallacy which has fixed itself in the minds of some very intelligent men. It is that there is something specially vital in the point of junction between root and stem. Some seem to think it as vital as the heart in an animal, or something analogous to it, but I have no experience to confirm that idea, and a great deal against it. A tree may be planted with this point of union considerably above or below the surface without injury. If a root-graft is made with a cion a foot long, and set out so that only a few inches is above ground, this neck will be formed at the surface and the young tree have a perfectly normal appearance afterward. As a reverse experience I may mention that several years ago I noticed that a number of Apple-seedlings which had been left in the ground over winter had been thrown out so that about three inches of the root was above the surface. As an experiment I merely trod the earth firmly to the plants as they stood. They grew and formed perfect new necks at the surface, while the portion of root above ground assumed the color and look of the wood above. The same thing happened at the same time to a young Russian Pear-tree, which was also left untouched. It made a growth last season of over four feet on the main shoot, and the new point of junction has the normal appearance. I may add that in experimenting with a collection of root-grafted Siberian Crab-hybrids some fifteen years ago I found one variety that absolutely refused to unite with the root on which it was spliced; but several of these sent out roots from the bottom of the cion and made a vigorous growth of top, forming perfect and well-balanced trees, which I have often shown to visitors as specimens of Apple-trees grown from cuttings.

Newport, Vt. *T. H. Hoskins.*

The Propagation of Ferns.

WHEN Ferns are propagated by means of spores, which is the usual way, the first matter to be attended to is the collection of the spores, and this requires the exercise of some judgment, for if the fronds are cut before the spores begin to ripen they will be of little value. The usual practice is to collect the fronds as soon as a majority of the fruit-dots appear to be opening. The fronds should then be wrapped up in a clean paper and put away in a warm, dry place for a week or two, after which it will be found that many of the spores have been shed from the sporangia into the paper. In order to secure the remaining spores, the fronds may be rubbed between the hands and then passed through a very fine sieve (a No. 40 mesh answers the purpose very well), to free the spores from the fragments of the leaf. If not sown immediately, the best method of storing the spores is to put them in small vials, such as are used for homœopathic medicines, and in which they may be tightly corked and put away in a dry place for future use.

Where Ferns are raised in large quantities for trade purposes the sowing of the spores is usually done during the fall and early winter, so that the seedlings may be ready for potting off in the spring or summer, the majority of such Ferns being sold in small pots within a year or eighteen months from the time the seed was sown. This raising of crops of seedlings at certain seasons is not, however, so necessary in private establishments, and consequently the spores may be sown at the convenience of the cultivator, though it should be borne in mind that in most cases fresh spores are preferable to those that have been stored for a long time.

The compost best suited for Fern spores in general is an open mixture consisting of equal portions of peat and loam, with enough sand to keep it porous, the various ingredients being passed through a fine sieve. Either pots or pans may be used to contain the soil, but in either case abundant drainage material should be provided, and about five or six-inch pots, or pans six inches square, are convenient sizes. The pots should be filled firmly with the soil and thoroughly watered, after which the spores should be thinly scattered on the damp surface of the soil and should not be covered. The seed-pots should then be placed in a propagating frame or covered with panes of glass, to prevent the soil from drying out rapidly, but in either case should be ventilated each morning, so as to avoid too great an accumulation of moisture on the glass.

The time required for germination varies with different Ferns. Some species of Pteris are among the quickest to germinate, and the young plants often appear in a week or ten days. As soon as this growth becomes visible more air should be given to the seed-pots or the minuter plants may be attacked by fungus, and the prothalli are so tender and so close together that it is exceedingly hard to arrest any such disease. It is under such conditions as these that the wisdom of sowing in small vessels is seen, from the fact that when the prothalli begin to "damp off," the entire contents of the seed-pot is often lost. Probably the best method of checking such disease is to give plenty of air to the seedlings and to keep the affected pots rather dry. I have tried sulphur, lime-water, sulphate of lime, dry sand, and some other remedies that have been suggested for this fungus from time to time, but with little success, and the cultural care above recommended has proved the most satisfactory remedy.

As soon as the seedlings are ready to throw up their first leaf they may be pricked out into other pots or pans, transferring them from one pot to the other in small patches or clumps, and as soon as these are large enough to handle they may be divided again into single plants and thus potted into two-inch pots. After potting, the seedlings should be kept moist and well shaded until they have begun to root afresh, and after this the culture of most species is easy. As new varieties are frequently found among Fern-seedlings additional interest is thus given to what is at all times a most fascinating branch of the gardener's art.

Holmesburg, Pa. *W. H. Taplin.*

Thorpe's Pedigree Seedling Chrysanthemums.

IT has often been doubted, even by competent cultivators, whether it be possible to hybridize the Chrysanthemum with any certainty. Not only are the composite flowers with difficulty preserved from the visits of the fly prevalent during their season of bloom, but they are also likely to be self-fertilized. Those who have watched carefully the productions of a few of our most noted growers can have had little doubt that they at least were working on lines of some certainty. It is unnecessary to say to the readers of Garden and Forest that John Thorpe is one of our most ingenious and accomplished hybridizers, and those who have had some hint as to his operations on the Chrysanthemum were not surprised to see his offering early in the year of a set of plants with parentage given. This was a notable event, it being the first time that any grower has offered plants with male and female pedigrees. At the most we have been given one parent, probably often determined by the shape of the seedling.

Mr. Thorpe's seedlings of the year were produced in an endeavor to supply early-blooming plants with the good qualities as to foliage of Gloriosum, Nichols (October Beauty), together with some range of color, and, if possible, of more pre-

cocious habit, for which purpose Madame Desgranges was used in some cases. The fine strong plants with which Mr. Thorpe favored me early in the year were planted out on the north side of my Chrysanthemum plot, where they had plentiful supply of light, without being too severely exposed to the sun, which is usually so trying to varieties of this section. This location was given, however, for convenience, not from any doubt as to their hardiness, and was somewhat detrimental to their early flowering, and the varieties this season were all behind the dates given by Mr. Thorpe. The plants were grown on with ordinary care given to the other plants, but were allowed to carry all the wood made by their various breaks. Mr. William Piercy, of London, who has been the chief propagandist of the early-blooming Chrysanthemum, says that an early variety to be of value must be a free bloomer and capable of throwing flowers of character and well formed without disbudding.

I have grown Mr. Thorpe's plants on this plan with very satisfactory results in most cases. The indications of the plants, except in one case, noted later, all point without doubt to the parentage as given. Salvator (Gloriosum × Roi des Precoces) is a dwarf stocky grower, very free blooming, the entire head of the plant being covered with good reflexed flowers of a red-bronze shade—a fine variety. Bolero (Nichols × Gloriosum) is a rather tall, free-growing variety, with good foliage but rather weak stems. It was covered with a mass of pleasing chrome-yellow flowers. Eurus (Gloriosum × Roi des Precoces) seems intermediate in habit between the two former varieties, and has bronze flowers of a lighter shade than Salvator. In Sallie McClelland (Nichols × Desgranges) I fail to see any indications of Desgranges blood. It seems a counterpart of Lady Selborne, and possibly my plant may be a rogue. Firenzi, Russell and Stratmeath are Desgranges seedlings, and may be of some value where Madame Desgranges does well, as it does not in my garden. The crosses of this variety do not seem to me to have produced results which will be generally useful in gardens, though in some latitudes they may prove valuable, but probably only where the parent does well. Garden and Forest has already noted the abundance of seedlings to be seen at Mr. Thorpe's place, and it is to be regretted that his labors as Chief of the Bureau of Horticulture will interrupt the introduction of other promising varieties for a time. However, we are likely to hear much of the early Chrysanthemum another season, when S. Delaux's new varieties are disseminated, with a promise of Chrysanthemums all summer, which would seem to be tiresome.

Elizabeth, N. J. *J. N. Gerard.*

Cleome pungens.—Several inquiries regarding this plant have reached me during the past season. It is a soft-wooded perennial, whose branching stems, beset with numerous spines, are from three to four feet high, and thickly furnished with large dark green digitate leaves, arranged alternately and covered with glutinous hairs. The flowers are borne in compact terminal racemes of twenty or more. The corolla, consisting of four spathulate or obovate petals, measures two inches in diameter, and is either white or rose-colored. An elegant appearance is given to the inflorescence by the dark purplish color and divaricate arrangement of the long slender pistils and stamens. The white-flowered form of *C. pungens*, under the name of *C. spinosa*, was cultivated as long ago as Miller's time, having been introduced into England from the West Indies about 1731. The other variety is a native of the same region, but it was not known in gardens until 1812. Both plants were to be met with occasionally in the greenhouses of British gardens about ten years since. A few years later they disappeared almost totally, except in the case of botanical institutions. Now the red-flowered form seems to be commonly cultivated in this country, some one having been sufficiently thoughtful or speculative to distribute a quantity of its seeds a year or two ago. It is well liked, judging from the comments of several, and is likely to attain some degree of popularity. In this climate, however, it should be treated as an annual. It blooms profusely from seed the first year, and the flowering season extends from July till the latter part of September. Mr. W. Miller, of Groton, Massachusetts, has had much success with this plant, and he says the seeds were sown on the greenhouse-bench on the 1st of June, the day they were received; the seedlings transferred to shallow boxes June 18th, and planted in the open ground July 25th, coming into flower August 18th. That was a good performance, but a longer season of bloom would have been secured by sowing in April or May, and getting the plants into the ground early in June. The seeds ripen freely, and both varieties succeed with equal satisfaction under the same treatment.

Sedum Sieboldii.—This is a pretty little plant and one that is, fortunately, common in gardens. It is generally grown in pots or baskets and used in the adornment of greenhouses. The decumbent habit of the stems renders it exceedingly effective in small pots placed along the edges of the stages, and that also makes it so valuable in suspended baskets. It is an excellent plant for the house, thriving well in the dry atmosphere of inhabited rooms. But, admirable as it is under these conditions, the chief merit of the plant is found in the hardiness of constitution which fits it for the herbaceous garden. The opinion that it requires the protection of a greenhouse in winter seems to prevail, even in the comparatively mild climate of England. That this is erroneous has been amply demonstrated in our rock garden, where a specimen has safely weathered the severest storms of several seasons. The slender, simple stems are from nine to twelve inches in length, and they are bent flat to the earth by the weight of the flowers and succulent foliage. The glaucous leaves, tipped with reddish purple, are round, tapering to a wedge-shaped base, and arranged in close whorls of three. The flowers, borne in dense, terminal, broad, compressed clusters, are of a bright rosy purple color, and remain perfect on the plant at least six weeks. Add to this the fact that the flowering season extends from early October until late in November, and we have an unusual collection of good qualities. In this locality we have already had several nights of frost which may be safely called severe for the time of year, but the flowers of this Sedum still hold their own and are as bright and perfect as ever they were. The plant is a native of Japan, whence it was introduced in 1838. There is a variety (*S. Sieboldii variegata*) distinguishable from the type by a large creamy white blotch in the centre of each leaf. Both plants do well in slightly raised sites of the rockery. They look best when planted so that their branches may spread downward over the sides of neighboring stones, and are easily propagated by division.

Tritonia crocosmiflora.—That celebrated hybridizer of plants, Monsieur Lemoine, of Nancy, France, obtained a cross between *Crocosmia* (*Tritonia*) *aurea* and *Tritonia* (*Montbretia*) *Pottsii* some years ago. The genera Crocosmia, Tritonia and Montbretia are close allies, and were then considered quite distinct, but Montbretia has since been incorporated with Tritonia. The names are yet exchanged indiscriminately among gardeners. The hybrid was called *Montbretia crocosmiflora*, and is still widely known under that name. M. Lemoine has been successful in obtaining numerous other forms of Tritonia, which, judging from the comments of European observers, are likely to occupy a prominent place among hardy plants. *T. crocosmiflora* is, so far as I am aware, the only hybrid yet planted in this country, and with rare exceptions its use is confined to those who can supply greenhouse cultivation. Its usefulness as a subject for pot culture is beyond dispute, but as the plant is hardy, under certain conditions it would prove useful to many who do not possess a greenhouse. The doubt which has existed regarding its hardiness may have deterred many who admire it from acquiring a stock for outdoor planting, but there is no reason why it should not be extensively cultivated in every garden from Boston to San Francisco. I am not prepared to say that it will prove entirely hardy when planted in flat beds of rich soil, as seems to be the practice in some parts of Europe. The large bulbs produced under such conditions migh prove to be too tender for this climate. But in a somewhat dry position, with soil of medium quality, the results are eminently satisfactory. That, at least, has been the experience here, and surely there are many other gardens throughout the country in which it may be repeated. *T. crocosmiflora* is about intermediate in character between the two parents. The narrow, sword-shaped leaves, sheathing at the base, are from twelve to eighteen inches long, and of pale-green color. The stem is from two to three feet high, developing at the top a branched spike of orange-scarlet, tubular flowers about an inch in diameter. It is a free-flowering plant, maintaining a perfect succession of bloom from August till October. The bulbous roots should be planted about two inches apart in patches of not less than a dozen in order to secure a good effect.

Cambridge, Mass. *M. Barker.*

Cattleya Walkeriana is one of the most beautiful of dwarf-growing Brazilian Cattleyas, and one which deserves to be more extensively grown. In the collection of Hicks Arnold, Esq., in 84th Street, New York, there is a specimen in excellent health, which flowers annually in great profusion, and is now a very pleasing picture, with its large warm, rosy purple blossoms. It appears to be a great lover of sun and is treated to an abundance of air while in active growth, and thrives best

in a basket or pan suspended near the glass. A remarkable characteristic of this Cattleya is that its blossoms do not present themselves from the apex of the pseudo-bulb, but after each new bulb is completed, a growth appears from its base, which afterward sends forth the flower-spike; when the blooms are past, this develops into a new bulb. Good fibrous peat and very little sphagnum is the best compost, with ample drainage.

New York. *A. Dimmock.*

Damping Off.—The conviction is growing in my mind that the trouble that propagators style "damping off" is a generic one, with a long list of species. If seedlings fall away on account of a decay which appears at or near the surface of the soil it is a clear case of this malady. The portion of a young stem that is most exposed to fungous attacks is that near the soil. Not only does the soil furnish the required moisture for the most rapid development of the fungus, but it also provides the fungus itself in nine cases out of ten. This seems to be true of seedlings, and therefore the precaution should be to have the soil as free as possible of the germs or filaments of the destructive fungus. And, furthermore, any remedy that may be suggested should contemplate a more healthful soil instead of looking toward the cure of a plant that is already ailing. For damping off, therefore, the remedy is not for the plant, but the medium in which the plant is attempting to grow, and from which it receives both its sustenance and the enemy that seeks its life. There are possibilities that the seed itself may be affected, and in such cases the trouble is to be met, if at all, before planting by soaking the seed in some fungicide. This I have tested at length during the past season with Beans, and have determined that the disease, which appears quickly upon the seedlings, was already in the seed before the beans were placed in the soil. It was also shown that by soaking such affected seeds in a solution of carbonate of copper the amount of the seedling trouble could be greatly reduced. While this is not known under the name of damping off, it does not differ from some of the forms of fungous disease called by that general name.

Again, the destructive agency we are considering may prevail among cuttings, and perhaps the amount due to outward conditions about balances the damping off due to a fungus already in the wood when it was placed in the sand. If healthy cuttings damp off, then it is assumed that the soil is greatly at fault; but if the wood is unhealthy, it does not matter much what the soil may be so long as it furnishes water and keeps the lower portion of the cutting wet, the latter will decay at the surface of the soil. I have in mind a bed of Abutilon cuttings which failed almost entirely because there was a fatal fungus in the stock used. It showed itself slightly in the foliage of the large plants, and only when the cuttings were placed in the moist earth did the fungus obtain the best conditions for growth, and damping off followed as a natural sequence. There is little or no hope of a preventive in such cases, unless the soil-water be impregnated with an effective fungicide, which again only shows that, even with unhealthy cuttings, the soil is the medium for treatment.

Correspondence.

In the Shore Towns of Massachusetts.—II.

To the Editor of Garden and Forest:

Sir,—The town of Rockport has no public holding of any kind available as a place of public resort, no park or common or right on the shore, except, perhaps, a landing or two. There are two or three beautiful headlands here, very convenient for picnics and out-of-door assemblies. They should be secured for public uses, as this region is certain always to have throngs of visitors. Unless steps to this end are taken very soon these specially attractive sites are likely to be taken up for dwellings by people of means. Pool's Hill, near the village of Rockport, affords a very extensive view of the ocean, of the shore regions, and of some points far inland. It is 230 feet high. The clerk of the town, Mr. Calvin W. Pool, has for several years found his chief recreation in the effort to distinguish and identify the various features of the landscape visible from this eminence. Several years ago he discovered that Mount Washington can be seen from here, and I saw letters from the officers of the United States Coast Survey and other eminent scientific men confirming Mr. Pool's triangulations and conclusions. The hill ought to be public property.

Rafe's Chasm is a wild, rocky cañon on the shore, a little below Norman's Woe, at the entrance of Gloucester Harbor. It is an interesting place, and attracts many visitors and picnic parties. It is dangerous in the present undefended condition of the ledges. There should be railings along the steepest places. One fatal accident, which occurred many years ago, is commemorated by an iron cross fixed in the rock, and if the chasm remains unguarded there will probably be other monuments erected here in time, as the number of visitors increases. There should be a small public reservation here. The view of the sea and of a wide expanse of the shore country is very attractive, and the public should have a right to come and enjoy it; but the adjoining land is likely soon to be put to use as the site of a fine house, and the chasm will then be included in the owner's private grounds.

Not far from Rafe's Chasm there is a Pine grove, which is very pleasant and convenient for picnics, and has long been used as a place of public resort by the people of the region. Some years ago it was purchased by a public-spirited woman, who is interested in the objects for which the Trustees of Public Reservations were incorporated. She is especially desirous that the people of the adjacent country shall have access to pleasant and interesting places by the sea, and wished to preserve this tract and the Pine grove for that purpose. She gladly gives the use of it to all comers, asking only that the trees shall not be injured, and that fires shall not be left burning to endanger contiguous property. She has had some rather discouraging experiences. The picnic people mutilate the trees, leave fires burning, tear down the notices which request caution, and show such a spirit of disregard and mischief that the owner is compelled to employ some one to care for the grove much of the time during the picnic season. This is an unreasonable burden, as the grounds yield no income or profit. It is probable that the abuse of the privilege here enjoyed by the public will lead to its withdrawal. A similar state of things exists in many places where the people are not sufficiently enlightened and public-spirited to make a proper and rational use of parks and open spaces for public resort. Among an orderly population the expense of caring for sylvan reservations of this kind is very slight.

Manchester has several open spaces of various kinds which are the property of the town, and are used as places of public resort. One has an area of perhaps seven acres, and is used for picnics. There is also a picnic ground at Tuck's Point, one-fourth of an acre, which is a town landing, used as such since 1730. There is a building here, fifty feet by twenty, for tables, etc., and the town provides a janitor. This feature I have not observed elsewhere. There are several other tracts—seven acres on the plain, bought with the idea of having the town Poor Farm there, but not used for that purpose; Old Neck Beach, more than half a mile long, with adjoining land, of varying width, running up the shore; Lobster Cove Landing, two hundred yards of shore, and the ground the powder-house stands on. The people talk of selling some of these, as they think the town has more land than it needs, or can afford to keep. One of the most valuable and interesting of the public holdings of the town, and highly appreciated by the people, consists of a belt of land along each side of the highway between Manchester and Essex. This was purchased a few years ago in order to preserve the woods along this road, which were then about to be destroyed. Their preservation is the result, chiefly, of the efforts of a few thoughtful women in the neighborhood. The title to the property is vested in the town, and the deeds have been deposited in the office of the Town Clerk.

The only public holding of importance in the town of Beverly is West Beach, which belongs to the West Beach Association, incorporated by a special act of the Legislature in 1852. This corporation is composed of all the resident inhabitants of the East Farms School District in Beverly, and of the people of a designated portion of the West Farms School District, and it is authorized to take and hold all that portion of the sea-shore, beach and flats of Beverly Farms which is included in the limits defined in the act of incorporation. There may be five or six acres of the land, but, I think, scarcely so much. Nobody appears to know how much there is. It is part of the land, beach and flats originally granted by the town of Salem to John West in 1666, and the title has ever since then been in him and his heirs and legal successors. The members of the corporation may use and occupy this piece of sea-shore for boating, bathing and gathering drift-stuff and sea-weed, and they are required to keep in good repair a certain small piece of road or causeway for public travel and a few rods of sea-wall, not a difficult or costly requirement. I find nothing in the act of incorporation requiring the association to take care in any other way of the property to which they are thus given title, and it has a neglected and unattractive appearance on the

landward side. Much of the area is overgrown with weeds, which, when I was there, were tall enough to conceal a group of artists who were sketching the sea view, which nothing can spoil. The place might be made much more attractive and valuable to the people who have a right to go there, especially to the women and children, and I think the act of incorporation should be so amended as to require the association to take reasonable care of the property and to keep it in a neat and orderly condition.

There is no common or public holding in the region which is still marked Beverly Common on the maps, nor has there been in any recent time. I think this reproduction and perpetuation of old terms by successive map-makers is probably the source of the popular notion or impression that there are still considerable areas of common or undivided town-land in many towns in Massachusetts. The Trustees of Public Reservations were made a corporation for the purpose of acquiring, holding and opening to the public "beautiful places and tracts of lands," and if we are to have anywhere a reservation for beauty and the delight of those who love beauty, I know of no place in the state better adapted to such uses than this region of high rocky pasture and encompassing woodland. The distant view is fine in every direction, and the whole of the vast visible landscape is full of character, strong, alluring, tonic and satisfying. It is a place for artists and for people with a developed sense of the beauty and value of fine scenery. Of course, it is good to be out-of-doors almost anywhere, but here there is the inspiration of natural beauty of a vivifying character, and the consenting soul of "the wide aerial landscape" speaks to the soul of the beholder. I wish the trustees might visit and examine the region, and that lovers of the out-of-door world might explore it and note their impressions regarding it.

Salem has a pretty common in the most populous part of the city, nine acres of sward with trees encircling it, paths and seats. It is for people on foot only, and is quiet and pleasant for women and children. It is, I believe, the old training-field. 2. The Willows, on the shore, said to contain thirty acres or more, adjoining the town farm or almshouse grounds. It is reached by a street-railway from the city, and is resorted to by throngs on summer nights. The area is not so large as it should be, but it is one of the most valuable of all the public holdings on the New England shore, and the cost of maintaining it is very small. The annual appropriation for this purpose is about $1,200. The rents from eating-houses, etc., amount to $800 a year. The real annual cost to the city is thus only about $400. Yet the people of the adjacent suburb of Juniper Point would like to see this place of resort closed. 3. There is an area of two and a half acres on Liberty Hill, in North Salem, with a few fine trees and a spring of very cold water, but the place is neglected, uncared for and abused. A park or common is needed here, as there is a populous suburb near by which has no other place of resort. When I was there on a hot afternoon in August a party of women and children came up at the same time, tired and thirsty, but a huge dog was laving in the spring, and the children had to wait till the water ran itself clear again. The city's neglect of this valuable property is sure to result in its injury and depreciation.

The region formerly known as Salem Great Pastures was held as common land in early times, but it was all divided into private holdings long ago. Much of it is still used for pasturage. It is separated into two parts by the occupied and inhabited belt along both sides of the highway leading to Lynn and Boston. It is to the portion on the eastern or shoreward side of this belt that Salem will probably look for the territory for new parks and commons in the future. I could not learn why it is not thought judicious to anticipate these future needs—which, indeed, already impress most observers—and to purchase the land which will be required while it can be obtained at small cost. There is much complaint by the working people of Salem that they are of late hunted and driven from all the places along the shore to which, from time immemorial, they have been accustomed to resort for small picnics and excursions and family and society outings. Several members of the police force say they are tired of being sent to drive away little parties of quiet and orderly women and children at the behest, as it often happens, of persons who have themselves no real title to the lands from which they want all visitors expelled as trespassers. There is need of additional public holdings on the shore in this region; for a small party to go to The Willows is often about the same as trying to have a picnic in a crowded street or public hall.

Salem is historically one of the most interesting places in New England. Some of the old houses have been destroyed which should have been preserved, but of course they could not all be kept forever. It costs money to acquire these old houses, and to take care of them. To the house in which Hawthorne was born, so I was told, an admission fee of twenty-five cents is charged each visitor. The prevalence of the witchcraft delusion here was a most sad and pitiful episode in the town's early history.

The officers and workers of the Essex Institute and those of the Peabody Academy of Science have done and are doing most useful work in stimulating and extending historical research and in promoting the temper and spirit which make history worth preserving. There are many objects of great interest and value in their museums. Mr. John Robinson, who is treasurer of the Peabody Academy of Science, has recently written a series of entertaining articles on the trees of the region. It has been published in the Salem *Gazette*, and it should now be issued in a more permanent form so as to be accessible to the public. Mayor Rantoul expressed much interest in the aims of the Trustees of Public Reservations.

Boston, Mass. *J. B. Harrison.*

Exhibitions.

Chrysanthemums in Boston.

BOSTON has never seen such a magnificent display of Chrysanthemums as those which last week filled the two halls of the Massachusetts Horticultural Society. For several years the liberal prizes offered by the society for this now popular flower have brought together very remarkable displays, but all of them have been eclipsed by that of this year. The specimen plants, perhaps, were no better than the best of Mr. Hunnewell's collection of last year, but there were more high-class plants in this year's exhibition, and the average of the whole was far better than anything seen in Boston before. It is a question, perhaps, whether the modern fashion for big blooms has not destroyed some of the real beauty of the Chrysanthemum; it certainly is a fact which no one with any sense of proportion will be able to dispute that a single spindling stem six or eight feet tall surmounted by one flower is not of itself an object of beauty, however great may have been the skill of the gardener who produced it; but allowing that size and substance of plants and of flowers is the chief aim of Chrysanthemum-culture, then the Boston show was as remarkable an exhibition of these flowers as the country has ever seen. It should be added, however, that while tall plants which carry a single flower are not objects of individual grace, there is yet one sufficient reason for cultivating some Chrysanthemums in this way. When several of these long-stemmed plants are cut and intelligently grouped in a vase, the flower is used to its best effect for decorating large rooms.

Cut flowers principally decorated the lower hall, and potted plants the upper, and in each the arrangement was excellent, both in the general effect produced and in the opportunity given to examine the different specimens in detail. The principal contest was in the competition for the prize offered for twelve specimen plants, as it has been for some time an open secret in the neighborhood of Boston that two of Mr. Hunnewell's sons were making extraordinary efforts to produce the best plants for this class. They had no serious competition, and Mr. Walter Hunnewell, whose plants last year were the admiration of every one who saw them, secured the first prize, and Mr. Arthur Hunnewell the second. The first-prize group consisted of short broad plants, with the exception of one splendid specimen of Louis Boehmer, the handsomest plant in the whole exhibition, all in the very pink of condition, but it seemed to us not quite as good, on the whole, as the plants which took the first prize last year. Mr. Arthur Hunnewell's plants were taller, some of them more than six feet high, but they lacked something of the finish which always characterizes Mr. Hatfield's Chrysanthemums.

Of the seedlings, which were shown in great numbers, few were particularly distinct, and it is plainly difficult to originate anything much better than what already exists in any of the strains which our florists are working. Of the seedlings displayed this year for the first time it is needless to speak, as very few of them stand the test of a second season, and no Chrysanthemum is worth propagating until it has flowered during at least two years. Of such plants there was nothing finer than A. H. Fewkes' Beacon, an immense white flower, fully ten inches across, and very solid and compact. It belongs to the incurved Japanese section, in which, also, were the following: Mrs. Jerome Jones, a large white flower, raised by H. A. Gane, Esq., of West Newton, Massachusetts; Pitcher & Manda's Harry May, and an excellent bronze yellow flower named Walter Hunnewell by its raiser, Mr. J. T. Hatfield. A very fine specimen of the last, and perhaps the most interesting plant in

the exhibition in the first-prize group, showed that it is a vigorous grower and well suited for exhibition purposes.

Besides the Chrysanthemums there were splendid displays of Roses from F. R. Pierson, of Tarrytown-on-the-Hudson, New York; from F. C. Cutts, and the Waban Rose Conservatories. There were Carnations from H. E. Chitty, of Patterson, New Jersey; Edward Swayne, of Kenneth Square, Pennsylvania, and others. Special collections of cut Chrysanthemums in competition for the special prizes offered by the Boston Gardeners' and Florists' Club were remarkably fine.

Besides the awards already mentioned, the principal prizes for plants were given to Francis B. Hayes, Dr. C. G. Weld, N. T. Kidder, John L. Gardner, Dr. H. P. Wolcott and Joseph H. White. For cut flowers the leading prizes were awarded to S. J. Coleman, Charles V. Whitten, Pitcher & Manda, E. A. Wood, John Simpkins, A. H. Fewkes, Dr. C. G. Weld, Joseph H. White.

Chrysanthemums in Philadelphia.

IT would be hardly fair to make a comparison between the exhibition last week at Philadelphia and the one the week before in New York. The entire collection at Horticultural Hall could have been almost hidden away in some corner of the vast floor-space of Madison Square Garden, and yet the display lacked neither size nor variety, and it was pervaded by a certain air of finish and refinement which is rarely seen. It would be fortunate for New York if the treasures of the private greenhouses in its neighborhood could be displayed on occasion to the delight and instruction of the public just as those of Miss Baldwin, Mr. A. J. Drexel and Mr. George W. Childs can always be counted on to add to the interest of an exhibition in Philadelphia. Enough plants were sent from the greenhouses of Miss Baldwin and Mr. Drexel to fill two long tables, and every one of them showed the skill of William Joyce and James Long, the well-known gardeners of these establishments. To mention the noteworthy specimens would be to give a catalogue of the entire list. Every plant was clean, thrifty and perfect after its kind. These collections, with some magnificent Palms which Mr. Hughes brought from the garden of Mr. G. W. Childs, together with the admirable collections of commercial greenhouse plants, sent by H. A. Dreer and William Ball, helped to form from different points of view an admirable background to the bright flowers, and softened the glare of color which would otherwise have been unpleasant. The stage was very beautifully arranged with masses of well-grown yellow Chrysanthemums, with abundant foliage banked against a line of Palms and Dracænas and other greenhouse plants, while in front was a stage of rare and beautiful Cacti, such as Mr. A. Blanc alone can furnish.

The Philadelphia exhibitions have always been strong in specimen plants. This year's collection hardly seemed to us equal to the one of last year; but, as usual, Mr. James Verner, gardener to A. J. Drexel, easily won the first prize for the best collection of ten plants of ten varieties. These were strong and symmetrical specimens, each one filled with flowers that were almost uniformly at their best. The plants of this collection were Mrs. Irving Clarke, Frank Thompson, Kioto, Robert Bottomley, President Harrison, Mrs. M. Wheeler, Lilian Bird, Puritan and Cullingfordii. Fine specimen plants were also shown by W. K. Harris, H. G. Standen, J. W. Colflesh, John McCleary, H. B. Surman, Gebhard Huster and Thomas Monahan. Mr. Verner took many prizes in other classes besides the principal one for ten varieties. It was noted by many of the experts present that the variety President Harrison, although the single flowers were not of the most attractive kind, showed admirably in specimen plants. Plants of Ruthven were also noteworthy for quality.

The cut flowers were never excelled; and, indeed, we have come to expect every year that they will be an improvement on those of the year before. All the old kinds were done so well that there is hardly any reason for selecting any of them for especial mention, although the vase which contained a group of the blooms of Frank Thompson could hardly escape notice in any company. For cut flowers the chief prizes were taken by James Heacock, Hugh Graham, Dailledouze Brothers, George Craig, J. W. Colflesh, Fred. R. Sykes. Silver medals were awarded to Hugh Graham for the Chrysanthemum Roselyn, an immense pink incurved flower, which had only one rival in its class, and that was Maude Dean, which seems to have a little more decided color; to T. H. Spaulding for Emily Ladenburg, the dark velvety red variety, which has already been described in our report of the New York show; to Robert Craig for Lewis Childs' Madeira, a bright yellow plant of perfect form, and probably the best Chinese incurved flower of the year; to Robert Craig for Mrs. Robert Craig, a flower of great depth and substance; to Peter Henderson & Co. for the Golden Wedding, an importation from Japan and a flower of the largest size, high in the centre, with the petals rather incurved and loosely twisted, while the outer ones are reflexed and somewhat drooping—a bold flower, of uncommon form and great sturdiness in stem and foliage; to the same firm for Good Gracious, a flower imported in the same lot, and which may be described as a large pink Kioto; to H. B. Surman for an immense yellow incurved flower of the very largest size. Certificates of merit were awarded to Hugh Graham, T. H. Spaulding, Robert Craig, Peter Henderson & Co. and Harry Surman for new Chrysanthemums.

The display of Roses was admirable for the season, and so were the Carnations of Mr. Thomas Butler, H. E. Chitty, Dr. Williams, Edwin Lonsdale and others.

Glimpses at the Plant World. By Fanny D. Bergen. Illustrated. Lee & Shepard, Boston.

It is amusing for older persons to look through a little book like this and see the pleasant ingenuity displayed in its treatment of facts which they have learned through dry scientific statements. But it is a question, perhaps, whether books of its sort do much of the good they are intended to accomplish. For they are evidently intended not merely to amuse children or to interest them in a broad way in the vegetable products which surround their summer steps, but to give them some definite knowledge of fundamental botanical facts. "Knowledge made easy" may be discussed, we think, in a general way as regards its beneficial effects upon youthful minds. It does not seem certain that such knowledge does more good than it does harm by vitiating a child's conception of what education means. Real knowledge can be gained only by real study, and real study is hard work, though good teaching may make it delightful work as well. To accustom a child to the idea that in swallowing bits of information sugared and gilded into the likeness of amusing literature is, we think, to labor against the formation of those truly studious habits of mind which early education should chiefly address itself to nurturing. Aside from the mastering of the three Rs the chief thing a child can learn in its first school years is simply how to learn. Not until its mind is better developed can it amass much information that will be profitable through life, while if right habits of study and a right conception with regard to what study means are not formed before the mind is developed the chances are great that they will not be formed later on. Of course, it will do a child no harm to peruse a few books like Miss Bergen's "Glimpses at the Plant World," for the information it gives seems to be accurate. All we intend is to protest against the idea that books of its class are in the true sense educational, to point out the danger that teachers and parents may come to trust too largely to their efficacy, and children may be persuaded to believe that when they have easily picked up a few scattered fragments of information they know something about the subject in question. Left to themselves, however, children are not likely to make too much of such fragments, for they are very likely to pass them wholly by. Instead of picking out, as they were expected to do, the kernels from the sugary mass, they will most often throw away the kernels and delight themselves simply in the sugar that surrounds them.

Every time, therefore, that we see a book of this sort we wish the enthusiasm and conscientious labor that had been put into its making had been a little differently exercised. Simple books about natural phenomena can play a wholesome and important part in the development of infantile intelligence, and this in two different ways. They can describe the pretty or amusing or odd or interesting things that a child sees in its walks so as to awaken the imagination, excite curiosity and quicken powers of observation. This service is performed by many passages of Miss Bergen's book. But we think its excellence would have been greater had she contented herself with this and not attempted to explain the scientific significance of this fact and that, or to give names to such things as the parts of a flower. A little mind will be only confused or repelled by the addition of such nuggets of fact, and even were they all to be assimilated its stock of information would not be enlarged to any valuable extent. The right effect of a series of informal talks about plants ought to be the impression that interesting things can be learned about them at the proper time and in the proper place. It ought not to assume any part of the office of an elementary botany; it ought simply to prove

to the child that botany must be an attractive study. This foundation once laid, the useful book of the second sort can be brought in play, and this of course is the elementary botany itself. This ought not to try to be amusing or to condescend to fanciful suggestions, poetic interpretations or the stimulating of mere curiosity. It ought to be simple and direct, systematic and scientific, although of course in its language, its choice of fundamental facts and its avoidance of all which can be left for later periods of study, it ought to be carefully adapted to budding intelligences. One such botany is, we all know, within the reach of every American child. No child too young to understand Gray's "How Plants Grow" is old enough to get valuable botanical information from other sources; and none who does not find it interesting will be charmed into botanical enthusiasm by the administration of sugar-coated pellets. The total separation of these two kinds of writing—of the kind which is meant to awaken interest from the kind which is meant to supply information—would, we feel sure, be of great benefit to the rising generation.

Notes.

A natural history society, with Mr. William M. Canby as president, has just been established in Wilmington, Delaware.

The English building on the grounds of the World's Fair in Chicago is to have the general character of an old English manor-house.

The popular French name for Cotinus is Arbre à Perruke, or Wig-tree, a term which expresses its peculiar appearance when covered with its abortive pedicels as distinctly, if not as prettily, as does the English term "Smoke-tree."

The Iceland Poppy shows its sturdy qualities by throwing up occasional blooms in spite of the frost. Perhaps the plants which are to bloom next spring would do better if they were kept from flowering the autumn before, but the flowers are very beautiful now amid the general desolation of November.

The beauty of the deep blue flowers of the low-growing and half-prostrate *Plumbago Larpentæ* has often been spoken of in these columns, but now that the frost has destroyed its bloom the plant is still beautiful for the bright scarlet of its foliage. A spread of a square yard or so makes a very brilliant spot at this season on rock-work or wherever else it may be planted.

About 10,000 corn-cob pipes are daily manufactured in this country, all being made in three factories, one of which stands at St. Louis, one at Greenwood, Nebraska, and the third in Kansas. The cobs are all procured in Missouri, and are supplied by the Collier variety of Corn, on which they grow usually heavy, woody and hard, while the stems are formed of the so-called Arkansas Swamp-cane or reed.

In a preliminary list of the plants of Franklin County, Ohio, lately made by Messrs. A. D. Selby and Moses Craig for the Columbus Horticultural Society, it is stated that 138 native plants and 85 introduced plants have been added to the number given in a catalogue made by William S. Sullivant in 1840. It appears that 15 per cent. of the plants of the county are introduced and that 8.5 per cent. of these have appeared during the last fifty years.

No more striking contrast to our beautiful rural cemeteries, filled with costly monuments and carefully tended plants, can be imagined than the City Cemetery of New York—the "Potter's Field," on Hart's Island in the East River. Here about 2,500 unknown and pauper dead are annually buried. There are some 75,000 drunkards' graves, and the most pathetic sight of all is the only monument, which bears sad tribute to the fact that some of the brave soldiers of the Civil War are here interred.

In the recently issued Proceedings of the Pennsylvania Academy of Natural Sciences a record is made of a double-flowered Skunk Cabbage (*Symplocarpus fœtidus*), and an illustration which shows the two spathes fronting each other is given in *Meehan's Monthly* for November. In the same magazine it is stated that in a Japanese work on botany there is a figure of this plant, which grows in Japan as well as in America, with two spathes, the outer one being a purplish violet with orange stripes within and darker lines without, and the smaller spathes in the interior striped with white and having a greenish border.

We have received from Mr. Joseph Meehan a branch of *Elæagnus umbellatus* which is thickly covered with fruit. This plant has been distributed very abundantly during a few years past as *E. longipes*, which, however, it does not resemble. It is much more like the one known as *E. parvifolius*, but this ripened its fruit more than a month ago, while *E. umbellatus* still has fruit on it, which will be frozen off before it ripens. The berries, as they came to us, were of a beautiful amber color, thickly set along the stem and about as large as currants. The fruit adds much to the ornamental value of this shrub, which is beautiful at all seasons of the year. The plant from which this branch was taken is in the garden of Mr. A. G. Elliot, of Germantown.

The little park known as the Bowling Green in this city originally lay in front of a fort built of logs in the year 1615, which, in 1626, was replaced by a store-house surrounded by palisades of Red Cedar, and was used as a drill-ground. In 1732 the ground was leased to residents of the neighborhood and converted into a bowling-green, and in 1770 it was chosen as the site for a leaden statue of George III., which had been sent from England, and was surrounded by an iron railing, for which the city paid £800. On the evening of July 9, 1776, when the Declaration of Independence was read from the City Hall, statue and railing were demolished by the excited populace, and the pieces of the former were sent to Oliver Wolcott at Litchfield, Connecticut. Here Wolcott's wife and daughter cast the lead into 42,000 bullets, and it was believed that four hundred British soldiers met their death by missiles which had once formed part of the statue of their king.

In eastern New England this year the autumn foliage of trees and shrubs is less brilliant than it has been in several years. The foliage of many trees, especially of the Ash, the Hickories, and the Virgilia, all of which usually turn to brilliant shades, was killed by a hard frost in the last week of October before they had changed color at all, and these trees are now generally leafless. The leaves, too, have fallen from many Maple-trees, both Red Maples and Sugar Maples, without any previous change of color. The Oaks, however, promise to turn as usual, and just now some White Oaks and the Chestnut Oak which, with its deep orange autumn color, is always one of the most beautiful trees at this season of the year, are particularly noticeable. The Red Oak and the Scarlet Oak turn later. It is interesting to note that in spite of the hard frost the Gleditsias still hold a large part of their leaves, which are almost as bright green as they were at midsummer, while its nearest relative, the Kentucky Coffee-tree, is quite leafless.

In an article recently published in the New York *Sun*, contrasting this year's fair of the American Institute with the one held fifty years ago, it is said that in the Floricultural Department of this latter the most striking attractions were "thousands of specimens of what was called 'that fashionable and esteemed flower, the Mexican Dahlia,' in all its varied shades. It was considered worthy of mention that the root of the Queen Dahlia had cost £10 the previous spring. G. C. Thorburn was credited with having imported the majority of the stock, or parent plants, cultivated in this country at the time. . . . Of the forty premiums for agricultural and horticultural products Thomas Addis Emmet, one of the most famous lawyers of the time, got a diploma for the best purple Egg-plants, William Niblo got a copy of Downing's 'Rural Architecture' for the greatest display of tropical fruits, and Niblo and Dunlap got a diploma for the best self-colored and various-colored Dahlias. . . . Among the exhibits of garden ornaments were 'splendid specimens of stained glass peculiarly adapted to the highest style of garden architecture.' The making of stained glass had been introduced here only a few years before. A cast-iron sun-dial was described as 'a very useful article to any one who sets a due value on his time. When its cheapness is considered, we should think it strange that any person who has a situation in which to place it should be without one.' An iron case was considered a valuable ornament where stone pillars were used, as in gardens and parks. Some iron settees were described as 'entitled to rank among the luxuries of life.'" But the "climax in garden ornaments" seems to have been an enormous cast-iron fountain composed of groups of "female figures of great beauty," with Tritons spurting water ranged about an upper basin. Among other exhibits of importance "were Amazon bonnets made of so-called Manilla-grass, which was the fibre of Aloes. The braids were both white and dyed, and the judges could not too highly commend its exhibitors for originating and bringing to its state of perfection a fabric of so much importance."

TABLE OF CONTENTS.

How a Village Gained a Park.

LIKE many of the very old towns lying near the great cities which cluster about the harbor of New York, the village of Jamaica, on Long Island, has a reputation for staunch conservatism. During the present year, however, it has been the theatre of a progressive movement which is worthy of being placed on record as an example of public spirit and prompt activity. Last winter a lady who lives in the village organized a society known as the Linnean Club, which had for its objects "the diffusion of botanical knowledge, the encouragement of floriculture, and the preservation of our native plants, shrubs and trees," and to promote these worthy objects the founder of the club gave "little talks," as she modestly called them, every other week, alternating with another member, who, like the founder, was a member of the Torrey Botanical Club of this city. These meetings proved attractive, and, what is better, they proved instructive and stimulating, and soon the club numbered some forty members. The idea of cultivating wild flowers and American plants suggested the advantage of a public place to grow them in, and this thought soon germinated into a conception of the necessity of something like a botanical garden or park for the Linnean Club and for Jamaica. The club could own no real estate, but advantage was taken of the law in this state, which was passed in May, 1888, to meet such emergencies, and to which we have often alluded before. This act enables any fifteen or more citizens, under certain restrictions, to secure lands for parks and playgrounds independent of municipal authority. These corporators can acquire property, by gift or otherwise, to the amount of half a million dollars, and such additional amounts as may be authorized by the Mayor and Common Council of any city or the Supervisor of any town in which it is proposed to establish such parks, and they are clothed with the power to employ officers for enforcing order and compliance with their rules. Fifteen members of the Linnean Club, therefore, incorporated themselves under this act as the Highland Park Association, so that they could take possession of the land which they had determined to secure, and two weeks ago a deed for this land was formally delivered to the corporators as a part of the festival exercises at the first flower-show of the Linnean Club—and the first flower-show ever held in Jamaica.

Jamaica lies just south of the range of hills which forms the backbone of Long Island and gives character to its scenery. Twenty years ago these highlands were well clothed with trees, but the forest-growth has gradually been swept away and the slopes have been turned into streets and building lots. On the summit of the range, just opposite the central part of Jamaica, lies a pond, which has been called from time immemorial the Goose Pond, because its shape had a fancied resemblance to the outline of that bird, where the village boys used to skate in winter, and swim and gather Pond Lilies in the summer. This pond, with half a dozen acres of land at one side of it, was the park area coveted by the new association, who wished to preserve from being covered over and blotted out the most interesting feature of natural scenery near the village, and to save for the boys and girls of the future the grounds where the boys and girls, who are now men and women had been free to gather nuts and wild flowers. Fortunately, the owner of the land was generous, and, being a native of the village, he held his birthplace in affectionate remembrance, although he now lives in a distant state. He, therefore, not only placed a low valuation upon the land, but subscribed half the sum needed to purchase it. The club went energetically to work to raise the other half, and gave all their neighbors the opportunity to help according to their means, the individual subscriptions ranging from two dollars and a half to a hundred dollars, and now Highland Park is public property, held in trust as a pleasure-ground forever by the fifteen corporators and their successors.

Of course, much remains to be done. The park would be worth a great deal more if additional land could be purchased, enough, at least, to include the entire shore of the pond within its boundaries. The time will come when there will be some grading needed for the playground, and, as the old trees are all gone, there must be some planting, or, at least, some care of the saplings which have already sprung up upon the tract; but the townspeople can be trusted now to improve their pleasure-ground and keep it in order, and their interest in it and affection for it will grow with the care they bestow upon it. The fact upon which the people of Jamaica are to be congratulated primarily is, that this area, at least, is rescued and held for public use, and their successors a century hence will hold in grateful remembrance the public-spirited women who have preserved this little section of the hill's crest to show the original conformation of the land.

Two or three phases of this work seem to us to deserve special mention. In the first place, the Linnean Club is composed entirely of women. The fifteen corporators who have acquired this park-property by purchase are all women. It is not strange that the need of a public garden should have made its first appeal to the finer sensibilities of women, but no association of business men could have carried the work through with greater effectiveness of organization or promptness of execution. Let us hope that it may occur to the women in many another town that they can accomplish as much in the way of local improvement by co-operative effort as their husbands and brothers can.

Again, it is to be observed that this was not originally a movement for a park, but it was an effort to increase the love of natural objects, and yet it was distinctly out of this that the conception of the need of a public park grew. Here is another hint of the value of organization for encouraging the study of nature out-of-doors and at first-hand. Such study is wholesome in a general way; it opens the mind to good influences, it draws away the thoughts from what is artificial and gives freer play to those elementary instincts which attach us to the soil and

enable us to enjoy those simple pleasures which come from sympathetic contact with the woods and fields; it has a special value in creating and directing sentiment in favor of public parks and gardens for towns and cities.

The Linnean Club has taken special pains to interest the children. This has been done in many ways. The idea of a playground has been a fundamental one throughout the whole discussion. In the beautiful flower-show which was held about a fortnight ago the prizes were not given to professionals, although the local florists kindly helped to make the show attractive, and one of them, at least, offered premiums for competition; but prizes were offered for wild flowers gathered by the children and for plants cultivated by persons under sixteen years of age. This not only encouraged the study of plants in the most practical way, but it insured the help of the children in the work of winning a park. The public schools entered heartily into the project for a pleasure-ground which was to be a place for the amusement of boys and girls as well as for grown people, and one of the most interesting features of the final ceremonies was a contribution of fifty dollars raised in small sums from the pocket-money of the pupils in the public schools. The children who gave their mites for Highland Park will not forget to care for it when they become men and women.

Jamaica was in special need of this public playground, and many other villages which lie just beyond the suburbs of rapidly growing cities have a like need of speedy relief. Even now there is often as little space in these suburban villages for public recreation and the playing of children as there is in compactly built cities. The great cities are steadily sweeping about them, and soon the whole area will be covered with compactly built business blocks and dwellings. The cost of securing open spaces will then be enormous. Even ordinary forethought suggests that park areas in such places should be secured at once. Wherever there is such a village there is room for a Linnean Club.

A description of the new Grant monument in Lincoln Park, at Chicago, recently published in the *American Architect and Building News*, well illustrates the importance of carefully considering the site and the architectural base if a statue is to produce a good effect. As a rule, our statues are injured by bases of insufficient size and dignity, but in this instance the designers seem to have fallen into the opposite error. "The Grant statue," says the writer, "is situated at the eastern side of Lincoln Park, close to the great lake. There has been partially completed this year, outside of what was formerly known as the Lake-shore Drive, a road with water on each side, the actual lake on the east and a stretch of smooth water on the west. In passing, it may be mentioned that this drive is a most wonderful piece of masonry, stretching, as it will, for over a mile, with a stone esplanade on the side toward the lake and a paved beach beyond sloping to the water's edge. It is from this walk and drive that the most comprehensive view of the monument may be obtained, and a slight feeling of disappointment is felt at the insignificance of the bronze compared with the stone. Viewed still closer from the old Lake-shore Drive, where the details of the substructure can be noted, the feeling of disappointment increases, and one is sure that the horse and rider lack that one kindling spark of genius that would lift them above mediocrity." However, the writer continues, when one mounts nearer yet on the road that leads over part of the substructure it is seen that there is "a spirit and strength in the handling of both horse and rider that one would never guess at in viewing the work as a whole," and he decides that the work of the sculptor, Mr. Rebisso, deserves high praise. "The entire trouble," he explains, "is with the substructure, which is so enormous that it dwarfs the actual statue. The possibility of obtaining a comparatively near view of the work makes it undesirable that the handling should be of the broadest; but at the height that it is raised above the spectator at most points, only the strongest work would be effective. Add to this that the belly of the horse and the soles of General Grant's boots were not the parts of the statue, doubtless, that the sculptor wished brought into the greatest prominence, and one can easily see that the effect of the work is lessened by the great height of substructure. If one approaches the statue from the back door, so to speak, up a gentle incline, where low trees cover the principal part of the granite-work, the fine effect of the horse and rider will immediately prove to the even careless observer how much the too extensive masonry detracts from the work of the sculptor, especially when the masonry be of such a crude and harsh character."

A large photograph of the monument, subsequently published in the same journal, confirms its correspondent's words. It shows a stone bridge, with a single round arch which appears to span a lower road, while the main road that it bears is conducted beneath a structure which is more properly to be called a building than a pedestal. With a large round arch at either end and an arcade of five on the longer face, its exact character is hard to explain. As a building it seems to have no special purpose; as a substructure for the statue it is utterly inappropriate. It is encircled by a sort of balustrade, and from the centre of its top rises the true pedestal, bearing the statue so far above the eye that one can well believe it may be a better work than it thus appears to be. Moreover, the whole construction is not only "crude and harsh" in the character of its masonry, but rude and barbaric in design. It exhibits that unfortunate tendency to which we called attention a few weeks ago — the tendency to mistake excessive massiveness for strength, heaviness for dignity, lack of refinement for simplicity. We suppose it would be called a Romanesque design. But no Romanesque builder in any community which had really preserved a memory of Roman civilization, or had evolved from the ruins of this a new civilization of its own, would have designed in such a manner a civic construction the purpose of which was professedly ornamental. These enormous, rough-faced stones; these clumsy angle-shafts; these ponderous arches springing from imposts that are mere rude blocks; these primitive attempts at cornice and balustrade, look like the creations of some rustic builder in a land and age when art was but a memory or a prophecy, when refinement was unknown, when manual skill was at as low an ebb as the power of skillful designing. As a feature in the pleasure-ground of a civilized, nineteenth-century town the cyclopean rudeness of the structure must equally disturb the mind and the eye, while nothing more inappropriate in size and character could be imagined as a support for the statue of a modern man. When we add that this work actually prevents the spectator from taking any point of view from where the statue can be well seen, we must conclude that the art of placing monuments in the open air is not yet universally understood in America.

The Shrubbery in November.

IT is now the middle of November, and our deciduous trees are all bare except the Birches, Beeches and the Oaks, and the foliage of these last has lost its brilliancy of tint, and they are settling down into the sober sadness of their brown and russet winter garb. The Birches still have a sparse covering for their upper branches, and the lower limbs of the Beeches are clothed, while the upper ones are bare. The brightest green foliage still decks the Plums, and some Robinias retain their summer robes, but much the worse for wear, shrunken, faded, tattered and forlorn. The Purple Fringe, a charming small tree, is now beautiful in full dress of orange; it is also remarkable for the exquisite soft, pinkish hues of their translucent young leaves in April, and I know of no tree which will give more pleasing variety in a season's growth.

On descending to the shrubberies I find some Weigelias, Kerrias and Euonymuses still holding green leaves, while Forsythias have a deep plum-colored shading, and the California Privets, which have not shed a leaf, are purpling in striking contrast to a group of Thunberg's Barberries, cheery with

sprays of orange and scattered scarlet berries, which are a god-send to the vagrant birds.

We possess a specimen of *Enkianthus Japonica*, which was very beautiful a month ago, but is now in winter bareness. Its foliage turned to a uniform blood-red, making it more showy than a Dahlia. The tips of the leaves turned first, as did those of a fine *Parottia Persica*, its near neighbor, which is now in full splendor of handsome persistent foliage, irregularly marked with shades of crimson and gold. These two rather rare shrubs are of easiest culture, and I know of none that are more valuable for autumnal effects.

Our Coluteas are still a lively green, and so is the grass, though we have had some sharp frosts. *Cytisus nigricans* retains vigorous leafage of a very dark plum color, almost black. Can this deepening of the foliage be the origin of its name? All Spiræas seem to keep their summer dress until very late, and all are desirable for this and many other good points. The old-fashioned *Spiræa prunifolia* has now shed most of its leaves, but *S. Thunbergii* is exceptionally beautiful, with light yellowish red shades and fairy delicacy of growth. Near by a mass of *S. Lindleyana* is fast losing its golden sprays, while the little *S. Bumalda* and *S. callosa alba* are scarcely changed, except that their leaves have lost their pristine freshness of appearance.

Fontanesia phillyræoides is a rich dark green, and *Hypericum patulum* makes a pleasing spot of verdure for the eye to rest upon. The Golden Elder is golden still, and the Witch Hazel is adorned with tassels and fringe, which do not wear as well as its tiny, inconspicuous yellow florets, which are the calyxes and will remain all winter to protect the ripening seed. The leaves have shriveled long ago. Very golden and strikingly handsome is the Ramanas Rose, while its Himalayan cousin, which shoulders it in our lower shrubbery, is a bright shade of orange, very distinct, as the florists say.

Chimonanthus fragrans is unchanged. It is to be left out all winter—perhaps a dangerous experiment, with no protection except leaves and limbs of trees to keep the mulch in place. This shrub is hardy in England. Although our winters are sometimes very severe, with the thermometer occasionally below zero, our southern Jessamine lives and flourishes with no protection except what is kindly afforded by the autumn winds that heap the withered leaves about its feet. The Iteas are still handsome, in dull red, to which *Elæagnus longipes*, with its grayish foliage, forms a striking and beautiful contrast. Near by a group of Cotoneasters are showy in their dark rich crimson shadings.

Very interesting still are the shrubberies, with changing combinations and lovely effects, delightful to an eye that appreciates color. Many berries add to their beauty; among them the bright hips of the Wild Roses and Sweet Briers, the red and yellow uniform of the Bitter-sweet, and the fiery glow of some Euonymuses are especially noticeable. A variegated Ampelopsis has metallic greenish blue berries, which are pretty and persistent, and the Saint Peter's-worts are sprinkled with white and red berries, which remain until very late in the winter. With a judicious admixture of Evergreens, the shrubberies may be made attractive at all seasons, and one can have endless enjoyment in watching their transformations.

I must not forget the rich verdure of the Honeysuckles and the elegant *Akebia quinata;* nor the Japanese Alder, which is now conspicuously green, with its curious cones and catkins; and I must spare just a word of appreciation of the wild Blackberry-vines, rioting along the lanes, whose ruby wine tints are fairly glowing in the sunshine this sparkling November day.

Rose Brake, W. Va. *Danske Dandridge.*

Filices Mexicanæ.—IV.

THE following concludes the enumeration of the Ferns collected in the states of Nuevo Leon, Jalisco, San Louis Potosí and Machoacan, Mexico, during the seasons of 1888, 1889 and 1890, by Mr. C. G. Pringle, of Charlotte, Vermont. The notes and descriptions, as in former numbers, are by Mr. George E. Davenport, of Medford, Massachusetts.

Ophioglossum crotalophoroides, Walter (3405). Damp soil, near Patzcuaro, November, 1890.

Ophioglossum vulgatum, L. (1564). Moist places, foot-hills of the Sierra Madre, state of Chihuahua, October, 1887. (Received too late for inclusion in notes for that year.)

Osmunda regalis, L., no number.

Pellæa angustifolia, Baker (1836); also var. *cuneata*, Baker (2026 and 2588). All from Barranca, near Guadalajara, September and November, 1888 and 1889. Moist bluffs and shaded banks.

Pellæa flexuosa, Link. (2832). Dry cliffs near Guadalajara, November, 1888.

Pellæa intramarginalis, J. Smith, var. *serratifolia*, Hooker and Baker (1986). Shaded grassy slopes of Sierra Madre, Monterey, June, 1888. Tall, elegant specimens.

Pellæa Pringlei, *n. sp.* (2591). Rhizoma short, stout, crowns clothed with a coarse, tawny, fibrous tomentum; fronds 6′ to 16′ tall; stipites 5′ to 10′ long, straw-color, with brownish bases, channeled, naked or with a very slight deciduous pubescence; laminæ bluish green, 2½′ to 6′ long, 1½′ to 4′ broad at base, deltoid-ovate, pinnate, or the lower pinnæ sometimes again pinnatifid; pinnæ three to five pairs, with long straw-colored stalks like the stipites, deltoid-hastate, terminal ones generally one-sided or sub-hastate, but sometimes deltoid-hastate like the others, lower ones sometimes divided into two unequal divisions, or several times unequally lobed, or even pinnately divided into from one to three pairs of oblique-stalked pinnules, the terminal one also stalked; texture sub-herbaceous, the copious free veins plainly visible; costæ prominent on both sides; fructification continuous round the revolute bluish margins.

Habitat: 2591, cool mossy banks, Barranca, near Guadalajara, state of Jalisco, October 19th, 1889; also 2029, collection 1888. Dr. Palmer's 543 of his 1886 collection, which was referred to *P. cordata* with some hesitation, from depauperate specimens, by Professor Eaton, in *Proc. Amer. Acad.*, xxii., p. 463, is identical with Mr. Pringle's plant. The illustration on page 560 is from a drawing by Mr. C. E. Faxon.

Pellæa rigida, Hooker (3298). Ledges and bare banks, San Jose Pass, October, 1890; also 2602 of 1889 collection.

Pellæa Skinneri, Hooker (2831). Of 1888 collection; 2603 and 2586 of 1889 collection. Moist shaded banks, Barranca, June, September.

Phegopteris rudis, Mett. (1844 and 1984). Wet places, near Guadalajara, November, 1888.

Phegopteris tetragona, Mett. (3409). In a cave partially lighted, whence issues the Choy River, June, 1890.

Polypodium aureum, L., var. *areolatum*, D. C. Eaton (2022). On calcareous ledges and banks near Guadalajara, December, 1888; and 2582, from ledges, Sierra de Esteben, October, 1889.

Polypodium ellipsoideum, Fée (3404). On trees, hills of Patzcuaro, November, 1890.

Polypodium furfuraceum, Schlecht. (3356). On trees, Tamasopo Cañon, June; and 3357, on Oaks, hills of Patzcuaro, November, 1890. I am indebted to Professor Eaton's kindness in placing these numbers, and must confess that I would not so have placed them from the description in "Synopsis Filicum," with which the specimens are wholly at variance. Not only are the "soft spreading hairs" wanting to these specimens, but the rhizoma is clothed with *distinct broad scales* instead of "woolly fibrils," as called for in the description. There is no question, however, but that they agree with specimens heretofore referred to this species by Professor Eaton; from Bourgeau's, Ghiesbreght's, Mohr's, Palmer's and Farlow's collections, and I am well content to leave Mr. Pringle's in such good company.

Polypodium lanceolatum, L. (3358). On Oaks, rocky hills of Patzcuaro, state of Machoacan, November, 1890.

Polypodium lycopodioides, L. (3355). Climbing on shrubs, limestone hills of Las Palmas, October, 1890. A very large fine form, in which the fronds are frequently bifid, and the climbing rhizoma unusually stout, very different in appearance from the usual forms of the species, but agreeing very well with Ervendberg's No. 9, from Wartenberg, Mexico, 1858, a specimen of which Professor Eaton very kindly sent to me for comparison.

Polypodium plesiosorum, Kunze (2023). Cold mossy ledges, Sierra Madre, near Monterey, June-July, 1888; also 3354, from rocks and earth, hills of Patzcuaro, November, 1890, and, with this last, from same locality; 3352 (ticketed *Polypodium plesiosorum*, Kunze, var.), a remarkable form, with larger, broader fronds, more strongly serrated pinnæ, lower ones obtusely lobed, and the unusually stout rhizoma densely clothed with large, long and beautifully ciliated pale scales. I was at first inclined to look upon this as a distinct species, but finding similar specimens from Kew in the Cambridge herbarium marked with a query, I sent specimens of Mr. Pringle's plant to Mr. Baker, who has referred it to *plesiosorum*, but thinks it is distinct enough to make a good variety. Subsequent examinations have convinced me that he is right, and as some slight acknowledgment of the many courtesies received from him from time to

time I venture to name it var. *Bakeri;* hills of Patzcuaro, November 14th, 1890. The variety may best be recognized by the great size and beauty of the shaggy rhizoma.

Polypodium plebeium, Schlecht. (3258). Shaded ledges, Tamasopo Cañon, September, 1890; and 3351, on trees and rocks, hills of Patzcuaro, November, 1890. The two forms are quite different, and both different from specimens previously collected by Dr. Palmer; but the species is apparently an extremely variable one, embracing many forms.

Polypodium plumula, H. B. K. (3353). On trees and rocks, hills of Patzcuaro, November, 1890.

Polypodium sub-petiolatum, Hooker (3328). On trees and rocks, hills of Patzcuaro, November, 1890; and a somewhat doubtful form (3406), not safely separable from this species, was collected on the hills of Rio Hondo, August, 1890.

Pteris cretica, L. (1985). Springy places, Sierra Madre, near Monterey, June, 1888.

Pteris longifolia, L. (3359*a*). Calcareous banks and ledges, Tamasopo Cañon, November, 1890; and with it 3359*b*, var. *sub-bipinnata*, n. var.; the latter a very remarkable form, with the lower pinnæ longer than those above, pinnately divided, with the lower pinnules gradually reduced, as in a normal frond of the species, and the apices very much prolonged. Stipes and rachis stout, and especially at the base, and surrounding the crown clothed with a coarse shaggy wool.

Pteris quadriaurita, Retz (3411). Tamasopo Cañon, September, 1890

Scolopendrium nigripes, Hooker (3366). Mossy ledges, Tamasopo Cañon, November, 1890.

Plant Notes.

Our Native Nelumbo.

The Nelumbo of the Orient has so occupied the attention of the public of late years since it has become a familiar object in many public and private gardens that it is not always remembered that North America possesses a second species of the same genus. Less beautiful, perhaps, than its Old World relative, the American Nelumbo, or Water Chinquapin as it is sometimes called from a fancied resemblance of its seeds to those of the true Chinquapin, is one of the most interesting and striking of all hardy aquatic plants, and there are many ponds in the eastern states which might well be covered with its great circular cupped leaves and pale yellow flowers raised high above the surface of the water.

Nelumbo lutea is by no means a rare plant in the Mississippi basin and in many of the states which border the Great Lakes. It grows sparingly in the Connecticut River near Hartford and at a few other places in the east, although it was probably introduced by the Indians into eastern rivers, as it is so rare and local in this part of the country that it does not appear probable that it grew here without man's assistance. And the theory of the spread of this plant beyond its natural limits by the help of the Indians is the more probable because it is known to have furnished them with an important article of food in its farinaceous tubers and sweet, mealy seeds. These last are still gathered in some parts of the west and north-west and ground into flour. Dr. William P. C. Barton, of Philadelphia, published just seventy years ago in his fragmentary "Flora of North America" a beautifully colored plate of this plant, and in his description tells us that the boys about Philadelphia gathered the green and succulent half-ripe seed-pods from the marshy banks of the Delaware and found a ready sale for them among people who considered them a delicate and nutritious luxury. Perhaps some of the readers of Garden and Forest can tell us whether the Nelumbo is still found in Dr. Barton's station in the Delaware, or if it has, like many other plants, been forced to succumb before the march of civilization.

Our illustration on page 557, from a photograph made by Mr. D. Burnett, of Olney, Illinois, represents a pond in the southern part of that state covered with the Nelumbo in flower, and gives an excellent idea of how this plant appears on ponds and lagoons in many parts of the United States.

London Letter.

Iron vs. Wood in Glass Houses.—A correspondent in the *Gardeners' Chronicle* this week raises the question, Why should not iron be substituted for wood in the construction of plant-houses? There is a general objection to the use of iron, because of its supposed contraction and expansion under the influence of heat and cold, the condensation of moisture inside and consequent production of "drip," and the excessive radiation of heat from iron as compared with wood. My own observation leads me to doubt whether these objections really have any foundation in fact. There are several large houses at Kew in which the rafters and sashes are wholly iron, and neither contraction nor expansion in them is sufficient to do any damage to the glass or even to loosen it. Drip is easily prevented by a proper pitch of roof, and by means of channels cast in the iron rafters Radiation is not easily measured, but I do not think there is any appreciable difference between the loss of heat from wood and iron houses; at any rate, the quantity of piping for the one is the same as for the other. On the other side, a great deal must be urged in favor of iron as compared with wood. First cost is, of course, greater; but an iron house need not cost more than, say, twice as much as wood, while it will last at least ten times as long, as is proved by the old Victoria house at Kew, which was built wholly of iron. Then comes the question of light, and here iron is immeasurably superior to wood. Sashes and rafters, if made of iron, may be so thin as scarcely to obstruct any light, and yet be strong enough for the largest houses and in the most exposed places. A wood structure, if lightly built, soon gets out of repair and is unsafe. In some gardens, famous for good cultivation, I know iron houses are in favor. I will mention one—that of M. Warocque, of Mariemont, near Brussels, whose splendidly cultivated Cattleyas, Odontoglossums, Vandas and other plants are the subject of a most eulogistic article in the *Gardeners' Chronicle* last week by no less an authority than Sir Trevor Laurence. The houses in which these plants are grown are iron, and that they are liked is proved by the fact that a new iron house for Cattleyas is about to be erected. I know the stereotyped objection to the use of iron for sashes and rafters, that it is bad for plants. But is it? Has any one ever proved it so? The three essential qualities in a plant-house are, I take it, durability, lightness and convenience. In two of these iron is superior to wood, and in the third I am inclined to think it is about equal.

[The tendency in America is steadily toward the most durable materials for greenhouses. The fear of losing heat by radiation from metal is considered groundless.—Ed.]

Effect of Fog on Plants.—The injury done to plants by winter fogs in the neighborhood of large towns has recently assumed quite alarming proportions. The subject has been under investigation by a committee of scientific men assisted by the Royal Society, and the first installment toward a report on the whole matter was contributed in the spring of this year by Dr. Oliver, of Kew. A second contribution to this end was recently made by Dr. W. J. Russell, F. R. S., in the form of a paper read before the Hygienic Congress, and which is now published in *Nature*. Dr. Russell deals with the whole subject of town fogs and their effects upon man as well as plants. An analysis of the fog-deposit collected from the roofs of glass houses at Kew, and which had been deposited in a fortnight in February, is most interesting. It is as follows: Carbon, 42.5 per cent.; hydrocarbon, 4.8 per cent.; sulphuric acid, 4.0 per cent.; hydrochloric acid, .8 per cent.; ammonia, 1.1 per cent.; mineral matter (silica iron), 41.5 per cent.; water, 5.3 per cent. Total, 100.0 per cent.

"These analyses give, I believe, for the first time a definite account of the composition of a fog-deposit. Soot and dust are by far its principal constituents, rendered sticky and coherent by hydrocarbons, but I should like to give

you the striking description which Professor Thiselton Dyer has sent me of this deposit He says, 'It was like a brown paint, it would not wash off with water, and could only be scraped off with a knife. It thickly coated all the leaves of the evergreens, and upon what have not yet been shed it still remains.' . . With regard to plants under glass the effect of fog is of two kinds: (1) That caused by diminished light. This checks transpiration. The plants are therefore in the condition of being overwatered. A well-known consequence of this is to make them shed their leaves wholesale. Many valuable plants which ought to be well furnished with foliage become perfectly bare, and it is impossible ever again to recover them into sightly specimens. (2) The toxic influence of the fog. This is most striking. I attribute it in the main to sulphurous acid, though I cannot help suspecting that some hydrocarbon may also have something to do with it. The toxic effect varies from one plant to another; some are scarcely injured, others are practically killed. I hope you will be able to arouse some interest in this horrible plague. If the visitation of last year is annually repeated it must in time make all refined horticulture impossible in the vicinity of London." That the number of fogs experienced in London is annually increasing is shown by the statement that while between 1870 and 1875 the number recorded for the three months December, January and February was ninety-three, the number for a similar period ending last year had increased to 156. Dr. Russell does not write hopefully of the possibility of getting rid of this winter plague. He says as long as coal is burnt we shall have dense fogs, and it does not appear probable that a substitute will be found for coal.

Fig. 87.—A Pond in Southern Illinois, covered with the Water Chinquapin (*Nelumbo luteum*).—See page 556.

Fruit.—Arrangements are being made to hold a great National and International Exhibition of Fruit in London in October, 1892. It is expected that all the English societies interested in the cultivation of fruit will co-operate to insure the success of this exhibition. A committee has been appointed to formulate a scheme, and a guarantee fund has been started. Should the scheme be practicable, and there does not appear to be any reason why it should not, this exhibition ought to prove an important event in horticulture, and even in agriculture, for there are signs now of the cultivation of fruit being taken in hand by farmers. Sir James Whitehead has almost promised on behalf of the corporation the use, free of charge, of a site on the Thames embankment for the exhibition, which will be extended over a period of about ten days. It is anticipated that the foreign section of this exhibition will be a prominent feature, and among foreign growers of fruits for the English market the United States occupies a very prominent place. No such exhibition has been held in England since 1866, when a great show of fruit was held in London and was so successful that after paying all expenses there was sufficient profit to purchase the Lindley Library for the Royal Horticultural Society and to present £1,000 to the Gardeners' Benevolent Institution.

I forward you a copy of a leaflet which is being distributed all over England by the Royal Horticultural Society. It is, as you will see, intended chiefly for cottagers and small farmers, and is meant to afford them reliable information on the best kinds of fruit for general cultivation. The list, with cultural notes, has been drawn up by forty leading experts in fruit-culture in England. It gives the names of the twelve best apples for cooking, the eight best apples for dessert, the twelve best pears, twelve best plums, and a selection of cherries, damsons, raspberries, currants, gooseberries and strawberries. The habits, time of fruiting and keeping qualities of each are given, with a few important directions on planting, pruning, manuring, etc. The aim has been to make the list applicable as far as possible to the whole of England, and to include only varieties possessing the four most necessary characteristics of quality, fertility, good growth and hardiness. The leaflet consists of eight pages, and it is to be had at the rate of 2s. 6d. per 100 copies.

The Grape Crop.

THE grape harvest of 1891 will long be remembered for its abundance and low prices, which was, doubtless, materially diminished by the superabundance of peaches in market. Hereabout, however, the volume of the grape crop was not as large in the aggregate as in previous seasons, though the quality was quite up to the average. The vines and fruit were exceptionally free from fungal diseases, and where fungicides were seasonably applied very little rot developed at any time during the season, while mildew was not observed till late in August. This unusual healthy condition might be attributed to the judicious use of remedies during this and previous seasons were it not for the fact that vines which had never been treated heretofore carried as fine and healthy fruit and foliage as others. The true reason for this exemption from disease is, doubtless, that the season was unfavorable to the growth of fungi. To certain conditions of the season may also be due the imperfect pollination and poor setting of the fruit, which helped to diminish the crop.

The cause for this imperfect setting is not easily determined. Conditions of temperature and moisture seemed favorable, as far as we could judge, but buds started unevenly, and clusters were much smaller than usual; yet some few varieties were not affected in this way, and exceeded all past experience, notably the Lindley (Rogers' Number 9), generally a poor setter, but this season producing the largest and finest clusters I have ever grown.

A severe drought prevailed in this section all summer. With two exceptions, up to late in August our showers had merely laid the dust, and this, too, may have helped to cause imperfect setting; and yet the growth of vines was strong, yielding an abundance of well-ripened wood.

Just after the seeds had hardened and the development of the fruit took place rains came for a few days, and this sudden addition of moisture forced a growth of pulp which seemed too rapid for the growth of the skin, and the consequent bursting caused great loss. This inability of the skin to grow as fast as the pulp, or lack of strength to hold its expanding contents, is a fatal defect in many otherwise excellent varieties. Toughness of skin and a tight hold on the peduncle are two invaluable requisites for any grape. No matter how good it may be in other respects, weakness in either of these points is fatal. The critical period, when these weaknesses are apparent, varies with different kinds and varies in different seasons. This enables a variety to pass through a sudden excess of moisture at one time or season with safety, when it would fail if this moisture occurred a few days earlier or later. This seems to explain why some varieties crack badly one season and not another. Among the varieties that cracked badly this season were the following, and I add to each the percentage of loss from this cause: Moore's Early, fifty per cent.; Worden, fifteen per cent.; Duchess, forty per cent.; Brant, fifty per cent.; Canada, fifty per cent.; Cambridge, ten per cent.; Lady, twenty-five per cent.; Salem, seventy-five per cent.; Massasoit, seventy-five per cent.; Concord, twenty per cent.; Jefferson, forty per cent.; Packlington, twenty-five per cent.; and Woodruff Red, twenty-five per cent.

Notwithstanding the troubles which beset the vineyards in this section, the yield throughout the country was immense, our markets were glutted, and prices ruled lower than ever. A correspondent in southern New Jersey informs me that he shipped half a ton of fine grapes to New York, in ten-pound baskets. The returns were, "Sold for ten cents a basket." Of course he did not need the advice to "Forward no more," which accompanied the return. And yet the wise counsellors who are writing about the causes of agricultural depression are constantly advising farmers to plant vineyards and orchards. I have often wished that some of these glib writers would go into commercial fruit-growing and teach us how to get rich. A few seasons like the past would dissipate the dreams of certain and immense profits. The situation was bad enough even before the stupid action of the New York Board of Health still further depressed prices. The newspapers reported that arsenic had been used by vine-dressers to suppress phylloxera. They had heard of copper sulphate and the rot, but Paris Green and the phylloxera looked more alarming in the head-lines. Still, this was quite as accurate as the report of a city chemist who stated that the Grape rot was caused by an insect.

The hot dry weather of September brought to perfection some varieties that are usually so late as to be classed among the uncertain ones. Black Defiance, Catawba, Roger's 32, and Isabella were among them. The fruit of Isabella was finer than I have grown for years. Of the newer varieties, Empire State continues to disappoint; Moyer is no larger than Delaware, and a feeble-growing vine; Berckmans is far better every way, except in size; Green Mountain is early and good; promises to be the best early white Grape. Colerain promises to be its peer in every respect save earliness; both vines are good growers; their weak points will develop in a year or two's trial. The best of all the new varieties this season was the Brilliant, originated by T. V. Munson, of Texas. This has fruited with me for the third time, and this season developed most excellent qualities. The vine is a good grower and appears hardy, but will suffer from mildew in bad seasons unless protected by spraying. The clusters were medium to large, berries the same, and the quality excellent. It is some satisfaction to plant and care for Grapes of this class, but a great many of the new introductions only tend to discouragement. Our list of Grapes, like our list of all other fruits, is far too long, and needs weeding out and pruning down. The probationary time of many new ones on trial is about up.

What is needed to relieve this oppressed industry, so that fruit-growers can realize a profit out of their investment equal to the labor they employ, is increased consumption or diminished production or less profits to the middle-men. Notwithstanding the low wholesale prices, from which the growers are compelled to find their profits, if any, the retailers have generally exacted ten cents per pound from the consumer. This, in many cases, represents a profit of 100 per cent. clear of all expenses. It is evident that the profit in the business is in fruit-selling and not in fruit-growing.

The profits of fruit-growing are sure and certain when pursued for one's own family consumption. No family ever satisfies its natural longing for good fruit as thoroughly when the fruit comes from the market as when it is furnished by trees and vines on home grounds. And then there is the added pleasure of watching its growth and the satisfaction which comes from superior quality, with perfect ripeness and assured freshness.

Montclair, N. J. *E. Williams.*

Fruits and Topography.

THERE are a good many mysteries attendant upon the relations which plainly exist between the growth of tree-fruits and the lay of the land. My experience and observation for more than half a century, first in the Kennebec valley of Maine, subsequently in the slightly elevated marine plain of eastern Massachusetts, afterward in the Ohio and Mississippi valleys, and later among the hills of north-eastern Vermont and the valleys running northward to the St. Lawrence River, have helped me to solve some of these mysteries. But there is large room remaining for future investigations, especially as regards special exposures; the effect of winds in modifying temperature; the relation of soils and manures to the resistance of trees against cold; the action of the sun in winter; the protective effect of snow; but, more than all else, the understanding of the rivers of the air in their downward flow.

I have orchards on a level plain near to Lake Memphremagog, on the east shore, and other younger orchards planted upon my farm two miles east of the lake, not less than 200 feet above it. Still other orchards, well cared for, are planted with trees from my nurseries upon the west shore, at greater or less distances from and above the water. All of these afford opportunities for studying the effects of climate in a region where twenty-five years ago it was firmly believed by its long-time residents that Apple-culture was quite impracticable, except for the Siberian Crabs and their seedlings. This unfavorable section extends south beyond the divide between the St. Lawrence valley and the Connecticut as far as St. Johnsbury; east beyond the Connecticut across New Hampshire, and some way into Maine; west across the Green Mountains nearly to Lake Champlain, and north to the immediate shores of the St. Lawrence, where around and above Montreal to Lakes Champlain and Ontario lies a region of somewhat milder winter climate.

The almost hardy varieties are those from which we can learn the most on the question of climatic effects, and I was early made aware that the location of my first orchards was one requiring hardier trees than were demanded for the opposite (western) shore and for the hills on both sides of the lake. That on the immediate lake-shore we often escaped light frosts in spring and fall, which struck sharply higher up, was no evidence that winter's cold would not practically destroy or prevent the profitable culture of a number of tree-fruits there which did well at higher elevations. Among these test-sorts are the Red Astrachan, Tolman Sweet and Pewaukee

Apples, and the Flemish Beauty Pear. At my lake-shore farm I cannot make them thrive, but they all do much better less than two miles away across the water, and 200 feet higher on my own side of it.

The cause is not quite the same in all cases. In fact I am not quite sure that I fully know the cause why fruit-trees that fail on the east shore endure the winter on the west. It may be in the different angle which the trunks of trees on the respective slopes present to the sun at different times of the day; or it may be in the greater angle of the western shore, which slopes steeply to the lake, while the eastern is a broad plain that receives the down-pouring cold air-streams from the eastern hills and retains them, while similar air-currents on the west discharge themselves quickly upon and spread over the lake.

Fig. 88.—Pellæa Pringlei, n. sp.—See page 555.

But one thing is certain, namely, that these cold, invisible torrents of air, pouring down from the high valleys, must be taken account of in the selection of varieties, especially for a commercial orchard. The land east of Memphremagog rises in great steps, about four miles wide, each forming nearly level areas, upon which are some of the finest grain and dairy farms in New England. On the first and second of these narrow plains or benches corn is grown without difficulty; but on those higher up it is planted only for fodder and ensilage, on account of late and early frosts; though otherwise these high farms are rather the best in their yield of the small grains, potatoes and grass, and are by no means inferior for orcharding, the winter's severest cold being less than below, while the shorter spring and fall ensures better keeping quality in the fruit. It would surprise some to know that in our hills, and in northern Maine and Canada, the Oldenburgh apple is often kept far into winter; and this also throws a clear light upon the fact, often commented upon as unfavorable to the truth of what is stated by Russians in regard to their winter fruits, which, in some cases, hardly keep into winter at all in Iowa and Minnesota. But when we remember the differences caused by both latitude and elevation these discrepancies are reconciled. Seeing the differences made in the same direction within a distance of twenty miles in my own county, I am enabled easily to understand that apples from central Russia, between latitudes fifty and sixty degrees, may be all-winter keepers, while the same fruit grown in Iowa and Minnesota, between forty and fifty degrees, may show very differently.

Newport, Vt. *T. H. Hoskins.*

Notes on Chrysanthemums.

As we have had no public competition of Chrysanthemum-growers in New York for some years, the recent show in Madison Square Garden was of great interest to those who have watched the rise of this flower into favor. John Thorpe labored for some years to convince the florists that the Chrysanthemum was destined to become of great value as a market flower, but for a time he had small success. But, judging from the recent show, it would seem that nearly all the prominent market-growers of cut flowers are now large growers of Chrysanthemums, and we have been able to observe the results which have followed their development into true greenhouse plants. The approved method of cultivation now seems to be the growing of plants entirely under glass, planted out either on benches or in solid beds. This method seems to have its dangers. The flowers at the recent show were not lacking in that refinement and purity of color which is shown in flowers grown under glass, and they were of good size and form, with abundant foliage. But why should flowers, some of which were apparently as solid as a stone-cutter's mallet one day, melt off the next as rapidly as some roses. This certainly is not the best culture of the Chrysanthemum, which, when properly grown, is one of the most lasting of flowers. Before me, as I write, is a vase of flowers in fair freshness, and they were plucked a fortnight since, and have had to endure the atmosphere of a furnace-heated room. I do not mean to say that soft flowers were universal at the late exhibition here, for there were notable exceptions, but they were so frequent as to be a subject of much comment.

The cultivation of the Chrysanthemum is so well understood now, and it is such a simple matter to secure large well-formed blooms, that there is little excuse for the production of such disappointing flowers, the fault, of course, being caused by overheating and lack of air in the houses. The fact cannot be ignored that the Chrysanthemum is a hardy flower, naturally blooming at a

low temperature, and the closer it is kept to the latter condition the more satisfactory it will prove in all that makes it valuable to the general public. Few persons are interested chiefly in the size of Chrysanthemum-blooms, but all of us enjoy their decorative effect.

The certificates at a flower-show are beyond the comprehension of an ordinary mortal, and one can only ask sometimes what they mean, unless it be to show the kind-heartedness of the judges and their desire to give a helpful advertisement to the originators or owners of new flowers. One is kept busy at this season noting certificates from all quarters, and by the time he has compared notes with other observers the novelties are reduced to a very short list, and he makes a rather longer one of some of the old favorites which continue to come to the front again and again. Still, year by year, we find great gains, some jumping into favor, and some creeping slowly. Such flowers of recent years as Viviand Morel, Mrs. Alpheus Hardy, W. H. Lincoln, Ada Spaulding, Minnie Wanamaker, Mermaid, Lilian Bird, Jessica, etc., leave little to be desired either in form or coloring. Good reliable dark-colored Chrysanthemums seem to be for the future.

Elizabeth, N. J. *J. N. Gerard.*

Fertilizers for Tomatoes.

THERE has always been, among market-growers, a belief that a heavy fertilization of Tomatoes will lessen the yield, and prevalent opinions of this kind among farmers or gardeners, even when no sufficient reason can be given for them, usually turn out, upon careful investigation, to have a basis of truth; and yet, in spite of the belief above mentioned, tests which have been conducted for some years at the various agricultural experiment stations have given almost uniformly larger yields where the land was heavily manured. Of course the character of the soil may have some influence, and the character of the fertilizer may have still more; but a recent bulletin from the Cornell Station is worthy of attention, because, while the experiments recorded still show that heavy fertilization increases the crop, it is also explained that under certain circumstances the popular view of the case may be the true one. The productiveness of a Tomato-plant depends largely upon its earliness or on its ability to give the greatest number of pickings before frost. Therefore, any fertilizer which starts off the plant rapidly in its early growth and hastens the appearance of fruit is beneficial. We can conceive, however, that whenever plant-food that is immediately available is applied late in the season it will cause a vigorous growth of the plant, and thus delay production and ripening of the fruit. The same effect might follow the early application of raw and coarse stable-litter, in which the plant-food cannot be made ready for assimilation until late in the season.

In order to determine the results of a late application of fertilizer, nitrate of soda was used at the rate of ten pounds to seventeen plants at one application, on the 25th of June, a fortnight after the plants were set. On a similar number of plants the same amount of nitrate was applied at intervals of about three weeks, in applications of two and three pounds each. The results showed striking differences. The first lot of plants up to the last week of September gave a much higher yield in the number of fruits to the plant and in the average weight of the crop. After that date, however, the intermittent application of the fertilizer in the second lot was beginning to be felt; and, as frost held off unusually long, this lot, taking the season through, gave the best yield. If, however, the frost had come at a time when it usually does the popular belief would have been vindicated. The rule seems to be that a quick fertilizer, like nitrate of soda, ought not to be applied in this climate as late as the latter part of August. As this fertilizer, however, is readily dissolved in water and escapes in drainage, it is not advisable to make it in one heavy application early in the season, but it should be distributed in different applications, and extended from the time of planting until midsummer. Of course, nitrate of soda is not a complete fertilizer, and both potash and phosphoric acid, in some form, may be needed, too. All these materials are found in good farm-yard manure, and no mistake will be made when this is abundantly applied early in the season, provided it has been thoroughly disintegrated.

A Chrysanthemum Blight.—The particular disease referred to appears upon the leaves of the plant, blotching them with brown until they wither and fall away. The trouble is due to a species of Septoria, and therefore close in kin to many kinds of fungi that prey upon cultivated plants, producing the so-called leaf-spot diseases. This Septoria is propagated from plant to plant by means of long slender spores that are produced in large numbers in pear-shaped bodies imbedded in the surface of the affected portions of the leaf. The diseased spot itself enlarges by means of the threads of the fungus already in the leaf, spreading out laterally into the surrounding healthy tissue. Moisture favors the development of these spots very greatly. Some varieties seem to be more subject to the blight than others, but probably all will take it when conditions are most favorable and the spores or germs of the fungus are present. There is no reason to doubt that spraying the young plants with the standard compounds of copper would do much to check this disease, and thus save the foliage. It is very important to spray when the plants are small, and not delay until the blight is present. No remedy can restore a blighted leaf to a healthy condition.

Rutgers College. *Byron D. Halsted.*

The Vegetable Garden.—Many of these are now covered with a dense growth of weeds that have ripened seed, which, if left, will fill the soil and give trouble for years. A large part of this can be destroyed by burning if the garden is covered with a thick coat of straw and fired when a good breeze is blowing. Straw makes a very hot fire, and even much of the seed which has fallen on the ground can be destroyed in this way. It is a great advantage also to plow the garden in the fall, and if plowed deep the weed-seed still left will be turned down so deeply as to give much less trouble than it would if near the surface. Besides, if the garden is plowed in narrow lands and the dead furrows opened so as to carry off the water, it will dry off so as to admit of being planted much earlier in spring than if left unplowed, and it will also be in much better condition.—*W. F. Brown, in The Tribune.*

Correspondence.

In the Shore Towns of Massachusetts.—III.

To the Editor of Garden and Forest:

Sir,—Marblehead has Crocker Park, a headland on the harbor, given to the town by Hon. Uriah Crocker—a fine view, rocks, no trees, very steep in places, and not safe in its present undefended condition. Railings are needed at the top of the ledges. There is another headland, or portion of a hill-top and slope, which was given to the town by Hon. J. J. H. Gregory. This also affords a good view of the water. The Old Burying Hill has few interments of late years. The title is in the town, and it is much used as a place of public resort. The site of the fort on the shore, occupied during the civil war, has been improved and cared for by the Town Improvement Association with the understanding that it was a public possession, but the owners of the adjacent land have recently built a fence across the area which had been used by the public, enclosing about half of it, and greatly impairing the value of the remainder for public use.

I spent a memorable day with Messrs. Chase, Eliot and Wigglesworth in the Lynn Woods. This tract of 1,600 acres of land and water is a possession of extraordinary importance. No other of the smaller cities of our country has anything to compare with it in extent. It is a region of unspoiled woodland, and it will so remain, as it is not intended that it shall ever be made a park in the ordinary sense of that word. There is an admirable system of roads, which will be extended, and there will be need of shelters at various points. There will be as little artificial construction as possible, no decorative gardening, no perceptible interference with the wild sylvan beauty, which is the essential charm of this great public resort. Its proper official and distinctive name is The Lynn Woods.

The two wolf-pits are objects of great historic value. I have not been able to learn of the existence of any similar remains anywhere in this country. They are perhaps eight or ten feet deep, but have been partly filled up by leaves drifting in. I thought them about eight or nine feet long and three or four feet wide. A recent newspaper article described them as circular, with walls narrowing at the top. I suppose the writer thought wolf-pits ought to have that form. But those I saw are parallelograms with vertical walls, their corners right angles, and, in short, with nothing circular about them. The smooth stone walls were so well laid that they are still not perceptibly out of plumb. These pits should be very carefully protected and preserved that they may never become mere restorations.

Quincy has Merrymount Park, seventy-five acres on the shore, woodland and ponds, given to the city by Hon. Charles

Francis Adams in 1885. It has not been improved very much, as one of the conditions of the gift was that the city should not expend more than $1,000 a year on the park for the first ten years. After this term expires more will be done for its improvement. Faxon Park, about twenty-six acres of woodland, in the region formerly called the South Common, not on the shore, was given to the city by Hon. Henry H. Faxon in 1885. It is not improved much. Before 1885 Quincy had no park or common. The people went to the beaches, and do now, but there are no public holdings on the shore outside of Merrymount Park. The city was incorporated in 1888, and has now 17,000 people. The Village Improvement Society has recently put up a fine granite fountain, costing about $6,000, on land belonging to the Street Department, formerly a part of the old Training-field.

Weymouth is fortunate in the possession of Webb Park, which has recently been presented to the inhabitants of the town by Mrs. Margaret T. W. Merrill, of Portland, and Mrs. Nancy B. Jackson, of Boston. The donors are descendants of the late Christopher Webb, a prominent lawyer of Weymouth, who represented the town in the General Court for thirty years or more. This park-land was formerly a part of the estate of Major John White, who owned a large farm here a hundred years ago. Christopher Webb married his daughter, Miss Susan White, and this is a portion of her inheritance from her father's estate. Its area is eight acres. It lies high, overlooking all the Weymouth Fore River country and the numerous islands off shore. In the deed of gift the donors say the land is given to the town "in consideration of our regard for our birthplace and as a memorial of our honored parents." It was an act of far-sighted beneficence, an admirable and enduring example to the people of other Massachusetts towns.

There is a small common at Hingham Centre, perhaps two or three acres. Fountain Square, near Hingham Station, is little more than a slight expansion of the streets which cross each other diagonally there. There are five large Elms here, planted about seventy years ago. There are no other public holdings. The town formerly owned a considerable area along the town brook, but sold it at low rates long ago. Much of this land is now built upon, and the town has repurchased some of it in later times, paying a good price. Melville's Garden, at Downer's Landing, a noted resort on the shore, had 275,000 visitors during the season of 1891. It is a private holding, with restaurant, etc., and brings a great revenue to its proprietor. Such resorts are sure to be multiplied in the shore towns, and to attract an increasing number of visitors from the cities and from the interior of the country. In Hingham I saw the Old Place which has been made historic by the story of its renewal, which Mrs. Robbins has told with such extraordinary vivaciousness and interest in GARDEN AND FOREST. The Agricultural Society has large grounds at Hingham, but they are not used as a place of public resort. The town ought to have a park or reservation on the shore. There are many things of historic interest here, and there should be an increase of popular interest and knowledge regarding them.

There are no public holdings in the town of Hull. The great beach at Nantasket is all private property. Some of the hill-tops and great reaches of shore lands should belong to the town, or to the state, for the use of the myriads of people from the cities who throng the island every summer.

Cohasset has one of the prettiest commons I have seen in any village: about four acres, fine trees and grass, enclosed with a fence of posts with two chains. A church, built in 1743, stands within, about the middle of one side. There is an enchanting view of the water and meadow shores. The common is obviously incomplete at this end, and I was told that the town owns an area outside at that point, and that a man living near had obtained permission to enclose a part of this valuable public holding for his own private use. Even if this were included the common would be small for the public need. By permitting such occupancy several of the shore towns have lost title to land which would now be an important public possession. There is a comparatively roomy playground around the new Osgood school, and the building has more architectural character and beauty than I have seen anywhere else in a schoolhouse.

The name Scituate appears to be a corruption of an Indian word, Sa-tu-it, accented on the second syllable, and said to mean brook, or cold brook. It is still in use. I think the meaning of Indian names is mostly uncertain and a matter of guess-work now, and the sound is more important, when it is pleasant or musical. We still have Cotuit, and some other names very similar in sound. The town had formerly extensive holdings on the beach. Deane's History says: "The beaches from the third cliff eastward to the river's mouth have been defended from waste by repeated acts of the town, forbidding the removing of stones, &c. Two landings at the harbor have been preserved by the town, and frequently surveyed for the purpose of keeping their bounds. These came into the town's possession in 1704, when the Conihassett Partners surrendered their highways, etc., to the town." These important shore lands have mostly been forcibly taken possession of and appropriated to their own use by some of the owners of contiguous grounds. The town has been the theatre of one of the great beach controversies of the country. It has vainly expended thousands of dollars in the effort to defend its rights on the shore. The people have grown weary of the unavailing struggle, and although the courts have not rendered a full decision on the merits of the case, it is not likely that the town will make any further effort to obtain redress. The men who have seized the public property say to the people of the town, "Come on this beach if you dare!" and if any citizen drives his team on the shore in the exercise of the ancient right to collect seaweed or drift-stuff they meet him with weapons and violence, attack his horses with pitchforks, and are thus able to "hold the fort" against all efforts to maintain the public right to the beach.

In early times the town had a large Training-field. A long time ago a man sat down on it and stayed there, and the town could not get him off, or it did not, and some of his family are living there now. A fragment of the old Training-field still remains unappropriated to private use, and now forms a small common.

The records say that when this region was first settled by white men the shores of the bays here were skirted with forest-trees quite to the water's edge, and some of the earliest entries mention the Live Oak forests in the vicinity of Coleman's Hills. What tree was this? Walnut-tree Hill was so named because the Black Walnut was indigenous there. It was a wild region of woods and waters. There were many beaver-dams, and for nearly a hundred years the town voted every year a bounty for the destruction of wolves. There is still a Town Swamp on the maps here, but the last of this public holding was assigned to various citizens long ago. I copied from the Town Records of 1706 the statement that eighty lots of Cedar-swamp were conveyed to individuals by a committee appointed by the town in February of that year.

At Hobart's Landing, on North River, in Scituate, ships were built as early as 1650. Here the ship Columbia (Captain Kendrick) was built by James Briggs in 1773. This was the first ship to visit the north-west coast from this country. Captain Kendrick explored the River Oregon and named it after his ship, the Columbia. Many of the whale-ships employed by the people of New Bedford and Nantucket during the latter half of the last century and the early part of this were built in Scituate. They generally rated from 300 to 350 tons. The largest of which I find any record was built in 1812 by William Delano, nearly 500 tons.

In 1830 Captain Samuel Barker received a premium from the Plymouth Agricultural Society for the best crop of rye in the country, and two other citizens had premiums the same year for general improvement of their farms. The year before Colonel James Curtis had received a donation for general improvement of his farm, and Thatcher Tilden a premium for the best crop of rye. I think that agriculture in Scituate has rather declined than advanced since then. An old cemetery here has been much neglected and abused. A public highway has been run through it, destroying many of the graves and head-stones. The sites of some of the smaller burying-places mentioned in early histories of the town are probably indistinguishable now. I hope soon to learn whether this is so or not.

Queen Ann's Corner has its name from Ann Whiton, who kept a tavern there in 1730 and many years afterward, where the Plymouth road crosses the town line to Hingham. I copied the earliest marriage notice preserved in the Town Records, "Resolved White, to Judith, daughter of Mr. William Vassall, November 25th, 1640." Resolved White came to Plymouth in the Mayflower with the first company of pilgrims in 1620, and had lands laid out to him in Scituate in 1638.

In Scituate I saw the birthplace of Samuel Woodworth, the author of the poem "The Old Oaken Bucket." He was born here January 13th, 1785. He early chose to be a printer, and was apprenticed to Benjamin Russell, editor of the *Columbian Centinel*, in Boston. He became a busy journalist and prolific author. He went to New York City in 1809, and in 1823 was associated with George P. Morris in establishing the *Mirror*. The Old Oaken Bucket poem was written in the spring or summer of 1817. Mr. Woodworth was then living in Duane Street. He came home to dinner from his office, near the foot

of Wall Street, on a warm day and took a drink of water, saying that he would rather have a drink from the old well at home. His wife said, "Selim, that's a pretty subject for a poem," and he wrote it. I have read an autograph letter written by him in August, 1835, in which he says that his second son, twenty years of age, was at that time on a three-years voyage to the Pacific Ocean as captain's clerk to Captain Morrell, who discovered the Cannibal Islands. Mr. Woodworth died December 9th, 1842, and was buried in New York, but his body was afterward removed to San Francisco. I wish to learn where it now lies, and whether there is any monument over his dust. I think the birthplace should be marked in some appropriate way, and should like to communicate with some of his descendants, in order to consult them regarding the matter. The well and the little old mill appear to be the same as when the poet saw them daily in his boyhood. I think we ought to preserve the well, and perhaps the millstones, which are still in use. The birthplace is visited by an increasing number of the summer dwellers on that part of the shore, sometimes as many as sixty in a day. The interest which attracts people to a poet's birthplace is wholesome and should be encouraged, but it cannot always be convenient in its results for the courteous family now having the care of the celebrated well. Pleasant attention is given to all visitors, and fees, frequently offered, are always refused. *J. B. Harrison.*

Boston, Mass.

The White River Forest Reservation.

To the Editor of Garden and Forest:

Sir,—Colorado has the honor of possessing the first forest-reservation under the act of Congress passed at the last session. This is "The White River Forest Reservation," for which a proclamation was issued by the President on October 17, 1891. I have carefully examined the whole tract, and a general description of it would, no doubt, be of interest to the readers of Garden and Forest.

This reservation lies in the western part of the state, and comprises the eastern portions of the counties of Garfield and Rio Blanco. It is just over the crest of the Continental Divide, where the rivers run almost due west, and where the greater rainfall produces a larger forest-growth than on the eastern side. The tract is rectangular, extending about fifty miles north and south and forty miles east and west, beginning about seven miles north of Glenwood and ten miles east of Meeker. It therefore has an area of about 2,000 square miles, or about 1,350,000 acres. Three rivers receive a large portion of their water here. In the southern part its slopes drain into the Grand River, which flows past its border. In the centre, near its eastern boundary, rise the White River and the many small streams which form its head-waters. In the northern portion rises the Williams River, the main tributary of the Yampa, which, like the White River, empties into the Green River near the Utah line.

The reservation is made to cover what is known as the White River Plateau, which, although broken with hill and valley, and nowhere strictly level, is crossed by no mountain ranges, and has a general level character, varying in altitude from 8,000 to 11,000 feet, with here and there ragged peaks rising as high as 12,000 feet. The formation is volcanic, and the immense forces which threw up these bold cliffs and great rocks are visible everywhere, forming a peculiarly grand and sublime scenery.

About two-thirds of the surface is covered with a dense forest, in some places almost impenetrable, consisting of one deciduous and three coniferous species. Each species has its own habitat or level, and seldom encroaches upon that of the other. The first tree we meet is the Aspen, at an altitude of about 8,000 feet. Above this comes the Red or Douglas Spruce (*Pseudotsuga taxifolia*) at an altitude of 8,000 to 9,000 feet, and from this to the timber-line, 9,000 to 11,000 feet, is the White or Engelmann Spruce (*Picea Engelmanni*). With the Engelmann Spruce, at an altitude of 9,000 to 10,000 feet, is mingled in large numbers the Balsam Fir (*Abies lasciocarpa*). But this tree is of little value commercially, so that the forests of this reservation may be said to consist of Red and White Spruce. Grand trees they are, rising slim and straight like a column of verdure to a great height, their trunks perfect, without a bend, and as straight as ship-masts. Many have reached their maturity, and are toppling to their fall. The forest-floor is covered with dead trunks in all stages of decay, among which, and fed by them, are young trees of every age. The Red Spruce is the more valuable timber-tree, and being easily reached on the lower slopes is cut to a considerable extent. The White Spruce forests are so inaccessible as to be of little commercial value, at least for many years to come. At present the main object for the reservation is to conserve the water for irrigation in the valleys below.

The soil is in many places boggy, and the whole country is full of springs and little rivulets. Wherever the nature of the ground will allow, lakes are formed of all sizes, from fifty feet to three miles across. On the highest portion of the plateau, where the surface is less broken and opportunities are given for the water to accumulate, the little lakes are innumerable, and one may ride for hours among them. This reservation will be the means of storing an immense quantity of water, which will be of incalculable value to the wide valleys in western Colorado and Utah, through which flow the three rivers which largely receive their supply from this region. In the winter the accumulation of snow is immense, lying in many places twenty feet deep, and never less than six feet, and not disappearing until July. The beneficial effects of the forest upon this mass of snow is evident to any student of its influences.

The reservation contains magnificent scenery, which in its way surpasses that of any other region. From the highest peak, Mt. Marvine, a little over 12,000 feet in altitude, a most extensive view can be obtained, which will repay the adventurous climber. At his feet is spread the whole of the reservation. He can note the nature and extent of the forest, and the open parks and valleys. He can follow the course of the large streams and rivers, until they lose themselves in the distance. He can point out the peaks of the reservation, and beyond them the higher ranges, white with snow, which bound the horizon as far as the eye can reach. Few more attractive places than this reservation can be found for the tourist, and a trip through this region is well worth any trouble. It must be done on horseback, with guides and a camping outfit. Glenwood Springs, a well-known watering-place on the Denver and Rio Grande Railroad, is the best place to start from.

Game abounds in this region. The lakes and streams are full of trout; and elk and deer, bear and mountain lion roam the woods. But the large animals are becoming scarce, and some method of game preservation must be adopted at once to prevent the total destruction of the deer and elk.

Perhaps in no state or territory are the forest-reservations more important than in Colorado. For, besides preserving the timber, they prevent the diminution of the waters for irrigation, without which the agricultural and fruit-growing industries, now fast becoming most important, would languish and fail. Several other reservations have already been asked, and still others are in contemplation. After long waiting it seems that we have now the opportunity to protect our streams, and it is intended to push the movement now begun until the head-waters of all Colorado rivers are reserved.

Colorado Springs. *George H. Parsons.*

The Specific Name of the Texan Cercis.

To the Editor of Garden and Forest:

Sir,—I have read with some surprise in Professor Sargent's "Notes" upon the synonymy of the Texan Red Bud (page 448, *supra*) that he proposes to call it *Cercis Texensis;* for I thought I was quite familiar with the fact that it had been duly published by Dr. Gray in the "Plantæ Lindheimerianæ," as long ago as 1850, under the name *C. reniformis*, taken up from Dr. Engelmann's manuscript. Only a glance at the place thus referred to is needed to show that my impression was correct. It was altogether erroneous to have stated, as was done in the "Botany of California," that up to 1876 *C. reniformis* had remained a manuscript name. The supposition of Professor Sargent appears to be that, since Dr. Gray did not himself recognize in this shrub of the south-west anything beyond a mere form of *C. occidentalis*, he could not, or did not, give due publication to the name *C. reniformis*, though what logical or historical reason he may have for the supposition I cannot imagine. While Dr. Gray did not adopt Dr. Engelmann's opinion, he, nevertheless, conceived it to be an opinion worth publishing, and published it, at the same time appending the name by which it was intended the species should be known in case specific rank should at some future day be generally conceded to it. It is certain that Dr. Gray had no other purpose in then printing the name *C. reniformis*, along with the means of identifying it, but this, that his esteemed collaborator's proposed name should forever designate the species in case it should be accounted a species. He did it in order to preclude all possibility of Dr. Engelmann's losing his right to the name. It was, in his intent, an effectual preventive of any possible future *C. Texensis*, for example. This provisional

publication of another's species, under just such protest, but with the certain effect of securing to the species its earliest proposed name in case of its acceptance as a species, was done over and over again by Dr. Gray, as by many another eminent botanist. I have never before heard the tenability of such a name called in question, and I am sure the verdict of botanists would be that, as an indubitably valid name for the Texan Red Bud, *C. reniformis* antedates *C. Texensis* by forty-one years.

University of California. *Edward L. Greene.*

[The point made by our correspondent relates to one of those questions of nomenclature about which different authors have maintained different views. The name *Cercis reniformis* is not Engelmann's, for he never published it. It is not Gray's name, for Gray did not adopt it, although he referred to it in the work cited by Professor Greene. Brewer & Watson mentioned it in "The Flora of California" (1876) with a short descriptive phrase, so that they must be considered the real authors of *Cercis reniformis*, whether that name is retained or is considered a synonym.—Ed.]

The Acorn Crop.

To the Editor of Garden and Forest:

Sir,—Referring to the failure of the acorn crop in Minnesota, as recorded in a note in your issue of October 21st, I would say that in this section acorns are very abundant. The Bur Oaks, of which there are numerous cultivated trees here, are unusually full. So also are the White Oaks, Swamp White Oaks, Rock Chestnut Oaks, Black Oaks, Scarlet Oaks, Red Oaks, Pin Oaks, Spanish Oaks, Post Oaks, Black Jack and Willow Oaks, all of which are here in their wild state. That there are no acorns on the Minneapolis Bur Oaks is the reverse of what I should expect. I have occasion to be interested in the acorn crop every year, and think I can safely say that, as a rule, a failure in one part of the northern states means a failure in all parts of them. That is, if the Scarlet Oaks of a given locality fail to yield acorns it is almost useless to look elsewhere for them, and the same is true of all other kinds. But this rule does not hold good in the southern states. To my knowledge, for perhaps twenty-five years past, demands there for acorns of *Quercus Catesbæi* and *Q. aquatica*, made yearly, have always been met. Referring again to the Bur Oak, the large specimen in Bartram Park here is unusually full of fruit this season, but a tree of *Q. lyrata*, which is near it, has hardly an acorn on it.

Germantown, Pa. *Joseph Meehan.*

Periodical Literature.

As represented on a detailed map of any important county in any of our states, says Mr. Isaac B. Potter in the November *Forum*, our country roads show an enormous extension, and "three of our states can be easily selected in which the total length of public roads, exclusive of town and city streets, is greater than the combined mileage of all the railroads in the world." Mr. Potter is the secretary of the New York State Roads Improvement Association, and his article, called "The Profit of Good Country Roads," is therefore entitled to earnest attention. How does he describe the condition of the public ways in question, after noting the immense sums which, in deference to the demands of capital—for the profit of individuals and corporations more immediately than for the profit of the people at large—the nation has spent in the establishment of commercial centres, in the development of railroads, in the improvement of river-ways and harbors, and the extension of telegraphic lines? "With the enlargement of concentric circles surrounding every American inland town," he says, "is to be found an apparently undue diminution of agricultural population, wealth and thrift." And this is because "the dirt-road, that only avenue of communication which connects the farmer socially and commercially with the world at large . . . is the same road that was used a hundred centuries ago by the naked savage when chased by a storm to the sheltering cave, and from him seems to have descended as an entailed legacy to the American government. In all these years it has not changed, except that the modern article is more or less churned and mangled by narrow wheel-tires and flanked by costly and useless fences—two species of property unknown to our primitive ancestor and first conceived at that later period which marked the dividing-line between instinct and imbecility. Measuring a million miles or more in its various ramifications, dissolving in the rains of April, baking and pulverizing beneath the rays of the midsummer sun, drifting and disappearing in the whirlwinds of November, and presenting at all times but little more than a roughened streak of soil to serve as a land highway for the great volume of internal traffic the time seems to have come when the American common road may rightfully assert itself as the most expensive and by all odds the most extravagantly maintained of all the public institutions. To the intelligent foreigner who comes to our shores the American 'system' of road maintenance is little short of ridiculous; to the thoughtful and inquiring native it is only a kind of legalized negligence, a relic of feudalism borrowed from England in the old days of governmental poverty and placed in the keeping of the most patient and long-suffering of our industrial classes, who have gradually been led by 'the ensnaring wiles of custom' to endure and embrace it." Then the author declares, and all sensible men will agree with him, that an understanding of the pecuniary benefits of good roads "is a national question; for these roads are the common care and property of all the nation, and any effect which grows out of their improvement must be found directly in the economic condition of the persons and property within their widened influence."

We cannot follow Mr. Potter through the explanation he then gives of the condition of American farms, illustrated by many facts and figures, showing how vastly the number of small holdings has decreased in the west during the past ten years while the extent of very large ones has correspondingly increased, and calculating the future need for good common roads by estimates of the rate at which the agricultural productiveness of many regions may be expected to augment during the immediate future. We can merely recommend his article to all good citizens as the most scientific exposition of the matter which has yet come under our eyes, and, therefore, of course, the most convincing. He then quotes the experience of foreign countries to show the value and ultimate economy of good systems of road-management, and likewise of a few American counties where experiments in this direction have been made. He cites, for instance, the testimony of a resident of Union County, New Jersey, where forty miles of telford and macadam road have been built at a cost of $10,000 per mile, which declares "that the property in Union County has actually appreciated in value far more than the cost of the roads, and this not only in cases of sale or exchange but upon the tax-levy. Notwithstanding the fact that $300,000 worth of county bonds have been issued to build these roads, and the interest must be met annually, the tax-rate has not been increased in the county, or in any city in the county, in consequence of the extra interest-expense; and it is but fair to say that the actual appreciation of property due to the increased value of lands benefited by the improved roads meets the increased taxes already. And none of our roads have been completed for more than a year, and some parts of them only within the present month. As an advertising medium alone they have been worth what they cost. . . . It is safe to say that the citizens and taxpayers of Union County would not go permanently back to the old system, with its old roads, if they were paid many times the cost of the new roads."

The agitations in favor of new roads recently begun in several states are then mentioned by Mr. Potter, and a deserved tribute is paid to the services of the "League of American Wheelmen," whose 25,000 members have done a vast amount of careful, conscientious, systematic work in the way of collecting statistics, printing and circulating information, and studying the best methods for improving the present state of things—work which has, of course, been largely inspired by a sense of their own personal interests and yet has been carried on in a truly public-spirited way, and will unquestionably conduce very greatly to the benefit of the people as a whole. In conclusion Mr. Potter says that he believes "the signs are hopeful, and the future of the American road is full of promise." Work for its improvement is already "well in hand," and he is cheered by the thought that soon "the government and the states will be brought to adopt that beneficent principle of statecraft which leads a nation rightly and fully to exercise its paternal functions and to direct the public hand to the aid and development of that great branch of industry which was born with the birth of the nation itself and upon the success of which all national wealth must eventually depend."

Notes.

A chute in the logging camp at Clifton, Oregon, is described as one of the longest in the world, measuring three-quarters of a mile. Its bottom is shod with railroad iron, and, on account of its smoothness and the steepness of the descent, logs traverse it in the space of twenty seconds.

Hungarian vineyards have been terribly devastated of late by the phylloxera, the celebrated establishments at Hegyalya, the headquarters for the production of Tokay wine, having been almost wholly destroyed, many other districts being in as bad a case, and the pest having spread through 1,500 parishes.

The Grand Falls of Labrador were recently rediscovered by an expedition of students from Bowdoin College, and prove to be one of the greatest natural wonders of the world. The precipice is 316 feet in height, and the rapids above the fall make the entire descent about 500 feet. The river is a powerful stream 200 feet wide.

The Canna, Star of '91, which was shown in abundance at the late flower-show in Madison Square Garden, proved to every one that it is to be classed among the very best of these dwarf varieties along with Madame Crozy. Some growers claim that Madame Crozy is best for outdoor work, but we could hardly dispense with either one of these constantly blooming plants.

A correspondent of the *Country Gentleman* states that the Locust-tree was brought to this section from Virginia by Captain John Sands, of Sands' Point, Long Island, about 1700. During the last twenty years the demand for locust-timber has been so heavy as to cause almost an extermination of the trees. With the small supply and increasing demand, Locust-saplings are sure to prove a good investment.

The first-prize seedling Chrysanthemum of this year at the Chicago exhibition was shown by Frank Leslie and named Mrs. A. C. Allerton; it is a distinct coppery yellow, incurved flower of large size. Mr. J. C. Vaughan received certificates for the King's Daughter, a large flower with petals of snowy white, and for Golden Gate, a large double reflexed chrome-yellow flower. Messrs. Pitcher & Manda also received a certificate for a yellow flower of the Mrs. Hardy type, and named W. A. Manda.

Among the successful Chrysanthemum exhibitions of the season the one held at Buffalo last week is worthy of mention. The correspondents speak in praise of seedlings raised by John F. Cowell, of that city, as very meritorious, one of them being a hybrid between Louis Bœhmer and Lilian Bird, in which the petals, although tubular, are strongly incurved. William Scott's collections of Carnations were praised, and an unnamed variety called No. 24, white with a fringed edge, strongly scented and numerous long petals, is spoken of as an excellent flower, as is No. 30, a pink, somewhat darker than Grace Wilder.

The annual Chrysanthemum-show at Indianapolis has usually brought out many promising seedlings, and this year there were a large number certificated, several of which have already been described in our columns, as, for example, Pitcher & Manda's Harry May, and E. G. Hill & Co.'s O. P. Bassett, Maud Dean, Edward Hatch, Mrs. Lewis Childs, Madeira and Mrs. Robert Craig. Henry Rieman won the prize for the best Pink with Olga, a fine well-built flower, full and double to the centre, on a strong stiff stem. Nathan Smith & Son showed the best yellow in Miles A. Wheeler, and the same growers won the premium for the best white flower with Mrs. Governor Fifer, a flower of informal shape, with broad petals and fine contour.

It is very plain that English growers have not found out how to treat the Chrysanthemum Mrs. Alpheus Hardy, as there is general complaint about it in the horticultural journals across the water. It is stated in *The Garden* that in the great national Chrysanthemum-show there were not more than half a dozen blooms of this variety in the whole exhibition, and only one of these could be called up to exhibition form. It is a misfortune that some of these English gardeners could not have seen the vase of cut blooms of this variety shown at the New York exhibition by Peter Henderson & Co. So far from not fulfilling the early promise of the flower, they were better this year than ever before. The blooms were absolutely perfect, although the stems were too feeble to hold them up as they should.

A few years ago the beautiful little Ram's-head Lady's-slipper was discovered in the Chinese province of Yun Nan by Abbé Delavay, and this was another illustration of the close relation between the flora of eastern North America and that of China and Japan. Orchids, however, are not widely distributed, and this fact was considered most interesting. We are now informed in a note in the *Gardeners' Chronicle* by our correspondent, Mr. R. A. Rolfe, that a collector on the Tibetan frontier, Mr. A. E. Pratt, has sent some fine specimens to Kew of *C. spectabile*, which is probably the most beautiful plant of the genus and one of the most charming of our North American hardy flowers. We shall, therefore, be able to speak no longer of this showy Lady's-slipper as an exclusively American flower.

Everybody admires the bold masses of white flowers in the autumn on well-grown plants of *Pyrethrum uliginosum*. In many places abroad it is used at the back of a mixed border with Dahlias and early-blooming Chrysanthemums in front. Some people, however, think that the size of this plant detracts from its decorative value, and they will be glad to receive the suggestion which Mr. R. Dean makes in the *Gardeners' Magazine*, London, that branches of this plant can be layered just before the buds are formed, when they root readily and make neat little plants, six or eight inches high, which will be covered with bloom. It is an easy matter to layer the plants in this way, as they root readily, and the dwarf plants which are thus produced will be found very useful for decorating cold greenhouses or as window-plants at this season.

Some years ago Mr. Heinrich Schmidt, of Erfurt, found in a neglected nursery-garden a wild Cherry-tree, which he cultivated, and which finally became a well-grown tree of good appearance, and with the remarkable peculiarity of bearing ripe fruit in September and October. Mr. J. C. Schmidt, who is now the proprietor of the same establishment, writes to the *Gardeners' Chronicle* to invite attention to this remarkable tree, which does not begin to ripen fruit until all other cherries are gone. The first ripe fruits are seen in early September, and up to the middle of October there appear ripe, half-ripe and unripe fruits on the tree at the same time. The fruit is said to be of a dark red color, of good size, with a fine acid, vinous flavor. Mr. Schmidt's letter was accompanied by a wood-cut taken from a photograph executed on September the 12th, in which the ripening fruit appeared. The firm has called the variety Hochgenuss von Erfurt, Great Satisfaction from Erfurt.

The King of the Belgians is well known for his devotion to horticulture and landscape-gardening. For ten years His Majesty has been designing and superintending alterations in the palace and grounds of Ciergnon Castle, which has been erected on the site of a small hunting-lodge used by the late Leopold I., where there is a large and well-stocked conservatory in which an electric-light can be made to glitter at the base of every plant by simply pressing a button. The engine which furnishes the electricity for the light also pumps water to a large reservoir which is used for watering the plantation in the park, and the tank is planned so as to be ornamental as well as useful. The ground about it is arranged in a natural manner, and little brooks and cascades have been made to course through them under raised bridges and through gorges which open vistas into the adjoining country. The grounds are near the woods of the Ardennes, and they extend for a distance of three leagues on a gentle declivity from the chief entrance for some distance, and then rise sharply to a Pine-clad ridge.

Professor Trelease, of the Missouri Botanical Garden, has issued his third announcement concerning garden-pupils. It will be remembered that two years ago six scholarships were established, which were to be awarded by the director on competitive examination to young men under certain conditions provided by the trustees. One candidate for these scholarships was to be named by the Horticultural Society of Missouri, and another by the Florists' Club of St. Louis, and of the three scholarships to be awarded by the director of the garden before the 1st of next April one is now reserved for the nomination of the Florists' Club of St. Louis. Applications for scholarships must be in the hands of the director before the first day of March next, and the examination will be held on March 8th at the Shaw School of Botany. We have before spoken of the thorough nature of the course presented by this institution, which aims to give thorough instruction in vegetable-gardening, small-fruit culture, orchard-culture, forestry, botany, landscape-gardening, vegetable physiology, economical entomology, etc. It is especially desired that the candidates for scholarship should not be much over fourteen years old, and they will receive all needed information together with the necessary blanks, if they will address Professor William Trelease, Director of the Missouri Botanical Garden, St. Louis. The course of instruction is not planned to be a mere repetition of the courses now offered by the numerous state colleges of the country, but it is quite distinct and held strictly to what will be considered necessary for the training of practical gardeners. There certainly is room for an institution of this sort in the United States, and it is to be hoped that many bright young men will avail themselves of the singular advantages which are here offered.

TABLE OF CONTENTS.

The Manzanita.

EVERY one at all familiar with the flora of the eastern states knows the Bearberry, a delicate plant which often covers rocky and sandy soil with a dense carpet of long prostrate stems clothed with small, thick, dark green evergreen foliage, and which in early spring covers itself with clusters of handsome flesh-colored flowers, in general form not unlike those of the Blueberries. These are followed in the autumn by red fruit which resembles that of the Cranberry, although it is smaller, less brilliantly colored, and of insipid flavor. This plant is the type of the genus Arctostaphylos, and botanists call it *Arctostaphylos Uva-ursi*. It grows in America from the mountains of Pennsylvania to the Arctic Circle, in the Rocky Mountains, on the Pacific side of the continent as far south as northern California, and in the mountains and boreal regions of Europe and Asia. There is another species of Bearberry which occurs on the alpine summits of the New England mountains and in British America. This second species is also circumpolar in its distribution, so that eastern America possesses no endemic representative of the genus, which, although our two species are beautiful plants, makes no great display here, and does not form a conspicuous type of our vegetation. West of the summit of the Sierra Nevada, the Bearberries, or Manzanitas, as they are always called in California, are so abundant, both in species and in the number of individual plants, that they are a feature of California vegetation, often beautiful in itself, and quite unlike anything seen in other parts of the country.

There are ten or eleven species of Manzanitas found in California; some are small and some are tall wide-branched shrubs; and one species, at least, under favorable conditions, attains the size and habit of a small tree. This is the plant to which the late Dr. Parry, who studied the Manzanitas for many years, and knew them better than any one else, gave the name of *Arctostaphylos Manzanita*. Like most of the species, and like their near relatives, the Madronas, the bark of this plant is smooth and bright red even on the small branches. One of the peculiarities of all the species is that the bark is renewed every year; in May or June, when the annual growth begins and the branches swell, the outer layer of the bark formed the previous year breaks into large loose flakes, which gradually fall and display the pale green new bark, which on exposure to the light soon turns red. It is the smooth red trunk and branches which make the California Manzanitas such peculiar and striking objects, and which excite the astonishment of travelers from other parts of the world. The leaves are ample, obtuse, bright green, and, like those of many of the species, appear vertical on the branches by the twisting of the stalks, a provision of nature by which many shrubs in dry arid regions are saved from unnecessary evaporation. *Arctostaphylos Manzanita* is one of the earliest of the family to flower, and it is not unusual to see it covered with its clusters of white bell-shaped blossoms at Christmas-time, although at high elevations the flowers do not appear before the month of May. It is a widely distributed plant, and there is still much to learn of its distribution and of that of several of the other species; but it is known to be abundant along the foot-hills of the Coast ranges north of the Bay of San Francisco and in the valley of the Sacramento, extending up the western slope and probably across the Sierra Nevada. At high elevations it is a low shrub; on the dry barren slopes of the foot-hills it is a tall, wide-branching, usually rather sprawling, shrub, but in favorable situations, where the soil is rich and water is near at hand, it occasionally attains the size and habit of a small tree. Such a specimen is represented in our illustration on page 571. It is believed to be one of the largest, if not the largest, Manzanita in existence. This wonderful plant is thirty-five feet high, and the branches spread out in one direction to a diameter of thirty feet, and in the other to thirty-six feet; but the thickness of the short trunk is more remarkable even than the spread of the crown. At the ground it girths eleven and a half feet. This size is maintained up to the division, which takes place two and a half feet above the surface of the soil, while the two principal branches at their point of separation each girt a little more than seven feet. This tree is growing on the estate of Tiburcio Parrott, Esq., in St. Helena, Napa County, to whom we are indebted for the use of the negative from which our illustration has been made. It stands near a spring in deep rich loam, and close by may be seen other specimens with stout trunks, several of which girt at least six or seven feet.

A happy chance has preserved this giant of its race which represents, no doubt, the growth of centuries, for the Manzanitas are usually slow-growing plants. The great scar of the wound made by an axe on its trunk shows how near it once came to death. Years ago a wood-chopper in the employ of the Napa Valley Wood Company had begun to cut it for fuel; a man passing by purchased its life by the payment of two dollars, and so saved a plant which is, in its way, as interesting as any of the great trees of California, and in doing so earned the gratitude of every lover of trees not only in California but in all the civilized world. It was Dr. C. M. Hitchcock who did this good deed. If he is still alive he has perhaps forgotten all about the great Manzanita and the two dollars which he gave to ransom its life. But his connection with it must not be forgotten, and we should like to see placed on the tree a tablet which should recite its history. The preservation of such trees is a matter of public congratulation, and the memory of the men or women who preserve them may well be kept green as an example worthy of imitation by all broad-minded and intelligent people.

OUR readers remember, perhaps, the portrait of the Red Oak which appeared two months ago in this journal. It represented a tree growing in Dedham, Massachusetts, one of the finest of its race in New England. This tree also owes its life, a correspondent now informs us, to the timely appeal of a man who appreciated its value. This

was Thomas Motley, the father of the historian, whose country-place joined the land on which it stands. It had been doomed to swell its owner's wood-pile, but Mr. Motley gave him ten dollars, and the Oak was spared. This wise action of a public-spirited man deserves to be generally known, and some public record of the fact should be made, so that every one who passes by the tree may be moved to follow so good an example. No one can see this great tree without being impressed by its grandeur and charmed by its beauty, and every one who knows the story of its rescue will feel more profoundly grateful that it is still standing.

The Dedham Oak now belongs to a rich man, a lover of nature and of trees. He can earn the gratitude of all other lovers of nature if he will cause to be placed on it some permanent memorial of its danger and its deliverance. The love of trees and the veneration for those which have attained great age or unusual size is not a distinctively American trait. It is one, however, which every lover of his country should encourage, and for this reason the action of Dr. Hitchcock in saving the great Manzanita in California, and of Mr. Thomas Motley in saving the great Oak in Massachusetts, deserve to be placed on record as worthy examples which others would do well to emulate.

New England Parks.

FOREST PARK, SPRINGFIELD, MASSACHUSETTS.

THE Connecticut valley is a region of beauty. As the traveler from the east comes toward it by rail, he is escorted part way on his journey by that lovely tributary of the Connecticut, the Chicopee, whose low bordering hills lead up gradually to the bolder slopes of the Holyoke range, with its fine commanding peaks and strongly marked outline, rising abruptly from the shores of the greater river.

In the month of July these heavily wooded slopes are golden with Chestnut-blooms, and at all seasons the wealth of forest-growth is apparent on the hills and in the rich, well-watered bottom-lands, through which flow numerous minor streams to swell the winding, stately river which is the pride of all central New England.

The town of Springfield is most delightfully situated, its business portion lying along the river-level and its dwellings climbing the hill to point above point, from which the outlook grows more and more commanding as you ascend, until the wide beautiful valley unrolls before the beholder with its imposing stream curving grandly at his feet.

In a boat at sunset, drifting under the great bridges, and looking up at the steep rocky shores from the level of the river, one feels regret that a boulevard could not have been planned along the brink of the stream for the greater enjoyment of the view, but on the heights there are fine outlooks from which the whole scene can be contemplated, and there is perhaps none finer than that from the estate of Mr. E. H. Barney, which is ultimately to form, perhaps, the most attractive portion of that noble pleasure-ground which the public spirit of certain citizens of Springfield has provided for its people.

Forest Park is comparatively a new acquisition of the city, but as many as twenty years ago the picturesque value of the locality was recognized by some of the inhabitants, and Mr. O. H. Greenleaf, Mr. George Hathaway and the late Mr. Samuel Bowles, editor of the *Springfield Republican*, purchased a tract of land in this region with an idea of reserving a part of it for a park and dividing the rest into building lots. Much of this property came ultimately into the hands of Mr. Greenleaf, who having, during his travels in Europe, become interested in places of recreation for the people, conceived the generous idea of giving it to the town, and accordingly in 1883 presented the city with a deed of seventy acres, with a request that it should be made into a public park. This included a boggy meadow bordered by ravines and some open fields edged with woods. The same year twenty more acres were acquired by purchase, which furnished the city with a tract of ninety acres, which it began forthwith to improve and utilize.

Slowly a sense of the importance of the acquisition dawned upon the inhabitants of Springfield. For a long time the appropriations for clearing and grading were made grudgingly, and the representations by the commissioners of the importance of buying more land were disregarded. The work was put in charge of Mr. Justin Sackett, a local landscape-gardener, who, without any definite plan, proceeded to free the land from rubbish, build the roads and drain the marsh, so far as the limited funds at his command would admit. Thanks to his judgment and sense of the picturesque, as well as to the conformation of the soil, the results of this happy-go-lucky, piecemeal method have proved much more satisfactory and pleasing than might have been expected from an unstudied scheme; and when, in 1890, the establishment of an electric railway brought the Springfield world easily to the gates of the park, everybody was full of enthusiasm and astonishment at the beauty of the spot.

The result was an appropriation for the purchase of some adjoining property, and the building of a Shelter at the entrance. During the past year 250 acres have been added to the park, partly by purchase and largely by gifts from other public-spirited citizens. The most notable acquisition is the fine estate of Mr. E. H. Barney, consisting of about 110 acres, in which he retains merely a life-estate, leaving the whole of it, including the homestead and other buildings, to pass to the city ultimately, as a memorial to his only son.

The city thus has come into possession of a well-watered and well-wooded region of nearly four hundred acres of extraordinary variety of surface and unusual natural beauty.

At the entrance, which is approached by the electric railway, the ground is level, and a wide grassy space is encircled by fine trees, among which the drives wind in leisurely curves, giving attractive views of distant hills, and sweeping aside here and there to spare some monarch of the forest. Two Pines thus left form a very noble feature near the entrance. After leaving this part of the grounds you reach a series of ravines, wooded and hung with ferns from top to bottom, around whose natural curves the path winds in a succession of undulations. These ravines consist of a subsoil of clay covered with about six feet of sand, which shifting surface, washed by the spring rains into charming hollows, is the cause of the fern-hung dingles which so delightfully diversify the park. Winding down the side of one of these declivities by a steep road, too steep for the comfort of pedestrians, you come to a long stretch of green meadow, a valley between two ranges of irregular hillocks, through which flows a little stream, the drainage of the former marsh.

This stream, dammed at intervals, forms a series of ponds, with many cascades, and a rivulet, which add to the beauty of the charming scene. The undulations of the steep little hills, covered with trees of all kinds, growing with that luxuriance peculiar to this region, the soft unbroken turf stretching beside the level, shaded drive-way, the wandering brook, the two ponds with their floating birds and tiny island, the long vista, down which one looks to more dark ravines crowned with magnificent Chestnuts, with Oaks, Maples and Poplars, and numerous other varieties of native trees, make a scene of park-like beauty, peaceful and joyous, suggestive of recreation and delight.

Pursuing your way down this long valley, with unexplored wealth of forest on the left, you ascend the heights once more at the other end, and, after some driving, come to an elevation from which there is an unrivaled view of the Connecticut valley, with the town nestling in a great curve of the river, and behind it the striking range of mountains, Mount Tom and Mount Holyoke, rising blue and imposing against the sky, with their attendant hills in jagged outline behind their two lofty peaks.

A little lower down is the Barney estate, which also commands a very beautiful view of the river, the mountains and the town, with its spires and bridges, and here there will, in the future, be a water access to the park, so that a line of little steamers can ply back and forth between the city and its pleasure-ground, giving a delightful means of access to its coolness and shade. This very beautiful view, combining the human interest of the town with the charm of the majestic river winding royally through its fertile valley, and the imposing group of purple peaks meeting into a cloudy background with forms that reproduce the outlines of the mountains, until one can imagine range upon range behind the Holyoke hills, is inexhaustible in attractiveness, and appeals to every taste. To me the touch of humanity in the picture gives it a final charm. Without those clustered towers and chimneys, with their light overhanging smoke to soften unsightly outlines into misty grace, the deepest tone would be lacking in this fine harmony, the human note being ever the richest and most penetrating, even as a clear voice is heard above an orchestra.

This part of the park rejoices in a wide brook, the Pecowsic, a stony-bedded brawling stream, once so dark and densely wooded as to be thickly stocked with trout. Its bed has been widened, and in places enlarged into shallow ponds, where

grow numberless varieties of Nymphæa and Lotus, and even the great salver-like leaves of the *Victoria Regia*.

The Lotus-roots live all winter under seventeen inches of ice, and send up their tall stems and great white and rose-colored and blue blossoms in wild profusion. Here the Water-lilies show all the varieties of color of which this charming flower is capable, even yellow blossoms mixing with the white and pink and blue ones.

Mr. Barney has interested himself largely in trees and shrubs, and the many varieties of valuable specimens that he has collected will in years to come help the landscape-gardeners of the park to new and interesting effects. He has planted numerous rare evergreens, and has large nurseries for the propagation of different arborescent and herbaceous plants, which, as time passes, will multiply so as to be of service in future decoration of other parts of the grounds, when formal gardening shall have entered into the scheme, thus making generous provision for generations to come as well as gratifying his own taste.

The land all about and in the town of Springfield lies with the same peculiar picturesqueness in these curious hills and vales caused by some long-spent tide, hinting of other ages, and a still more magnificent river, the ice of which may have ground out these lovely curves and modeled these varying surfaces through untold bygone years.

Long ago the green valley of Forest Park must have been a water-course, flowing between those high wooded banks to swell the mighty flood of that primeval river. What changes it has known, from the time when the receding tide left it to swampy solitude till the care of man reclaimed it from picturesque desolation to its present cultivated beauty!

One fault I must find with the management of the little stream that drains the former marsh, and that is, that in portions of its career it is so straight as to resemble a canal rather than a natural stream. This is a fault most easily remedied by widening and curving the channel at intervals, and introducing some large rocks, over and around which the water might tumble and meander with more seeming naturalness. It is ungracious to criticise where there is so much already to delight the eye, but Forest Park is not a completed work of art, and is still open to suggestions as the labor progresses.

With its unrivaled natural advantages, the luxuriance of its vegetation, its diversified surface and its glorious points of view, there is no reason that the artistic sense of many landscape-architects should not contribute to the entire development of its extraordinary natural beauties to their best advantage. Its miles of as yet untouched surface can be treated in new and charming ways, for there is scarcely any limit to the surprises which it possesses and the artistic use that can be made of them.

Year by year new acres will be added to its already magnificent extent, affording fresh outlooks on the noble river and its attendant mountains. The little streams that now drip from its rocks into natural basins, to satisfy the thirst of the pedestrian, can be utilized in many a graceful fashion. The rustic pavilions that already afford agreeable shelter to its visitors will be multiplied in yet more charming forms, without detracting from the general effect. There is room enough for wild and undisturbed forest, and for pleasure-grounds to satisfy the requirements of an urban population constantly increasing.

The admirable generosity of the citizens is not to end here, and as time goes on the men of Springfield will rejoice in adding to their beautiful pleasure-ground such architectural and sculpturesque decorations as seem appropriate to its development. The haphazard arrangement which has proved so popular in Mr. Sackett's hands will probably, as the park's resources increase, be supplemented by careful planning of the yet untouched portions of the grounds, and new combinations will be formed to give added interest and variety to the endless drives and walks, and less abruptness to their slopes.

Not more than one-fifth of its surface has as yet been developed, so that it still has enormous possibilities. The trees are very vigorous and healthy, and many of them are of great size. Some of the huge Chestnuts are a hundred feet high, and the groves of tall Hemlocks and Pines are of exceeding beauty. Among them the birds sing and squirrels chatter, and the rabbits sit by the edges of the paths, so tame that they have been known to bite the children who sought to play with them.

The whole aspect of this charming retreat is joyous and attractive. Everything about it suggests recreation and delight, the admixture of wildness and cultivation, the lack of formal gardening, and the sweet rural aspect even of its most carefully tended portions, are gratifying and enjoyable.

The Springfield people may well take pride in the possession of a resort of such unusual and varied beauty, and it is to be hoped that in time they will honor the men to whom they are so largely indebted, by some memorial tribute to their munificence here on the spot which they owe to their wise forethought and admirable beneficence.

It seems, too, as if some name more distinctive and of less common usage might surely be found for so unique a spot as this, a name that would characterize its peculiar features, and separate it in the memory from other pleasure-grounds in other cities where forest-parks abound; and to a spot which, from the numerous aboriginal relics found here, must have been a happy hunting-ground of the red men, some Indian name, significant and melodious, might well be applied, in the syllables of which might be embodied the slopes and streams, the trees and river, which in this lovely park are so rarely and beautifully combined.

Hingham, Mass. *M. C. Robbins.*

Late Persisting Leaves on Trees.

AS the autumn advances and the leaves fall more or less gradually from the different kinds of deciduous trees, it is of interest at the north to note those which have a tendency to hold them the longest. A study of this point might be particularly interesting to people planting trees about residences which are only intended to be occupied until the late autumn, perhaps until the latter part of November.

It is well known that different species of deciduous trees vary very widely in regard to their character for shedding or holding leaves, but no hard-and-fast rule can be applied to any of them, because even different individuals of the same species show a marked variation in this respect.

Such a frequent question as: What species of New England Oak is it which holds its dry leaves until well into the winter, or until the buds start in the spring? may be answered by the statement that it is a habit common to no particular kind, but may occur on individuals of several species and also on other trees besides Oaks. Very often it is an indication of disease, and sometimes we may infer from the circumstance that the wood has not thoroughly matured and the leaves ripened before being unnaturally checked. Almost every practical man must have noticed that the dry leaves cling long to a limb which has been cut off before the end of the growing season.

Of course, in some cases, the late holding of leaves indicates that the plant is likely to prove evergreen in more southern regions. *Magnolia glauca* is a fair example of such a case. In our northern gardens the leaves keep comparatively green and fresh-looking, and persist until very late; but, unless the trees are in exceptionally moist and sheltered situations, the foliage usually disappears before the winter is over.

Other truly deciduous trees at their northern limits appear to have a tendency to hold their leaves late, and it is also noticeable in many trees of a naturally more southern range which have been introduced and found hardy further north.

It is often a peculiarity of our White Oaks (*Quercus alba*), and occasionally of other trees, that the leaves on the shorter, lower branches remain on them in a dry and withered state long after the upper leaves have fallen. The reason for this is not very clear, but it may be that the lower branches, being much shaded, do not mature so well as those above. Young trees, more than old ones, often show a tendency to hold their leaves; and situation sometimes has an influence.

Fruit-trees, as well as shade-trees, share similar peculiarities, although here there is a greater uniformity among the individuals of each variety, brought about by cultivation. The early Astrachan, for example, ripens and loses its leaves many weeks before the American Baldwin, the fruit of which matures late, and which retains a large proportion of its leaves in a comparatively fresh condition through the month of November.

Of the foreign trees which have been introduced, a few are noted for the persistence of their foliage, as compared with allied native species. The English Elms (*Ulmus campestris*) are almost invariably covered with leaves when the American Elms beside them are leafless. The English Oaks grown in this country are also often remarkable for the abundance of fresh-looking foliage which they occasionally retain to the end of November; and the English Hawthorn sometimes retains its verdure better than almost any other of the smaller trees.

Among our native trees the Scarlet and Black Oaks (*Quercus coccinea* and *Q. tinctoria*), the Red Oak (*Q. rubra*) and one or two others hold their leaves quite late, and they remain dark and smooth, without bleaching and twisting as do the leaves of the White Oak.

Our Walnuts (*Juglans*) are notorious for the ease with which they part with their foliage, while, on the other hand, their allies, the Hickories (*Hicoria* or *Carya*), generally hold a considerable quantity of their dead, dry and shriveled leaves with a surprising tenacity through many hard frosts and high winds.

The Beech also holds its leaves later than the majority of trees, and, apparently, there is not so much difference between the indigenous and the European species in their period of falling, although the latter keeps a fresh appearance for a longer time. Young Beeches are, apparently, apt to retain their dry foliage longer than large trees; but any one who has walked through Beech woods in winter cannot have failed to notice numerous cases of both old and young trees retaining a considerable quantity of leaves which had become so bleached that they were almost of as pure a white color as the snow beneath them,

Arnold Arboretum. *J. G. Jack.*

The Colors of Flowers.—I.

TO answer the question, "What is the primitive color of the flowers, and what is the order of progression in 'color-change,' if such there be?" it is not necessary to trace the development of the flower back to primitive times, nor to know whether it was a Buttercup which first unfolded its petals to the sun, or whether it was a Dandelion or something entirely different from either, for the same laws govern the coloration of all flowers, whether they belong to the order *Ranunculaceæ* or not, and whether they are primitive or recent; neither is it important to know whether petals were originally flattened and enlarged stamens or modified leaves. Any one can easily solve the problem for himself by a study of the native wild plants growing by the road-side or in the fields and woods, and even if he should restrict his observation to a few acres about his summer residence in the country that amount of territory would be ample.

Mr. Grant Allen, in his admirable treatise on "The Colors of Flowers," published in London in 1882, concludes that yellow is the primitive color of flowers, and he also takes the ground that petals are altered and modified stamens. He writes as follows: "As the stamens of almost all flowers, certainly of all the oldest and simplest, are yellow, it would seem naturally to follow that the earliest petals would be yellow too." Again: "All flowers, it would seem, were in their earliest form yellow; then some of them became white; after that a few of them grew to be red or purple; and finally a comparatively small number acquired various shades of lilac, mauve, violet or blue." "Petals are, in probability, originally enlarged and flattened stamens."

This opinion is also held by others. The Rev. George Henslow, in the "Origin of Floral Structures," writes: "Again, when we come to Dicotyledons and find the prevailing tint of stamens is the same (yellow) . . . we gather probabilities in support of that view, etc. . . . but why the first color was yellow and why it ever gave place to red or blue is unknown."

There are two methods employed by Nature in the development of colors: one may be called the imperfect or foliar development, the other the normal floral process. In the first, the colors, at least apparently, are evolved directly from the green chlorophyl, as the reds, yellows and purples of autumn leaves, for from some green-colored flowers a rather limited number of dull reds, purples and yellows are produced. The reds and reddish purples are, however, rare, and seen mostly on the scales of involucres, where they are common, also on the spathes of several of the *Araceæ*, as *Symplocarpus fœtidus* and *Arisæma triphyllum* (Jack-in-the-Pulpit), also in Salicornia of our salt-marshes, which turns red in the fall, and in the Castor-oil plant of gardens, which turns a reddish purple in all its parts—leaves, stem and flowers. I do not find a satisfactory example of yellow evolved directly from green among our native plants. It is extremely doubtful if any pure yellow ever immediately succeeds green. This is somewhat surprising when one considers the fact that yellow is one of its component parts. There are, however, some greenish yellow flowers, and these will be considered further on. Among the green native flowers we find *Smilax herbacea*, *S. rotundifolia* and *S. glauca*, central florets of *Aster umbellatus*, *Ampelopsis quinquefolia* and variegated garden varieties, also the garden *Evonymus Seboldianus*, and many smaller, low, degraded plants.

We will now turn our attention to the normal floral method of the development of color, by which all the bright attractive hues of the flowering world are produced, and first take up for inspection *Spiranthes gracilis*, a pretty little plant of the Orchis family, with white flowers spirally disposed at the summit of the scape. The lip is green, fringed around the edges with white, and the other petals are wholly white. A small section of the petals, placed under a magnifying-glass, appears to be colorless and transparent, while the delicate net-work of the tissue glistens like crystal; yet this colorless tissue, in a mass, reflects white. In the same manner a single leaf-like bract of *Monotropa uniflora*, severed from the stem, appears colorless, but two or more placed together, making a greater thickness, reflect a decided white color.

This feature should be especially noted for the reason that, whenever the term colorless is used in this paper, it is not to be taken in its literal sense, but is intended to signify a state of incipient whiteness. Another point to be noted is, that the white color directly succeeds the dark rich green of the lip. In this one plant is found a clue to the solution of a problem which has greatly perplexed botanists, namely, the problem of the priority of color. In *Spiranthes cernua* green has disappeared, the corolla being entirely white. We will now endeavor to demonstrate that the universal law of progression in color, as regards the floral structure, is first from green to white; or, differently stated, Nature, before she begins to paint the more refined and delicate tissue of the petals, by some secret chemical process, completely eliminates the chlorophyl and prepares a perfectly pure and white canvas upon which to essay higher flights of fancy.

The universality of the law that white directly follows green may be demonstrated by the following illustrations, taken from native plants in flower in August and September in south-eastern Massachusetts, from which section also all other illustrations are drawn, excepting an occasional garden-plant, referred to on account of the facility in obtaining it for inspection. By confining our investigation in the main to wild flowers we avoid the complications arising from high cultivation, hybridization, reversion, etc. One should bear in mind, in this investigation, the well-recognized fact that the limb or expanded portion of a petal, and especially the edges of the same, usually are the first to assume the new color; and that where the change of color is not complete the base of the flower, which is least exposed to the light, retains more or less of the primary color.

Examples: *Nymphæa odorata*. Sepals green outside, white inside; petals first partly green, followed directly by white.

Mollugo verticillata. Petals green outside except the edges, which are white; white inside.

Cornus florida. Corolla-like involucre changes from green directly to a brilliant white. This is a large and beautiful flower.

Gnaphalium polycephalum. Bases of the many white involucral scales green.

Hydrangea paniculata. Gardens; marginal flowers green to pure white.

Spiranthes gracilis. Green to pure white.

Bartonia tenella. Base of petal dark green to white.

Daucus Carota. Flowers at first greenish, becoming white, as also the upper half of all the pedicels.

Erechtites hieracifolia. Flowers and tube frequently remaining green, but in many heads the minute corolla becomes pure white, while the tube does not change color.

Habenaria tridentata. Petals light green, becoming white.

Cobea scandens. Gardens; green, seemingly simultaneously to white and purple.

Plantago major and *P. lanceolata*. Green to colorless or faint white.

Cakile Americana. Calyx green, with colorless to white edges, claws colorless or white, limb purple.

Achillea millefolium. Tube and base green, limb white.

Anthemis Cotula. Tube and base green, limb white.

Rhus copalina. Usually green; several shrubs, however, were seen having a considerable number of white flowers, which afterward turned red.

Lilium superbum. Broad base of midribs green, surrounded first by an area nearly white, succeeded upward by many shades of yellow deepening to red. This is interesting in that the whitish region lies between the green and yellow and does not follow yellow.

Heliotrope. Gardens; like preceding, the greenish centre is followed by white, farther up by red or blue-purple.

Chelone glabra. Green to white, the tip remaining slightly green.

Parnassia Caroliniana. White petals show the basal color in the pretty green veining and green color on the outside of the tip.

Polygonum arifolium, *P. Hydropiper acre*, etc. Sepals green to white.

Solanum nigrum. Bases of white petals green, forming a distinct green eye; stamens green.

Polygala sanguinea and *P. cruciata*. The flowers are inconspicuous; the bracts, the showy part of the flower, change from green to white, and afterward to purple.

Calla Lily. Greenhouses; base green, upper portion white.

Petunias and Four o'clocks of white variety have green tubes.

Mignonette. Gardens; green petals have a beautiful snow-white fringe.

Stock. Gardens; base of white variety green, as also of many other flowers.

Examples might be multiplied indefinitely.

Then, too, the inconspicuous, degraded, weed-like plants, such as our two species of Atriplex, Ambrosia, Amarantus, Acalypha, Ludwigia, Euphorbia, Salicornia, Xanthium, Cuscuta, Urtica, Pilea, Chenopodium, etc., some of which have colored, the development is precisely the same as in the petals and stamens; the outer edge or margin of the green sepals first discharges its chlorophyl, becoming white, which gradually spreads over the surface to a greater or less extent.

This tendency to change to white in the sepals is very common; a complete list, however, would require too much space, and, furthermore, be unnecessary, as a few examples from common plants will suffice for our purpose, namely, Cerastium, Stellaria, Buda, Plantago, *Polygonum aviculare*, Amarantus, Arctium, *Eupatorium perfoliatum* and many other species of the *Compositæ*, etc. Commonly, the color of the sepals, after changing, is the same as the petals, as a white Burdock has the scales of the involucre white, a rose-colored Burdock has the scales rose-colored, etc. Thus every part of the flower first changes from green to white, there being ample evidence to prove that the pollen also is at first white. It has been

Fig. 89.—Rosa Wichuraiana.—See page 570.

no petals, and in which the colors of the flowers generally are scarcely developed, yet give valuable testimony, for in every example the color of the stamens and pistils at least, and often some part of the sepals, begins in precisely the same order, namely, from green to colorless and faint white; indeed, in Pilea, which is monœcious, the fertile flower is green, while the staminate has developed to a conspicuous pure white. The yellowish color of Ambrosia is not in the corolla but in the pollen. The tendency, therefore, of these lowly plants is clearly to white and not to yellow.

The color of the expanded portion of the petal especially attracts the eye, but all parts of the flower, including the calyx, may be colored. As a rule the stamens and styles are colored like the petals, but the anthers frequently are of a different color from the filaments, while the pollen at times differs from both anthers and filaments. When the calyx or involucre is used as an argument for yellow as a primary color that the base of the petal of the Rose was yellow. But every one knows that green is composed of blue and yellow, and as either the one or the other element predominates, so will the tone of green be affected. Not only in the fall, but in early summer, the foliage displays various shades of green, and even a blade of grass of one species will differ in shade from that of another, one being, perhaps, a dark or blue-green, the other a lighter or yellowish green; under these circumstances it is not surprising that, by the eliminating process, a yellowish green, very much thinned down, may be mistaken for a true yellow, especially when the area of color is of the smallest dimensions. The writer has examined many petals of *Rosa Carolina* and is convinced, notwithstanding the smallness of the light-colored base, that the color immediately below the rose or pink is white and below the white a mere vestige of

the original color, namely, a yellowish green, and this is in exact accordance with the principles laid down in this article. Concerning the list of wholly green flowers near the commencement of this paper it is not necessary to consider the question of degradation or retrogression from brighter hues, the simple fact being that there are such flowers, and that when they change color, as they frequently do, it is always to white. Examples: Erechtites and Rhus.

All wholly white flowers, except where the transition could be observed, of course, would be of no avail in our researches, and so are not referred to. Without a single exception every flower that came to hand of a white color was developed directly from green, without any intervening color. The proof is overwhelming that white immediately follows green and is the primitive color, unless it can equally be proved that some other color also directly succeeds green.

New or Little-known Plants.

Rosa Wichuraiana.

THE handsome Rose which is figured on page 569 was sent to the Arboretum by Mr. Louis Späth, of Berlin, in 1888 as *Rosa bracteata*, but when it flowered two years later it was found to be the *Rosa Wichuraiana* of Crépin,* a native of Japan, and previously confounded with *Rosa Luciæ* of that country, and still earlier with *Rosa sempervirens*.

Rosa Wichuraiana is remarkable in producing slender prostrate stems, which grow ten to fifteen feet long in a single season, and cover the ground as with a dense mat; they are free of prickles and produce short, stout, straight or slightly recurved spines, and in moist ground develop rootlets freely. The leaves are three to nine-foliolate, with obovate or nearly orbicular blunt leaflets, which are sharply and coarsely serrate, glabrous, very dark green and lustrous, and from a third to two-thirds of an inch long. The stipules are adnate, usually conspicuously toothed, and vary from a third to half an inch in length. The flowers are produced here in great profusion from about the 8th to the end of the month of July, and during the remainder of the season appear irregularly and less abundantly; they are pure white, an inch and a half to two inches across, very fragrant, and are borne in short, broad, pyramidal, terminal, few or many-flowered clusters. The primary bracts are lanceolate, foliaceous, dentate and persistent. The pedicels are stout, an inch long, slightly glandular-hispid, and furnished with lanceolate, denticulate, rather persistent, bractlets. The flower-buds are a third of an inch long, ovoid and abruptly contracted into short points. The sepals are oval, contracted at the apex into rather rigid points, coated with pale pubescence on the inner surface and reflexed at maturity. The petals are broadly obovate, slightly emarginate at the apex, and sometimes rather remotely dentate toward the base. The stamens are bright golden-yellow and very conspicuous; and the column of styles is elongated, rather thick, and pubescent. The fruit is oval or obovate, dull red, and from a third to half an inch long. It matures here late in the season, producing good seed every year.

Rosa Wichuraiana has been used very largely during the last two years by the Park Department of the city of Boston, especially in Franklin Park, for covering rocky slopes, embankments and such spots as it was desirable to clothe quickly with verdure. It appears to be admirably suited for such purposes, and as it grows more rapidly than almost any other vine which has been tried in similar situations, soon making a dense mat over the ground, it seems destined to become a popular plant. Its remarkable habit, its hardiness, the brilliancy of its lustrous foliage, and the beauty of its flowers, which appear when most shrubs are out of bloom, certainly recommend it to the attention of the lovers of hardy plants. *C. S. S.*

London Letter.

Chrysanthemums.—The great annual exhibition of the National Chrysanthemum Society has been held this week in the Royal Aquarium, at Westminster. The plants and cut blooms shown were on the whole of the finest quality, and almost every class was abundantly filled. I did not see any very striking new variety among those shown for the first time, Louis Bœhmer being, perhaps, the most remarkable of these. As a flower, this variety has little to recommend it, ugliness of form and dullness of color characterizing all the blooms shown here; but as a wonderful development from the original Chrysanthemum it has much interest. There were about 500 varieties submitted to the Committee of Certificates, but only the following obtained awards:

Comte de Galbert (Calvat), Japanese, with large, full, pale flesh-colored flowers; Lord Brooke (Carter & Co.), a large bright orange-colored incurved Japanese variety; Miss L. Allen (Pitcher & Manda), Japanese, incurved; Delaware (Pitcher & Manda), Anemone, large-flowered, with white ray-petals and a yellow centre; Excelsior (Owen), Japanese, very large, colored bright cerise, with white reverse; Mrs. G. C. Schwabe (Owen), Japanese, pale rose and salmon, tipped with gold; Mrs. R. King (Owen), incurved, a good bold flower, full, and colored rich yellow; Florence Davis (Davis), Japanese, a very pretty white-flowered variety, with long elegantly twisted petals; Kate Mursell (Mursell), a pure white sport from Lady Trevor Lawrence; Coronet (Mursell), Japanese, incurved, large, full, deep yellow, a first-class variety; Louis Bœhmer—some very large well-formed flowers of this were exhibited, and obtained a certificate.

Perhaps the most interesting feature of the exhibition was the collection of flowers of Anemone-flowered varieties. The improvement made in this section of Chrysanthemums in the last few years is most marked. Some of the newer varieties have almost entirely lost the character of *Compositæ*, the ray florets being reduced to a single row, while the disk-florets are so large and well formed as to appear like a bunch of Erica-flowers, say, of *E. ventricosa*. Enormous crowds visited the Aquarium during the three days on which the exhibition was held. Certainly this is the most popular flower-show held in London, though not the most select.

Chrysanthemum Sports.—A paper upon this subject was read by Professor Henslow, F. L. S., at the conference of the National Chrysanthemum Society, held on the opening day of the exhibition. Professor Henslow has for many years been identified with studies of plant phenomena as revealed by horticultural art, therefore anything he may have to say upon such a subject as sporting in plants is deserving of attention. He confessed to being unable to explain this peculiarity of cultivated plants, but suggested that ingredients in the soil had something to do with it. He also pointed to the occurrence of sports simultaneously at various places at the same time as indicating that climatal conditions had some influence in causing a plant to sport. From the fact that "nearly all the early imported varieties from China were much more inclined to sport than those raised from seeds in Europe" it is supposed that sporting may be induced by frequently introducing plants from as different a climate as possible from our own. The most remarkable case of sporting is that of Queen of England, a pale blush variety which has sported into six different colors, namely, two golds, two bronzes, a rose and a primrose. It is possible that, by careful observation and experiment, the exact causes to which sporting is due may be discovered, and the production of new varieties in this way be under the cultivators' control. At present we only know that sports do occur, but when or in what form they will come we have absolutely no means of knowing. Varieties of Chrysanthemums are so easily

obtained from seeds that new and promising sorts are now raised in great numbers, as shown by the number put forward for certificates. Some time ago it was hinted that the crossing of different kinds of Chrysanthemums with each other was easily done, and would be demonstrated by an American grower. I am doubtful whether any trustworthy instance of an actually cross-bred Chrysanthemum can be pointed to. One may guess that a seedling bears the characters of two given sorts, but that, of course, proves nothing.

[The Chrysanthemum is, without doubt, a difficult plant to cross-fertilize. It is not difficult, however, to emasculate a few of the outside rows of florets and fertilize them with foreign pollen. If the central florets are then treated with some solution of gum, which will prevent the development of seed in them, it is reasonable to conclude that we know the parentage of the seeds which are produced. When the resulting plants show evident traces of the blood of both parents our conclusions have this additional confirmation.—Ed.]

Gerbera Jamesoni.—Although flowered at Kew two years ago and figured in several periodicals, this pretty Cape Composite is unknown in horticulture. A specimen of it was shown this week at the meeting of the Royal Horticultural Society, and obtained a first-class certificate. It is a stemless plant, with leaves not unlike those of the Dandelion, but more leathery in texture, and nearly erect. The scape is erect, a foot long, bearing a nodding inflorescence as large as that of *Rudbeckia Newmanni*, its color being a rich orange-scarlet. The plant is almost hardy, having stood outside all winter both at Cambridge and Kew. Its scarcity is owing to its failure to ripen seeds in England and to the slowness of growth in its fleshy rhizome, which forbids division. At Kew it has proved a good pot-plant for the greenhouse.

Nerine pancratioides, Baker.—This is a distinct and pretty plant, and will, no doubt, prove valuable to the hybridizer. Nerines being very mobile in the hands of plant-breeders. It differs from all other Nerines in having small projecting teeth between the filaments of the stamens, so that it has almost a distinct corona, a character which is indicated in the specific name. The flowers are otherwise not unlike those of *N. pudica*, but slightly smaller. They are pure white, with uncrisped segments, and are produced in umbels of from twelve to twenty flowers upon a scape two feet long. The leaves are produced at the same time as the flowers, and are narrow, nearly terete, and about a foot long. Mr. J. O'Brien has recently introduced this species from Natal. A description of it is published in the *Gardeners' Chronicle* this week.

Dendrobium Leeanum, Sander.—A plant of this in flower obtained a first-class certificate this week. It was imported by Messrs. Sander & Co. along with *D. Phalænopsis*, to which it bears a close resemblance in the character of its pseudo-bulbs and in habit. The inflorescence, however, is more like that of *D. superbiens*, but the flowers differ from this in being white, shaded with pale mauve on the sepals, with a deeper shade of mauve on the petals and labellum.

Fig. 90.—A Manzanita Tree (*Arctostaphylos Manzanita*).—See page 565.

Phajus maculato × grandifolius.—This is a hybrid raised from the two species named by Messrs. J. Veitch & Sons. It has the habit and robustness of growth of *P. grandifolius*, to which there is also a resemblance in the size and form of the flowers, their color being soft primrose-yellow, tinged with brown, the front of the lip deep chestnut, and curled in as in *P. maculatus*. It obtained a first-class certificate.

Dendrobium Phalænopsis.—The recently imported plants of this Australian Dendrobe have not been long in revealing their true character, there being some hundred and fifty

spikes of flowers expanded on the plants now in the St. Albans nursery. There are no less than fifteen fine flowers on one spike; another has pure white flowers, others pale rose, and so on to the deep crimson of the variety known as *Schræderianum*.

Vanda cœrulea.—Large importations of this Vanda have recently reached England, chiefly through Messrs. Low & Co. and Sander & Co. Many of the plants arrived in perfect health, having scarcely lost a leaf on the way. The treatment required by Orchids of even the most delicate constitution during transport is now so thoroughly understood by experienced importers of Orchids that many plants, which previously reached England with scarcely any life left in them, are now brought long distances over land and sea without much loss of vitality. As an instance of this I may point to a plant of *V. cœrulea*, imported last year, and flowered lately in Lord Rothschild's collection. It was one plant, not a made-up specimen, and it bore seventeen flower-spikes with over two hundred flowers, all opened together.

Notes on Small Fruits.

ALLOW me to make a few observations upon Mr. Hunn's "Small-fruit Notes" in your issue of November 11th. I have not found Carman any earlier or better than Souhegan. Lovett's Early and Brackett's 101 fruited with me this season for the first time, but the drought was so severe I defer an opinion of them till another season. I fear they will prove an easy prey to anthracnose, like all the Black Cap family. I think No. 101 will be nearly equal to Gregg in size, more hardy and of better quality, but not as sweet as Palmer. Schaffer, for size and productiveness, beats them all; but it is not hardy here, and suffers badly from anthracnose.

A few years ago I was one of a club to purchase 10,000 or more of Quinby's Favorite Raspberry. Investigation as to its origin resulted, in the statement of the party furnishing the plants, that it came to him in a lot of Cuthberts, and proved so superior to them that he was rooting the latter all out and planting all his spare ground to the new foundling. He said that he knew nothing of its origin, and cared less; that it would not increase its value a particle to know its parentage, etc. When the plants fruited a small proportion proved to be Cuthberts, or, at least, so nearly identical with the Cuthberts I had that I could not detect the slightest difference, and the remainder of the plants, fully two-thirds, if not more, were of feebler growth, and produced a much smaller roundish berry, many of which were imperfect and inclined to crumble. After gathering three or four crops I became disgusted with the whole patch and tore them out. As far as I have learned, the venture with other members of the club met the same fate. I have never seen any mention of the variety since, till Mr. Hunn's article met my eye. I had never made any report on it, and should not now but for Mr. Hunn's note. He says: "It resembles in a marked degree Cuthbert, both in growth of canes and the questionable habit of growing a large number of suckers; in flavor it resembles the Cuthbert also." The only difference he marks is that the fruits average larger, are deep red and very firm; but Cuthbert is also deep red and firm. I have repeatedly examined Quinby's Favorite, have picked bushels of them, and am free to say I consider them Cuthberts, and nothing else. If there are two varieties there ought to be some distinguishing features by which they can be recognized. Variation in size may come from soil or cultivation, and firmness may depend on the weather. I should like to hear some further testimony. Perhaps Mr. Hunn's Quinby differs from ours. It is an important matter to have the identity of the plant established.

Erie Blackberry seems to be mixed—some plants giving heavy crops, a whole cluster ripening together; others bearing very lightly, and ripen gradually. They gave us a better crop this season than they ever did, but they differ but little from the Rochelle. They must be carefully picked and thoroughly ripened, or they are too sour; but many persons relish this acidity. The old Dorchester is the only blackberry I ever found that I consider palatable in a fresh state unless fully ripe. This need not be dead-ripe to be good; but, after all, I have never found the berry that outrivaled the Kittatiny, all things considered.

Of Black Currants, the English, Naples and Lee's Prolific differ but little, and are the only ones tried. Beyond a few bushes for those who like them, they are of little value.

Montclair, N. J. *E. Williams.*

Apples in 1891.

Summer Apples.—The Early Harvest, so popular with our fathers, is too far surpassed by recent acquisitions to be worth growing. The Sweet Bough remains our best summer sweet apple. It does not bear as well as formerly, nor are the trees as healthy. All our sweet apples, with the exception of Talman's, are favorites of the codlin moth. Red Astrachan has been overplanted, and is no longer a profitable market sort, but is invaluable for home use. It is an enormous bearer in alternate years. This year it was nearly a dead loss to large growers.

Summer Rose is the most delicious of summer fruits. It is a small apple of exquisite coloring, and overbears. It must be thinned early after setting. It is not valuable for market. Yellow Transparent is one of the Russian apples, of fine quality and great beauty. It bears when very young, and continues a heavy cropper. It must not be too largely planted, as it ripens with too many good rivals. Primate is an apple of which too much cannot easily be said either as to quality, looks or liberal yield. It is of the first class. For table use it is not surpassed at this season. Summer Strawberry; this begins to ripen close after Astrachan, and is not through till October. For a table apple, it is one of the best. I know nothing finer to pick from the tree and eat from hand. It has done admirably this year.

Autumn Apples.—Alexander, one of the Russian fruits, is a fairly good apple every way—large, handsome, prolific. Fall Pippin is a name given to several kinds of apples, but the one entitled to the name is a large, extra fine, very old fruit, yellow and rich. It drops too easily, and is unprofitable every way. But as it ripens in November it is invaluable as a home fruit. Fameuse, or Snow, surpasses all other late fall apples, either for table or market. It is medium-sized, almost entirely red; quite a copy of Jonathan in size and color. It bears enormously and ripens through October and November. It does not rot easily, and, with a few others, fills the breach between fall and winter fruits. Gravenstein is a September apple of the finest quality and best size. It is equally good for table and cooking. It begins to ripen early in September, and holds out till the middle of October.

Porter tallies very well in ripening with Gravenstein. It varies in quality on different trees; is best on old ones. It is a great cropper, and this year thousands of bushels have gone to waste. Autumn Strawberry is a noble apple, of medium size, striped red. It is a first-class dessert fruit, and an excellent cropper. Does rather better in Michigan than here. Harding is a delicious fruit, to which my attention has recently been drawn, just in time to save it from extinction. It is a seedling among the trees planted from seed by Dominie Kirkland, missionary to the Oneidas, and is one of the most admirable table apples I have ever eaten. It has been locally called, sometimes, Kirkland; but that name has gone to another apple. It grows on the farm of Lyman Harding. It is ripe through November, along with Fameuse, and is quite as good and larger.

Clinton, N. Y. *E. P. Powell.*

Carnations.

THREE years ago my employer imported a number of English tree, or winter-blooming Carnations, for the purpose of comparing them with American kinds. The varieties were imported for the best, and, no doubt, they were as good as any grown abroad. We did not find one worth perpetuating, and this was after what seems to have been a fair trial. The plants were imported in the spring, and were evidently layered plants, which had been kept over in a cold frame. As the American method of preparing plants for blooming is very different, I at once began to apply this treatment to them, with the object of testing them along with the ordinary kinds in the greenhouse the following winter. They were planted out with the others in the open ground, and, being stocky plants, made quite large stools. They were housed at the same time as the others, and in every way were subject to the same treatment, but refused to bloom until late in the spring, and consequently were of no value for the purpose for which they were imported. They behaved very much as ordinary summer-blooming, or border Carnations.

I did not, however, consider that this test was fair, and therefore I took "pipings" of these along with the American varie-

ties, determined to subject them to the same conditions all through the season. The result was the same. As, however, a few blooms were of colors we desired, I kept them till last winter, with scarcely better results. I recently visited the greenhouses belonging to Joseph Tailby, of Wellesley, the veteran Carnation raiser and grower, who kindly gave me some valuable information regarding the history and development of the American type of Carnation. When I told him of my experience with the imported varieties, he said the same had generally been his, especially with regard to the English varieties. His opinion is, that the American Carnation, as it is, is the result of adaptation, by selection and acclimatization; and when I suggested to him that the first Carnations came from somewhere, he said that the French varieties had always succeeded better here, and had been the parents of the best American varieties. Boule de Neige, La Purite, Madame Carle, A. Alégatière and De Graw (parent of Mrs. Fisher, perhaps best, new white) are French varieties which are still grown to some extent. The ideal Carnation, in addition to blooming freely, should have solid, erect, pointed foliage, through which air and sunlight can strike the soil. The importance of this will be readily apparent when it is remembered that broad, flat, dense foliage must hold moisture, causing dampness and decay of foliage. Stiff, wiry foot-stalks are another necessity which we too often get with the lack of solidity of bloom, as in the case of Lambourn and Lizzie McGowan, two very pretty whites, which, however, are thin and will not travel. A. Alégatière is one of the best scarlet flowers we have, but the stem is too weak, and, withal, brittle, causing the flowers to droop, and so is fast being displaced by Florence and Hector, American varieties with stiff stems. Grace Wilder, the best and most extensively grown of all rose-colored varieties, was raised by Mr. Tailby. It was a seedling from Boule de Neige (white) × La Purite (rose). Boule de Neige proved an excellent seed-parent, and along with Grace Wilder came some seedlings, giving shades of color, which would be valuable at this time although undesirable then.

A good marketable, winter-blooming yellow variety is a want long felt, but soon to be filled. Among border or summer-blooming varieties we have some excellent yellows, but they almost refuse to bloom in a greenhouse. The French have produced a few doubtful yellows of free habit, but poor constitution and color, and it is on these, with the good border-yellows, that Mr. Tailby has been working. Results were unsatisfactory, and so he, last year, tried Florence (scarlet) with better results, getting good and distinctly intermediate color as a result of the cross, but no clear yellow; still he is satisfied he is on the right road, and thinks by crossing back he will get what he needs. It is a great step, certainly, to get an infusion of yellow and yet retain the free habit of the seed-parent. The crossing of Florence (scarlet) and Anna Webb (deep crimson) has produced an intermediate shade reminding one more than anything of the Chrysanthemum Cullingfordii, having precisely the same velvety texture. But there is something more important than this in this seedling, and that is its excellent habit, for it is far superior to Anna Webb and Ferdinand Mangold, the two prevalent crimsons, in constitution and free-flowering qualities.

Numerous sports have been produced, including white, pale rose, salmon and purple flowers, from Grace Wilder. Lately there was in bloom a salmon-pink sport from Hector, the new scarlet. It is a color which several raisers have been trying to get. All of them, however, have lacked a sufficiently hardy constitution or free-flowering habit to make them worth perpetuating. If this variety holds its color, with the good qualities of Hector, it should prove valuable. Strange to say, however, the habit is different and considered better, being more dwarfed and erect.

There appears to be an established conviction among Carnation-growers that locality has much to do with success or failure in the case of certain varieties. Soil, probably, has more influence than locality. One thing is certain, that Grace Wilder needs a light soil, and Anna Webb and crimsons generally, a heavy one; and here I venture to suggest, that as most marine plants are characterized by glaucous foliage, those varieties, like Anna Webb, having a distinctly glaucous foliage might be improved if a little salt were added to the soil. Wood ashes, containing the salts of potash and iron, ought also to have a beneficial effect.

Wellesley, Mass. *T. D. Hatfield.*

Eulalia gracillima univittata.—This fine ornamental grass should not be confounded with the well-known varieties of *E. Japonica*. The newer plant has been extensively catalogued as *E. univittata*, and the tendency is to associate it mentally with the older kind, and therefore it has not been so widely distributed as it deserves, for it is quite distinct in appearance, and it may be employed in places where the older *E. Japonica* would be quite unsuitable. *E. gracillima* does not exceed four feet in height under the most liberal treatment, and this is one of its most useful characteristics, for it can be used as a centre plant in large vases to the best advantage. Its foliage has a tendency to assume a horizontal position when fully matured, and this, with the white midrib of the leaf, gives the plant a very distinct appearance among ornamental grasses.

Our plants were originally obtained from Monsieur Lemoine, Nancy, from whom so many desirable plants have emanated, but the native country of *E. gracillima* is, without doubt, Japan. It has been described as perfectly hardy in the United States, but this needs confirmation. Perhaps some reader may be able to enlighten us. Our own stock has hitherto been too limited to risk losing it by leaving it out during winter in these colder states, and there is so little trouble involved in lifting the roots and storing them in sand in a cellar that we usually adopt this method and plant them out again in newly enriched soil in spring. According to Bentham and Hooker, we must no longer call our plants Eulalias, the proper name being Miscanthus; but probably the garden name will be Eulalia for a long time.

Dahlia imperialis.—This is at present one of the rarest of Dahlias in cultivation. Why this is so is not easily understood, for there is no other Dahlia so worthy of a place as this species, if space can be given it at this season, in a greenhouse. The word space means a good deal here, for, while two square feet of pot-room is enough for a well-developed specimen, it must have at least eight feet of head-room. Our plants were grown out-of-doors until frost came, when they were about five feet high; they immediately showed flower-buds, while the plants rapidly grew three to four feet higher. The first blooms are now open, and we shall have a succession of them all winter. They are very suitable for cutting, as they last a long time in water. While most other Dahlias have a flat outline, the flowers of the Imperial Dahlia are broadly campanulate, and resemble a Lily much more than a Dahlia in outline, the flowers often measuring eight inches across, and the petals being over an inch across and pure white, except at the base, where they are pink. The anthers and pollen are bright orange, forming a pretty centre to the flowers. *Dahlia imperialis*, in common with most of the other species, is native of Mexico, whence the plants were originally introduced into Europe over a century ago, and were at first grown for the tuberous roots, which were said to be eatable, but they never found much favor with man or beast, owing to their acrid or medicinal flavor. All the species of Dahlia are single, the double varieties being the result of the gardener's art.

Montbretias (Tritonias).—In a recent article in GARDEN AND FOREST Mr. Barker says that, so far as he is aware, *M. crocosmæflora* is the only hybrid in cultivation in the United States. But Mr. Gerard and others have noted on more than one occasion some half dozen others of Monsieur Lemoine's productions, such as Etoile de feu, Bouquet parfait, Drap d'or, Rayon d'or, Tigridie, Transcendant and others, all of which are distinct and equal in merit to the original *M. crocosmæflora*. It is a mistake to treat Montbretias as hardy plants, for they certainly are no more hardy than the Gladiolus here in the eastern states. I have known after a mild winter a few stray bulbs to come up here and there in a feeble sort of way, precisely as do Gladiolus-corms of Monsieur Lemoine's so-called hardy kinds; but there seems to me no sort of reason for risking Montbretias in this way when it is so easy to take them up at the same time that Gladioli are dug, and store them away in a cellar in sand or earth that is moderately damp. To grow these plants well requires a rich soil, the richer the better, hence one of the advantages of transplanting every year to a new position. There are, I know, several others who cultivate the newer kinds. My own were received partly from a correspondent in Oregon and partly from another in Indiana. It would be interesting to have the experience of these western growers.

South Lancaster, Mass. *E. O. Orpet.*

Galanthus Octobrensis.—It was with surprise and delight that I found this autumnal Snowdrop flowering in my border in the middle of November. This was somewhat late for the variety, but as the bulbs were received in early September with some other east European varieties, it speaks much for their precocity that they have bloomed with such a short establishment. It is interesting to speculate on the conditions which, through the course of years, have imparted to a local strain of *G. nivalis* the precocious habit of this variety. Like

the other fall-flowering kinds, *G. Octobrensis* is said to be found only in the Grecian Archipelago—this particular one in Albania—from which it was sent some years since. It has been rare in gardens till lately, when the increasing interest in various forms of the Snowdrop has led to the collection of the hitherto scarcer kinds. This plant seems to have considerable vigor, since the recent hard weather—fifteen degrees of frost with high winds—does not affect it. The danger would seem to be that it would weaken from insufficient ripening. Perhaps a warm covering of leaves later will help it in this.

Snowdrops are always beautiful and dainty, and one welcomes them even at this season, though now there is an unmistakable lack of that sentiment which has endeared this flower to so many and is so associated with their normal early spring-blooming habit. Snowdrops are, even when plentiful, not very striking flowers in the garden, and it will be well when small plots of the varieties are grown to cover the beds with some neat-growing Sedums, or similar plants, to serve as a foil to their fragile loveliness. *G. Meehani* would be a capital plant for the purpose. These autumnal Snowdrops will probably never be useful garden-plants or offensively common.

Elizabeth, N. J. *J. N. Gerard.*

[The specimen sent to this office by Mr. Gerard, and which is, perhaps, the first, or at least among the first, to flower in America, was almost a precise copy of the single Snowdrop which ordinarily blooms in late winter or earliest spring.—Ed.]

Correspondence.

What are the Experiment Stations Doing for Forestry?

To the Editor of Garden and Forest:

Sir,—The twelfth number of the *Experiment Station Record*, completing the second volume, has just come from the press. Its issue has been delayed by the preparation of the very full index and table of contents, embracing more than a hundred pages. The *Record* is composed of abstracts of the annual reports and bulletins of the experiment stations, and the index is, in fact, an index to 42 of the reports and 329 of the bulletins issued during the year 1890 and a part of 1891, and comprises 14,781 printed pages. It becomes, therefore, the ready means of surveying the field of experiment station work and seeing what the fifty stations are practically accomplishing.

I find out of between eight and nine thousand entries of the index there are only five under the words "forest" and "forestry." Under the title Trees there are nine entries relating to forest-trees. Under Insects only two have special connection with timber trees. Under Conifers there is a single entry, referring to some valuable notes on this class of trees by Prof. Popenoc, of the Kansas station, and under Evergreens there are two entries, one referring to a list of trees growing on the grounds of the Oregon station, the other to an account by Professor Keffer of the evergreens in the nurseries of the South Dakota station.

There may be, here and there, in this extended index an entry bearing upon forestry subjects in addition to those now noted, but they must be few. So far as a quite careful examination of the index shows, it appears that only seven out of fifty or more stations have as yet published anything relating to forestry. Some of the stations may have done some experimental forestry work which they have not carried so far as to give results warranting publication. But with all reasonable allowances, does not this official record show a marked neglect, on the part of the stations generally, of a subject which has the closest and most important relation to agriculture?

This neglect seems the more inexcusable when we see the work done by some of the stations. In South Dakota, for example, the station originally established for the whole territory of Dakota—though dating its existence only from 1887—has already done such experimental forestry work as to warrant the publication of four forestry bulletins besides what is published in the annual reports. In the very year of the establishment of the station three acres of ground were planted with tree seeds. In April, 1889, Professor Keffer gave the public the results of this experiment. A statement was made of the kinds of seeds sown, the varying depths at which the seeds were placed in the ground, the per cent. of those that germinated, the influence of deep or shallow planting on germination, the greatest growth of the various kinds of seeds, the method of cultivation, atmospheric conditions, and the general result at the time of publishing the bulletin. An account is then given of the planting, in the spring of 1888, of a forest-tree nursery, comprising 12,000 or more seedlings and embracing thirty species. The method of planting and the subsequent treatment are given, with the results at the time of writing. In November of the same year another forestry bulletin was issued. In this Professor Keffer gives an account of the planting of the seedlings in permanent forest-plats, which was done in the spring of 1889. The situation and character of the ground are given, with a diagram showing the relative location of the various species. The method of planting and the subsequent management are described, and the growth from month to month is tabulated. A third bulletin was issued in January of the present year. This bulletin is a report of progress in lines of work previously recorded in the other bulletins. Analyses of the soil of the experimental plats are given, with observations on the root-growth of transplanted trees, and a discussion of the value of a dense leaf canopy. A list of trees specially valuable for forest-plantations in South Dakota, as shown by observation and information, is also given. Still another bulletin was issued in April of this year. In this the importance of tree-planting is urged, methods of grove, street and lawn planting are discussed, and the advantages of certain varieties of trees for groves, streets or lawns are set forth.

It is impossible to overestimate the value of these forestry bulletins, though no adequate idea of them can be given in this brief space. But the question at once arises, Why are not similar bulletins issued by all or most of the fifty stations, instead of being confined to less than half a dozen? There is not a state in the Union where there is not manifest need for forest-experimentation, though it may not be the same as in Dakota. The forest-crop is the great agricultural crop of the country, most important in itself, as also in its relation to other crops. The problem is confronting us, How shall this crop be maintained in adequate measure when consumption is increasing, while the area of ground occupied by trees is decreasing because of the demands constantly made upon it for tillage purposes? We appropriate $728,000 annually to the experiment stations to aid them, in the language of the act by which they were established, "in acquiring and diffusing among the people of the United States useful and practical information on subjects connected with agriculture, and to promote scientific investigation and experiment respecting the principles and applications of agricultural science." The farmers of other treeless states, and of those also where trees abound more or less, may well ask whether the stations established among them are carrying out the full purpose for which they were endowed so liberally, when they fail to give instructions in regard to the uses and management of trees, the kinds adapted to their soil and climate, and the relations of trees to the whole business of agriculture.

Department of Agriculture. *N. H. Egleston.*

Winter Weather in North Carolina.

To the Editor of Garden and Forest:

Sir,—We have just passed through the most sudden and early cold snap I have yet experienced in this locality. The autumn has been continuously dry and sunny, and the cold wave which struck Raleigh on November 16th was the first killing frost we have had. The true temperature was not far from nineteen degrees above zero. Since then we have had sunny and pleasant weather, and I have been much interested in observing the effects of the sudden cold. The day before the frost our late Irish potatoes were still green, and the cold was so intense that it froze many of those which were near the surface. Our beds of Scarlet Geraniums had just taken on new growth from a shower a few days previous, and it is curious to notice that of two beds in the same exposure one had all its plants completely blackened, while the other, not twenty feet away, is scorched all over the top, but still shows green leaves below. In this bed the growth was more dense, and the mass of leaves above protected the lower parts of the plants. Pittosporums do not show a singed leaf. *Gardenia florida*, sheltered by the walls of the college building from the west and north winds, was not hurt at all. Oonshin Oranges, on an exposed hill-top, where the north wind had a full sweep, show no sign of injury. *Agave Americana*, planted on the same lawn, is quite uninjured, and a three-year-old bush of Jerusalem Cherry (*Solanum Pseudo-capsicum*), near by, looks just as happy and full of its scarlet fruit as ever. Olives, of several varieties, received from California last spring and planted for the purpose of testing their endurance of our climate, show no signs of injury. The Tea Roses look worse than anything else,

for the shoots, so red the day before the freeze, are black and drooping now, and the numerous buds are ruined, of course. Our Fig-trees dropped their remaining leaves in a hurry, but no injury to the wood can be seen. A large plant of *Ipomœa Texana*, an erect, tree-like Morning Glory, from the lower Rio Grande, the hardiness of which we are testing outside for the first time, was killed half-way down. It stood in a sheltered place, and was about eight feet high. The lower wood is so hard and ripe that we have strong hopes that the mound of earth we have built around its base will save it.

The extremely dry and sunny autumn had doubtless a great deal to do with the immunity of some things from harm, and the short duration of the cold also should be considered. But this sudden hard frost, coming after such a warm spell, gives me more confidence in the hardiness of the Japan Mandarin Orange, the Oonshin or Satsuma, than any test it has heretofore had. Whether permanently hardy here or not, it seems pretty certain that this variety will move the Orange belt, at least for Mandarins, a long way north of its present limits. Our trees are grafted on the *Citrus trifoliata* stock, which will dwarf them to the size of shrubs rather than trees, and at the same time will make it comparatively easy to give them some protection. We are studying the effects of different modes of protecting half-hardy plants, but with these Orange-trees we prefer to test their hardiness with full exposure.

One Olive-tree, planted on the south-east side of a high board fence, shows a suspicious brownish tinge on the leaves, while the others look as fresh as ever. This is doubtless because the morning sun struck it when frozen. Among other mulching materials, I am trying broken rocks, a little smaller perhaps than good macadamizing metal. As a summer mulch they are admirable; whether they will be of service in protection from frost I am not yet sure about, but in the last short chill the soil did not freeze under them. As a mulch to keep strawberries clean they are first-rate, and I believe hasten the ripening by their rapid absorption of heat by day and radiation at night. Broken flint-rocks are such a plentiful material here that trials are easily made.

In one of our Fig-plantations we have set Pine-bushes all along through the rows upright in the soil. These bushes are a little taller than the Figs, and give the plantation the appearance of a rather thinly set Pine-thicket. Another lot of trees north of these, and on a little higher ground, will have no protection whatever, the object being to try the effect of a light shelter with a free circulation of air. But little will be shown, however, unless the winter is unusually severe, as Figs seldom suffer here, except in hard winters. *Agave Americana* will be tested with full exposure, and also with a shelter to keep water out of the centre.

The behavior of the Pittosporum for the past three years convinces me that this handsome evergreen shrub will prove hardy much farther north than it is generally planted. In the *Gardeners' Monthly* for September, 1876, Mr. Walter Elder writes: "A plant of *Pittosporum Tobira*, four and a half feet high and three feet in diameter, was planted in the open garden of James C. Smith, Esq., 2104 Walnut Street, Philadelphia, in June, 1875. It stood out all last winter without injury, and now, June 5th, 1876, it is in a flourishing condition, covered with sweet-scented blossoms and filling the air with fragrance for a long distance." It would be interesting to know how long this plant survived.

Raleigh, N. C. *W. F. Massey.*

The Paulownia in Kansas.

To the Editor of GARDEN AND FOREST:

Sir,—A spreading tree by the side of the main drive-way in the college grounds here has often attracted the attention of passers by its very large leaves. It is usually taken for some remarkable variety of Catalpa, the resemblance to those trees both in foliage and habit being quite striking. The specimen is a Paulownia, doubtless the most western tree of its kind to be found in the Mississippi valley. It was grown from seed in 1884, and up to 1889 was cut back each spring to the ground, and grown for the rank sprouts which bore enormous broad leaves. In the summer of 1888 one sprout from this root grew to be nine feet high and two and a half inches in diameter. Some of the leaves were nearly two feet broad. In autumn this sprout was cut back to six feet high and wrapped thickly with hay. The winter following being a mild one, it came through without injury, and by the next fall measured four inches in diameter and had made a top growth of seven feet. At present the tree measures twenty-eight inches in circumference and is about eighteen feet high, with a spread of sixteen feet. This is a four-years growth, which it would be hard to find equaled among our native trees.

During the past summer the tree formed its first crop of flower-buds. These are borne in large terminal racemes, and are about the size of a Morello cherry, and have the appearance of being made of thick soft buckskin, so snugly are the embryo blossoms protected from frost by the thick calyx-lobes.

In spite of this care many of the buds were blackened to the heart by a severe frost early in October, and it is very doubtful whether any of them survive the winter.

Kansas Agricultural College. *S. C. Mason.*

Winchell and Green Mountain.

To the Editor of GARDEN AND FOREST:

Sir,—As my note in GARDEN AND FOREST in regard to the similarity of the foliage of the Winchell and Green Mountain Grapes has been extensively copied, it may be proper for me to say that both Ellwanger & Barry and Stephen Hoyt's Sons sent me samples of the grapes which they grew respectively under the above names. If the clusters received from the two firms had been placed side by side and the names removed I should probably have been unable to distinguish them from their appearance. There seemed to be a slight difference in flavor, which may have been caused by different degrees of ripeness or by difference in soils. The vine of Winchell which I have growing did not come from Messrs. Ellwanger & Barry direct, but they have now sent me vines which will be planted for test. Judging from the fruit sent me, if the vines prove as nearly identical as the fruit it will be unfortunate if they go out under two names. We expect to fruit them (or it) next summer and to settle for this section the date of ripening.

So far, the White Diamond is the earliest white grape we have tested. Its clusters are not so compact and handsome as the Winchell or Green Mountain clusters sent us, but the grape is better in quality, and promises to hang on the stem better. A large grower of early grapes in Florida, who was here a few days ago, told us that the Diamond is being largely planted there for early shipment, and he was quite enthusiastic over its quality and productiveness. Grape-growers in the south are rapidly finding out that the Delaware is particularly adapted to sandy lands, and is more exempt from black rot than many others. There is a growing inclination to plant largely of this fine old sort.

Agricultural College, Raleigh, N. C. *W. F. Massey.*

Notes.

The Central Park in this city contains nine miles of drives, five and three-quarter miles of bridle-paths, and twenty-nine and one-half miles of walks.

The house called Claremont, at the end of the Riverside Drive in this city, now used as a restaurant, was occupied long ago by Viscount Courteney, and later by Joseph Bonaparte.

The American Forestry Association will hold a meeting in Washington on December the 29th and 30th. A full attendance of the members is desired, and a strong effort will be made to secure national forest-reservations.

The yield of potatoes to the acre is larger throughout the country than it has been for ten years past, and in some states, according to the Government crop reports, the average for a state is rated as high as 120 to 125 bushels per acre. For the whole country the yield per acre is given at nearly ninety-four bushels.

Chrysanthemum-shows have been successful beyond precedent in England this year, and the same is true of the exhibitions on this side of the water. Before the shows many complaints were heard that the season was unfavorable, but never before were fine blooms displayed in such numbers. Exhibitions were held in a dozen cities, any one of which was superior to the very best in the country a dozen years ago.

In an article on the "Literature of the Garden," published in a late number of the *Gardeners' Magazine*, Mr. F. W. Burbidge, in speaking of John Parkinson's famous "Paradisus Terrestris," says: "I know of no book on gardening and flowers, etc., which possesses quite the delightful old English tone of Parkinson, and, among other remarkable things, this work is famous as containing the first systematic arrangement of Daffodils, or Narcissi, no less than ninety-six species and varieties being illustrated or described in its pages. A modern garden stocked with all the plants of Parkinson's book would be a very good garden, even although it lacked a great many

beautiful flowers introduced since his time—*i. e.*, 271 years ago. It is essentially a book of hardy or open-air flowers and fruits, such as were commonly grown before the days when cheap glass and coal made greenhouses and hot-houses possible."

The sixth annual meeting of the Pennsylvania Forestry Association was held last week in Philadelphia. Addresses were made by Professor Rothrock, Herbert Welsh, John Birkinbine and the Rev. J. P. Lundy, President of the Association. Professor Rothrock offered a resolution, which was unanimously adopted, that the Superintendent of Public Schools in the State of Pennsylvania should recommend that each of the state normal schools should give five lectures every year upon the principles of forestry as related to the public welfare. It was also resolved that a committee should be appointed to consider the advisability of preparing forestry tracts for general circulation, in order to spread a knowledge of the subject as an essential preliminary to any effective legislation.

In the current number of *Meehan's Monthly* it is stated that the Girard estate has been making small forest-plantations in an experimental way to see if it was practicable to grow timber in the coal regions, where nearly every stick has been cut away for props and various other uses connected with mining, so that now almost every piece of plank used there has to be brought from a distance. Eight years ago seedling English Larches and Scotch Pines, one year old, were planted in furrows driven through the underbrush which was growing up where old forests had been cut away. The Larches now average from seventeen to eighteen feet high, and are noticeably healthy. The Larch is a mountain-tree, and thrives in comparatively poor soil, and as these plantings are 1,500 feet above the sea-level the tree has something of its natural conditions. The vigor of the trees shows that they appreciate this position.

Dr. Rudolph Stoll, professor in a pomological school near Vienna, has issued a treatise on "American Early Peaches," illustrated by fourteen colored plates. Peaches of the sort he describes have been cultivated in Europe since the middle of the century, but what he calls "a new epoch in the culture of early Peaches" began in the seventies with the introduction of varieties received from the American grower Hales. These are now very largely grown in the south of France and also in Austria, where the preferred varieties are Amsden, Alexander, Musser and Wilder. "Propagation by means of seeds," says Dr. Stoll, "is as yet certain only with seeds imported from America, as most of the seeds grown in Europe do not come true, and it also seems doubtful whether as early-bearing trees would be produced by European seeds." Propagation by graft is therefore exclusively relied upon in the orchards of Professor Stoll's school. He says that in a climate where the Vine flourishes these Peaches will also flourish either as shrubs or as low trees; that in middle Europe, where Vine-culture is no longer profitable, they will do well on walls facing south, and in more northern countries only on espaliers under glass. The comparative excellence of different varieties as regards flavor he expresses in the following list: Cumberland, Saunders, Amsden, Wilder, Gouverneur Garland, Briggs' May Peach, Waterloo, Musser, Hales' Early, Bowers' Early, Canadian Early and Harper's Early.

The degree to which irrigation must have been practiced by the indigenous tribes of the west, in regions that now have relapsed into a desert condition, is well shown by the station of an Indian "fort" recently discovered about ninety miles below Phœnix, Arizona. The ruins, which are said to be the largest yet found, lie more than four miles distant from the Gila River, and are about a square mile in extent. In the centre is the fort, still very well preserved, and covering about six acres. It is built, says a writer in the St. Louis *Globe-Democrat*, in a very peculiar way. The first of the stories or "tables" of which it consists is about twenty feet in height and "is made of dirt with a wall of boulders laid in cement about the outside. On top of this and of the same height, though only half the size otherwise, is the second table, walled up as the first. On this a smaller one of the same height, and on top of that is the fort proper, constructed of stone and durable. The edges of the tower-tables were used as gardens, and around the walls are hundreds of boulders brought from the river, doubtless for the purpose of casting down on the heads of a foe. In the top fort are many skeletons and human bones, and in all probability the place was besieged and the people died of starvation. A ditch four and one-half miles in length runs by the base of this structure and brought water from the Gila. It is well defined and about thirty feet in width, though it is stopped up and no water runs through it." This immense construction, which was only the central feature of a large settlement, now stands in one of the most desert parts of Arizona, and no one had seen it until it was recently discovered by some miners who had lost their way in the wilderness.

Professor B. D. Halsted concluded a lecture on Injurious Fungi, delivered before the Ohio Horticultural Society, with a suggestion that we should not trust to fungicides alone for the eradication of plant-diseases. He said that healthy plants of strong stock, well fed and not overworked by undue cropping, are the best able to withstand the inroads of enemies of every sort. The half-starved plant is no better able to struggle among the vicissitudes of life than the ill-fed and half-sick man. Blights overcome the one as scurvy does the other. Therefore, the best conditions for the production of profitable crops are the same as those that will most assist in warding off its fungous enemies. Let the seed, soil and surroundings be the best, and a fungicide, so to speak, has already been used when it will do the most good and render the application of others, when needed, all the more profitable. In short, strive to do the best for the fruit-tree or shrub, as such, and a long step will be taken toward overcoming the enemies that break down the weakest hosts first. Having done this we are ready to take up the direct fight of the fungus foes with the long end of the lever. It must be a good, promising crop that will warrant the expense of fungicidal applications, and the larger the promise the greater the profit. Again: When a house or a community is afflicted with some contagious malady, pains are taken that the germs of the disease shall not remain lurking in out-of-the-way places. The carpets, and even wall-paper, are removed and the whole house fumigated or otherwise treated with some germ destroyer. While as thorough a cleansing as this is not possible in orchard, vineyard or garden, there are some measures that could be taken with profit. If weeds are left to mature and scatter their seeds, weeds are expected to follow. In like manner, if all diseased leaves, stems and fruit are allowed to pass the winter undestroyed, we shall reap what we have sown. The burn heap is to be a potent factor in future horticulture. If we continue to scatter the seeds of fungus decay, of that sowing we shall reap corruption.

Mr. Waldo F. Brown writes to the *Country Gentleman* that the Black Locust can be profitably planted for posts, at least in Ohio. He asserts that farms have been sold there at from $20 to $30 an acre, which, if planted in Locust-timber, would yield several hundred dollars an acre in posts within twenty years, and then would make a second harvest quicker than the first grew. He cites an instance of a ten-acre grove which was cut off between 1860 and 1870 and then sold for posts. How much this first cutting brought could not be ascertained, but it was certainly profitable. In just eleven years after the present owner began to sell posts from the second growth, and he has since had a regular income every year. Between 1879 and 1883 he cut 6,608 posts from the ten acres which brought $991, or an average of fifteen cents a post, and ever since then he has cut and sold large quantities. For ten years past this land, which is a steep hill-side unfit for cultivation, has yielded more profit than the remaining ninety level acres of the same farm which have been under cultivation. In another case a row of thirty-three Locust-trees, which had been planted along the north line of a farm for twenty rods, was cut after having grown twenty-five years. The harvest was 400 good posts, worth twenty-five cents each, 600 fence-stakes, worth five cents each, and enough wood to pay for cutting and splitting the posts. From the second growth of this grove the owner has cut all the posts needed to keep the fences on his farm of 150 acres, and he has now 200 posts seasoned for future use. These trees occupy only a quarter of an acre of land. How long one planting of Locust-timber will continue to yield crops no one knows. As soon as a grove is cut off it begins to send up a new crop, which grows rapidly, and will be large enough for post-timber some years sooner than such timber could be grown from seed. Mr. Brown once examined a grove of two acres on which the trees had been cut eleven years before, and found that each stump had thrown up from three to seven sprouts, the largest of which were then being cut. This thinning process went on for several years, until all but one of these sprouts to each stump was cut, and then enough trees were left to make a dense forest. In the thirteenth year after the original cutting 400 posts were cut from two acres.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, DECEMBER 9, 1891.

TABLE OF CONTENTS.

Mountain Forests and Mountain Streams.

HITHERTO the people of this country have suffered so little from mountain torrents that reports of their ravages in other lands too often sound like a tale of little meaning, and yet wherever there are high mountains with a sufficiently precipitous slope, and wherever streams flow through material which can be eroded, there is an absolute certainty that the short-sighted policy of clearing away the mountain forest will cause a repetition of the ruin which has been wrought in the French Alps and in many another place within the memory of living men. It is time, therefore, for intelligent Americans to inform themselves as to what an unchained torrent can accomplish, and we begin, therefore, in another column of this issue, the publication of an article which depicts the devastation caused by these furious freshets, which points out their causes and shows the only way in which they can be subdued. The article is not theoretical merely—that is, it does not state what might happen if certain laws are violated, but it records facts, and it has an especial value because it is prepared by the one man who is recognized the world over as master of the subject—a man who has not only observed and studied, but who has been the administrative head of the organized forces employed in the most extensive effort ever made to restrain the outbreaking violence of these mountain torrents, and even to subdue them to human use.

M. Demontzey, who read this paper before the Association for the Advancement of Science in Paris, has been in the French forest-service for forty years, and has risen from grade to grade until he is now at the head of one of the three bureaus into which the forest-administration in France is divided. Under his control come all the operations of reforesting, and in his field he is easily the first living authority. As early as 1853 he was engaged in the important work of reforesting a portion of Algeria, and ten years later he was placed in charge of the immense work which had been recently authorized by law of reforesting the mountains in southern France. The magnitude of these operations, and the success with which they have been carried on, give them high rank among the achievements of human science and skill. M. Demontzey has written a practical treatise on "Reforesting and Returfing Mountains," and his book is the authority on that subject. It has been translated into German, Italian, Spanish, and many extracts from it have been translated into English. The fame of his work has reached all countries, and wherever any laws are to be enacted or experiments made which look toward the protection of mountains from eroding streams, a commission is at once sent to France and to Demontzey for instruction. Italy and Austria, England, Prussia, Denmark and other countries have in this way received direct instruction and inspiration from his labors, and his influence will be felt for good in many lands and through many generations.

The testimony of such an authority ought to have convincing weight, and when he asserts that the clearing away of mountain forests renders the soil a prey to rushing waters, it becomes us to inquire how long we can keep on stripping the timber from our own highlands without disturbing that stable equilibrium which comes from the balance of opposing forces. It is a wearisome thing to repeat such warnings as this, but if Demontzey, after a lifetime spent in the work of reforesting the devastated mountains of France, finds that the story of it is still fresh enough to interest a body of men of science in the capital of France, we ought hardly to wonder that so little attention is paid to the subject in America. That forests preserve mountains has been demonstrated after fifty years of experiment in France, and that the forest is the only means of restoring a wasted mountain has also been amply proved. Fortunately, we stand as yet in no need of such restorative efforts, but it is well for us to know that if we bring this desolation by flood upon ourselves our only salvation will be found in replacing the woods which have been destroyed. Dams, retaining-walls and other works of engineering skill are helpful, but they are dead barriers only, and avail little against forces full of eager life. The aggressive violence of torrents can only be held in check by living agents, which are ever alert, and oppose themselves and their growth unceasingly to counteract and restrain the destructive work of flowing water. There is no safety for torrent-worn mountains until they are clothed again with living trees and vegetation.

It is more than the work of a day to reclothe a mountain with growing wood, but the law for reforesting the mountains has been long enough in force in France to demonstrate that some of the most violent torrents can be tamed. Agriculture has been renewed in places where cultivators had been driven from their farms. Mountains once a waste have been turned into homes for energetic workingmen. Desert slopes, which were not only useless but injurious to the valleys below, are now growing wood, which is not only a protective covering, but it is constantly increasing in value for human use. All this work, however, is accomplished at an enormous outlay. The labor and cost of the work, and the infinitely greater expense from previous loss, might all have been saved if the mountain forests had been administrated with ordinary prudence. The necessity for reforesting is the strongest argument for preserving the forests which already stand. The lesson we need to learn is not that it may be possible for us at untold expense to follow the experience of France and rescue our mountain-slopes and water-courses after the process of degradation and destruction are under full headway, but on the contrary, that we may escape all this loss by a timely effort to save the forest, which France is now taking such infinite pains to restore. We hardly need to be taught that the reforestation of a devastated mountain region is altogether too great an undertaking for private enterprise. But it has been also proved in France that forests are never safe without the protection of some power above that of individual owners. It is the state alone which can restore wasted forests or preserve those which already exist.

A Typical New England View.

TO any stranger desiring to see a typical New England coast landscape, the view from a house built a few years ago on the so-called "Beverly Commons," in the town of that name, might well be exhibited as combining many of the features which make our northern shore interesting and imposing.

The house itself is a rugged stone building, rising abruptly from a crag whose shelving surface slopes almost to the sills of the windows on the land side. The approach to it is through a wild and rocky dell, bordered with Pine-trees, some of which are of great size, with widely spreading branches. The rocks and trees are very striking in form and prepare the mind for what is to come. Little attempt at cultivating the grounds has been made, and the few exotic conifers that have been planted mar rather than improve the natural distinction of the surroundings. Their chief beauty consists in the masses of wild shrubs and herbage which come to the very edge of the irregular fragments of lawn that are here and there apparent near the dwelling, from the sea-front of which the view in all its majesty meets the eye.

In the foreground rises a great ledge of rock out of which spring great High-bush Blueberries of particularly graceful grouping. Beyond and around the ledge Golden-rod and Sumach follow the fine curves of the rocky surface, and then the eye is led gently into the middle distance where the soft outlines of Pines rise in gentle undulations, till suddenly a round, wooded hill forms a strange and striking curve in the sky-line, which is further diversified in the purple distance by bits of the shore, with a light-house on a point running out into the bay, and glimpses of the blue sea broken by the contours of distant islands. As far as the eye can reach the solitude is unbroken, nothing visible but the thin blue water-line with its rocky bluffs in soft haze of remoteness, and the great swell of the Pine-clad hill, of deepest softest green, rolling in noble curves to other masses of verdure that fill the hollows and rise again in echoing curves on either hand, with wide-spreading arms of Pine-trees, a single one outlined here and there against the sky. The middle-distance has somewhat the effect of a great rolling heath, which resolves itself near at hand into component parts of Blueberry-bushes, and Sumach, and other familiar herbage.

When I saw this view the Golden-rods were fading and the Sumachs just touched with autumn red, but when these last are one glowing flame, in startling contrast with the unchanging evergreens, the effect must be still more wonderful, as brilliant color would then combine with noble form to render the landscape extraordinarily beautiful.

A distant view of the Danvers Hills, rising along the western horizon, adds to the charm of this remarkable scene, and glimpses of other points and islands are caught between the swelling outlines of wooded hills, so that the outlook is perpetually varied, and as the mists veil and unveil its loveliness, must be full of mysterious suggestion to those who are privileged to contemplate it at all seasons and hours.

So strange and lonely is the spot, so rugged the house, and so wild the aspect of the ledges with their fringe of native shrubs, that the imagination takes wing, and weaves legends, and dreams of stories of uncanny deeds done in this desolate place, and peoples it with imaginary denizens, with histories and experiences to match the beautiful but savage landscape. The house when I visited it was uninhabited, which added still more mystery and charm to this lonely scene, leaving the fancy free to roam, and to evoke appropriate forms and events for this American Wuthering Heights, which on a windy winter day must be as eerie a dwelling as the one Emily Brontë pictured on her Yorkshire moor.

Unique as is the view, it is curiously characteristic, seeming to combine all the various elements that lend beauty to the majestic New England shore — rocks, hills, the sea, with glimpses of distant islands and elevations, and the simple but impressive forms of vegetation that can find sustenance in the decomposing surface of stones and arid downs.

The Pines are of exceptional loveliness; there is a furry softness about their great masses of foliage, full of lights and shadows, that seems to clothe the rugged surfaces with warmth and comfort. No tree seems so appropriate for a bleak and tempestuous region as this in which nature loves to enwrap her dreariest and most uncompromising wilds. Its aspect consoles, suggests shelter and protection; the roundness of its masses seems to soften the asperities of the hard surface from which it springs. Amid desolation it is the friend of man, affording him a roof by day, light and warmth by night — a pillow for his weary head, a carpet for his aching feet.

In this wide view the Pines appeal most strongly to the heart and give softness and beauty to a scene otherwise appalling in desolation. The fine sky-line without their feathery foliage would be harsh and unsympathetic, the intervening spaces barren and stern, the foreground unsheltered and drear. Thanks to their welcome presence, the eye rests gratefully upon as beautiful a prospect as can anywhere be viewed on the Massachusetts coast, the foreground being in perfect keeping with the distant views, and the whole making a delightful combination for a nobly representative type of New England scenery, in which woods and the ocean are happily combined, in the way that is best seen on that part of the coast north of Massachusetts Bay.

Hingham, Mass. *M. C. Robbins.*

The Colors of Flowers.—II.

Yellow.—Having proved the primary color of flowers to be white, the query naturally arises, Which is the second in the order of progression? Is it red, yellow or blue? Is there, indeed, any established sequence?

Following the method already pointed out we shall endeavor to answer these questions, first taking up yellow flowers. Of course, we must put aside all corollas wholly yellow, such as Buttercups, Potentillas, Caltha, Celandine, Œnothera, etc., and find some whose claw, throat or tube is other than yellow.

The tips of the yellow central florets of the Sunflower (*Helianthus annuus*), for instance, are chocolate-brown, but this cannot be the foundation color, for one should look for it at the base rather than tip; but we find the tubes of *Sonchus oleraceus*, Prenanthes, Hieracium, Lactuca, Leontodon, Taraxacum, the bases of Oxalis, yellow Pansies, the true yellow flower of *Polygala sanguinea*, garden Snapdragons, etc., all of them to be white, some more so than others, but never any other color except it be a special marking. In *Gnaphalium polycephalum* the long tube remains green, while the minute corolla quickly turns from white to yellow. Garden Nasturtiums, Tropæolum, are traced down from orange-red, or even a deeper shade, through every degree of yellow to the most delicate cream color, thereby establishing white as the foundation. Yellow in its lighter shades being nearest to white is more difficult to detect than any other color. Specimens of *Prenanthes alba* would probably be called white by some, yet when placed beside a pure white, as that of *Maruta Cotula*, they are seen to be "off color" and inclined to yellow, while *P. serpentaria* is clearly yellowish; quite likely, in course of time, their colors will become more pronounced.

Within half a mile of my summer residence are sixteen species of Golden-rod (Solidago), fifteen of which are bright yellow; but these are of no avail for our purpose. Nature, however, comes to our aid by leaving the sixteenth in its original white state. We examine it carefully, and find it even lighter than cream-color, substantially white. Yet its variety, *S. concolor*, is yellow. The pappus of the Golden-rods is pure white. Turk's Cap Lily exhibits a small area of white low down about the midrib before the yellow develops.

Mr. Grant Allen remarks in regard to the Daisy tribe as follows, p. 53: "Now, the earliest ray-florets would naturally be bright yellow, like the tubular blossoms of the central disk from which they sprung. And to this day the ray-florets of Sunflowers, etc., are like the central flowers. In the Camomile, however, the Ox-eye Daisy and the May-weed the rays have become white; and this, I think, fairly establishes the fact, that white is a higher development of color than yellow.'

Now, as to the ray-flowers of May-weed becoming white from yellow, we have already proved them (above, under white-flower section) to be derived from green, and therefore primary; as to the central florets, which are yellow and whole-colored, we have, of course, usually no direct proof, but simply because they occupy a central position is not sufficient evidence that yellow is their primary color. Among the Asters similarly with white rays, as in *A. dumosus*, *A. diffusus*, etc., indeed, in many others we find yellow central florets, also red-purple, and both on the same plant, and also mixed in the same head! In *A. diffusus* and several other species the colors change directly from yellow to purple. Here we have, according to that theory, the lowest color and "the latest fabrication" growing side by side under exactly the same conditions, and yet no white or intervening color between them!

But in regard to the central florets of *Maruta Cotula*, notwithstanding the very short tube and the usually well-covered corolla, it has been noticed that the yellow is much paler at the base, and, moreover, some specimens growing in the shade were found in which the tube showed no yellow. Then, too, *Aster diffusus* has central florets varying from deep yellow to nearly white. If specimens of this lightish variety growing in the shade, as, for instance, in a grove or open wood, are examined, flowers can easily be obtained without a trace of yellow in corolla or stamens, and of that apparently colorless but really faint white character noticed in *Spiranthes gracilis*. The tubes of several of the larger species, as *Aster Novæ Angliæ*, *A. Herveyi*, etc., and *Senecio vulgaris*, are at first white.

There is a greater natural tendency to yellow than to red or blue, as shown in the number of yellow-colored flowers, which exceed all others but white. The color, too, responds very quickly to the sunlight, and varies in the smaller Asters, according to the amount of light. Why this tendency exists is not known, but certainly yellow in its lightest shades is nearer to white than any other color—so near that the eye cannot detect its commencement, and on that account alone it would seem to be most natural to diverge in that direction.

A breeder of Cochin fowls of large experience, and himself an artist, and therefore well versed in color, informed the writer that to obtain a perfectly white color the fowls must be kept in the shade, and that if exposed to the sun the white became a straw-color! Another artist remarked: "Yellow color has a great deal of sunlight."

The foregoing examples are of themselves ample proof that yellow is derived from white; but if any one should prefer to see with his own eyes the actual development of a rich, pure yellow from a snow-white petal his wish can be gratified; let him observe *Lonicera Chinensis Halli*, now very common in our gardens. This flower opens a pure white corolla, with pure white stamens and pistil; almost immediately a change of color begins—the precise moment it would be difficult for human eyes to determine—and in a few hours both corolla and stamens become a beautiful yellow. The flower has not wilted nor faded in the least, but, while still fresh, the transformation from white to yellow has been accomplished. Both the pure white and the pure yellow blossoms, with intermediate shades, can always be seen at the same time upon the same vine, the yellow continuing fresh several days. Some flowers show color in the bud, others delay their permanent coloration, like the Fringed Gentian, which is green in the bud and only becomes blue as it unfolds its fringed lobes to the sunlight; others still, like *Cobea scandens*, do not change the green corolla for a day or two after full expansion.

With the example of *Lonicera Chinensis Halli*, before one, the evidence is complete. There appears to be a misapprehension regarding the prevalence of yellow-flowered species; they are not as supposed, at least in this region, in excess of white; the writer, in his "Flora of New Bedford and the Shores of Buzzard's Bay," estimated their number to be equal to the white; but in that estimate the main color only was counted, as, for instance, a flower with a white ground and purple dots or streaks was called purple; a Thistle, with a chalky white tube much longer than the colored part, was counted rose-purple, and disk tubular florets were not counted in; if, however, each species were credited with all its colors, it is plain from the preceding and following examples, which show white in nearly every instance, that that color greatly predominates, and, of course, it cannot be said that "nearly all stamens," if filaments are intended, "are yellow," when not more than one-third of the flowers are of that color. The proportion, however, in tropical or arctic regions may vary from this.

Greenish yellow in petals appears to result from imperfect elimination of chlorophyl from the thicker parts of the petals, such as the veins, etc. The effect is seen in white flowers, as Chelone and Parnassus, also in Fringed Gentian, where the green, frequently remaining on the outside of the lobes, gives them a dingy appearance, or it may result from the development of some blue in a yellow ground, as purples often follow yellow.

RED.—We now direct our attention to the reds, which are the easiest of all the colors to trace, for the reason that the change can always be seen in progress, and that whereas the inception of yellow in its lightest shades cannot be detected, any one can recognize a red on a white ground. It will require but a few illustrations to prove what is already so well known, that red is derived from white, namely:

Achillea Millefolium. Turns from white to rose; specimens occurring wholly rose-colored.

Rhododendron viscosum. White Swamp Honeysuckle is often tinged with pink, while *R. nudiflorum* is wholly pink.

Burdocks. Both white and red occur on the same plant.

White Clover becomes red.

White Pond Lily (*Nymphæa*) becomes pink in varieties.

Cornus florida has a pink variety.

Hydrangea paniculata grandiflora. Changes from white to red.

Daucus Carota is generally tinged with red on its outer circle of umblets as it opens, and in, perhaps the majority of cases, the central floret of the entire umbel, composed of 1,000 or more separate flowers, is usually of a reddish color.

Saponaria officinalis has a white base.

Pluchea camphorata. Base of perfect tubular flowers, colorless to white; the lobes only are reddish.

Many plants, commonly red, often revert to white, as, *Gerardia purpurea*, *Cnicus pumilus*, *Polygala sanguinea*, *Rosa Carolina*, *Spiræa tomentosa*, *Convolvulus sepium*, and others fade to nearly white; and it is a fact proved from observation, that yellow, red and blue colors all fade toward white.

BLUE.—All of the following blue or purple flowers have their tubes or the bases of the corollas of a white color:

Lobelia inflata. Base white; also the tube of garden Lobelia.

Trichostema dichotomum. Lower half lip and tube white.

Sisyrinchium. Occurs white.

Lathyrus maritimus. Keel white.

Liatris scariosa. Tube white.

Gentiana crinita. Base white.

Ilysanthes riparia. Tube white.

Chicory. Has a nearly white eye.

Mikania scandens. Varies from white to red-purple.

Cakile. Claw colorless to faint white; limb purple.

Brunella. Throat and tube white.

Aster patens. Shows white at base, forming a whitish eye.

Morning Glory (Ipomœa). Tube white.

Centaurea Cyanus (Batchelor's Button or Corn-flower). Base of central florets half pure white and half pure blue. This is a very interesting study; the white turns rose-color, the rose coalesces with the blue, and the whole becomes purple.

It is a common occurrence that when blue and red develop nearly simultaneously, or even in adjacent parts of the flower, that they soon blend into purple. A blue Morning Glory of a light color changes to a very light red-purple, and a dark blue one changes to a dark purple. Other instances are seen in *Symphytum officinale*, *Lathyrus maritimus* and in many of the Asters, etc. Colors are affected by the proximity of other colors; the reds in a Turk's-cap Lily, the "honey-guides" in Oxalis and the "eye" in Coreopsis, all having a yellow foundation, are not so vivid as the reds in white flowers. The honey guides in a white Snap Dragon of the gardens are light lemon-color, in *Gerardia tenuifolia* a darker yellow, in a light blue Lobelia a different tone of yellow, and in a dark blue Lobelia they are substantially green.

One exception only has been found in our wild flowers where the base apparently was not white, namely, *Myosotis palustris* (True Forget-me-not). Here the tube is clearly yellow, but the blue lobes are not attached in the usual manner, that is, on the end of the tube, making one continuous cylinder, but the tube extends above the lobes, forming a crown, while the lobes are attached a little below on the outside of the tube, giving them an exceptional character. This flower is also remarkable in color changes; the lobes of the corolla, at first white, become tinged with rose and then change to pure blue, while the tube remains yellow. Thus four colors appear in its development. It is no more difficult to believe that this yellow tube was originally white than that other whole-yellow flowers were derived from white. The blue, it will be noticed, was derived from white, and a small portion remains at the base of the lobes. In Centaurea it also should be noticed that blue appears much before red, as it does also in Ipomœa. There was discovered in an examina-

tion of *Monotropa uniflora*, in a single instance, on one of the petals, a spot of the purest cerulean blue; it was, of course, accidental and is only mentioned as showing that the color sprung from white.

Stamens.—There would seem to be no good reason why stamens should be yellow, while petals of the same flower are white, red or blue, and the general impression that they are so, as shown by the quotation near the commencement of this paper, is found to be erroneous. In an inspection of nearly all the late summer and fall flowers it was found that, with only half a dozen exceptions, the filaments corresponded in color with the petals, and that in many instances they copy the same special markings, as: St. John's-wort has a small black dot at the bottom of every serrature of the finely serrate corolla, and a similar dot on the anther of every stamen; *Gerardia tenuifolia* has its white stamens dotted with rose-colored spots similar to those of the tube; *Cassia Chamæcrista*, base of some of the stamens purple, like the base of the petals. In Buda and Cakile the stamens are merely in a less advanced state of coloration, being colorless to white, and the petals rose and purple, and in *Hibiscus Moscheutos* the stamens also are white, branching from a central column, and the corolla rose-colored; also in *Linaria vulgaris*, with corolla two shades of yellow, the stamens are white, but in Rosa and Nymphæa the stamens are found to be in an advanced state of color—that is, each has yellow stamens, while Nymphæa has white, and Rosa pink or rose petals. The writer can only suggest as an explanation of these abnormal conditions that the white of Nymphæa has been infused with the yellow color of its abundant pollen, and not changed by the usual chemical action, and that the flat position of the stamens of the Rose on a broad receptacle, allowing insects to directly alight and trample over them, may be the cause.

Pollen.—Pollen is not universally yellow: it is found of all colors from pure white, as in Polygonum Hydropiper, etc., through every shade of yellow, from cream to the reddish brown of *Lilium superbum* and the purple of Gladiolus and other plants. It is a fair inference that, next to green, the primary color, not only of petals, but of all parts of the flower, is white.

Conclusion.—1. The primary color of flowers, next to green, is white.

2. There is no regular order of progression in colors, as, for instance, that red follows yellow, or that blue follows red or was produced at a much later date, as it has been demonstrated that the principal colors, yellow, red and blue, are derived directly from white, and therefore are of equal rank, although some are more prevalent than others.

Insects probably have aided in "fixing" and determining color to some extent in certain families, but before they could be established they must have appeared; and if the quality of sunlight and the texture of the tissue of petals was the same in primitive times as now, and there is no reason to doubt it, then, in all probability, as soon as petals were formed, however remote that time may have been, all colors, including blue or purple, began to appear. Indeed, in the simplest and, presumably, the oldest types of flowers given in Gray's Manual of Botany as Clematis and Anemone, the prevailing colors are white and purple.

The rainbow and the prism reveal the many-colored rays of a beam of white light; the colorless tissue of the petal gathers up these scattered rays of the sun and forms them again, not into an intangible sunbeam, but into a material substance, shining with the original white, from which the sun calls them forth, re-habilitated in all their pristine splendor.

New Bedford, Mass. *E. Williams Hervey.*

Deciduous Shrubs with Late Persisting Leaves.

OUTSIDE of the coniferous class there are very few shrubs which are of a truly evergreen character, and, at the same time, which prove sufficiently hardy to withstand the rigor of our northern winters. It is true there are a few belonging to different genera which survive, and are always interesting, but most of them require some protection in winter, and even with protection their endurance is not to be depended upon.

In the absence of any number of thoroughly hardy evergreen species, it is of interest to note those deciduous kinds which maintain their leaves until quite late in the autumn, usually until mid-November or later. A careful review shows quite a number of these, and the foliage of several of them holds a good color through many hard frosts. With the possible exception of the Privets, no one group or genus can be called distinctly characteristic for this quality, the original home and environment of each species having influenced the period of defoliation, and the habit being perpetuated in cultivation. But abnormal garden forms often differ from the type in a very marked degree, and the foliage of young plants is often more persistent than on older ones.

A look over the shrub collection of the Arboretum on November 21st showed the following which were noticeable for still retaining many leaves after the severe frosts and high winds to which they had been subjected. The list is a comparatively short one:

The common Barberry still held a few leaves, and showed some variation among individual plants, some of the garden forms holding more than others, but none being particularly interesting. Japanese species, such as Thunberg's and Siebold's Barberries, had not retained a leaf.

Near by the little Yellow-root (*Zanthorhiza apiifolia*) of the Alleghany Mountains had hardly dropped any of its foliage, and it was still fresh and bright with its yellow and orange colors, once more enforcing the lesson that it is one of the very best of low shrubs for covering the ground.

Only one deciduous hardy Euonymus held its leaves. This is merely a monstrous form of the common European Spindle-tree, and is known in catalogues as *E. Europæus, erecta nana*. It has never been known to flower here, and as its foliage does not assume any of the bright autumn colors of its parent species it is hardly worth cultivating except as a curiosity. The leaves at this date were still a dull green color and all persisting.

Spiræa Thunbergii was still splendidly covered with its rich-colored feathery foliage, and it stood alone in all the genus, as no other species retained any quantity of leaves, and the few that remained were not conspicuous for coloring. Complaint will be made that the lower portions of the stems of *S. Thunbergii* become naked and unsightly with age, a fault common to many shrubs, but one which may be overcome by proper pruning.

Nearly all the forms of the common European Blackberry (*Rubus fruticosus*) hold their foliage in a remarkably fresh and clean condition, and with much richness of color, proving a good late covering for rough places. Our own *R. hispidus* holds its foliage even better than the European species, and, in fact, it lacks little of being an evergreen. It is a slender trailing plant, and is useful for forming a thick covering over rocks, stumps, etc. The Dewberry (*R. Canadensis*) also holds many of its leaves until quite late—later than our native Blackberry.

Of all the hardy wild Roses the little Scotch, or Burnet Rose (*Rosa spinosissima*), is by far the best when regarded from the standpoint of late foliage bearing. When all the other species are leafless, the neat compact bushes of the Scotch Rose still hold a quantity of fresh, rich-colored leaves. An exception should be made in the case of the new and rare *R. Wichuraiana*, which was figured and described in the last issue of Garden and Forest. The leaves of this plant are still all retained and are almost as bright and fresh as in midsummer, but, on account of its low trailing habit, it is not conspicuous. *Parottia Persica* holds many of its leaves, though they have lost much of their color and are becoming dry; but *Itea Virginica* is almost as fresh and brilliant as at any time during the autumn.

Several deciduous members of the Heath family are conspicuous, the best of them all being *Leucothæ racemosa*, with abundant foliage, purple and brown above, the under leaves being yellow. The Stagger-bush (*Andromeda Mariana*) still holds foliage on the ends of its branches, and *A. speciosa* has not lost any of its clear light green, yellowish, or sometimes brown and purplish leaves. The Leather-leaf (Cassandra) is fairly an evergreen here, and so does not come under the present list.

Our largest shrubby Composite (*Baccharis halimifolia*) holds enough of its fresh green leaves to effectively set off the bunches of conspicuous white pappus borne by the pistillate plant. The Indian Currant, or Coral-berry (*Symphoricarpos vulgaris*) retains all its leaves in a very fresh state, the branches being bent under the weight of the regularly abundant crop of deep red berries, and *Viburnum Lantana* retains more than any other of its genus, but it is dull and uninteresting.

The only Honeysuckles which here hold good foliage so late are *Lonicera Standishii* and *L. fragrantissima*. The first has lost fully half its foliage, which falls while yet fresh-looking; but the leaves of *L. fragrantissima* seem to retain their chlorophyll and vigor until much later. Indeed, the habit of this plant here shows that it is quite evergreen in climates a little less rigorous than this.

The rich green-clad climbing Japanese Honeysuckle (*L. Japonica*) and Hall's variety of it are certain to attract atten-

tion, but it comes under the head of evergreen rather than late deciduous shrubs.

Nearly all the Privets are admirable for the late persisting quality of their foliage, the only exceptions in the Arboretum collection being *Ligustrum Ibota*, which is leafless, and the closely related plant called *L. Amurense*, which only retains tufts of foliage on the ends of the more vigorous shoots.

The true *Forsythia Viridissima* is often conspicuous by holding its leaves late. *Elæagnus angustifolia* and *E. umbellata* and the Hippophaës retain a large quantity of fresh-looking leaves of no particular interest or ornamental value.

Finally, the fine leafy condition of *Smilax glauca* seems to show that it is at this season superior to the common Greenbrier (*S. rotundifolia*) and to *S. Pseudo-China*, which have very few leaves left among their tangle of prickly stems.

Arnold Arboretum. *J. G. Jack.*

Fig 91.—Hypericum Buckleyi.

New or Little-known Plants.

Hypericum Buckleyi.

THIS pretty and delicate Hypericum, of which a figure appears on this page, is one of the rarest of the North American species, it being known only on a few of the higher mountains of the Carolinas and Georgia, where it was first noticed many years ago by the botanist whose name it bears. It is a wide-branched plant with slender stems from eight to twelve inches long and covered with loose reddish bark. The leaves are oblong-obovate, from a half to two and a half inches long, rounded at the apex, gradually narrowed at the base, bright green on the upper surface and pale on the lower. The flowers, which are solitary and terminal, are borne on long slender bracteate pedicels; they are an inch across, with obovate sepals, bright yellow striated strap-shaped petals more or less rounded or acuminate at the apex, united styles and three-celled ovaries.

Hypericum Buckleyi was sent to the Arnold Arboretum in November, 1889, by Mr. F. H. Boynton, of Highlands, North Carolina, and flowered profusely here this year in the open ground at the end of June. Nearly all the American Hypericums are desirable garden-plants; most of the species are very hardy, their habit is good, and they usually produce their showy flowers at midsummer. *Hypericum Buckleyi* promises to be a good addition to a not very long list of small, handsome-flowered, and easily grown hardy shrubs, suitable for small rockeries or the margins of small shrubberies.

Our illustration is taken from a drawing made by Mr. Faxon from a cultivated plant.

London Letter.

Bordeaux Mixture for Potatoes.—A fortnight ago I sent you some particulars of a trial of this mixture as a preventive to disease in Potatoes by Messrs. Sutton & Sons, of Reading, the result of which was most unfavorable to the mixture. Dr. C. B. Plowright, the eminent fungologist, now reports a trial of Bordeaux mixture on Potatoes which shows an immense gain in the yield of the dressed Potatoes as compared with those which were not dressed. The experiment was made in Donaghmore, Tyrone, only Champion Potatoes being tried. They were grown upon two different farms, the treated and untreated plants grew side by side, and were identical as to seed, manure, cultivation, etc. The mixture used was 32 lbs. copper sulphate, 16 lbs. lime, and 160 galls. water. It was applied by an Eclair Knapsack pump, price thirty-five shillings; the cost, including labor, being about ten shillings per acre. The leaves of the untreated plots were destroyed by August 21st, but the foliage of the dressed plots was quite green for nearly a month longer. The total yield from the plots treated with the mixture was 78 tons 14 cwts., while from a similar number of plots which were not treated the yield was 66 tons 13 cwts. The difference per acre was between one and a half and two tons in favor of the treated plots. This experiment certainly proves that in this particular case the application of the fungicide to plots of Champion Potato made a considerable improvement in the yield. But there are good reasons for believing that, under other conditions of climate and soil, the same Potato would have behaved quite differently, and, possibly, would even have proved better without the mixture. Further experiment is necessary before any definite opinion as to the value of the mixture as a fungicide for Potatoes can be reached.

[Experiments carried on for some years in this country seem to show that spraying Potato-plants with the Bordeaux mixture hinders the spread of the rot by preventing the germination of spores which are carried by the wind from infected to healthy plants.—Ed.]

Cypripedium insigne, var. Sanderæ.—According to a paragraph in *The Times* a plant of this Cypripedium has lately been purchased by Messrs. F. Sander & Co. for £250. The history of this variety is as follows: It was introduced by the St. Albans nurserymen in 1888 among a batch of *C.*

insigne, only one plant of the variety being found. When it flowered it was named by Mr. Sander in compliment to his wife. It was afterward divided into two, one of which was disposed of by auction for £70, Baron Shrœder being the purchaser; the other was sold to Mr. R. H. Measures, whose collection of Cypripediums is famous for its richness and splendid condition. Mr. Measures divided his plant into four, one of which was sold to F. L. Ames, Esq., of New York, one to Mr. R. J. Measures, and the third is that for which Messrs. Sander & Co. have paid £250. At this rate the single plant introduced three years ago has now a value of £2,000; at any rate, one-eighth of it has been sold for an eighth of that sum. Of course, the plant has this value only to collectors of Cypripediums.

Dendrobium formosum giganteum.—This is a most attractive Orchid at this time of year. Several very large importations of it were made last year and the year before, consequently the plant is abundantly represented in collections here now. Plants one and a half feet high, with stout leafy pseudo-bulbs bearing terminal clusters of from three to five flowers, each fully four inches across and suggestive in form of a Cattleya. They are pure white, with a blotch of deep yellow on the curiously plated lip. They remain fresh on the plant about a month. This species is abundant in north-east India and Burma, and as it travels well it is always plentiful and cheap in England. Its one drawback is its failing in health after about two years' cultivation. Still it is by far the largest and most beautiful of all white-flowered Dendrobiums, and it never fails to flower freely the first year after importation.

New Roses of 1891.—A writer in the *Gardeners' Magazine* calls attention to the following new kinds of Roses as being the best this year:

Margaret Dickson (Hybrid Perpetual) was sent out by Messrs. A. Dickson & Sons, who last year obtained a gold medal for it. Messrs. Dickson describe it as follows: "White, with pale flesh centre, petals very large, shell-shape, and of immense substance, magnificent form, growth very vigorous and covered with stout spines, foliage very large and dark green in color. Unquestionably the greatest acquisition made to Roses during the past ten years." This is a little too much to say of a Rose which has had only a year's trial, although at the National Rose Society's Exhibition it was awarded first prize for a stand of twelve flowers of a new Rose, as well as first for a stand of twelve white Roses.

Salamander (Hybrid Perpetual). "Flowers bright scarlet-crimson; very vivid in summer and deep and glowing in autumn; large and full outer petals reflexed, centre erect; free-blooming, strong in growth, constitution good." This is another gold-medal variety raised by Messrs. W. Paul & Son, with whom it was in fine condition in August.

Marchioness of Dufferin (Hybrid Perpetual). The raisers, Messrs. A. Dickson & Sons, describe this as "a worthy partner of our Earl Dufferin, which has attained a world-wide celebrity as the best dark Rose introduced since 1869. The flowers are of enormous size, their color a beautiful rosy pink, suffused with yellow at the base of the petals, which are reflexed. The growth is vigorous." This Rose was highly commended at the National Rose Society's Exhibition, held in London, and afterward obtained the gold medal when exhibited before the same society in Hereford. It is distinct in color, being almost lilac, and it is excellent in form and size.

Crimson Queen (Hybrid Perpetual). This is a most beautiful Rose, which I saw among Messrs. W. Paul & Son's flowers at the Temple Show. It has velvety flowers, colored maroon, shaded with fiery red in the centre; very large, full; globular in form. The plant is said to be very vigorous and to produce abundant and large flowers equally well out-of-doors and under glass. It will probably prove a good early variety.

Waban (Tea). This is of American origin, and is a sport from Catherine Mermet. It is described as resembling its parent in foliage and growth. The flowers are carmine-pink, splashed with madder-red, the reflexed petals more delicate in color. Roughly it may be called a deep-colored Catherine Mermet. It is being distributed in England by Messrs. W. Paul & Son, who have a very high opinion of it as a Tea Rose.

Medea (Tea). Raised by Messrs. W. Paul & Son, who describe it as having "flowers lemon color, canary-yellow in the centre; clear and bright shades of color; large in size; very full; buds inclined to be high-centred, but expanded flowers more globular; growth vigorous; a grand tea-scented Rose."

Mrs. Paul, another of Messrs. W. Paul & Son's new varieties, a Bourbon, is also spoken of very highly.

Kew. *W. Watson.*

Cultural Department.

Apples in 1891.—II.

Winter Apples.—Belmont is one of the early winter fruits that ought to be more generally grown. It is most popular in Michigan, is of fine quality and a very handsome blush yellow. It is often called Waxen, from its oily skin. It grows rapidly and bears heavily. The wood of the tree is brittle. Baldwin is too well known to need any description. It varies immensely on stock and with soils, and is best when grown on old trees grafted high. Spitzenburg is really the best of apples for cooking. For a time it was argued that the Spitzenburg had run out, and could no longer be grown; but if the fruit is syringed against codlin moth and the bark washed with kerosene emulsion, it will thrive, but it needs rich soil or high feeding. Hubbardston is a superb apple in December. In January it begins to lose its spicy flavor. It is a beautiful apple and borne here in abundance. Young trees often overbear. The wood is rather brittle. This year a tree of this variety in fruit has presented an appearance truly splendid.

Grimes' Golden is a fairly good apple of medium size and bears well. It does not rank as high here as in the west, but for vigorous growth and health the tree is admirable, and every orchard should have a few. Jonathan is an apple of the very first quality. It is a seedling of Spitzenburg, deep red in color and strikingly handsome. It bears enormously. Northern Spy is a superb fruit, and is almost a universal favorite. Throughout the whole Apple-belt, from the Atlantic to the Pacific, it does well. To be at its best it should grow on very open trees and in strong soil. When ripened in the shade this apple is flavorless. It is now our most profitable apple for general culture; this year, however, for some reason, the fruit is not high-colored. Rhode Island Greening is a long name, but we must retain it, as there are several Greenings in our orchards. It is not easy to get the genuine Rhode Island Greening, which is yellow fleshed and very rich-flavored. Eatable in December, the Greening is in good condition and high quality until April. Roxbury Russet is among the ten best Apples here. It bears admirably, the trees are very enduring, and for baking no late winter apple surpasses it. The tree is inclined to bear early, and to grow low and spreading. It is a favorite of the codlin moth, and the fruit is specially relished by fowl and cattle. Princess Louise, a seedling of Fameuse, is a handsome, delicious fruit, with flesh white, and a flavor much like its parent. It is beyond price, and very hardy. The Newtown Pippin, Peck's Pleasant and Canada Red are local fruits, and so, practically, is the Tompkins County King. This last never gives full crops outside a few favored localities unless syringed, and even then the crop is too largely defective. Swaar is an old English sort of extraordinary quality, a large, handsome fruit; and the tree is hardy, but not a first-class grower. Westfield Seek-no-farther has done as well as ever, and always does well, giving large clean fruit, handsome and very excellent for table use. Yellow Bellflower has done but poorly in this section, and generally in the east, but in the west is a prime favorite. It is specially in need of syringing. The Kirkland, a seedling from the Bellflower, is a grand acquisition, for a very large, very showy and very late keeper. Wagner I do not place low in the list because of its inferior quality. It is one of our very best; and for table-use in late winter is invaluable. For my personal preference I place together Greening, Jonathan and Wagner for late winter. It is a northern Apple, and will probably fail in the south.

Sweet Apples.—For summer I have named the old Harvest Bough, or Sweet Bough. For early winter, the Pound Sweet, grown as it should be on open trees, is the best. It is growing in favor again, after being displaced in part by Tolman's. It

gives enormous crops of fine large fruit. Properly handled it keeps till April. The best late sweet that I have yet seen is the Belle Bonne, an old Connecticut fruit, that does well here, and almost everywhere. A fine tree, early to bear, and a grand cropper of clear golden apples, and a fruit of delicious quality for table or baking that keeps till May. I have found a seedling sweet which seems the handsomest and best of all, but the tree is a poor grower, and apparently diseased. I am trying kerosene emulsion with some advantage.

No well-instructed apple-grower will hereafter attempt to raise this fruit without spraying against the codlin moth. Unless we use the well-tested remedies against insects and fungi our orchards will be simply nuisances. We have also to comprehend that no fruit needs more care in handling, and no tree more good feeding and careful pruning. Apples can no longer be successfully grown without brains.

Clinton, N. Y. *E. P. Powell.*

A Few Good Flowering Plants.

HEDYCHIUM CORONARIUM.—This is an admirable plant for decorating conservatories, and when planted out in rich compost and well supplied with water is seldom out of bloom, the pure white flowers being produced in terminal spikes after the companion plant to the last, the flowers being tubular in form and bright yellow in color. The foliage is smoother than that of *C. elegans*. *C. fasciculatum* and *C. Newelli* are also worth cultivating, the first bearing some resemblance to *C. elegans*, while the latter produces larger flowers of bright crimson color. All the members of this genus are readily increased by cuttings from the young growth, but for conservatory decoration old plants that have been cut back are preferable, as they usually produce a better crop of flowers, although they require some stimulating with liquid manure to develop their best form.

BEGONIA INCARNATA.—This is a very useful species of this useful genus, and is specially adapted for pot-grown specimens for winter flowers. It is possibly better known as *B. insignis*, and bears a profusion of large light pink flowers during the whole winter. The color of this Begonia is a very pleasing one. A few plants of it dotted about a conservatory are extremely effective, and it is a beautiful plant for any indoor decoration. *B. Froebeli* is another remarkably handsome species, but is not quite so easy to manage as the preceding. It has large cordate light green leaves that are more or less covered with dark hairs, which are more noticeable on the young foliage. The flower-spikes are quite strong

Fig. 92.—The Körner Oak, near Carlsbad.—See page 586.

manner of the Cannas, but possessing the additional advantage of being very fragrant. Under favorable conditions the plant will attain a height of six to seven feet, and soon forms a large clump of growths. *H. Gardnerianum* is another handsome member of this family, of somewhat smaller growth than the preceding, and with light yellow flowers. This species is somewhat more hardy than *H. coronarium*, and may be used to advantage out-of-doors in the summer. It is propagated by division of the roots, which is most satisfactorily performed in the spring.

CESTRUMS.—These rather old-fashioned greenhouse shrubs are seldom seen now, though quite useful for cool-house decoration, and not to be despised as cut flowers. *C. elegans* is one of the best, and, in common with its fellows, has simple leaves of more or less lanceolate outline. Its growth is rapid, so that it needs to be pinched occasionally in order to make a shapely plant. The flowers of *C. elegans* are purplish red, and produced in small terminal clusters. *C. aurantiacum* is a good on well-grown plants, and bear a considerable number of large brilliant scarlet flowers. This Begonia prefers a light soil, well enriched with dry cow-manure, and in watering it is best to avoid wetting the foliage, as this species is rather impatient of moisture on the leaves.

PRIMULAS.—The Chinese Primroses especially are among the most useful small-growing plants for winter-flowering either in the dwelling-house or in the conservatory, and a succession of young plants should be provided each season for such use. They should be coming into bloom about this time in order to be most valuable. *P. Japonica* is also a showy plant, though quite variable in color, and may be had in bloom during the winter and spring months with but little difficulty. The flowers are about one inch in diameter, produced in successive whorls on a stout spike, the prevailing colors being shades of crimson and red. *P. verticillata* is another very pretty species of this extensive genus, and does not seem to have become common, though in cultivation for

many years. It has long lanceolate leaves that are covered with a white powder, and the flowers are quite large, yellow, and produced in whorls on a scape. This species does not relish much water over its foliage, and its beauty fully repays for any care required in its cultivation.

Holmesburg, Pa. *W. H. Taplin.*

A November Garden.

IT ought to be possible to make our gardens more interesting in November. Of course, this is the time of Chrysanthemums, which are apt to overshadow other things. But, however much one may value their useful flowers, it is well to have a few quiet plants in the garden as a relief from their rather dazzling prominence. A well-filled garden should have something of interest at all seasons, if it serve no other purpose than to draw us more to the open air. Many of us have managed to stock our gardens with plants which respond to the first indication of warmth, but most of us have relied on the Chrysanthemums to give us our latest pleasures in the open.

My list of small plants has been lengthening, and they are gradually giving me suggestions which I hope to utilize in the future for providing quiet dainty bits in the border to be enjoyed till the final closing of the garden-year, usually about the first of December in this latitude. Of course, there are few flowers to be had out-of-doors in November. An occasional Primrose opens, *Bellis perennis* is not easily discouraged, the Globe-flower, *Trollius Europus*, gives a few blooms, and, showiest of all, the Marigolds, if in a warm corner, may be depended on for stray flowers.

The flowers in the November garden must, however, be had mostly from bulbs—the Crocus and Colchicum. The autumnal Crocuses pleased me so much this year that I have an idea of trying for a bright autumnal effect in a border planted also with spring-blooming bulbs. There is a long stretch of time after such a bed is cleared and planted when, to say the least, it is not attractive. It has occurred to me that if, with the spring-flowering bulbs, we planted an assortment of autumnal Colchicums and Crocus, the bed could be made to do double duty and be attractive quite through the month of November. It might be necessary to provide temporary shelter for occasional very hard weather, but these flowers will stand a fair amount of severity. The available varieties, both of autumnal Crocus and Colchicum, are numerous, and they vary considerably the time of blooming, so that it would not be specially difficult to arrange for such an effect.

But any one who is really fond of plants finds that flowers are only one of the elements of beauty; and at this season one finds dainty bits to enjoy among the small hardy plants which, in the presence of luxurious summer growth, are too frequently overlooked. There is a never-failing fascination in some of the little alpine plants. The encrusted Saxifrages are really jewels, with their attractive rosettes, and always enjoyable even when not in flower. The mossy Saxifrages, also, may be had in never-ending variety, and when established are mostly gems. The low-growing Sedums are another family among which may be found numerous attractive plants. Some of them take on wonderful tints of coloring at times. Mr. Whittall sent me some Cyclamens from Asia Minor, whose leaves are so beautifully marked, and which are so very hardy, that they are even yet attractive. This has induced me to plant other available kinds, of which I find there are about a dozen. In slightly shaded places and well-drained soil I shall probably find a fair number successful. The present plants are as attractive to me as my favorite greenhouse varieties.

There are, of course, numerous other small things—Androsaces, Drabas, Arabis, etc.—which will gladden the gardener when well established. Small things are these, and many of them require much skill and care. One who gardens for pleasure does not consider them troublesome, and they are never tiresome. Some plants are like a mathematical demonstration, they go on in orderly reliable sequence. There is pleasure in the demonstration, and pleasure, too, in such plants, but seldom so much as in those which require more attention. At this time will often be observed the first signs of the spring harvest—the Muscaris have their foliage developed; in few Narcissus the tips are just evident; the foliage of Spanish and a few other Irises is appearing; and many interesting things may be noted in the borders. I do not share the fear of some that early developed foliage will suffer by hard frosts and cover nothing except the Oncocyclus Irises. Such foliage is usually developed slowly under hard conditions and is not readily injured. A slight covering of leaves, such as nature and kind winds scatter over the beds, is not objectionable and serves a useful purpose in preventing sudden thaws; but in my case, like that of many others, the demon of tidiness and destruction in the way of the occasional helper, usually carefully removes such evidences of apparent unthrift before one thinks to give warning. The same sometimes useful person also enjoys raking out the crowns of one's favorite plants unless restrained by a strong hand, and I am afraid he is not the only one who thinks a bare patch of earth an ideal fall and winter garden.

Elizabeth, N. J. *J. N. Gerard.*

Bacterial Disease of Celery.—There is a bacterial disease of nearly everything, and Celery proves to be no exception to the rule. About a month ago, while in the Celery-fields, near Greenville and Bayonne, New Jersey, looking after troubles of a fungous nature among the truckers, attention was attracted to a peculiar blight of Celery, particularly the variety known as the Golden Plume. The affected leaves were badly blotched with brown, the diseased spots having a watery appearance that suggested the work of nematode worms as much as that of bacteria. A microscopic examination of the infested leaves showed that, while nematodes and all forms of filamentous fungi were absent, there was an abundance of bacteria uniformly in all the diseased patches. It was an easy matter to secure these germs free from all others and grow them for purposes of inoculation. Leaves of Celery from healthy plants were then treated to the pure germs, and at the end of three days the disease had spread throughout their whole extent. From these decayed specimens the bacteria were again transferred to the cores of plants, and from these tender centres the disease spread with still greater rapidity, and the whole plant became decayed and worthless.

In these experiments it was determined that the bacterial decay proceeds most rapidly when the part of the Celery is kept constantly moist, but not wet. Celery-stalks placed partly under water, to which bacteria had been added, decayed quickly near the water's surface, and the submerged portions were the last to spoil. The practical lesson from this, so far as our limited knowledge suggests any lesson, is: Keep the Celery dry and cool as possible.

Rutgers College. *Byron D. Halsted.*

Prolonging the Fruit Season.—A curious fact in Pear-culture, and indeed in fruit-culture generally, is, that if the bulk of the crop is picked when ripening, and a portion of it, say a fourth or less, is left on the tree, the latter will cease to ripen and will remain on the tree in good order for a month longer. I picked some fine solid Buffum pears that were left on the tree a full month later than the main crop, which was gathered September 20th. The most perishable Plums, such as Washington, will behave in the same way. Nature provides in some fruits for a long succession by loosening the ripe ones from the stem. This is peculiarly true of the Gravenstein and Summer Strawberry apples; but it is often worth our while to follow Nature, and secure a long season of some favorite fruit.

Morristown, N. J. *M.*

The Subjection of Torrents by Reforestation of Mountains.

IN March of this year, before a special session of the French Association for the Advancement of Science, there was presented a paper so suggestive in connection with efforts now being made to arrest needless forest-destruction in our country, that we reproduce the essential parts of it in translation, kindly furnished by Mr. H. B. Ayres. It was from no less an authority than M. P. Demontzey, Forest Administrator of France, to whose indefatigable work for the last twenty-five years or more is due the success in redeeming the devastated mountain regions of southern France.

The author's vivid descriptions of experiences in the mountains of France remind us of the damaging and dangerous floods and erosions not only in the scantily wooded regions of the west, but also in portions of the eastern states, especially in the sandy regions of the south.

It was in France that the reforestation of mountains was first made the object of legislation. A long time ago, numerous statesmen, economists, engineers and woodsmen, far-sighted and impartial observers, acquainted by long residence there with the mountainous regions of southern France, warned the state of disaster and ruin, and unanimously urged

the necessity of modifying a condition that formed a singular contrast with the prosperity of other regions and threatened to compromise them also.

The government was apathetic, and, heedless of danger, continued to ignore a matter which seemed to interest only some poor districts crying faintly in their distress. But, at length, the disastrous inundations of 1840 brought from the lower Alps another cry of alarm that suddenly aroused public opinion.

A young engineer, Surrell, originally from the most densely forested district of Lorraine, published, under the guidance of Dufaure, then Minister of Public Works, his "Etude sur les Torrents des Hautes-Alpes." This masterly work was characterized by the most thorough analysis, the clearest observations, the most definite conclusions and the most advanced ideas of economy. It was the grandest plea ever uttered in favor of mountain-forests, and was awarded a Montyon prize by the Institute in 1842.

From that time the reforestation of mountains has taken rank among matters of high public interest in France; the government brought this important question to the attention of the general councils of many interested Departments, and the Forest-administration, while preparing a code of law, began in 1846 a series of experiments in reforestation, the results of which have not ceased to be of value. Political events caused a long delay, and it was not until 1860 that a permit for experimentation was granted. This was the first law looking toward the reforestation of mountains, and it was the result of aroused public opinion after the inundations of 1856, the losses by which have been estimated at more than 250,000,000 francs. There were clamorous politicians who maintained that reforestation of mountains was a chimerical and impracticable enterprise, which would only lead to disappointment. But the government was gaining knowledge from the experiments, and by 1876 it was able to lay before Parliament a new plan, which, after many debates, resulted in the law of April, 1882, for the Restoration and Preservation of Mountain Lands, in full force to-day.

The provisions of this law are of two classes: (1) Measures of encouragement, which consist in the power given the government to incite, by means of bounties, landed proprietors, communities and private citizens to improve lands hitherto unproductive, desolate and liable to erosion. (2) Measures of coercion, which authorize the state to demand the declaration of the public need of works termed "obligatory" at all points where a careful investigation shows that their execution is demanded by deterioration of the soil and real dangers.

If we investigate the causes of deterioration we find that the great enemy, in fact the only one that we have to combat, is erosion, the power of which is determined by the inclination of the slopes, the volume of water that may flow in a given time, and the friability of the soil or of the underlying rock. The maximum effect is accomplished by a torrent—that is to say, a stream of water with very steep beds and sometimes intermittent—conditions which give the greatest power to erode and transport from the mountains the materials which the stream deposits in the valley. This notable characteristic of the torrent helps to make the floods in the plains still more resistless by the enormous mass of solid material, which, washed into the rivers, increases the volume of their flood and constantly elevates their bed.

The problem of restoring and preserving mountain-lands must necessarily be stated thus: On one hand to suppress in existing torrents the possibility of erosion, and the consequent transportation of material, and to diminish the volume and the suddenness of floods—that is to say, to transform the torrents into harmless and even beneficial streams; on the other hand, to anticipate or to prevent all erosion which may give rise to either the formation of new, or to the renewed activity of extinct torrents.

Such a delicate enterprise should, therefore, not be left to the discretion of the owners of the soil, but should be carried on by some agency of wider authority. Hence these obligatory reforestations prescribed by the law, which gives to the state, in case of the refusal, the negligence, or the inability of the private owner, the duty of preparing for the formidable struggle, which it alone will be able to carry on with success. Upon the state, therefore, devolves the restoration of torrent-worn mountains.

It was estimated in 1860 that the area of denuded mountains needing reforestation would reach 2,964,000 acres. After the extensive surveys from 1884 to 1886, covering 8,645,000 acres, the total area to be placed under management by the state was fixed at about 790,400 acres, or a fourth of the whole area to be reforested. The operations upon the lands most needing them, however, will cost more than the reforestation of the three other fourths, which are to remain in the hands of their present owners and be made valuable by means of the state bounties.

Before going too far, it may be well to define clearly certain terms of our special vocabulary:

We say of a torrent that it is "in activity" when it erodes near its sources, deposits material of all sorts in the valley, and spreads out over its deposits.

We call a torrent "extinct," which, after a period of activity (be it long or short), becomes, owing to special circumstances, no longer able to transport eroded material, but has longer periods of high water, rising less suddenly and in diminished volume, so that it passes into the condition of a brook.

By "correction of a torrent," we mean the construction of certain works which give stability to beds and banks in order to arrest or to diminish the transportation of materials and to reduce the rapidity of drainage.

Finally, we distinguish among "active" torrents two different modes of action, according to the nature of their floods. In case the volume of water is greater than the volume of the materials it carries, the latter stop one after the other, as their resistance exceeds the transporting power. The coarser are left first on steep slopes, then pebbles, gravels and sands, as the grades grow less and less, the change of grade being well shown by the upward concavity of the profile of their beds. On the other hand, in the case of violent and sudden torrents, from the rapid melting of snow, or a hail-storm, where the volume of materials is much in excess of the volume of water (perhaps double or triple), the current may be seen in the form of mud more or less thick, in which rocky materials of all dimensions nearly touch, and which on very steep slopes are borne onward en masse. When this current flows into the valley, no longer confined between high banks, and reaching more gentle slopes, it slackens. But the larger rocks, by virtue of their acquired velocity, are less inclined to stop, and the deposition of material is in this case in exactly the reverse order of that by selection in regular floods.

The very characteristic name of washes, or washouts, is given to these strange floods which sometimes cross the river to which the torrent is tributary, dam it for the moment and leave on the opposite bank great fragments of their advance-guard, which remain for years in testimony of the violence with which they have been swept along.

The field of action affected by the forester covers in great part three mountain systems in the south of France: The Alps, the Cévennes and the Pyrenees.

I.—THE FRENCH ALPS.

The group of the French Alps presents all possible forms of erosions, washings, land-slides and other devastations that the torrent is able to produce in the most diverse climates, and at various altitudes from the sea up to perpetual snow. This is the classic land of torrents, which there rule as terrible masters, to accomplish what Michelet strikingly called "la mort de la montagne."

In 1846 the illustrious economist, Blanqui, in a report to the Academy of Science, by which he had been charged with a special study of the situation in the French Alps, made a startling representation, from which I make some extracts.

"One who descends from Dauphiny toward Provence, along the summit of the Alps, is delayed at every step by the wild irregularities of the mountains. In nearly a hundred leagues he does not find a single navigable stream, not one of those great basins, like those of the Marne, the Saone, or the Yonne, which give life to whole provinces. The rivers of the Alps partake of the character of torrents, by reason of their rapid descent and their capricious course over a bed obstructed by rounded stones. Such are the Drac, the Romanche and the Durance, into which are discharged, through innumerable affluents, the melted snows from the perpetual glacial reservoirs, and the rains of all the upper region.

"The Rhone receives, in the lower part of its course, the astonishing product of these great floods which have acquired, in these later years, such alarming proportions.

"The bright clear skies of the Alps of Embrun, of Barcelonette, and of Digne remain, during entire months, free from the least cloud, and engender long droughts only broken by storms as violent as those of the tropics. The soil, deprived of herbs and trees by pasturing and by clearing, and dried by a burning heat, is washed quickly to the bottom of the valleys, sometimes in the form of lava—black, yellow, or reddish—followed by streams of pebbles and even by enormous rocks, which bound impetuously on with horrible crashing and destruction.

"From an elevated point the picture of this torrent-scoured country is that of desolation and of death. Immense beds of rounded pebbles, many yards deep, cover great areas, surrounding, and even covering to the top, the largest trees, and making a hopeless desolation of the farm land. There is nothing more depressing than the sight of these deep cuts, from which the mountains seem to have rushed out upon the plain to cover it over with rocks.

"The débris of these torrents can be seen a great way off, spread out at the mouth of the gorges, in the shape of a great fan, sometimes to the width of 3,000 yards, higher at the centre and inclined toward the edges like a mantle of rock over all the country. Such is their appearance when they are dry, but human language has no words to describe them at the moment of a sudden flood, when they break out with unrestrained violence which has no parallel in the ordinary behavior of river waters. Sometimes the unchained torrent strikes a river at right angles and forcibly rolls it back toward its source; elsewhere, two torrents, from opposite slopes, rush together in the middle of the river between them and assail each other with rock and gravel.

"The district is pastoral in the higher portions, and slightly cultivated in the valleys. Forests are rare, and, unfortunately, belong to the community. Their product is almost nothing. The expense of protection is beyond the local revenues, and the inhabitants vie with each other in destroying what is public property.

"The road system in the Alps is exposed not merely to the elements of destruction common to other parts of the country. The road engineers in the Alps are always ready for war; in winter, to open the road; in the spring, to repair it; in the summer, to guard against torrents. A warm wind, which suddenly melts the snows, a storm accompanied by pouring rains, a flock of goats or sheep which start a shower of stones, an avalanche which tumbles across the path, is sufficient to block all travel. The abrupt and often precipitous nature of the land leaves no escape from dangerous grades, and often compels the engineers to suspend the road over dizzy precipices. Works of engineering art are seen at every step, in the form of bridges, dams, embankments, or tunnels. Notwithstanding these constant efforts, travel is often arrested, and but few months pass without some tragic accident to spread alarm and terror among the hearts of the people."

Twenty years later, following the investigation of 1866, the Councillor of State, charged with the study of south-eastern France, in his report, prepared in 1868, described the Department of the Lower Alps as follows:

"What impresses one first in traversing the mountainous parts of the department of the Lower Alps is the imposing, but sad and desolate aspect which they present. Instead of the great forests or green pastures, which, according to local traditions, once covered them, they only show bald summits, arid slopes where a little brush still retains the scanty vegetable mold which the waters have not washed away, and deep ravines, where the torrents have rolled enormous avalanches of rocks and gravel. Here and there, as if lost in the devastation, upon heights or on slopes, apparently inaccessible, one sees a few poor dwellings; some abandoned, others, poverty-stricken relics of some industry which had managed to survive the land-slides brought on by ignorant clearing.

"At intervals, one comes upon villages surrounded by small estates that a rude population have laboriously created, and still more laboriously defended against the storms, torrents and avalanches which threaten our French Alps. Then, far apart, appear a few meadows, wooded hill-sides, or plateaus of good pasturage, whose slight inclination has saved them from the prevalent ruin. These are the oases of these immense wastes, and about them slowly, but incessantly, goes on the work of impoverishment which began more than a century ago.

"Every year the coat of vegetable mold, which has clothed the heights, is torn and diminished more and more. Every year the gravelly bed of the torrent is enlarged, and its débris encroaches upon the fertile plains of the river valleys. Every year some poor family sees its modest patrimony reduced, and it is small wonder if a population, with its means of subsistence ceaselessly threatened, becomes discouraged and emigrates to more hospitable regions. The ruinous condition of our frontier Alps produces the same painful impression upon all who see it. Every one is impressed with the necessity of making a vigorous struggle against these causes of impoverishment and depopulation."

Statistics furnish mournful information in this respect: In 1846 the population in the Department of the Lower Alps reached 156,675; in 1886 it was only 128,295. This shows a loss in forty years of 28,380 inhabitants, or eighteen out of every hundred. The population to-day is not more than 18.45 per square kilometer (247 acres), and there are districts like Barcelonette where it is reduced to 12.75 over an area of 1,716,800 acres. More than one-third of the land consists of abandoned fields and worn-out pastures.

Besides these districts, where formidable torrents develop into their highest activity, there are many other regions in which torrents of the first rank give place to myriads of smaller ones, which cover the hill-sides like a leprosy, and although their ravages appeal less strikingly to the imagination, they are quite as disastrous to the country.

The recent inundations, which caused in the lower valleys of Isère and of Durance a damage of thirty million francs, prove this only too well. Later rains only affected the lower part of the mountain-sides, and, fortunately, gave place to heavy snows in the higher part, but this only gives cause for apprehending a more sweeping destruction in the future. A rise of two or three degrees in the general temperature of the higher regions, a warm wind like the Foehn of Switzerland or the "Chinook" of North America, would melt the snow or change it to rain, and would more than triple the volume of water.

(To be continued.)

Correspondence.

The Körner Oak.

To the Editor of Garden and Forest:

Sir,—In my Garden and Forest of August 19th I read a brief notice of the great "Wurtemberg Linden." This notice had already attracted the attention of a gentleman now here, General W. J. Palmer, President of the Rio Grande Western Railroad, whose interest in the preservation of forests led to the recent withdrawal from sale and impending destruction of some 90,000 acres of woodland around the beautiful Rocky Mountain watering-place, Manitou. Our conversation about the Linden led to the discovery that one of Germany's celebrated trees, the Körner Oak, was but two miles from Carlsbad, and soon thereafter we visited it and made the enclosed measurements and photograph (see page 583).

The tree is 27 feet 10 inches in circumference six feet above the surface of the ground, 30 feet two feet above the surface, and by approximate triangulation is 75 feet high. One of the larger branches has recently fallen, and the giant evidently feels the weight of years. It is the largest of a group of primeval oaks that adorns the park of Herr Von Riegel, a gentleman connected by marriage with well-known New York families, and stands near his country-seat on the left bank of the Eiger.* It spreads its roots through the rich soil but a few hundred feet above the seams of brown coal, from which German students of fossil plants have drawn such an abundant harvest of specimens. From an inspection of the foliage I believe it to be *Q. pedunculata.*

It is widely, in Germany, known as the Körner Oak, and a tablet bearing the name of that "hero of the lyre and sword" is attached to its bole. The poet occasionally visited Carlsbad during his brief but remarkable career. He studied at the mining academy in Freiberg, and was familiar with the silver-bearing mountains that rise in rough serrations north of the Eiger on the Saxon horizon. His last visit to the neighborhood was in 1813, a few months before his tragic death. Beneath this Oak he is said to have composed his poem ending,

Deutsches Volk du herrlichstes vor allen,
Deine Eichen steh'n du bist gefallen!

In that admirable combination of scientific exactness and pleasing art, Henry Brooks' "Typical Elms and other Trees of Massachusetts" (which is praisefully introduced to its readers by the life-long lover of plants, Oliver Wendell Holmes), I find recorded the dimensions of some New England Oaks that will give the reader of these lines a basis for comparison.

The Eliot Oak, Dedham (*Q. alba*); girth, five feet above ground, 15 feet 11 inches; height, 80 feet. The Society Oak, Charlemont village (*Q. rubra*); girth, five feet above ground, 14 feet 6 inches; height, 58 feet. The Carter Oak, Lancaster (*Q. rubra*); girth, five feet above ground, 18 feet 5 inches. The Beaman Oak, Lancaster (*Q. rubra*); girth, five feet above ground, 17 feet 8 inches; height, 70 feet.

May I suggest to the amateur photographers in each of our four and forty states, six territories and the Federal District that they would earn the gratitude of a large and increasing circle of their most intelligent fellow-citizens if they would secure for publication and preservation the portraits and dimen-

* Cuttings from the Körner Oak are growing in the gardens of Oswald Ottendorfer, at 135th St., New York.—R. H. L.

sions of such remarkable trees as still remain to bear witness to pre-Columbian times—trees that, like their feral contemporaries, the Indian, the bison and the elk, are growing more interesting as they gradually disappear into the dim domain of history and legend?

Carlsbad, September 17, 1891. *Robert H. Lamborn.*

A Precocious Chrysanthemum.

To the Editor of Garden and Forest:

Sir,—A Chrysanthemum, bought in May from a city florist as "Mrs. Andrew Carnegie," began blossoming in the open ground about the middle of July, and continued to flower in a desultory way till October. The blooms were white, with a yellowish centre, not especially fine. What should have been done with this plant? Should it have been discarded as a passing freak, or taken in hand as having useful possibilities?

Whitewater, Wis. *A. S.*

[This Chrysanthemum might possibly have proved to be a precocious one. This is not at all probable, however. It is not unusual for these plants to bloom at any time, especially if they are checked and the wood is hardened up. It is very likely that the plant in question was from a stem-cutting, and, from the description, it may have been from the early Madame Desgranges. Any check which may have arrested the growth of wood would cause the early buds to develop. Ordinarily, when a plant is full of vegetative vigor the flower-buds are abortive, and it is usually only after the plant has practically finished its growth that perfect blooms are produced.—Ed.]

The Nelumbo.

To the Editor of Garden and Forest:

Sir,—In your issue of November 25th, referring to the Nelumbo, you say "Perhaps some of the readers of Garden and Forest can tell us whether the Nelumbo is still found in Dr. Barton's station in the Delaware." I regret to say that the plant is probably not to be found there now. About four years ago, in company with Mr. William De Hart, who is familiar with the locality where the plant grew, I went to search for it, where, four or five years before, Mr. De Hart had seen the plant still growing. The place was not the river proper, but the large ditches, deep and wide, of which there are so many in "The Neck," as this part of Philadelphia is called. There was not a plant left of the many he had been accustomed to see. From a trucker who lived near by we learned that the roots had been carried away by gardeners to place in ponds at home, the last plants disappearing some two years before our visit.

Germantown, Pa. *Joseph Meehan.*

The Land of the Lingering Snow. Chronicles of a Stroller in New England from January to June. Frank Bolles. Houghton, Mifflin & Co., Boston and New York.

This little book is made up of chapters, some of which have been previously published, describing the rambles, in the neighborhood of Boston, of a man interested in all natural objects, but more especially in birds. The title of the book and the names of its chapters are particularly happy, and form a pleasing introduction to the experiences of the rambler, who goes forth to see reeds shaken by the wind, and other natural phenomena, within an easy journey of Old Cambridge, which appears to be his starting-point. He begins to wander in January, taking his latest trip the 29th of May; so that it is mostly with winter and spring landscape he has to deal, and he sets forth his experience in an agreeable way with many charming touches, but a certain monotony of tone, perhaps resulting from the fact that the book is not a connected whole but a series of separate sketches, more or less resembling each other in their general character.

The most vivid of them is the Equinoctial on the Ipswich Dunes, which is very breezy and spirited, and gives a clear impression of a wind-beaten shore and drifting sand, lashed by an angry sea, with accompaniment of whirling gulls and black ducks and some bright color in vegetation.

There is, in an account of a trip to the Waverly Oaks, the following suggestive though gloomy picture:

"At the sunset hour a strange glow permeated the mist, but it soon vanished. I left the hills and crossed the Belmont meadows. The twilight was weird. The mud of the Concord turnpike seemed unnaturally yellow; the pollard willows assumed horrid shapes; head-lights on distant engines made menacing gleams on the wet rails; the great excavations in clay beds, near the brickyards, were filled with black shadows from which rose vapors; brooks, once clear, now polluted by slaughter-houses, gave out foul clouds of mist, and, as electric lamps along the road suddenly grew into yellow balls in the fog, they showed, rising above them, crucifixes of this nineteenth century, on which are stretched the electric wires, whose messages of good or evil keep the nerves of society forever uneasy."

There are accounts of the sea in a snow-storm; of the Minute Man in a snow-drift; of views through winter sunshine that contain good and secure touches. Here is a bit of Concord, Massachusetts:

"About sunset, on Saturday, I was in a grove of venerable Red Cedars. The lower half of the trees was in shadow, the upper half in sunlight. Below, all seemed cold and dreary—the unbroken snow, the rough trunks of the trees, their sombre foliage. Above, all seemed warm and cheerful—the bright blue sky, the passing bits of white cloud, the upper branches of the Cedars glowing with golden olive-green. I sought an open ledge, where I could see from Blue Hill to Monadnock, and watched the sun sink into a bed of clouds. The after-effects of color were pronounced. Overhead, the sky was cobalt; low in the east it was pale Prussian blue; in the north it was deep orange, and in the west, silvery, with a few dark, ragged clouds shredded over it. After sunset, and just before darkness comes, colors, irrespective of the outlines of the objects to which they belong, stand out more forcibly than at any other time. This was noticeable Saturday evening. The red of a distant steeple was aggressive; so was the yellow of some tufts of dead grass, waving in the wind, and so was the russet of the dried leaves on a grove of Oaks or Beeches two miles distant. The sky at that hour was a matchless background for the copper-colored stems of the Willow-trees, the bewildering network of descending lines in an Elm's branches and twigs; and the distant rows of Maples, marching along an opposing hill-top, with the orange light of the northern sky burning through them."

An account of a night under a Pine-tree, with a great horned owl for a neighbor, is very entertaining, in the chapter called A Voyage to Heard's Island; and here, too, are some graceful descriptive passages, while throughout the book there are numerous pen-pictures that show a power of delicate and poetic observation.

There is a little too much cataloguing of birds, which appear in rather too exact numbers for artistic effect, though possibly not for the precision of the ornithologist, but in this our author is in touch with the modern microscopic idea, which will not permit a man to eat a piece of pie without telling the size and nature of it. The charm of mystical vagueness is not now a literary fashion; let us be thankful that Mr. Bolles is still permitted to employ his eye for the picturesque and his poetic feeling in such passages as the one about Chocorua "dimly present in the smoky heaven as conscience is present in the mind of man."

"The stars burned near it like altar candles. The smoke of fires rose round it like incense, the song of myriad frogs floated softly from the lakes below like the distant chanting of a choir, and the whispering of the wind in the Pines was like the moving of many lips in prayer."

There is a capital description of a swallow in the chapter called Chocorua, and much sympathy is shown everywhere for the feathered throng, with the names and habits of which Mr. Bolles is evidently familiar, so that their chirping seems everywhere audible in his landscapes, and their songs to form an orchestral accompaniment to his writing.

The country about Boston, even within a day's journey, seems to furnish much to interest this close observer, who keeps his eyes and ears open as he travels on foot or by train among the hills and marshes of his neighborhood. It is interesting to see how an enthusiasm for our immediate surroundings is developing in the youth of this observant age, and how they are learning to love their own dells and fens, and to honor them in song and story. Whatever opens the eye to the beauty about us is of value; whatever calls attention to the often unheeded charm of familiar surroundings is of distinct service, and this service Mr. Bolles has rendered in his carefully written pages. It is a book to be enjoyed as it was written, in detached chapters, when the full value of each passage can be felt as it deserves. Read continuously the work loses something of its charm, which arises from truth of detail, beauty of expression and a tender sympathy with all nature. For mountains, for the depths of the forest, for the raging sea, for the bittern in the

marsh, and the wren in the orchard, he has a genuine love, which finds expression in felicitous epithet and picturesque phrase, and in an inward correspondence of feeling which interprets as well as observes the objects which attract his eye.

The paragraphs that close The Bittern's Love Song and Warbler Sunday are evidences of the meaning which he finds in common sights, and prove him to be gifted with that poetic sense which gives a value to the simplest and homeliest objects.

Notes.

During the last five years the importation of oils into India has increased eighty-seven per cent., which means that mineral oil has almost altogether supplanted the vegetable illuminants of indigenous origin upon which for ages the population had relied.

Some years ago, when Hans Christian Anderson was visiting Tennyson, he said to the poet that Ivy seemed to be his favorite plant, to which Tennyson replied, "To tell the truth it is. Ivy needs no nursing; it knows neither cold nor heat; it is the plant of immortality."

Messrs. E. H. Krelage & Son, well-known horticulturists of Haarlem, in Holland, announce the introduction of a new strain of self-colored Tulips, which they declare to be of singular excellence and which they have named Charles Darwin. It is offered in many varieties. It would be interesting to know how nearly black is the variety which is not only blacker, they claim, than any Tulip previously produced, but presents "the most absolute black in the vegetable kingdom."

The *Gardeners' Chronicle* gives the picture of a new erect-flowering Verbena which has been introduced by some of the Erfurt seed-growers. This compact new type of Verbenas is said to have branches and spikes arranged about the principal stalk in a strictly upright position. There have been introduced before this year three colors of the type, which are all various shades of scarlet or lilac. The last one is said to have a velvet-like dark blood-red color, and so nearly constant that when grown from seed but few of the plants run back to scarlet.

A specimen of *Dichorisandra musaica* in the group of greenhouse-plants exhibited by Thomas Long, gardener to A. J. Drexel, at the recent exhibition of the Pennsylvania Horticultural Society, was an excellent example of good cultivation. The plant was grown in a ten-inch pot, and formed a perfect mass of shoots from twelve to eighteen inches in height. *Phrynium variegatum*, in the same collection, was also shown in admirable condition, the variegation being very clear and distinct, while the Golden Livistona, which occupied a prominent place at one end of the table, proved how effectively this plant may be used, especially when under artificial light.

In the current number of the *Gardeners' Magazine* the new *Lilium Henryi* is figured, and the figure shows how aptly the plant has been described as a yellow-flowered *L. speciosum*. It grows between three and four feet high, and the flowers have the same reflexing, lanceolate segments and the same raised excrescences on the surface. What distinguishes the plant is its color, which is a bright and decided yellow, relieved by the bold red-brown spots near the centre. As *L. speciosum* makes a good garden Lily in this country, it is not improbable that *L. Henryi* will do the same. It was found in 1888 on the slopes of precipices at an altitude of from one thousand to two thousand feet above the sea, near the town of Ichang, in the province of Hupeh, in China.

As an effort is now being made to set apart a forest-reservation about the wonderful and beautiful Crater Lake in Oregon, it is important to note how rapidly that region is being turned into a desolation. Mr. E. W. Hammond, who was there not long ago for the first time since 1875, reports that where a forest of Firs and Spruces stood sixteen years ago, with branches sweeping the abundant grass, which was knee-high everywhere, he found the ground as bare as a public road, the whole country having been pastured to death by cattle and sheep. Hundreds of blackened trunks of once beautiful Firs and Spruces now stand by the dried-up water-courses to mark the track of fire. In the midst of this desolation stands a great log corral, which was deserted because all herbaceous vegetation had been stamped out for miles around. Of course, it would be well if the entire region about the lake should be put under proper control, but the immediate approaches to it, at least, should be preserved from such vandalism.

Mr. John Thorpe, Chief of the Division of Floriculture in the Columbian Exposition, has been in this city on business connected with his work in Chicago. Mr. Thorpe speaks with enthusiasm of the possibilities which the great Exposition buildings and the broad grounds offer for a horticultural display which has never yet been equaled. He realizes, however, that time is crowding the work and that every moment will be needed to establish and develop the plants suitable for this colossal enterprise. It is to be hoped that the managers of the Exposition understand this point as thoroughly as Mr. Thorpe does, and that they will afford him every facility for hurrying forward the work in its earlier stages. It would be an incalculable misfortune if Mr. Thorpe were compelled to say at last: "What a magnificent exhibition I could have made if the proper support had only been given me at the proper time!" We ought to add that Mr. Thorpe himself has no fear that the enterprise will fail, in any particular, to justify the expectations of its most sanguine friends.

Mr. Edward Whittall, writing in *The Mayflower* of his recent discoveries in Asia Minor, says that a new Scilla was found on the western spurs of the Taurus in the same location where *Scilla bifolia Taurica* was said to have been discovered. This is the variety, no doubt, which has lately been named by Mr. Baker, of Kew, *S. bifolia Whittalli*. The Crocus family is largely represented in these regions, a beautiful variety strikingly like *C. Sieberi* being found on the Taurus, above the town of Adalia, the ancient Attalia. The Fritillarias have been found in great variety by Mr. Whittall. Previously he had found *F. Armena* (yellow and green), *F. aurea* and *F. acmopetalis*. This season's discovery is a Fritillary of checkered lilac and yellow, and somewhat smaller than *F. Meleagris*. It is peculiar in blooming in July, fully two months later than other sorts in these parts. The Snowdrop seems to be represented in Asia Minor only by *Galanthus Elwesi*, and this beautiful plant is found growing abundantly over all the region from the Straits of Mytelene to the heights over Samos. Mr. Whittall has heard of a yellowish variety, which, if description is true, will be welcomed by fanciers of the family.

In the private gardens of the palace at Osborne, on the Isle of Wight, where only, it is said, can Queen Victoria plant and cut and arrange as she pleases without consulting the officers of the Crown, she has a long array of memorial trees commemorating events which have occurred in her family circle. In one spot stands a row set out in February, 1862, when each member of the family dedicated a tree to the memory of Prince Albert, who had died during the preceding December, the one which the Queen herself planted being a Pine-tree. In another place is a group each of which records the marriage of one of her children, and it is under the shade of these, we are told, that Victoria prefers to have her afternoon tea-table set. Not far away is a large, luxuriant bush of Myrtle which has grown from a sprig which the Queen took from the bridal bouquet of her eldest daughter, the Empress Frederick. Myrtle is always used at bridal ceremonies in Germany as Orange-flowers are with us, and this bush now contributes to the adornment of all the brides among the Queen's descendants. Her grandchildren are now adding on various occasions to her collection of historical trees at Osborne.

In the last number of *Insect Life* we find a report of a new branch of entomological commerce which has just been started by a French firm—that is, the sale of culture tubes for the destruction of the white grub. The circular which the firm sends out explains that there has been discovered a specific vegetable parasite which destroys this grub. Following the methods of Pasteur, the firm have undertaken the artificial production of this parasite, and they offer to sell tubes containing the spores. They guarantee their cultures to be capable of communicating the disease to several hundred worms. The method of treatment advised is, to put about a hundred grubs in a vessel containing some moist sand. The contents of the tube are then sprinkled over the grubs, the vessel is covered, and at the end of six hours the grubs will have the disease. They are then taken out, one by one, and placed six or eight inches deep in the ground in different parts of the infested field and gently covered with earth. Of course, it would be prudent to place the diseased grubs in the portions of the field that are the most thoroughly infested. These grubs, inoculated with the disease, will communicate it to others, and if it spreads as rapidly and proves as deadly as the malady which has destroyed so many silk-worms, it may prove the most effective means of warfare against the white grub. But, after all, it seems at first like an unfair advantage to take of a worm.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, DECEMBER 16, 1891.

TABLE OF CONTENTS.

Yellowstone National Park.

IN the early days of the last session of Congress we invited public attention to the necessity of prompt legislative action in regard to the enlargement and better protection and maintenance of the Yellowstone National Park. We expressed at that time a fear that nothing would be accomplished, owing to a persistent and untiring lobby that would prevent the enactment of any law which did not carry with it an exclusive right or franchise for a railway through the north-east corner of the park. The event proved that this apprehension was well-founded. No action was taken by the House of Representatives on the excellent bill which passed the Senate, and which was practically the same bill which had passed that body on four separate occasions. The House, upon receiving the bill from the Senate, referred it to the Committee on Public Lands, and it was by them, after a long delay, reported back to the House with an amendment granting a right of way to the Montana Mineral Railway Company to enter the park and to lay fifty or sixty miles of track to a mining camp lying in Montana outside of the reservation. This amendment was in no way germane to the bill, but a positive injury to the park and the beginning of special privileges and jobberies which would in the end hand the park over to corporations who had no generous or patriotic interest in it or appreciation of it, and cared only to use it for their own selfish purposes. Those who took the deepest interest in the park preferred the postponement of the passage of such a bill until it could be placed on the statute-books without such an objectionable feature as the Montana Mineral Railway franchise.

In the last days of the last session, Congress passed a law entitled, "An Act to Repeal Timber-culture, and for Other Purposes," and among its provisions was one to which we have often alluded. It reads as follows: "The "President of the United States may, from time to time, set "apart and reserve in any state or territory having public "land bearing forests, in any part of the public lands, or "wholly or in part covered with timber or undergrowth, "whether of commercial value or not, as public reserva- "tions. And the President shall by public proclamation "declare the establishment of such reservation and the "limits thereof." In accordance with this provision the President issued a proclamation setting apart as a public reservation a large tract of country immediately adjoining the Yellowstone Park on the east and south. The boundaries of this forest-reservation are essentially the same as those laid down in Senator Vest's bill providing for the enlargement of the park. As a matter of fact, we believe the boundaries were taken from the bill. This action on the part of the President was most commendable as it prevents the cutting of timber and prohibits settlement within the reservation. But as the President had no power to enlarge the Yellowstone Park it is now all the more important that this reservation should be included in the park by Act of Congress and its care and protection made a part of the duties of the superintendent of the park, with authority to see that the rules and regulations established by the Secretary of the Interior are enforced. At the present time there are no penalties for depredations committed, and no power to enforce them if there were any.

Secretary Noble, in his last annual report recently published, calls attention to the needs of the park and takes strong grounds against the admission of any railway. We can do no better than to copy his words: "The Secretary's "opinion, as hitherto expressed, has been that a railroad "would be detrimental to all the purposes for which the "park was set apart. It is earnestly hoped that Congress "will not give up to a private enterprise any part of what "it has set apart for the education and enjoyment of the "whole people. If once such railroad franchise is granted "it will result in the practical abandonment of that region "as a forest and game-reserve. Each year demonstrates "the wisdom of Congress in setting apart this magnificent "domain and the necessity of keeping it under govern- "ment ownership, free from private or corporate intrusion. "It embraces one of the largest forest-bearing districts in "the Rocky Mountains, and contains the head-waters of "some of our greatest rivers. The importance of preserv- "ing such tracts, as affecting the water-supply of the coun- "try, has already been discussed in this report."

Senator Vest, who takes the deepest interest in all matters pertaining to the Yellowstone Park, has for many years earnestly endeavored to obtain favorable action by Congress, and intends introducing the bill of last year in the early days of this session. The tract of country which it is desired to add to the park on the east embraces all the high portion of the Absaroka Range, and is a belt of country between twenty-four and twenty-five miles in width, including all the sources of the upper Yellowstone River. The region is almost wholly made up of volcanic lavas, barren and rugged, but possessing great natural beauty and grandeur. The country which it is proposed to add to the park on the south measures about eight and one-half miles in length, stretching across the entire width of the park and the additional territory which it is proposed to annex to the eastward. It is a somewhat less rugged country than the Absaroka Range, but is equally grand and far more picturesque. It abounds in springs, brooks and lakes, all of them sending their waters westward to the Pacific. The country is one of the best breeding-grounds for elk and deer to be found anywhere in the Rocky Mountains, a knowledge of which is becoming only too rapidly known by hunters and sportsmen. For agricultural and grazing purposes this elevated region is useless. The forest, both in the park and the country which it is proposed to add to it, is essentially coniferous. More than one-half the trees are what are known as Black Pine (*Pinus Murrayana*), which rarely attains any great size, although for economic purposes, for the storing of water, it is quite as serviceable as the more stately trees. The Balsam (*Abies subalpina*), the Spruce (*Picea Engelmanni*), cover large

tracts of country, while all three of these species occur more or less mingled. That sturdy and stately tree, the Red Fir (*Pseudotsuga taxifolia*), in certain localities, stands out grandly conspicuous for its size and the vigor of its growth. Already fires kindled by accident or malice have swept over large areas of this timber, and the forest has no protection against such vandalism in the future.

Secretary Noble, in his recommendation quoted above, only repeats what has been urged before by Secretaries Vilas and Lamar. The need of extending the park and protecting it from invasion is universally recognized. The Senate Bill interferes with no one's rights, and the new boundaries leave an open highway for all needed traffic to the mines. How long shall we be compelled to admit, in the face of all this, that a little knot of speculators, in the hope of securing special privileges, are strong enough to defeat a measure which is to the evident advantage of the whole country?

The appearance of the little book entitled "The Land of the Lingering Snow," which we reviewed last week, suggests anew a reflection which has, no doubt, occurred to many of our readers, and that is one of surprise at the number of books about Nature which are annually published in America, many of them, too, characterized by delicate feeling and pleasing style. More books of this type are published here than in England, where sentiment and the love of natural objects are believed to flourish much more luxuriantly than in our hurrying, supposedly prosaic and distinctly urban communities. Most of these books, too, are written in New England and about New England scenes and plants and birds; and this fact has a curious interest. At first sight we may think that it simply means that only in comparatively old communities do men find leisure enough to devote themselves to the harvest of the quiet eye, or are they apt to inherit a culture broad and deep enough to endow them with that literary sense which must go hand-in-hand with a sensitive mind and keen vision if nature is to be worthily interpreted on the printed page. But a little reflection shows that New England is no older than the other communities along our eastern coasts, and also that the sons and daughters of the east have spread themselves abroad to west and south, where, one might fancy, their natural instincts would be more strongly stimulated by the scenes about them than they could be by a climate and a soil like those of New England. Nevertheless, it is New Englanders living at home who give us most of those books about nature which are not strictly scientific accounts of dry facts and recondite phenomena. Here are born and here write our prose poets of nature. Is this so because Thoreau chanced by an accident to be born here, and set a local fashion? Or was Thoreau a natural, typical product, and are his successors likewise natural, typical products of the same conditions—men and women who would have felt and written just as they do if Thoreau had never lived?

The latter view is, we think, the true one. And, perhaps, it can be interpreted to mean that men always value most highly the gifts which are not too lavishly bestowed, delights which are not too constant and monotonous, pleasures for which they have to work a little and of which they are sometimes unexpectedly deprived. It is the strong contrasts of the New England climate which have filled the souls of her sons with so keen a sense of the beauty of her bright winter days and the loveliness of her sunny summer hours. It is the contrasts which her soil affords—from rocky to verdurous sea-coasts, from high mountains and forest-clad valleys to fertile plains and Elm-bordered rivers—which make their eyes sensitive to each of her changing pictures. It is the length and vigor of her winters that have forced them to study what charms winter as well as summer may present. It is the late shyness of her springs that thrills them with a sense of spring's enchantment. It is the burning heat of her hottest summertime which puts a touch of enthusiasm into blood that would be chilly but for such a potent quickening. It is the royal splendor of her long-drawn autumn, with its soft Indian summer following almost wintry weeks, that gives them that love for color which we miss by contrast when we turn to books that Englishmen have written.

An inhospitable land New England may be called by the agriculturist or the man who likes simply to draw his breath without care or trouble or any noting of outward phenomena. But to the true lover of nature there is, perhaps, no other which offers a more generous hospitality and has its hands more profusely laden with rapidly changing, beautifully contrasting gifts.

Notes of a Summer Journey in Europe.—I.

The following notes of observations, made during a few weeks of the past summer spent mainly in seeing something of collections and botanical establishments in Europe, are not intended as studies, but chiefly as a record of impressions with the natural comparisons one is apt to draw among new scenes and on coming in contact with examples and practices not commonly met with at home. Very often, too, the meeting of familiar objects proves almost as interesting as the novelties. The short time at command necessitated leaving out many interesting places and specimens even on the line of the journey, and, for the same reason, it was not found possible or advisable to fully write out the notes at the moment.

Perhaps one of the first things which attract the attention of an American, if he is interested in the botanical side of Nature, on landing on the Continent and traveling through the country is, that vegetation, as shown in harvesting, etc., is generally not so advanced or hurried as it is at the same date in that portion of New England which nearly corresponds to the same latitude. The cooler summers and the generally greater humidity of the air, of course, account for this, besides giving those regions nearest the sea the perpetually green appearance for which they are noted. It may be for this reason that hybrid Perpetual Roses appear to be much more truly and satisfactorily perpetual bloomers than they often prove in our gardens, where the heat is much drier and more intense.

On arrival at Boulogne, the first landing-place, on July 15th, the Hybrid Perpetual Roses were found bearing an abundance of bloom, and the same was true at Paris. The blossoms of these Roses, however, were no better than we commonly grow at home, and, as is too often the case with us, the plants were badly attacked by mildew and infested by aphides. The latter were evidently greatly checked by lady-bird beetles and their larvæ, and by small parasites similar to those which we find in America assisting to keep the pests in check.

One of the most peculiar features in the landscape in crossing certain parts of France, noticeably in the lowlands and as we approach the Swiss frontiers, is the Lombardy Poplars, which loom up everywhere, like decorated telegraph-poles. Very frequently the greater portions of the trunks have been stripped of their branches, which gives them an even more singular appearance than they naturally possess. It may not be generally known that it is the staminate, or male form, of this tree which we commonly find in cultivation both in this country and in Europe. The female, or pistillate form, is very rarely seen. It is said to chiefly differ from the male in being much less pyramidal in its habit of growth and general outline.

As we approach Switzerland and get among the hills, the Walnut becomes abundant, and it may be seen planted singly, in groves or in orchards, alternately with Apple, Pear or Plum-trees. The size and shape of these Walnut-trees vary greatly according to the quality of the ground and the exposures to which they are subjected; but in the good rich soil of the sheltered valleys they assume a handsome rounded or globular form. They do not usually attain a great height, and, except for the color of the foliage, which is also less dense, they might at some distance be mistaken for very large Apple-trees. Wherever grown throughout Switzerland, the nuts are largely used for the oil which is extracted from them; but they are not generally grown in such abundance as they are south of the Alps.

Although Geneva gets none of the direct modifying influence of the Gulf Stream, is over 1,200 feet above sea-level, and is situated in a latitude somewhat further north than that of Montreal, in Canada, its vegetation shows that it enjoys a winter climate generally quite as mild, if not milder, than that of Washington. The last winter was considered an unusually severe one, the Lake of Geneva being completely frozen over,

an event of extremely rare occurrence. Our great southern evergreen Magnolia is frequently planted in gardens here, and a large number of them were noticed as either dead or very much injured. In fact, the straggling appearance of the best of the survivors showed that the trees are here liable to more or less injury every winter. Some were bearing a good number of their beautiful blossoms, for the sake of which no lover of flowers could resist having these trees in his garden so long as there was a chance of their living at all. The trees do not attain large size here, but grafted plants may be expected to bloom when only a few feet high.

At this time (July 17th to 20th) some large trees of *Catalpa bignonioides* were in full flower, or nearly so, and were apparently quite as much at home and as vigorous as in our own gardens. Specimens of a fastigiate form of our common Locust were noted here and there, the shape being so much like that of the Lombardy Poplar that unless closely observed this form of the Locust might be mistaken for it. The variation of the Locust known as *Robinia Pseudacacia, monophylla*, is occasionally seen in the streets and yards here, presenting such a distinct aspect that many people, not familiar with the numerous forms which the species has developed under cultivation, might readily mistake it for something new. This form often has only one, and usually not more than three large leaflets to each leaf. It must be propagated by grafting, layering, from pieces of roots, or other modes of division, in order to be true, as seeds would probably simply produce the common type, except in a very few cases. Although it is one of our own native trees, the Locust in Europe has a much better chance to develop into good specimen trees when planted singly, because it is, apparently, not liable to injury from such destructive borers as we have to guard against.

Some fine specimens of our Black Walnut (*Juglans nigra*) are to be seen in Geneva, and a tree of the Striped Maple (*Acer Pennsylvanicum*) was noted as having a spread of branches of about thirty feet, and with an equal height. It was grafted on the Sycamore Maple (*A. Pseudoplatanus*), and the stem was ten inches in diameter, being smaller than its dark shaggy-barked stock.

A peculiar feature of some of the streets and quays where shade and, at the same time, an unobstructed view of mountains or lake from houses or hotels is desired, is the rows of trees cut back so that they have a low, flat, or umbrella-shaped top, while the lower branches are trimmed high enough to allow of all ordinary passing beneath. The species most subjected to this treatment, and one which apparently bears it very well, is the variety of the Oriental Plane-tree known in nurseries as *Platanus acerifolia*. This form is very much planted in many Continental cities, and, altogether, as a street tree it compared very favorably with any other kind which came under my notice. The trees rarely showed any evidence of disease. Such a serious blight as the fungus (*Gliosporium nervisequum*), which destroys the growing tips of, and is so injurious to, the Planes in many parts of America, is, seemingly, unknown among the allied trees in Europe; or, at least, it does not appear to a noticeable extent. The foliage, too, is usually remarkably exempt from depredations by insects. The trunk is not liable to attack by borers, and although the peculiar blotched appearance of the trunk is objected to by some people, it has the merit of being smooth and looking as if scraped —facts which are greatly to its advantage in localities where a mania prevails for having the trunks of rough-barked trees smoothly planed or shaved.

The trunks of the trees in the streets of Geneva rarely show any evidence of mechanical injury. Stems of the smaller trees are very simply and effectively protected by having shoots or branches of Locust or Buckthorn placed around them and held in position by two or three bands of light iron wire.

Three species of European Lindens, or Lime-trees, were particularly noticed in the streets and squares. One of these, known as *Tilia platyphylla*, had been out of blossom for some time and the fruit had already attained almost full size. The second species, perhaps, should be known as *T. ulmifolia*, although it is most commonly called *T. parvifolia*, and, among other synonyms, frequently passes as *T. Europæa*. This was in full bloom and attracted many insects. The apparent reason of the name *ulmifolia*, or "Elm-leaved," was quite noticeable in some very large trees here, because the foliage and even the outline of the tree gave much the same effect as that of the common European Elm (*Ulmus campestris*), the leaves of the Linden not being much larger. The foliage of this and the preceding species was sometimes greatly injured by the attacks of aphides and red mites. The third Linden noticed was *T. petiolaris*, a species differing from the others in its distinct habit, its long, petioled leaves with white under-surfaces, and especially in the fact that it had not yet opened any of its flower-buds.

Other Lindens may be referred to later, but attention is called to those mentioned because here were three species flowering in such succession as to furnish a rich and continuous harvest of nectar for bees during a period of six weeks or more—a fact, perhaps, well worth considering when planting trees in a country where apiculture is much followed and where the honey made from the flowers of the Linden is especially prized.

Arnold Arboretum. *J. G. Jack.*

The Colors of Leaves.

IN my article on the colors of flowers the conclusion arrived at is that, next to green, white is the primary color, and the color from which all other colors are derived.

Another question has suggested itself to my mind since writing the former paper—a question entirely germane to the subject—namely, Is the green color of leaves and vegetation generally the original, primordial color, or is it secondary?

The method to be employed in answering this is somewhat different from that used in regard to flowers. We do not find any leaves with a different color at the base, as is common in the case of flowers as, for instance, white; indeed, rarely is a leaf any other color than green when it is found on a stem growing spontaneously in its native habitat, except in the case of vigorous saplings, where the old trees have been felled. On these not uncommonly the leaves are reddish or purple. In cultivated plants, also, we have copper-leaved Beeches, Maples, etc., and some herbaceous plants with reddish foliage. The colors of autumn leaves are not referred to for the reason that they are clearly secondary. One other color occurs more rarely still, and that is white. Dr. E. Lewis Sturtevant pointed out to me at Nonquitt, Massachusetts, growing spontaneously on a border of a marsh, a grass called *Phalaris arundinacea*, var. *picta*, which had longitudinal stripes of white running parallel with the green, and similar in appearance to the garden Striped Grass. In my former article I referred to the fact that sepals and involucres sometimes become white, as, also, some of the smaller upper leaves and upper portion of the stem in *Daucus Carota*; but while native plants with white leaves are rare, there are frequent examples of white in cultivated foliage plants, so called. Among the latter is a variety of the Ash-leaved Maple, which has every leaf bordered with white, presenting to the beholder an odd and fantastic appearance, also a shrubby Althea, similarly marked; also Euphorbia, Ivy Geranium, Coleus, Funkia, Century-plant, etc., are bordered, striped, or splashed with white. The inner leaves of Cabbage are white, and Celery blanches white. This etiolated condition of the foliage is regarded by gardeners to be the result of disease or unhealthiness, and, therefore, not desirable, but yet is tolerated on account of the striking, if not wholly pleasing, effect produced by the unusual contrast of colors. From the foregoing we get pretty strong hints that green is derived from white. There remains one more clue. Every botanist knows that the seed contains a miniature and rudimentary plant; that generally the most prominent parts of this seed are the cotyledons, or seed-leaves, and these are, of course, the first leaves of every species of plants. Now, if we ascertain the color of these seed-leaves we find the original color of all leaves. This color is uniformly white.

Take, as a few familiar illustrations, the seeds of apple, pear, peach, grape, tomato, cranberry, bean, corn, hickory, chestnut, oak, filbert or almond. Of course we do not refer to the colored integuments of the seed, which, as in the case of garden beans, may be white, red, yellow, blue, black, or mixed colors, but to the kernel, or meat. There are a very few instances only where the green color of the plant has impressed, somewhat, that characteristic upon the seed, as in peas, nasturtiums and maples, which present a pale green color in the pod, or shell. In some instances, these cotyledons appear above the surface of the ground changing from white to green; while in others they remain below, where planted, only to nourish the growing stem and succeeding leaves.

Nature, which has all colors at her disposal, has selected green as being the best adapted for the vegetal function; that is, green is "the survival of the fittest" for that purpose. For the promotion of the fructifying function insect agency is important, both in fertilization and cross-fertilization. Insects are guided, doubtless, by bright colors, as well as by scent, and that the colors may be attractive they must be different in hue from the general foliage and in strong contrast thereto;

hence green barely "survives" in flowers, being more rare than any other color.

We learn from this study of color, therefore, that white is the primary color of root, stem, leaf and flower, and the foundation of all color. This assertion, as regards the flower, may demand a word of explanation, for the reason that in my article above referred to there was an apparent exception in favor of green; but there is really no necessity for any exception or qualification whatever, as white is not primarily derived from green, but, on the contrary, green is derived from white in precisely the same manner as any other color is so derived; but as the floral organs in the great majority of cases are formed after the development of chlorophyl in the plant, they naturally, at first, partake of that color; then the green color is completely eliminated and obliterated, the flower resuming the original color of the rudimentary plant.

It follows, therefore, that green is a secondary color in flowers of that color, of which there are a considerable number still to be met with; but in *Monotropa uniflora*, and doubtless others of like character, we have an illustration of flowers of the original white color which never have been preceded by green.

I may be permitted to add in this connection, as confirmatory of my opinion, that all colors appeared in primeval times, that in Lichens, plants which rank low in the vegetable kingdom, colors are found in as great a range, and possibly greater, than is found in Phænogamous plants, as will be seen from the following partial list of the colors mentioned by Tuckerman in his description of North American Lichens, namely:

White, ashy white, grayish white, dirty white, greenish white, glaucous white, brownish white, ochroleucous, whitish, palescent, decolorate.

Cream, straw, sulphur, lemon, orange, old gold, ochre, gamboge, greenish yellow, orange-saffron, waxy yellowish, tawny yellow, whitish buff.

Sage-green, apple-green, leek-green, brown-green, dark green, black-green, olivaceous, brown-olivaceous, glaucous, glaucescent.

Orange-red, scarlet, vermilion-red, brick color, reddish flesh-colored, blood-red, vinous red, rosy, rose-red, rusty red, rufous, cinereous-rufescent.

Cœrulescent, steel-blue, purple, bluish, pale bluish; sky-blue in *Leptogium cæsiellum*.

Olive, cinnamon, greenish, yellowish, chestnut, russet, tawny, purplish, reddish, smoky, livid, lurid, leaden, liver and blackish brown, tawny.

Black, blackish and olive, greenish, blue and violaceous black, fuscous, fuscescent, brownish and pitch-black.

Lead, greenish lead, smoke-colored.

Whitish, livid, lurid, leaden, greenish and brownish ash, cinerascent, glaucous-cinerascent, cinereus-glaucescent.

Leaden, bluish, yellowish, glaucous and greenish gray, grayish.

The variety of tints, shades and hues of these colors is something remarkable.

In the foliage of Musci we meet the following colors and hues: Hoary white, silvery white, yellowish and greenish white; golden-yellow, greenish yellow, fulvous; reddish, dark vinous red; bright olive, yellowish, lurid, dull and blackish green; green with a bluish or indigo tinge; pale brown, dark brown, purplish brown, brownish, blackish; drab-colored.

In the capsule we find whitish, yellow, orange, orange-red, dark red, deep purple, dark brown and chestnut.

At times the foliage and the fruiting parts are differently colored, as in *Barbula cæspitosa*, which has pale green foliage, yellow capsule with a red operculum.

The sporules are also of different colors; so in Lichens the apothecia or Lichen-fruit, namely, in the part called the disk, differ more or less in color from the thallus. In these respects both classes of plants resemble the frequently different colors of pollen, anthers, petals and leaves in the same plant, so that it may be questioned if the bright colors of ordinary flowers were created primarily to attract insects, unless the apothecium of the Lichen and the capsule of the moss subserve the same purpose, which question should be investigated.

In *Hepaticæ* the colors are similar to the Musci, with the addition of pink, rose-purple and violet.

The *Algæ*, or sea-weeds, lower forms of vegetable life, rival the Lichens in their great variety of color; and the Fungi, plants next higher than the Lichens, display many tints and shades of white, yellow, red, blue and green.

The lowest and the most minute of all known organized structures are *Bacteria*. "These are usually white in color, although some species possess beautiful tints of red, of blue, of yellow, or even green."

New Bedford, Mass. *E. Williams Hervey.*

Cacti in Landscape-gardening.

CACTUS-GARDENS and Water-lily ponds are the most notable additions to the practice of ornamental planting in America during recent years. The Water-lilies have many advocates, but Cactus management does not seem as well understood. In our immense country there is a width of variation in soil and conditions which we hardly realize. Industrial conditions compel many of our people to live in barren or arid regions, and in these Cactaceous plants are of the greatest value. In some of the dry parts of the far west plant-loving people have formed Cactus-gardens of the greatest interest, and of a beauty that vies with the herbaceous gardens of the east. Some of them are stocked with the Cactaceous riches of the earth, and are world-wide in their fame. Even in the showery east there are situations where some varieties of Cactus can be employed. They should not be permitted to occupy positions which can be more acceptably filled by other plants which are by nature more thoroughly adapted to such surroundings, but in a few situations where they are perfectly in keeping, and other things will not thrive, they are most useful. They will flourish in a stone-paved court with only soil enough to root in, and where one day's roasting in summer sunshine would dry other plants to death. They will take their chances on a roof with perfect success, while their owners can spend the summer away from home. For those who still incline to carpet-bedding, the employment of large Cactus-plants, with numerous small ones in geometrical patterns, will afford great pleasure. They do not soon outgrow their space, and they give a most interesting variety of color. The delicate and complicated designs produced with them associate harmoniously with the cut stone and terra cotta of modern buildings.

Their proper arrangement in beds by no means confines us to regular forms, however. The picturesque growth of many sorts especially fits them for irregular arrangement. This can be made with rocks and stones common to the soil in any particular region. The plants need thorough drainage and full exposure to bright sunshine, if they are to bloom the following season. Enough of one variety, especially of the low-growing kinds, should be grouped together, to show their true character and expression. The ground can be as irregular as fancy dictates or chance ordains, for this displays their distinctive qualities to best advantage. Rock-work is a combination that suits them admirably, but it requires great skill in management to insure artistic success. Peculiar and striking stones should, as a rule, be avoided. Those with weather-worn and lichen-covered surfaces are desirable. An exception to this I have noted in a bed where the surface of the ground not occupied by Cacti was entirely covered with pieces of white marble, which brought the plants out in strong contrast. In this case there was so much marble and many white objects in the vicinity that the color was not obtrusive as it otherwise must have been.

When tender kinds are used for planting out in summer, the plants are better kept in their pots, which, however, should be entirely covered by earth or low-growing plants and stones. Sods can be used to advantage when there is grass in the surroundings, but it should be kept shorn short among the plants. Houseleeks, Sedums, Mesembryanthemums, Stapelias, or any low-growing succulent plants that do not need a moist soil are useful for covering the ground and pots. In the warmer parts of the United States permanent Cactus gardens of great beauty can be constructed of many varieties, but the number of these that will endure a temperature of ten degrees below zero is so limited that our efforts north must be less ambitious.

The common Prickly Pear (*Opuntia vulgaris*) and the nearly allied *O. Rafinesquei* and *O. Missouriensis* are the most useful. Some of the little Mamillarias are hardy, but so small and delicately beautiful that a quantity must be employed to be effective. The hardy Opuntias can be grown in flower-beds, if dry enough, with the same cultivation given other flowers, but are more satisfactory if employed where other things will not flourish. As a successful example of their use I recall a spot on one side of a lawn where a rocky ledge came close to the surface. The ledge was once visible but the top had been blasted away and covered with soil. Every summer, however, the grass here dried up and disfigured the lawn. Soaking the place with water twice a day finally kept it green; but this was expensive, and, after all, the turf differed in color and texture from the rest. Some good-sized stones, brought from a neighboring pasture and relaid in the ground on the troublesome spot, following somewhat the irregular outline of the brown grass, and some suitable soil filled in between them, and then more weather-worn rocks

partly embedded in it, gave the whole once more the appearance of a natural ledge. The spaces between the stones were thickly planted with hardy Cacti, that have flourished for four years with no care, and have annually shown a crop of blossoms that vie in beauty with any on the grounds. The place is always interesting and never looks bare.

Again, at one of the finest country places on the north shore of Long Island Sound there is a most attractive summer-house built on a rocky bluff overlooking the water. Before it became part of the pleasure-grounds the top of the bluff had been blown off with dynamite, leaving the surface in a raw and shivered condition, which was depressing to the artistic sense. Covered with soil it yielded a little grass in spring, but this soon died, as did every plant and shrub set there. Vines could not reach it, and contrasted with surrounding beauty it seemed more mournful than ever. This almost hopeless spot was at last planted with native Opuntia, which found the situation congenial, and they now cover the entire surface, hanging over the edge of the bluff in the most effective manner. Starred with brilliant yellow and orange flowers, the effect is particularly fine when seen against the blue water. A hard gravel path leads to the summer-house, and the whole is so uncommonly attractive that visitors always admire it.

At another place hardy Cacti and Stone-crop in variety are used to fill some vases of stone and terra cotta on a terrace overlooking an extensive prospect. The situation is such that other plants could not receive proper attention, but these enduring things hold their own, summer and winter, and the weather-beaten old plants have an attraction all their own.

Cacti are not good playthings for small children, but plants that are often left lying about a greenhouse or garden in summer, objects of no beauty in themselves and a nuisance to everybody who comes in contact with them, could often be grouped about a rock or some barren spot, and thus be made one of the admired features of a place. Like Orchids, Cacti must be studied to be appreciated. If we attempt to grow and arrange them like Roses we shall fail. They are not strictly greenhouse-plants, and forcing often fails. They are the delight of people with moderate appliances and little time to spare for the garden. A light, warm, dry cellar or room, where an even temperature can be maintained through the winter, and all the exposure we can give them in summer, will enable us to keep almost all tropical kinds, while those native to the northern states want but one planting and a chance to grow. They can be moved at any season when the ground can be broken. The monstrosities produced by grafting and mutilation are fit only for people fond of freaks, and not to be considered in serious landscape-work.

New York. *John De Wolf.*

New or Little-known Plants.

Viburnum tomentosum.

THE Japanese Snow Ball, *Viburnum plicatum*, as it is called in gardens, is now one of the best known and most highly prized of the Japanese shrubs commonly cultivated in this country. It is one of the garden forms of *Viburnum tomentosum*, a species widely distributed through China and Japan, whose portrait is published on page 594 of this issue. *Viburnum tomentosum* is a handsome plant, with foliage very similar to that of *Viburnum plicatum*, but the flowers, instead of being all sterile, are mostly perfect, with a few large pure white sterile flowers on the margin of the broad flat cymes which resemble in general appearance those of the familiar *Viburnum Opulus*.

Viburnum tomentosum, although botanists have known it for more than a century, appears not to have been much cultivated outside of its native country, and I do not remember to have seen it in any European collection, although the name appears in the catalogue of the plants in the Arboretum Segrezianum. It seems, however, that it has been in this country for a number of years, and I received last spring specimens from Mr. E. Williams Hervey, of New Bedford, Massachusetts, from a plant which had been growing for many years in Mrs. Edward Haskell's garden in that city, and also from Mr. John Robinson, of Salem, whose plant, originally purchased from Ellwanger & Barry, the Rochester nurserymen, is now twelve feet high and eight feet through the branches. An illustration of this plant in bloom appears on page 595, and shows how completely the flower-clusters cover the branches and render it an object of singular beauty. *Viburnum tomentosum* may be seen, too, in at least two other Salem gardens, and, no doubt, now that attention has been called to it, it will be found to be not uncommon. It is probable that the Japanese use the single form as a stock on which to graft the sterile *Viburnum plicatum*, and that the plants in this country are stocks which have grown at the expense of imported plants of *Viburnum plicatum*. But in whatever manner it may have first reached the United States the normal form of *Viburnum tomentosum* is a handsomer plant in every way than its garden variety, just as *Viburnum Opulus* is a more beautiful and desirable plant than the Snow Ball, a variety derived from it.

Our figure is from a drawing made by Mr. Faxon of a specimen for which we are indebted to Mr. Hervey.

Deterioration of Varieties.

IS there any such thing as a real deterioration of the varieties of our cultivated fruits? By this I mean to ask whether, when a new and valuable seedling of any of our cultivated fruits (or even of our wild ones) is produced, we must expect to see it, with the passage of time, lose its desirable qualities, and fall out of cultivation, necessarily, for that reason? I know that with many growers this view of the subject finds more or less acceptance, and I have held the matter in mind for a long time, subject to the tests of observation and inquiry.

It is not altogether a bad thing perhaps to live in a hard place to grow something that one ardently desires to grow. On this one point I was rather trapped in coming into north-eastern Vermont from eastern Massachusetts. A kind friend cautioned me to look out in regard to schools, and I settled in an academy town; but nobody hinted to me that there were places in New England where the common tree-fruits of the country could not be made to endure the winter's cold. For a while, buying the hardy varieties of the nurserymen's lists, I paid careful heed to the advice of our best books in regard to more or less tender kinds. These were, chiefly, not to grow them on too rapidly, and to cut back severely. Well, I followed the advice, and a few of the many sorts I was trying lived along "at a poor dying rate," bore a little poor fruit, and succumbed to the first test winter. I supposed this to be all in the order of nature and circumstance, until my kind friends, Mr. Goodale, of Maine, and Mr. Manning, of Massachusetts, respectively, sent me trees of Oldenburgh and Tetofsky. When these got fairly under way I found no need whatever to starve or to cut back. They grew according to their own sweet will, barring a little gentle guidance, and soon were loaded with abundant fruitage. Even the extra-hardy Talman Sweet, Fameuse, Yellow Bellflower and Red Astrachan of the catalogues had shown their inability to stand our highland temperatures; and this experience with the last-named had prevented me from having much faith in the alleged superior hardiness of the Russian Apples. But since then I have learned that, though Astrachan is a part of Russia, it is the extreme southern part, with winters little, if any, more cold than those of southern New England. It is only in central Russia, or about the latitude of Voronesh and Riga, that the true iron-clad tree-fruits of Russia are found.

Now, further observation has instructed me that there are other causes, besides extreme cold, which affect some varieties severely and others in the same place not at all. "Yellows" is not known, or is very little known, as a disease of the Peach in our southern states. The blight of the Apple-tree on the black prairie soils of Illinois and Iowa is a most destructive disease—as prohibitory in its effects as the severe cold of our northern mountains in regard to many varieties. Black-spotting of valuable apples, like Fameuse and its seedlings, is not remarked to a great extent in suitable localities. Fameuse Sucrée, for instance, or McIntosh Red, I can get from ninety miles away, near the St. Lawrence River, quite free from spotting, but I cannot grow them so. The weakening of the vitality of these trees by our greater cold, though it does not kill them, so affects them that they do not resist their fungous foe. I hear from many places in middle and southern Maine, where I have distributed cions of these excellent dessert apples, that they grow quite fair, and are likely to prove valuable acquisitions, worthy of extensive planting.

Now, reflecting on all these facts and taking full account of

what they may be made to teach, is it not probable that what we are asked to call the "running out" of varieties is simply a local yielding to unfavorable conditions of soil, temperature, or certain atmospheric conditions? May it not sometimes be justly attributed to erroneous methods of culture, or even to neglect? In the case of the apricot, for instance, is it not now plain that the reason why our eastern markets rarely exhibit them, after a hundred years of effort to grow them, is that we were trying to grow them on the wrong side of the continent? It seems to me that everywhere we must expect that under unnatural conditions no fruit-tree will long be able to maintain itself in perfection of growth and fruitage.

While these thoughts have been the direct result of practical experience as a grower of tree-fruits, in different localities, for many years, I do not want to put myself on record as entirely disbelieving the possibility of the deterioration of varieties under even favorable conditions. Some varieties must be weaker than others in constitution. We know this to be true of animals and may reasonably infer it to be so of fruit-trees. For instance, the Fameuse, though so long successfully grown on the Island of Montreal, is apparently going back on its record within the past ten years. Perhaps this may be owing to the growth of the city and the effect of atmospheric vitiation in consequence. We cannot be certain on any of these points, but I would remind your readers that these "run-out" sorts may often be capable of renovation through a mere change of conditions.

Newport, Vt. *T. H. Hoskins.*

Fig. 93.—Viburnum tomentosum.—See page 593.

Cyclamen Persicum.

TO grow Cyclamens in perfection it is absolutely necessary to avoid all extremes in temperature. An equable moist atmosphere is the only condition under which the best qualities of these plants can be brought out. The Cyclamens being by nature woodland plants—that is, growing in groves, thickets or other moderately shady spots, where changes of temperature are not sudden—it is easy to understand why the plants thrive best in the surroundings above indicated. It is not always easy to guard against excessive heat during the summer months in this country, but by means of shading canvas, open-air cultivation and sprinkling of the ground about the plants, this can be accomplished well enough for ordinary practice.

Another important fact to be remembered is, that old seed is unreliable, and a greater difference in size will be observed in plants obtained from such seed than in a lot from fresh seed. Fresh seed should be sown, and sown as soon as possible after it can be obtained. August is a good time, and the seed should be sown in well-drained shallow pans in a compost of peat, sand and loam, with some finely chopped sphagnum added, and then lightly covered and kept moist by careful sprinkling. The pans should be placed in a frame in a temperature of no less than fifty-five degrees. If the seeds are fresh the young plants will appear in four or five weeks, and should be pricked off in shallow pans, with a somewhat richer mixture of soil, omitting the sphagnum. As soon as the plants have a few leaves, and are deemed sufficiently strong, they should be potted singly in two-inch pots, and all check to their growth should be avoided by keeping them in a temperature of fifty-five or sixty degrees, near the glass, moist and shady. Of course, they must be repotted as the roots fill the pots, every time in a slightly richer soil. Plenty of fresh air is necessary under all conditions. Early in spring the corms of the plants ought to be as large as a walnut and well studded with short robust leaves. Now, as soon as the weather will permit, put them out in the open air, in a shady position, and plunge them in a layer of sawdust or well-decayed horse-manure; if the latter, it must not be allowed to heat. All summer long the young plants must never suffer from want of food, water or air. A light syringing overhead every bright morning is advisable, and on hot days the ground around and the woodwork of the frame should be thoroughly soaked several times a day, to keep the air cool and fresh. A canvas shading stretched high above the plants, so as to prevent direct sun rays, but permit plenty of light and a free circulation of air, should not be omitted.

By autumn the corms should be about two inches in diameter, the sturdy leaves will cover the pots, and signs of flower-buds can be seen. They should now be potted for the last time, in seven or eight inch pots, removed to their winter quarters in a light, airy greenhouse. They will commence flowering in December, and, if kept cool, when in full bloom will, as everybody knows, keep a long time in perfection. Few plants can compare with a well-grown Cyclamen for lasting beauty, and even when most of the flowers are gone the handsome leaves are in themselves an ornament. I have seen Cyclamens kept in living-rooms and parlors a considerable part of the winter without losing their freshness and beauty; but care must be taken not to overwater them when in bloom. This is the time when the greatest caution in watering should be exercised, as Cyclamens, like most similar plants, flower during the drier season. It may be necessary to remind novices that the corm should not be buried, but that its upper half should be left above the soil.

New York. *N. J. Rose.*

Fig. 94.—Viburnum tomentosum in Flower.—See page 593.

Winter Gardening in the South.

THE longer I live in North Carolina the more I become convinced that our people hardly realize the great possibilities of winter gardening here. Of course every one knows that such hardy things as Lettuce, Kale and Spinach will grow thriftily here all winter, and many plants which can only be wintered with fire-heat at the north come through safely in a glass-covered pit. But few realize the amount of enjoyment that can be secured from a cold frame here on a rich bed of soil with no protection but the sashes. It is known that Violets, Roman Hyacinths and plants of equal hardiness can usually be had outside all winter, but now and then a cold snap spoils the blooms, and this danger can be warded off by a simple sash, and the flowers will be produced in great perfection. In a cold frame here, with no protection but the sashes, we bloom not only Violets and Pansies but Mignonette of a size never seen in a heated house, Phlox Drummondii of all colors, Petunias like Countess of Ellsemere; Candytuft, particularly the perennial, which often blooms outside as the Phlox does; and we can have Roman Hyacinths and Daffodils untouched by the frost, which frequently spoils them outside. With a little higher frame, to give head-room, Carnations bloom well, and Tea Roses like Safrano, pegged down, will give an abundance of buds. Even such flowers as can be expected in the open air are of much better quality under the sashes, and this superiority alone would be worth the little trouble and expense, especially as hot-bed sashes three feet by six can be had in Raleigh, glazed and painted, for $1.50 each.

It is not only in the flower-garden that this simple protection gives rich returns. Lettuce will grow outside in winter, but it is often scorched by frost, while a few sashes would give fine crisp heads. I have an experimental frame in which seventeen varieties are now growing. To my surprise, the sort known as All-the-Year-Round headed first, Yellow Seed Butter next and larger, with Prize Head close behind and better. The old Brown Dutch is also remarkably fine, and the Paris Green Cos has made fair heads without tying. Our old favorite, Boston Market, while heading well, does not compare with the others. Of the loose types the Black Seed Simpson is very fine. This Lettuce was sown October 1st and has had the sashes pulled over it only on two cold snaps, November 17th and 29th. As fast as the Lettuce is cut out, its place can be filled with later-sown plants from the open border. The first of January we will sow in frames Early Wakefield Cabbage, with Early Summer and Fottler's Brunswick for a succession. These will alternate in the frame with rows of Radishes. The Cabbage-plants will go into the open ground in February, and Tomato-plants from the greenhouse will take their place, and the Radishes will be used. At the same time the Cabbage-seed and some Onion-seed will be sown also in frames and transplanted outside in February, and then part of the frames will be used for starting the early plants of Sweet Potatoes.

The multitude of uses to which a simple cold frame can be adapted in a mild climate is a constant source of pleasure and surprise even to an old hand at the business. Our truckers do not use one-tenth part of the glass which they might use with profit. Most of them use none. The oiled cotton cloth commonly used for spring protection is a poor substitute for glass, and a gardener accustomed to glass soon votes the plant cloth a nuisance except for greenhouse shading. By the way, for a light greenhouse shading, giving a ground-glass effect, the best I have ever tried is two gallons of boiled linseed-oil, a half gallon of Japan varnish, and a half gallon spirits of turpentine, mixed, and applied with brush. The first rain turns the varnish to a milky color and breaks the glare without shading materially. I use it all winter.

Agricultural College, Raleigh, N. C. *W. F. Massey.*

Cattleya labiata.—This new old Cattleya, the rediscovery of which has caused such a sensation in Orchid circles, is now being distributed by several firms—a decided advantage to the purchaser, and, what is satisfactory to all, the supply does not seem to diminish but to assist also in the introduction of other new and desirable plants from the same district. In future, there is no reason why Cattleya-flowers should not be as plentiful in November as in the flowering seasons of *C. Trianæ*, *C. Mendelli* and *C. Mossiæ*, from early spring onwards. It was my privilege a few days ago to see some ten or twelve varieties in flower in the gardens of H. H. Hunnewell, Esq., at Wellesley. The plants in question were bought a year ago for *C. Warocqueana*, and are obviously the true *C. labiata*, and of the many plants in bloom no two were alike; all are distinct, resembling in this respect the favorite *C. Trianæ*. We are told that this Cattleya is easy to grow, and certain it is that owing either to the inherent vigor of the plants or Mr. Harris' skillful treatment, or perhaps both, all of them were perfectly happy and growing and flowering vigorously in their new home. One could not help wishing a long life to *C. labiata*, for the lives of some of the very best are all too short under cultivation.

Scabiosa Caucasica.—Now that the seed catalogues are in process of construction it may not be out of place to protest against the way that seeds of choice hardy perennials are persistently omitted. True, some of the commoner kinds are sometimes included, but for the really good and choice kinds we must send to the seed-growers in Europe, and these, in their turn, will sometimes refer you to their wholesale buyers here, whose lists, you know, do not contain the desired seeds, even if the dealers are aware of the merits of the plants in question. It is quite time that some firm here took up this branch of the seed business and made the fact known. There is no doubt that they would be supported by the flower-loving public now that perennial border-plants are better known than ever before. It was with considerable difficulty that I obtained seeds of *Scabiosa Caucasica* last spring, and they grew and flowered well. During the last week of November I was much surprised to see some of the bright blue flowers in the open border that had many times been frozen, but which were still unhurt. Many complain of this Scabious as being difficult to cultivate, but it is not so here. In moist heavy soil they thrive and bloom the first year, and are perfectly hardy, though the plant is said to be indigenous to arid places in the Caucasus and Armenia. Hardy, or even annual plants that possess this pleasing shade of lavender-blue are rare, and should be made the most of in gardens, especially where cut flowers are desired in quantity.

South Lancaster, Mass. *E. O. O.*

Rust of Carnations.—This fungus, *Uromyces caryophyllinus*, Schr., was noted in the last issue of the *Botanical Gazette* as having recently been brought to the attention of Dr. Arthur, of the Indiana Experiment Station, who, upon examination, found it already pretty well distributed in his state, "some large greenhouses not having a plant free from it." To-day a package of Carnation-leaves was received from a firm in Philadelphia, with an urgent inquiry as to the nature of the trouble that has come so suddenly upon their plants. That they were badly infested with a genuine rust was determined at a glance, and, upon a microscopic examination, it proves to be the same as reported so recently for Indiana. To florists who are interested in this new pest, that is, new to this country, for, like many other such fungi, it has long been known in Europe, it may be said that the trouble can be distinguished from any of the other fungous diseases of the Carnation by the medium-sized plump gray blisters produced upon the leaves, and the larger because longer ones, here and there upon the stems. Like the various other species of rust upon grains, grasses, etc., the mischief is largely done when these blisters appear. The fine threads have previously ramified throughout the plant and taken from it the nourishment that was afterward used up in producing the large crop of brown spores that are packed away under the skin of the blister. It therefore follows that when once a plant is badly rusted there is little hope of curing it. All diseased parts should be removed and burned, and with the worst cases the whole plant should be destroyed. With perfectly healthy plants it is probably true that the rust might be kept out by spraying frequently with copper salts. However, the disease is new to us, and we therefore cannot speak from experience. The chief point of this note is to call the attention of Carnation-growers to the widespread distribution of the new-comer that they may look for it and report new localities as they are found.

Rutgers College. *Byron D. Halsted.*

Spiræa Filipendula, flore pleno.—The plants of an attractive character which thrive in almost any position are none too numerous, and those we have should be known as widely as possible. The double *Spiræa Filipendula* is one of our most useful, and, at the same time, one of the most beautiful hardy perennials. It is equally at home in the rich soil of a border and the almost barren patches of earth which the crevices of a dry rockery afford, in partial shade and the full blaze of sunshine, in the city lot and the country garden. It is also a cheap plant —a plant that every one may have and grow. The species is a common European plant, with Fern-like foliage, which forms a dense mass of the richest green color. The charming clusters of small creamy white flowers are borne at the top of sparsely leaved, erect stems about two feet high. They ap-

pear early in June, and last nearly a month. The variety differs in having double flowers, and in blooming more freely. The flowers of the double form continue in a perfect state much the longest, and they are excellent for cutting, lasting from two to three weeks in fresh water. The stems should be cut away immediately after the flowers fade, and then the foliage will retain all its luxuriant beauty throughout the summer and autumn. The variety can be propagated only by division in spring and autumn; but seeds of the species are obtainable occasionally, and they should be sown under glass early in spring.

Thermopsis Caroliniana.—As the specific name implies, this excellent plant is a native of Carolina, the northern state of that name, where it is said to occur plentifully in the mountainous regions. The plant ranges in height from four to five feet, the unbranched stems bearing large ternate leaves of bright green color, and a terminal spike of showy yellow pea-shaped flowers closely packed around the stalk in a mass from six to nine inches in length. The flowers are very attractive in the mixed border during the month of June, and the plant blooms quite freely. The best position for it is the back line of a narrow mixed border or the centre of a broad bed or border in which the plants decrease in stature to more sides than one. I have seen a large mass of it planted in an isolated and fully exposed position, but it is more striking than beautiful in this way. It is more effective when planted in strong clumps among other plants of similar size and contrasting colors, and the flowers light up the dark green of dull shrubberies wonderfully while they last. The various stems of each clump should be loosely secured to a stout stake in the centre when they become too long to stand against wind and heavy rain, but established plants may otherwise be safely trusted to care for themselves. It is not exacting in its requirements as to soil, and is often found in luxuriant health where many plants of similarly robust appearance would certainly succumb. The large crop of seeds ripened annually afford a ready means of propagation; but they are, however, slow to germinate, and should be raised in heat during early spring.

The Forest.

The Subjection of Torrents by Reforestation of Mountains.—II.

CÉVENNES.

THE range of the Cévennes is formed by a series of massive, but less rugged mountains than the Alps or the Pyrenees. These mountains are veritable fountains of water, and the rains there fall in deluging showers, such as are seen nowhere else, and all the waterflow there is eminently torrential. It is usually in September that these terrific water-spouts are formed, when the mountains (relatively slightly elevated) are unable, as in the Alps and Pyrenees, to store a part of the precipitation in the form of snow.

As a consequence of the orographic arrangement of the ground, the valleys are continuous, and do not empty, as in the Alps, directly and abruptly into an alluvial plain. Thus one never finds there, even among the most powerful and erosive streams, the great cones of eroded material so characteristic of the mouth of torrents. The transportation of the materials which they bear, after having torn them from the mountains, continues in the torrential river, whose channel becomes wider and wider as it fills up, more erratic and hence more dangerous for the rich farm-lands or the great industrial centres in the lower valleys.

The absolute denudation of the summits and of the higher basins is characteristic of this region. Forests there are still more rare than in the Alps; the slopes are there furrowed by a series of torrents side by side, and by myriads of deep and yawning ravines, even on the most gentle inclinations.

THE PYRENEES.

The chain of the Pyrenees is a geographic unit clearly defined. It includes a variety of climates less complete than the Alps, but having this inestimable advantage that limestone is replaced in great part by igneous rocks, which are more solid and less easily eroded. The general exposure is toward the north, and rains are copious and frequent. The forests, as well as the pastures, reach over vast areas, and are in a comparatively good state of preservation.

The torrent is only found here as an exception, but an exception that will become general if no restraint is placed upon it, and the Pyrenees would suffer what the Alps have undergone, notably in the upper basins of Gave de Paul, the Garonne and the Ariège. The remembrance of the inundation of 1875 is still thrilling, and the activity of certain torrents shows a disquieting tendency to increase. It is characteristic of this region that the active torrents are all of recent formation, most of them having arisen within our own memory.

A comparison of the three regions leads to these conclusions: (1) That restorative work in the Alps will demand far more energy and expense than in the two other regions combined; (2) That in the Pyrenees the important work of correction could be carried through in a relatively short time, and that reforestation there would not be necessary over any great areas; (3) That in the Cévennes a long series of small corrective operations should be carried on in connection with the creation of great masses of forest at the sources of the innumerable streams which descend both toward the ocean and the Mediterranean; (4) Finally, the Alps require the greatest as well as the most numerous corrective operations; and in most of the higher basins a reforestation so complete as to hold in constant subjection the formidable torrents which threaten to make a very desert of the frontier so important to south-eastern France.

SUMMARY.

These works for the public safety are needed in seventeen departments where torrents develop full activity, but adjoining districts also need the benefit of the law, and it would be well if at least one-third of the entire area of France should be made the theatre of "permissible treatment" by the government.

From the beginning of this century means of defense against torrents have been studied.

In articles on this subject engineers have usually confined themselves to the question of the regulation of the deposit of material loosened by the streams, and its retention within the gorges or at the point where they empty into the valleys. But these studies and plans aimed solely to diminish the ravages of the torrents; no one even dreamed of suppressing them entirely. Surrell first introduced the idea of fighting torrents to their utter extinction.

After having discovered by a series of precise observations the causes of the formation and the action of torrents, as well as the causes of the quieting or the extinction of certain ones among them, he set forth the following propositions:

1. The presence of a forest on a surface prevents the formation of a torrent.

2. The clearing away of a forest renders the soil a prey to torrents.

3. The development of forests leads to the extinction of torrents.

4. The felling of forests increases the violence of torrents, and may even cause them to be renewed.

Experiments were carried on during thirty years by foresters over all the mountainous regions of southern France. Innumerable observations, made in the mean time, on the unexpected appearance of new torrents and the influence of existing forests in the same regions, and the definite extinction of a great number of torrents, even in this short period, have fully demonstrated the immovable solidity of these fundamental principles in the great enterprise of the restoration of mountain lands.

As Surrell has said, "Nature, in clothing the mountains with forests, placed the remedy by the side of the danger; she opposes the active forces of the waters with other active forces from the kingdom of life. Ineffectual, indeed, are all our efforts beside these great remedies which Nature dispenses and patiently uses through the centuries! Our paltry works are only defenses, as their name indicates; they are passive masses opposed to active forces, inert obstacles in opposition to eager forces which are always aggressive. Why, then, does not man utilize these living forces to suppress torrents at his will? The fundamental problem is simply to find the best means of covering with a mantle of vegetation the lands ravaged by torrents now or threatened by them in the future. The defense must not begin in the lower reaches of the streams; these will defend themselves as the conditions above are corrected. The real warfare must be carried into the higher regions of the mountains. Every system of defense which does not first check the erosions in the mountain will always remain incomplete."

These ideas were not shared by all. Eminent engineers divided torrents into two classes: the curable ones, which they thought might be subdued by reforestation; and the incurable, whose basins did not seem susceptible of being covered with trees. The first class they would commit to the foresters, the second to engineers. The Legislature did not

admit this classification, but entrusted to the foresters the bold mission of reclothing the mountains, under the inspiration of Surrell, the apostle and master of this wise and beneficent policy.

THE EXECUTION OF THE WORK.

In an enterprise without precedents the best guide was indisputably the "Study of Torrents," by Surrell; but, notwithstanding the correctness of its principles, the task was, at the outset, beset with difficulties, and at times, it seemed, with impossibilities. It is small wonder that the engineers considered many of these torrents invincible. The impression produced by the sight of these devastated regions is a sort of stupor, or, at least, of discouragement, which makes one doubt the power of man in the face of such disasters. But if we analyze the conditions with care—if we compare the land in question with other regions less devastated or still wooded—if, finally, we study precedents which exist, although on a very much reduced scale, we shall feel confidence in the means of regenerating the mountains, which man alone has brought to a state of apparent ruin. This re-assuring faith which inspired the foresters was well expressed in the beautiful aphorism of Viollet-le-Duc, in his work upon the grandeur of Mount Blanc: "In Nature there are no little forces, or, rather, the work of Nature results only from the accumulation of little forces. Man is, therefore, able to act his part, since these little forces are under his dominion, and his intelligence enables him to appreciate their effects."

It was indispensable for the foresters to begin cautiously, and to try first a series of experiments of a duration and of a magnitude sufficient to enable them afterward to adjust the remedies to the extent of the evils to be corrected. Their first efforts were to create forest-masses on the denuded slopes, and it is only casually, and on certain small typical torrents, that cautious corrective trials were made, from the results of which a series of well co-ordinated observations was to be built up as a basis for the treatment of greater torrents. Having become familiar with the kind of dangers to be met, and once armed by long study and observations, they dared to assault resolutely the most formidable torrents. It is thus that in the lower Alps the correction of the torrent of Labouret, subdued after eighteen years, furnished a complete series of most valuable observations. It only remained to use the principles thus established in treating the great torrents of the valley of the Ubaye, the extinction of which, begun in 1872, is to-day accomplished.

The experimental methods in the Alps of upper Provence were ultimately applied in Savoy, Dauphiny and the Pyrenees. Everywhere they have given the quickest, the most economical and the most conclusive results. We possess at present, therefore, all the most desirable and most varied experiences in all the kinds of work that may be necessary for the extinction of the greatest torrents.

I will not detain you to describe the divers operations executed throughout our field of action, but I desire to deduce from these experiences of more than a quarter of a century the principles which have been justified by facts.

The method of treatment is based ultimately upon the entire reforestation of all the tributaries of each basin susceptible of being eroded. The forest, thus re-established in its natural place in the upper basins, is alone capable of insuring the ultimate extinction of the torrent by maintaining forever the beneficent effect of corrective works which are temporary and precarious at best. These works, in fact, have usually proved ephemeral, except certain great works of unusual importance, which, kept up by proper repairs, will be found in the future the only witnesses of the first temporary construction by which the forest will have profited to establish itself firmly and develop vigorously, until its perpetual vitality is finally substituted for inanimate works. The regular course pursued is as follows: (1) A survey and map of the boundaries of the lands to be reforested or to be kept wooded in the basin of the torrent; (2) Reforestation, as prompt as possible, of all the stable lands within the boundaries; (3) The fixing of the unstable lands by corrective works; (4) Reforestation of unstable lands as soon as they become fixed; (5) Finally, the selection of the engineering works which it will be necessary to preserve in the future.

On the side of sylviculture, the first question to consider was to know whether forest-vegetation could be introduced into altitudes much above that of the actual forests. Upon the solution of this primary question depended in most cases the justification of the method, because a great many of the larger torrents have their origin in altitudes of nearly 3,000 meters, while the actual forests hardly reach 2,000 meters.

It has been made a rule to stop only where the snow lies for several consecutive years, and we have sowed or planted, as the case demanded, either Larch or Cembran Pine. Each Pine or Larch becomes the centre of a circle of herbaceous vegetation, increasing spontaneously from year to year, following a law of selective association, which impresses every observer. In a little while the mountain recovers its double helmet of forestal and herbaceous vegetation, and nature regains her rights.

The reforestation of stable lands may be accomplished in a very few years. If care is taken to prepare at the outset the nurseries necessary for the different altitudes it is possible to attack in the same year all the different climatic zones in their most favorable seasons. At great altitudes special nurseries may be dispensed with if some small grassy plats are provided. It will suffice at first to sow appropriate seeds very thickly, which at the end of four or five years furnish myriads of plants that may be taken up and set out with pieces of sod, a course that would hardly succeed with plants from a cultivated nursery. Seedlings thus produced may be kept until seven or eight years old, to use in banks and crevices, where the young plants run great risk from stones brought down by the melting snows and the hail-storms. Years of experience justify the utmost confidence in our ability to reforest stable lands.

The unstable lands usually occupy the steep banks of the torrent or the slopes immediately above them. This instability is nearly always due to erosion by the torrent, sometimes longitudinal, and again lateral, by cutting under the bottom of slopes, which induces destructive landslides.

When the slide is over, the earth is left in the form of a series of shelves or steps, at the bottom of which the soil has a slope opposite to that of the general surface, and the result is a series of depressions, into which the snows are drifted by the winds. In spring the water from the melting sinks into the fissures, saturates the earth, and thus causes the formidable slipping away of entire mountain flanks or enormous washes of mud in certain sections. It is in these sections that corrective operations act the most important part.

Correspondence.

The Great Wurtemberg Linden.

To the Editor of Garden and Forest:

Sir,—In one of the August numbers of Garden and Forest you mentioned the remarkable Linden of Neustadt, in Wurtemberg, and the readers of your journal may take some interest in learning a few more facts concerning this giant, which can rival some of the Big Trees of your Pacific coast, if not in height, at least in the size of its trunk, and in age.

Mr. Falter, a resident of the said town, writes as follows on this subject:

In 1867 the trunk was described as having a diameter of twelve feet and a circumference of thirty-seven feet. The botanists Kemmler and Von Martens, in their flora of Wurtemberg, published in 1882, gave a circumference of forty-two feet. In reality these dimensions are difficult to verify, because the main trunk is surrounded with a solid wall of support two feet in height. One of the principal branches, which threatens to fall off, is likewise protected by a wall, and these make measurement impossible. The height of the trunk to the branching is only six feet. The branches extend horizontally over the ground. Eight young Lindens have been planted at different times to fill the gaps in the dome of verdure of the principal tree. The total height of this is to-day seventy-two feet. On June 17th, 1773, a storm broke off one of the two vertical branches at a height of thirty-two feet from the base. The scar is now well covered with a new bark, but the tree suffered greatly by this amputation. On July 18th, 1847, during a hard tempest, the second vertical branch was broken thirty feet from the trunk, and this grave wound is seen very plainly through the foliage, and will never be cured. The diameter of the whole crown, from one extreme branch to the other, is 114 feet. The original trunk and the principal branches are filled with masonry in order to delay the destruction of the tree, which is visibly approaching, for in many places the sap has ceased to circulate. The tree belongs to the species *Tilia grandiflora*, Ehrhart, while the trees planted around it are *T. parviflora*, Ehrh. The columns intended to support the horizontal branches of the tree still exist to the number of ninety-eight, ninety being of stone and eight of wood. A few are no longer in their places. Kemmler and Von Martens add, that this Linden marks the place of an ancient tribunal which was held in the open air. Indeed, everywhere in Germany during

the Middle Ages it was under the shade of Lindens that the people were accustomed to assemble and discuss matters of public interest.

The age of this tree is believed to be about 700 years.

The fact that a place which is the capital of a district has the name of a tree added to its official designation, "Neustadt-by-the-Linden," speaks sufficiently for the size of the latter.

Of the two species, it is *T. grandiflora*, Ehrh. (syn. *T. platyphyllos*, Scop.), which produces the largest trees, and Wurtemberg can boast of possessing the very largest of all. Another large Linden is standing near Leukirch, while at Isny there is one thirty feet in circumference and ninety-five feet in height. Such trees are supposed to be more than 600 years old.

Basle. *H. Christ.*

Damping Off.

To the Editor of GARDEN AND FOREST:

Sir,—This subject, recently (November 18th) discussed in GARDEN AND FOREST by Professor Halsted, is of such profound interest to propagators and growers that it would have been instructive had he given in his article a synopsis of the methods he employed to determine the existence of the fungi which he discovered in the seeds of Beans that he tested for that purpose the past season. It is clearly of the first importance to know decisively and incontrovertibly if the disease does have its genesis in the seed or in the soil, as the best methods of combating it for one is inapplicable to the other. If in the soil, thorough roasting of the soil of seed-beds, boxes or pans will be all-sufficient. If inherent in the seed, we must have recourse to germicides.

I have subjected various tree-seeds to close microscopic examination, failing even in the dust which lodges upon rough-coated pericarps to find an appearance of micro-organisms. The same lot of seeds germinated in moistened cotton exhibited no fungoid tendency, but, sowed in good loam, damped off at an alarming rate. The recommendation of some works on gardening is to use for seed-starting leaf-molds, peat, rich garden-soils or various composts of the three.

Such soils, rich in nitrogenous compounds, furnish the best possible vehicles for the rapid development of the disease.

Another practice much in vogue and equally pernicious, is the "riddling" or fine pulverization of the soil. The necessary sprinkling tends to further disintegrate the fine particles of the soil and resolve the surface into a nearly air-tight skin, prejudicial to seed-sprouting and favorable to fungoid life.

The so-called mineral soils, such as limestone, decomposed granite, and even clays, reduced to a proper mechanical condition by admixture with sand, I have found excellent media for this purpose. With these, when thoroughly roasted, I have so nearly attained immunity from damping off, that I have small faith in the notion that the disease originates or exists within the seed, except in isolated cases.

The stress with which Mr. Halsted urges the necessity of having "a healthy soil" for such operations, exactly falls in line with my own observations, and, I think, covers the whole field.

If his postulate of the inherency of disease in the seed holds good, no amount of health in the soil will help us, not even purification by fire, and we must have recourse to antiseptics.

California Experimental Forestry Station. *Wm. S. Lyon.*

Are Large Strawberries a Modern Production?

To the Editor of GARDEN AND FOREST:

Sir,—In the "Quadripartitum Botanicum," by Simon Paullus, a Dane, in 1708, the author says he has seen a variety of Strawberry, of the kind Bauhin calls Prune-sized, which produced a fruit nearly the size of a peach. I give the original Latin, on account of the interest:

"Vidi enim eam Fragariæ speciem, quam Bauhinus: *Fragariam fructu parvi pruni magnitudine* . . . fructum produxisse, ut fere æquaret magnitudinem mali Persici, nondum perfecte maturi, cui tamen similis altero anno."

South Framingham, Mass. *E. Lewis Sturtevant.*

Periodical Literature.

The December number of the *Overland Monthly* contains an interesting illustrated article on Flower and Seed growing in California. The growing of seeds for commercial purposes is quite a recent industry, and even the California Poppies which have been planted in gardens there were often raised from seeds which have been imported from Europe. This plant, both in eastern states and in Europe, is said to be inferior in the size and color of its flowers, and hence the Poppy grown from foreign seed in California is not so beautiful as the wild plants in the fields. The bulbs of the Mariposa Lily, or "Butterfly Tulip," however, have been for some time articles of export, a single collector in Ukiah selling 100,000 every season. These have not yet begun to return to California from the bulb-growers of Europe. However, a glance at the catalogue of European florists shows Scarlet Larkspur and Lobelia, elegant varieties of Dodecatheon, Brodiæa, Mimulus, Ceanothus, Phacelia, Azalea, Rhododendron, Clematis, and a late acquisition—the Scarlet Perennial Pea. Lily-bulbs, too, and many wild plants are collected here for European commercial establishments. Californians have discovered also that they can grow seed and bulbs of many plants which are not native, so that Onion-seed and Tuberose-bulbs are sent to the east in carloads. The trade in cut flowers is much more local, but two carloads of Orange-blossoms and Callas were sent to Chicago last April. The stems of the Orange-flowers were first dipped in wax and afterward placed between layers of moist cotton. Thirty-five thousand Calla-blooms were placed in wet sawdust, with their heads supported by damp moss. This suggests a new way of disposing of the flowers of the Calla, which is most prolific here although it is raised chiefly for local ornamentation and for the shipment of its tubers. The picture of a Calla field in bloom reminds one, by its shining whiteness, of the great fields of Lilies in Bermuda, only the Callas are grown here on a larger scale. Another industry is found in the Pampas plantations of Santa Barbara, where this tall grass is grown in rows from ten to fifteen feet apart. The second year each stool will produce from fifteen to a hundred plumes on stalks twenty feet high, and in 1870 they were in demand at from $50 to $60 a thousand. The average wholesale price, however, is $30 a thousand. An acre has been known to yield 10,000 plumes a year. England and Germany send the largest orders for these plumes. The latest development of floriculture is seen in the Rosalita Farm in Los Gatos, where the manufacture of the essential oils of Rose and Geranium has been put to practical test with gratifying results. Ten thousand Rose-bushes were imported directly from Grasse, and a still was brought over from France. The essential oil, which floats on the surface of the water from the condensed steam, is the attar of Rose, which needs only settling to be ready for market, while the water accumulated in the reservoir is soft and fragrant and sells on the place for $1.75 a gallon. Besides Roses there are acres of Geraniums, Cassia, and a peculiar species of Orange-tree used only for its flowers.

The sale of cut flowers in California is very large. The Violet is the most prolific flower which bridges the gap between the fall Chrysanthemum and the early spring firstlings of the nursery. At Sherwood Hall there are five acres of choice varieties of Violets growing thriftily in the rich leaf-mold in a grove of gigantic Oaks. The rows of plants reached up to the very trunks of the trees. The work of picking these flowers is left to Chinamen, who are kept busy for six months of the year, and every morning the crop is sent to San Francisco. Sweet Peas are another specialty in this nursery, and transportable flowers, like the Violet, the Aster, Chrysanthemum, Tuberose, with thousands of varieties of Maiden-hair Ferns, are sent to Tacoma, Salt Lake, and even to Chicago.

Many women in California gain a livelihood by raising flower-bulbs and seeds for market, and many others send huge hampers to San Francisco every day of wild flowers and ferns which have been picked from the neighboring cañons. Mrs. Theodosia Shepherd, of Ventura, stands foremost among these successful floriculturists, although only eight years have passed since, without means and broken down in health, she grew her first seeds for market in the old mission town of San Buena Ventura. She now fills orders from prominent eastern florists, with occasional calls from Europe, Australia and the Sandwich Islands. Her gardens comprise eight acres of fertile soil, which are under her personal supervision. She grows all the new seedlings among the French Cannas, for example, and one of her own called Ventura, which is said to be as large-flowered as the famous Star of '91. Last year she harvested 160 pounds of Smilax-seed, which were packed and shipped by Mrs. Shepherd and her three daughters.

Notes.

In the address of Mr. James Fletcher, President of the Association of Economic Entomologists, it is stated that insects cause the enormous loss of $380,000,000 annually to the agricultural products of the United States; that is, more than a

million dollars every day. It should be added that investigations in economic entomology, during late years, have given the farmers of the country the means of successfully combating the most destructive of these insect pests.

More than 200,000 sacks of Lima beans are piled up at Ventura, California, waiting for better prices. A year ago these beans brought five and six cents a pound; this year only two or three cents are offered.

To a correspondent who asks if the Jerusalem Cherry is a suitable plant for a window-garden, we would say that this fine old-fashioned plant is really one of the very best of house-plants. It is handsome, and can be grown with very little trouble. Visitors at the late flower-show in New York will remember a row of these plants about the fine mass of Cannas exhibited by Mr. Dean. For a border of this sort, and for many other kinds of decorative work, the Jerusalem Cherry is invaluable.

On the Experiment Grounds of the United States Government at Medicine Lodge, Kansas, forty acres of land were plowed and then subsoiled to a depth of eighteen inches and planted with Sorghum cane, and another piece of ground was plowed to the ordinary depth and planted to cane of the same variety without subsoiling. Both fields received the same cultivation, and the subsoiled land yielded eighteen tons of cane to the acre, while the best yield of the other ground was only ten tons.

When ground is cleared for agricultural purposes in California the standing trees are sometimes removed by the aid of explosives. By removing a little dirt from around the tree the position of the main roots or the tap root can be located, and a hole is driven along the tap root or between the principal roots with a long crow-bar, and this is charged with dynamite. Sometimes dynamite is placed in an auger-hole bored into the main root. After the explosion the tree falls, or the earth around it is so loosened and thrown out that it is not difficult to finish felling the tree.

A correspondent of the London *Garden* writes with enthusiasm of the beauty of a second flowering of *Daphne Cneorum* in mid-November, and, truly, it is difficult to say too much of the delicate charm of this little plant even in our colder climate. After occasional blooms through the summer its autumn crop of flowers is sometimes quite abundant here also. Even as late as the 12th of December, this year, it was blooming in the neighborhood of New York, opening its flowers perfectly and giving forth a fragrance which seemed even richer than that of its spring bloom.

The Oak-leaved Hydrangea in Georgia and northern Florida, where it is native, sometimes reaches a height of fifteen or eighteen feet, with a habit almost tree-like. It is not perfectly hardy, however, north of New York, and in cultivation in this neighborhood it rarely attains large proportions, although it is beautiful both in leaf and in flower, and its foliage in autumn turns to a rich claret color. Mr. Meehan states that one of the finest specimens of this plant is growing in the old garden of Washington at Mount Vernon, where it was planted by Lafayette. If this is true, this specimen is probably one of the oldest in cultivation.

The pavilion planned by the State of Florida for the Chicago Exposition grounds will reproduce Fort Marion, supposed to be the oldest structure in the United States, which was built at St. Augustine by the Spaniards in 1620, the year when the Pilgrims landed at Plymouth. The reproduction will be constructed of wood, but covered on the outside with Florida phosphate rock, simulating the original stone work, this use of the material constituting the phosphate exhibit of the state. The deep moat which surrounds the old fort will also be reproduced, but will be utilized as a sunken garden, in which plants native to Florida may be shown.

Some twenty-five years ago there was a great impetus to fruit-growing in western New York, and in order to get as much as possible from the ground, Apple-trees were planted at about thirty feet or two rods apart each way. Now that these trees are of full size it is hardly possible to raise a ladder between many of them, and good judges think that much of the imperfection and lack of color in the fruit this year can be attributed to the fact that the proper amount of air and sunlight has been excluded. Mr. Irving D. Cook, of Geneva, New York, writes to the *Rural New Yorker* that in the judgment of the best growers in that region forty feet, or even forty-five feet, is not too far apart for planting Apple-trees, especially trees of winter varieties, if the best fruit as regards size, color and flavor is to be expected.

Smith, in his "Dictionary of Economic Plants," makes the following statement: "In a volume containing a miscellaneous collection by Dr. Richard Pocock, in the British Museum, is the copy of a letter written by Philip Herbert, third Earl of Pembroke, Lord Chamberlain, to the Sheriff of Staffordshire. It is as follows: 'Sir—His Majesty, taking notice that the burning of Ferne doth draw down rain, and being desirous that the country and himself may enjoy fair weather as long as he remains in these parts, his Majesty has commanded me to write to you to cause all burning of Ferne to be forborne until his Majesty be past the country. Wherein, not doubting the consideration of their own interest, as well as of his Majesty's, will invite the country to a ready observance of this his Majesty's commands, I rest, your very loving friend, Pembroke and Montgomery.'" Here is a hint for some of the rain-makers of our Department of Agriculture.

It is well known that among the prizes which Egyptian monarchs brought back from their foreign wars were exotic plants of many kinds, and that even large trees were transported for long distances to be set up in the courts of the temple-palaces. In Miss Edwards' new book, "Pharoahs, Fellahs and Explorers," we may find an account of such transportation illustrated by interesting pictures copied from the bas-reliefs of the great temple built by Queen Hatasu, near Thebes. In several of the best-preserved pictures we see the Egyptian sailors carrying half-grown saplings which have been taken up with a ball of earth about the roots, and are being transported in baskets slung upon poles, each pole carried by four men. Over the saplings is inscribed *Nehet Ana*—that is to say, the Sycamore of Ana. Elsewhere we see the full-grown trees. The trunk is massive, the leaf is a sharp-pointed oval, and at the junction of the trunk and the larger branches are seen little copper-colored lumps of irregular form, representing the resinous gum which has exuded through the bark. A passage in Pliny . . . shows that this tree, the odoriferous Sycamore, can be none other than the Myrrh-tree, whose gum was brought by the ancients from the so-called land of the Troglodytes, and, especially if of the green sort, was highly esteemed by the ancients as the material from which incense was made.

A pamphlet prepared by Dr. E. M. Hale, of Chicago, has just been published by the Department of Agriculture on the history and uses of *Ilex Cassine* (*I. vomitoria*). It is from this plant that the decoction known as "black drink" was made by the Indians of the Atlantic and Gulf states, and this paper contains much curious information about its ceremonial and economic use by the aborigines. The most interesting point brought out is that an analysis of the plant by Professor Venable, of the University of North Carolina, shows that it contains caffeine, so that this is really an aboriginal North American Tea-plant. Another species of Holly, *I. Paraguariensis*, furnishes the maté, or Paraguay tea, so that it is not surprising that this Yaupon, or Cassena, contains a similar alkaloid. Professor Venable's analysis of other plants of this family in North America shows no trace of theine or caffeine. Dr. Hale quotes many interesting passages from early writers to show the extended use of the Yaupon by the Indians. The leaves were roasted and kept in dry places, and there can be little doubt that it was an article of commerce, collected by the savages on the coast of North Carolina and sent to more western Indians and sold. Dr. Hale finds that an infusion of Yaupon-leaves boiled for half an hour gives a dark liquid like strong black tea, with an aromatic odor not like coffee, but more like Oolong tea, although without its pleasant rose odor. The taste is like that of our inferior black tea, quite bitter, and with little delicacy of flavor. It is not an unpleasant drink, however, and Dr. Hale thinks that one might become accustomed to it as to maté, tea or coffee. The Indians used to say that the drink prevented hunger and thirst, and the similar effect of Coca-leaves, used by the Peruvian Indians, has brought that plant into medical use. One author states that the Indians transplanted—that is, cultivated—this Yaupon. Dr. Hale concludes that a beverage which contains caffeine should fall into disuse and become forgotten is a singular fact. If it has any economic value the plant could be cultivated over a large section of the southern coast country, and would produce an enormous crop. Dr. Hale states that it does not grow more than twenty or thirty miles from the sea-coast, and that its western limit is found about half-way from the Louisiana line to the Rio Grande. A note from Professor Pammell, however, states that he has seen it at least a hundred miles from the coast in Texas, and in the "Silva of North America" (I., iii.) it is said to penetrate the interior to southern Arkansas and the valley of the upper Rio Blanco, in western Texas.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

NEW YORK, WEDNESDAY, DECEMBER 23, 1891.

TABLE OF CONTENTS.

Hemlocks in Winter.

IN our northern climate, with its long and often rigorous winters, the sight of evergreens is a comfort and delight. Their soft green masses seem to mitigate the severity of the season, and to temper the bitter blast. This the aborigines well understood, and in the depths of the forest the Indian built his winter camp, securely sheltered from the searching winds, which are the unendurable part of that tempestuous portion of the year.

Goodly is an assemblage of Firs and Spruces when skies lower and tempests howl, comfortable the aspect of a Pine wood, with its furry branches and brown carpet, when the bare twigs of deciduous trees are shivering in the northwest wind; but more impressive than all is the sight of a group, or forest, of Hemlocks, such as is depicted on page 607, with their bending boughs laden with snow, and their graceful forms emphasized by their regal border of ermine.

Growing, as they best love to grow, on a rocky northern slope, their majestic height is enhanced by the elevation on which they stand; their columnar trunks catch the light from above upon their snow-besprinkled bark, till the whole forest seems a Gothic cathedral, marble-roofed and pillared, with wild fret-work and intricate design of shaft and capital, cornice and rafter, buttress and corbel, sculptured like a shrine with fantastic forms, and built into a quaint wonderful series of aisle and nave, chapel and sanctuary.

To walk here gives a strange and solemn delight; the gray rocks take on grotesque forms in their white sheathing, the ground is like a mosaic floor beneath the feet, the winter birds chatter in the branches overhead, the great trunks, with their rough bark, show a rich hue amid all this whiteness. A snow-shower greets the traveler from the light branches stirred by the approach of man as he advances through the solitary wood. No wind reaches the sheltered region, but in the high snow-laden tops there is a murmur, the voice of the forest, the diapason of creaking bough, and sigh of stirring foliage shaking off its burden. New and lovely forms greet the beholder as he strays in this trackless wilderness, where the Indian of yore found protection and warmth for his wigwam built of the red-brown bark. The thought strays back to that time before the white man penetrated these wilds to drive the sachem and the squaw from their happy hunting-grounds, and he would gladly give a voice to the old trees to tell their story and recall the past, singing in runic rhyme some strange, wild legend of an older savage day. What more mysterious than the forest? What voice more vaguely impressive than its confused complaint? What poet may catch the echo of this melody and weave it into verse? To wander in a Hemlock wood is to commune with Nature, to listen to an unknown tongue, to struggle with the secret of the unspeaking trees, which suggest questions forever to man, but never reply, nor share with him their experience.

A single Hemlock, standing alone, with every curving line ridged with snow, through which the feathery green shines darkly, is a fair sight, a Christmas emblem, a tree of beauty. When the sun shines and the snow melts, a faint aromatic fragrance emanates from the dripping foliage, as if the tree were burning incense. This delicate perfume, full of soft suggestion, completes the charm of this wonderful tree, precious alike for nobleness of shaft and grace of branch and leafage, seeming forever to associate it in one's mind with that dear holiday of childhood, which is the solemn festival of maturity.

For the Hemlock is, above all, the Christmas-tree. Its perfume, whenever we inhale it, brings to our minds, not only a vision of the green wood, but a thought of dim and quiet churches wreathed with its boughs, of a deep chancel embowered in its branches, of joyous hymns from white-robed choristers, of the great angelic chorus,

Gloria in Excelsis Domino,

with which Christmas Day first dawned upon a waiting earth, and which echoes still in solemn chant of earthly voices from cloister and cathedral, from chapel and fireside, as year by year the happy day returns, on which we wreathe about the Christmas altar and the Christmas hearth the Hemlock-bough to give forth the sweet incense of its fragrance.

Then a vision of joyous little ones dancing around its gayly lighted form succeeds the solemn suggestion of its holy service, and our careless youth returns in memory, cheery and full of hope, or in maturer age we rejoice in the pleasure of our children and our grandchildren, as we gaze indulgently upon their frolicsome glee around this bearer of precious burdens.

So must this stately and beautiful Hemlock ever come near to our hearts, twined as it is with thoughts of praise and of generous giving; and with its undying verdure, its wide-spread, kindly shelter, its solemn loveliness, its breath of praise, it is a fitting emblem of the season with which it must ever be associated in our thoughts—the blessed Christmas-tide.

A FEW weeks ago we published the announcement of Professor Trelease concerning the examination of candidates for garden pupils at the Shaw School of Botany, in Saint Louis. It will be remembered that there are six scholarships in this institution, where young men can receive theoretical instruction in botany, horticulture, economic entomology, and enough of land-surveying and book-keeping to equip one to take charge of a large estate. The aim, however, of these scholarships is not to make botanists or entomologists, but gardeners; and as the only way to learn garden practice is by the practice of gardening, these young men will be employed in the work of the different parts of the establishment and receive pay for the same, besides having comfortable lodgings near at hand and free tuition. The pupil is expected here to learn the practice of small-fruit culture, orchard culture, forestry,

vegetable gardening, landscape gardening, etc., and therefore it is entirely distinct in its purpose from the horticultural courses established in the various state agricultural colleges.

We have lately received several letters to confirm us in the opinion that young men who now take a thorough training in horticulture, either at this Shaw School or under the instruction of skilled gardeners and the growers of choice plants, can easily find remunerative employment. There is an increasing demand for men who understand the cultivation of greenhouse-plants and who are familiar with the care of outdoor gardens. Besides this, seedsmen and commercial growers of high-class plants find it hard to secure men with sufficient practical knowledge to enable them to be efficient salesmen either of new introductions or of well-known plants. One of the letters to which we have referred states that there is general complaint among large dealers of the difficulty in securing thoroughly posted and capable salesmen; and while it is true that many of the gardeners in charge of greenhouses and grounds in this country are as good as can be found elsewhere in the world, there are others who have not sufficient knowledge or ambition to take the proper care of a fine collection of plants; and the owners of such plants are, therefore, discouraged from buying more or taking such an interest in gardening as they otherwise would. It is a well-known truth that there are comparatively few good gardeners or salesmen who are American-born. The greater number of the leading men who fill these positions have received their training in Great Britain, France, Germany, Belgium, Sweden or some other foreign country. Certainly Americans have as much natural aptitude for this work as have men of any other nationality. Indeed, some of the most skillful propagators and enterprising growers in the country are Americans. Why should not more of our young men prepare themselves for labor in this promising and useful field?

New England Parks.

DEERING'S WOODS AND THE PROMENADES, PORTLAND, MAINE.

WHOEVER has read Longfellow's "My Lost Youth" must have desired, at some time or other, to see "the shadows of Deering's Woods" for himself—those woods in which the gentle poet played when a child, and which he has embalmed in one of the most exquisite of his poems.

It is the privilege of the poet to thus secure immortality to some spot dear to his heart, and to make the name of that unseen region a household word even in distant lands. The steep brow of the mighty Hellvellyn will ever be a feature in the mind's landscape beside the Dowie Dens o' Yarrow and the Banks o' Doon. How many pilgrimages have Scott and Burns caused to view the ruins of Melrose or of Alloway's Auld Haunted Kirk? Is not all Scotland pictured to us in the ringing verse of Scott, till every loch and glen are dear to us, and Ben Nevis and Ben Lomond, Stirling Castle and its "winding river, twined in links of silver light," are as familiar to our imagination as the New England coast?

The Rhine—the poetical watchword of two nations—what wreaths of verse and legend hallow its hills and vineyards! How the yellow Tiber, with its tumbling flood, is a clear vision to the man who never hopes to see the "City of the Soul"; while the peaks and streams of ancient unseen countries live for us in the undying strains of the bards who have sung them, till Scamander and Simoïs, Olympus and the distant Caucusus, Avernus and the Stygian Grot, even the lone Corasmian shore, have a reality to our minds that no geography or history could impart, and dwell forever in our memories, embalmed in one sweet sonorous line.

What Washington Irving has done for the Hudson, what Whittier and Emerson have done for Monadnock and Chocorua, Longfellow has done for Portland—his native city—and for its pleasant woods. Forever in his verse will linger "the beautiful town that is seated by the sea," while we

> —can see the shadowy lines of its trees,
> And catch in sudden gleams
> The sheen of the far-surrounding seas,
> And islands that were the Hesperides
> Of all my boyish dreams.

Nor is it merely a poetic license to call the chief city of Maine beautiful; for whether approached by sea or land it has an impressive aspect, girt about, as it is, with waters, and overshadowed by fine Elms. Yet its full beauty cannot be felt until you explore the high peninsula on which it stands, really an island, since a bridge is its connection with the mainland, and see the continual rise from the encircling bay to the lofty centre, with shady streets ever climbing or descending hills, while from the high upper windows of many houses, far-away views of sea or mountain gladden the dweller in that favored town.

For some reason I had falsely fancied that Deering's Woods were to be found somewhere upon those heights

> o'erlooking the tranquil bay,

where sleep the dead sailors who fell in the famous sea-fight between the Shannon and the Chesapeake in the war of 1812; so that it was with surprise I discovered the old grove in a valley near the water, hard beset by screaming engines and partly belted by iron rails. I was disappointed, too, in the extent of this classic ground; for, though there are sixty-six acres in the city reservation, not all of it is covered with trees, and some of it is in a rough, unfinished condition.

The woods which were presented by the Deering family to the town in 1879 cover a space about as large as Boston Common, and consist almost entirely of Oaks, venerable with age and russet with the touch of autumn when I saw them. Drives wind in and out among the antique trees, under which the turf is fresh and green. The underbrush is all cleared away, and in the centre is a natural pond of pleasing contours, which is a beautiful feature of this easily accessible pleasure-ground.

It is to be hoped that the city will acquire a certain slope beyond the railroad-cut, which could easily be bridged over to connect it with the grounds; and I understand that more land contiguous is soon to be purchased to give greater importance to the proportions of the little park—for park the local newspapers persist in calling it, though far more preferable and hallowed is the homely name of Deering's Woods, given to it by the poet, or that other appellation by which it is still known to Portland boys—Deering's Oaks. It is neither large nor imposing enough to be properly called a park, and the old name fits it perfectly, while it seems to me that somewhere about its gates might be engraved the quotation from the well-known poem, which makes it classic ground:

> And Deering's Woods are fresh and fair,
> And with joy that is almost pain,
> My heart goes back to wander there,
> And among the scenes of the days that were,
> I find my lost youth again.
> And that strange and beautiful song
> The groves are repeating it still,
> "A boy's will is the wind's will,
> And the thoughts of youth are long, long thoughts."

So associated is her poet son with the city of his birth, that, as one walks under the overarching trees, it is pleasant to come upon Mr. Simmons' seated statue of Longfellow, at the shaded junction of several avenues, looking down "those well-known streets" which he as sweetly commemorates in his verse as "the black wharves and the slips," the "bulwarks by the shore," and that

> breezy dome of groves

which was the occasion of my pilgrimage to the dear old town, which cherishes his memory by preserving the spot he so highly honored with the undying tribute of song, as a perpetual playground for its children.

Even more important as a breathing-space to the sea-girt city is the fine system of promenades with which she has crowned her heights—wide, smooth drive-ways, from which the harbor is grandly commanded. Here on the eastern promenade you skirt ancient earthworks, and come out upon the esplanade where are the ruins of Fort Sumner. From this point you look upon the Back Bay and the city climbing its promontory, while due east is a great harbor with a peaceful opposite shore, and islands dotted with summer homes, and a view of Cape Elizabeth, which has many villas along its windy and sea-smitten coast, that are a favorite resort of Portland people. This high and breezy avenue is shaded by tall trees much dejected by constant exposure to northern blasts, but the outlook upon bay and land is imposing. This system of drives encircles the summit of the peninsula, which, from its lofty elevation, commands a great extent of country; but the western view is the finest of all.

Upon the western promenade front some of the best Portland houses, and perched on the side hill is the Maine General

Hospital, a large, admirably situated building, from which the patients must enjoy a noble sight, for here the eye wanders over a vast extent of level country, relieved by hills and distant homes, through which meanders the River Fore. In the far middle distance uprise the mountainous hills of Oxford County, blue and impressive, while in the remotest background, half-hidden by shifting clouds, loom up the peaks of the White Mountains of New Hampshire, Mount Washington clearly relieved with its unmistakable purple profile against a pale gray sky, and now and then veiling its head completely in drifting clouds. From November until May these peaks of a clear evening can be seen in white silhouette against the golden sky as the traveler leaves Portland by train or boat.

Such a champaign, diversified with near glimpses of the bay and the winding river which empties into it, with that vast hundred-mile stretch terminating in mountain-peaks, is a wonderful thing to look out upon from a busy and populous city. But there is a drawback to this fine boulevard which should not be permitted to exist.

Unfortunately, the steeply descending hill-side, clothed with scattered Pines, that intervenes between the Western Promenade and its great outlook, has not yet been acquired by the city, though the opportunity has been afforded by the heirs of the J. B. Brown estate to exchange this land for other lots lying in a different part of the town.

When I recognize how much public spirit is shown by rich men in Massachusetts towns; when I see the great gifts of land for parks made in Springfield, in Lynn, in Worcester, and even in little Plymouth, I cannot help hoping that a similar generosity may be found in Portland, and that like munificent gifts may be made to it by some of the inhabitants. But, failing this, it seems a lack of foresight in any town to relinquish such an opportunity as this for securing to its dwellers for all time so magnificent an outlook as that from the Western Promenade. Such a mistake would be forever regretted, until some day, at enormous expense, the city would see fit to repair its error by resuming control of the property and destroying the intervening buildings. The town has, I understand, but a limited time in which to come to a decision; but a city which has been, heretofore, willing to pay between six and seven thousand dollars a year for the construction and maintenance of its park system, cannot afford to draw the purse-strings between it and one of the finest views in the whole beautiful state of Maine.

So far Portland has been wise and generous in her outlay, and, with all the wealth of that thriving town to call on, it is not to be believed that she will be wanting to so great an occasion.

Hingham, Mass. *M. C. Robbins.*

Notes of a Summer Journey in Europe.—II.

NO doubt, Geneva is indebted for much of her wealth of American and other foreign trees and shrubs to the influence and work of her illustrious botanists, the De Candolles, who have always made the city their chief home. The Botanic Garden here was planned and arranged early in the century, by the first illustrious botanical member of the De Candolle family, according to what is known as the De Candollean system of classification, and although the garden is not large it is quite worth a visit from any botanist or horticulturist. It occupies a sheltered situation almost in the heart of the city, and is divided into a number of sections, each enclosed by low fences and intersected by numerous paths. On account of its limited area, there is not a great deal in it of much interest to an arboriculturist or dendrologist; in fact, the most interesting trees, about thirty-five in number, comprising twenty-five species, are crowded into six rows, covering a piece of ground less than two hundred feet long and sixty feet wide. This group is not within the systematically arranged enclosures, and it is said to have been planted in the second decade of the present century. Here, among others, are two large Gingko-trees, labeled as staminate and pistillate; a Cedar of Lebanon, with a trunk about twenty-eight inches in diameter at three or four feet from the ground, and a specimen of *Zelkowa crenata*, with a smooth trunk two feet in diameter. While this tree has very much the habit of some Elms, to which family it belongs, the bark looks something like that of the Plane-tree (Platanus), or it may be said to be even smoother, the old bark scaling off in comparatively thin plates. In a corner of the garden is a Paulownia, with the largest trunk of any tree in it, while a specimen of our Cucumber-tree (*Magnolia acuminata*) is the best and almost only representative of its genus.

The herbaceous collection is a fair representative one, in good condition and apparently well labeled. The labels mostly in use here are made of thick, heavy zinc, and are either tied to the plants or fastened to stout iron rods. The names are cut into the metal by an acid which is applied after the zinc has been covered with engravers' wax and the desired name written through it. The name thus eaten out by the action of the acid is afterward filled in with black paint, making a fairly indelible record, and one that is easily legible at close quarters. It is, however, rather a laborious and slow method of getting an ordinary written label. As in most Swiss and German collections, one of the chief prides of the garden consists in the rockeries, or collections of alpine plants, as they are called, although they are by no means limited to plants of the mountains. The rockeries here are arranged in a rather formal and inartistic way, comprising several symmetrical piles of stones and soil. The plants, however, were in a flourishing condition and showed good care. At the time of my visit (July 20th) most of the alpine plants had long since passed their flowering stage, but a few were still conspicuous, chief among them being Campanulas, Poppies, Rock-roses, Gentians, Sedums, various species of Dianthus, Statice, etc. High up in the cooler, moister atmosphere of the mountain-slopes many species were still blooming freely, while in the garden they had passed on to the fruiting stage.

Quite as interesting, in a way, as the Botanic Garden, and a place well deserving of a visit by any enthusiast in the study of alpine floras, and particularly the flora of the Swiss Alps, is the Jardin Alpin d'Acclimatation. This establishment was started in 1884, under the patronage of the Swiss "Association pour la Protection des Plantes," an organization started a few years previously.

The object of the association itself is to save from destruction the beautiful and rare native plants of Switzerland, many of which were so fast becoming exterminated by botanists, tourists, foreign plant-collectors, and, worst of all, by the native population, who had found a remunerative pursuit, first in the sale of the flowers, and then in the collection and sale of the plants, which were dug or torn up by hundreds and thousands. Among the methods of accomplishing the desired end, as stated in the articles of organization, are the following: By the example of its members; by issuing popular publications for the purpose of educating the public in the manner of raising and cultivating these alpine plants; by appeal to the civil authorities, and by encouraging the culture of the plants by regular horticulturists and others, so that they may become common.

The headquarters of the association is at Geneva, and branch societies are established wherever a sufficient number of persons can be found interested in the subject. An annual fee of about forty cents (two francs) is charged, and citizens of any country are eligible as members. The association publishes periodical bulletins and also issues catalogues of seeds and plants. The establishment of the garden is intended to assist amateurs and others in obtaining at a very small cost the seeds of alpine plants or plants raised from seed. As plants thus raised can be depended on to thrive if given proper conditions, it is the hope of the society that the incentive to tear the wild plants from their native soil may be greatly lessened; because, besides leaving the valleys, mountain-slopes and rocks denuded of their beautiful flowers, it is well known that only a very small percentage of these ruthlessly torn up plants ever live to bloom or get adapted to their new homes. An instance of extermination may be mentioned in the case of *Potentilla fruticosa*, which, though found all around the northern hemisphere, and once common in Switzerland, is not now found within the limits of the country, the last of it having disappeared within a few years.

The plan of the association seems a good one, and much good can be accomplished through its garden if it is efficiently conducted and its existence and aim become well known. At present the garden is small, and so are the means at command for conducting it, and no doubt much of the interest manifested and the success of the undertakings thus far is due to the enthusiasm of M. H. Correvon, the president of the association and the director of the garden. From the garden the true plant-lover or the mere souvenir-hunter may obtain good healthy pot-grown plants of the much sought for Edelweiss, with directions as to its culture, and also of the Alpine Rose or Rhododendron, of the Anemones, Cyclamens and innumerable other plants which contribute to make Switzerland so attractive to the traveler. The catalogue, however, will be found to contain the names of many plants not natives of Switzerland, as well as some which are not strictly alpine.

Among other objects of the association is the establishment of gardens or reservations in various parts of the high Alps,

where the native plants can be grown and protected in their natural habitat, with congenial climate and surroundings. One of these stations, started two years ago, is called the "Linnæa," and is situated high up at Bourg-Saint-Pierre, on the Grand Saint Bernard route.

The free use of trees for decorative purposes, apparently, prevails as much in Switzerland as with us. During my stay in Geneva the city was gayly decorated in honor of a congress of athletic societies, and, besides the usual display of flags, bunting, etc., immense quantities of greenery were used, being brought from the surrounding country and neighboring mountains. Both branches and young trees of the native Balsam Fir were used in great quantities, also some Norway Spruce and Swiss Pine, while the native Ivy (*Hedera Helix*) and the Box were the chief materials used in making up festoons and other trimmings.

Arnold Arboretum. *J. G. Jack.*

The Weeds of California.—VI.

THE *Convolvulaceæ* supply only two obnoxious members, one native, *C. Californicus*, and the European *C. Arvensis*. These are not hurtful as "bindweeds," but simply on account of obstinately holding their ground against culture plants by dint of their long root-stocks that penetrate the ground to great depths, and which it is impossible to kill otherwise than by exhausting them, keeping the persistently reappearing tufts of foliage constantly cut during at least one season. The native species, which is erect without creeping stems, is especially hard to subdue in the "black prairie" or adobe soils of the Coast ranges, and its pretty white flowers adorn many an abandoned orchard in the Bay country. The "convolvulus" is the most dreaded of the perennial weeds.

Cuscuta trifolii is naturally a much-dreaded pest in a country in which Alfalfa is so important; and it annually makes its appearance here and there, but is promptly checked by the simple expedient of close-pasturing for at least one season. Alfalfa-seed is usually required by the purchaser to be warranted "free from Dodder."

Of the *Solanaceæ*, *Solanum nigrum* appears as a weed in waste places or fields without being troublesome. The *Datura Stramonium* has been introduced, but makes little headway, and is rare, while the native *D. meteloides* maintains itself obstinately against cultivation in the great valley and in south California, taking the place of the "Jamestown weed." Its range is nearly co-extensive with that of one of the native tobaccos—*Nicotiana attenuata*—whose viscous stems and foliage combine with an unpleasant odor to render it objectionable in the fields it invades.

Of the *Scrophulariaceæ*, the only weedy accession from the outside is an occasional occurrence of *Veronica peregrina*. *Scrophularia Californica* is locally somewhat troublesome; *Mimulus lyratus* is an obstinate but hardly noxious guest on the black lands of the Bay region and elsewhere. The most troublesome member of the family is *Orthocarpus purpurescens*, which locally not only disputes the ground with grain in the Coast ranges, but must be strongly suspected of adding injury by semi-parasitism, etiolating the remnant of grain-stalks. The same must be suspected as regards several others of the same genus that are frequent among the grain, and in pastures in California, as well as of *O. campestris* of Oregon and Washington.

The cosmopolitan Brunella, though occurring in the mountain-pastures of northern California, obtains no foothold south of the Oregon line. *Stachys bullata* is locally troublesome in the Coast-range valleys; the intensely scented Trichostema (Camphor-weed) maintains itself in the cultivated fields of the warmer parts of the state as on its original ground, defying heat and drought, and playing the part of a "Tar-weed" very successfully. But no other Labiates can be counted as weeds.

The *Verbenaceæ* are represented only by *V. officinalis*, which, in the irrigated lands of the great valley and lower foot-hills, attains a vigorous development.

Of the *Plantagineæ*, *P. major* and *P. mollis* give some trouble in lawns and irrigated grounds, but cannot be considered generally troublesome. It is quite otherwise with *P. lanceolata*, which in company with *Setaria glauca* is the most formidable enemy of irrigated grounds and pastures in the foothills of the Sierra, and more or less in the adjacent portions of the Sacramento Valley. The Plantago frequently shares the ground evenly with the grain, and in company with the Setaria forms steadily increasing patches in the Alfalfa fields, until the whole ground is taken. Such ground is difficult to reclaim from these weeds so long as field-crops are grown.

Urtica holoserica, the tall, stout native Nettle, makes itself disagreeably conspicuous in low grounds; while *Urtica urens* is a common invader of cultivated grounds all over the state.

Of the *Euphorbiaceæ*, it is chiefly the decumbent tribe that represents the Euphorbias proper in the fields, notably *E. Serpyllifolia* of the east, and *E. albomarginata* and *E. ocellata* as natives. All these are popularly credited with curative properties against rattlesnake bites. *E. Lathyris* has locally escaped from cultivation, and is periodically brought forward as a much-needed remedy for the troublesome "gopher" *Thomomys umbrinus*, which, in sandy lands particularly, it really seems to abate materially, probably through the poisonous properties of its pleasant-tasting seeds.

The most universally diffused weedy member of the order, however, is the *Eremocarpus setigerus*, a broad-leaved, hirsute, spreading annual, commonly known under the name of Turkey weed. While it prefers light sandy soils, and is, therefore, more especially at home in the San Joaquin Valley, it is also found throughout the Sacramento Valley and within the Coast ranges, from Mendocino County on the north to San Diego on the south, and on the valley and mesa lands of the interior; it does not even omit the Mojave Desert, but there changes its dichotomous spreading habit to an erect one, and appears in large patches densely crowded with almost unbranched stems, as much as three feet in height; suggesting the use of its strong and abundant fibre for industrial purposes. The extremely irritating nature of the dust arising from the dry stems when handled would alone probably prevent such use. The extreme resistance of the plant to drought enables it to survive almost any other annual vegetation; but the ease with which it is killed, even by a kick at the root-crown, renders it much less objectionable than most other "summer weeds."

Sisyrinchium bellum, the handsome blue "star grass," is apt to overrun moist but overstocked pastures, and is sometimes not easily subdued.

Oddly enough, one of the "California Lilies," the pale blue *Calochortus invenustus*, is a veritable weed in some of the warmer parts of the state, where it persists in grain-fields, though without material damage. A Zygadenus is charged with poisoning lambs and their hungry mothers in early spring in northern California and Oregon.

Of weedy Grasses, the troublesome Chess, *Bromus secalinus*, is found here and there, as an importation with seed grain or packing straw; but it utterly fails to gain a foothold as a weed. Its place is, however, very successfully occupied by the corresponding plant of Europe, the Darnel (*Lolium temulentum*), which not only holds in the cereal fields a place similar to that held by the Chess in the east, but is in addition charged with the same sin of transforming itself at will, in unfavorable seasons, into the very grain of which it has usurped the place—wheat, barley, oats or whatever the crop may happen to be. The echoes of warm discussions on this issue, both in journals and in agricultural clubs, have hardly yet subsided, and there remains many a staunch believer in the changeling supposed to perform such surprising feats. Not the least amusing feature of this discussion was that Darwin was repeatedly cited as supporting and proving the occurrence of such transformations.

Bromus mollis finds the climate much more congenial than does *B. secalinus*, and, with *B. sterilis*, may be classed as a weed grass, common on roadsides and in neglected fields. But it has attained a wide importance as a more or less welcome successor of the native grasses on natural pasture-grounds, so completely adapted to the Coast-range climates that it may be found waving on the slopes as thickly massed as though sown on purpose. Locally it has been thus used, and is likely to become more popular since it has been found to be effectual in driving out the most dangerous enemy among the grasses of both pastures and fields—namely, the *Hordeum murinum*, variously known as Squirrel-grass, Foxtail and Barley-grass. This undesirable immigrant, while affording early green pasture for a short time, becomes a fearful nuisance so soon as its long-awned ears are developed. The bristly awns, provided like the paleæ with retrorse serration, accompany the three-flowered spikelets to the end; and the latter, being sharp-pointed at the base, adhere to and penetrate almost anything in the way of woolen or cotton materials from the sheep's fleece to ladies' dresses; they work up the nostrils of cattle and the laborers' sleeves to the neck, and generally make themselves obnoxious to a degree not easily surpassed by any plant outside of the tropics. Although an annual, its extirpation has proved extremely difficult; and the advent of a natural enemy in the Soft Brome-grass is therefore most welcome.

The Wild Oat (*Avena fatua*) is so generally diffused even in the remote portions of the state that it is commonly considered indigenous, since it is mentioned by the early explorers as covering the hill-sides of the Coast ranges as well as of the Sierra foot-hills. While an unwelcome guest in the grain-fields, it is highly esteemed for hay, despite its hirsute glumes

Fig 95.—Cypripedium reticulatum. The Plant.

that, when too ripe, sometimes give trouble in "choking" cattle not used to it.

Of the numerous Paniceous grasses that trouble the eastern farmer—the barn-yard grass, crab grass, feather grass, and the several Paspalums—not one seems to gain a permanent foothold in the fight for existence. Only the purposely introduced *P. halepense* (Johnson grass) has in some sandy soils proved an almost ineradicable pest. The *Setaria glauca*, however, is a terrible pest in the irrigated Alfalfa fields of the foot-hills, as stated above.

Of the various Poas only the *P. annua* can be counted as at all troublesome. The pestilent *P. Eragrostis* (*Eragrostis vulgaris*) does not maintain itself where introduced; and of the wild grasses all those comprehended under the general name of bunch grasses (mostly species of Festuca and Poa) not one troubles the farmer save by the difficulty with which the turned-up root-stocks decay under the arid climatic conditions.

The most widely troublesome grass is the native *Distichlis maritima* ("alkali grass"), which long maintains itself in "alkali" ground, particularly in the lighter soils, in which its long root-stocks penetrate to depths of several feet and propagate from any fragment of a few inches, especially in irrigated lands, resembling in this respect the Bermuda grass as known elsewhere. The latter, however, can, in California, do no more than hold its own where planted, except on the borders of ditches, for the reason that during the dry summer its runners are unable to cast root, thus preventing its spread.

The Eagle Fern, common on the northward slopes of the Coast ranges, maintains itself somewhat obstinately here, as it does in Oregon and Washington, but persistent cultivation for a few years overcomes it.

While the above enumeration seems, at first sight, to present the weed question as somewhat formidable in respect to the number of species concerned; yet, as matter of fact, "getting into the grass," that constant bugbear of the eastern farmer, confronts the California cultivator only in exceptional seasons; and with ordinary and intelligent care, adapted to the nature of the local weeds, he can usually rest from the weed war from June to November, or whenever the rains happen to set in. In the older-cultivated regions, in fact, the extirpation has frequently been so complete that, in the absence of the supply of vegetable matter usually furnished by plowing-in of weeds, the green manuring of the clean orchards and vineyards is being seriously taken in hand.

University of California. *E. W. Hilgard.*

Plant Notes.

Cypripedium reticulatum.

THIS very interesting plant, closely allied to the rare *C. Boissierianum*, although it has been in cultivation for many years, is seldom seen in flower. It has a remarkably robust habit of growth, although established plants have never yet attained such proportions as it reaches in its native home, deep in the interior of Peru, where its leaves often measure four feet in length, and the flower-scapes are three and four feet high. The flowers are large, and several are produced on a stem. They are of a pleasing green shade, reticulated with darker veins, and the finely fringed petals stand boldly out and measure five inches in length.

Mr. Hicks Arnold is the fortunate possessor of the plant figured on this page. It is growing in his collection in Eighty-fourth Street, in this city, in a moist and cool position. It has three growths; its leaves are two feet long, and it is thriving luxuriantly, although in a house containing a wide range of species, all of which seem to find their special requirements met, as they are in the best of health. *A. D.*

Cultural Department.

Sowing Seed.

THE last flowers of the Chrysanthemums are now hanging their heads. Even in a well-aired house weak necks are the rule with these plants so late in the year, and, naturally, this detracts much from their value, though the last of the blooms will come in well for bold Christmas decorations. The first of the early forced bulbs are now coming on, and the greenhouse is daily becoming more attractive. But I never thoroughly enjoy the greenhouse until the winter sets in in earnest and the seed-pans are brought out and filled; for propagation from seeds seems to me one of the most pleasurable parts of gardening. There is always the gentle excitement of securing seeds of promising plants, the studying of their possible peculiarities, the uncertainty of a good catch, and, this secured, the watching of the growth during the various stages to the mature plant, which is not always the most satisfactory part of the process.

From some observation I am inclined to believe that the successful grower from seed is born, not made. I have known a professional gardener to fail utterly with Beans, and I have known others for whom hardly a seed refused to germinate. Of course, the one did not think, but planted his seed in cold

Fig. 96.—Cypripedium reticulatum. The Flower.

earth, and gave them a good supply of water, and his imitators may be observed in many gardens in the early spring. The successful growers give their various seeds intelligent study, planting each in well-prepared earth, under proper conditions of warmth and moisture. While my friends appreciate my products, and do not decline to carry them away, they look askance at my seed-pans, which, from my point of view, is rather puzzling. Of course they all try a lot of seeds every spring, and usually imitate nature by sowing generously and reaping niggardly. The watering-pot generally does the business. Where there are no greenhouse facilities, altogether the best plan for the ordinary run of garden-seeds is to plant them in a frame in a warm corner, say, about the 15th of April in this latitude. Such a frame need be only four boards nailed together and covered with coarse sheeting, which, if oiled and inclined, so much the better. All but the most tender seeds will quickly germinate here, and need very little attention except a slight care in airing, and the annuals will be mostly ready to set out in the open as soon as the ground is warm. Any one who has had sowings in various places in the garden, each one of which must be protected from cats and hens, to say nothing of watching that they are kept properly moist, will appreciate a frame where they can be observed with a single glance. Of course, Poppies and such hardy annuals are better sown during the winter, mixing them with earth and scattering them over their destined beds.

There are many seeds of hardy plants which seem to do better under rather rough conditions, and seem to need frost or melting snow to start their germination. For seven or eight years I have had under observation the seeds of *Scilla Sibirica*, which are usually the first things to start in the garden under certain conditions. I have found that seedlings of these are never so abundant and so early as in those years when the trickle from melting snow reaches them. One year those in the border under these conditions germinated three months earlier than those in a cold frame, not quite free from frost but free from melting snow. While many seeds of hardy perennials will germinate as readily as those of annuals, it is not so as a rule, and the cold treatment (in a well-drained place, of course) will be found more frequently the successful one. For such seeds growers frequently expose the pans to snow and frost, and then bring them into a moderate temperature to sprout. But many of these seeds are so slow and irregular in their germination that in ordinary cases it is as well to leave them in the borders.

For pans of slow-germinating seeds I have had success in using burnt earth, which will stand for months without becoming mossy. This is prepared from clayey soil by heating to a red heat. These slow seeds not only weary all but the devoted gardener, but also the seedsman ; and it is slight wonder that they are kept in stock by few dealers. The demand is small, and they would be the source of endless complaints from disappointed growers. The seedsman may have his special sins, but I do not find that selling bad seeds is usually one of them. Not only do they find it profitable to furnish the best seed, but the majority of these have longer vitality than is usually supposed. A large proportion of them will be good the second year at least, and many longer. But there are enough which start too slowly for careless planters—a few hardy perennials which need special care—and of these seedsmen are naturally cautious. Seeds of some plants will preserve their vitality for one, two, three or more years, and then all go off, while of other plants one could tell the age of the seed by counting the diminishing percentages in the seed-bed.

Elizabeth, N. J. *J. N. Gerard.*

Rose Notes.

At this time of the year many growers are tempted to give some extra heat in the Rose-houses in order to secure a larger number of flowers for the holiday season. In most cases, however, they regret such action afterward, because the plants so treated lose much vitality by the operation, and consequently fail to respond later in the season when another crop is expected. Preparation for the holidays is best made several weeks beforehand, so that a crop may be brought on in regular order without injurious forcing.

Careful handling in the matter of temperature is also fully half the battle in forcing Hybrid Perpetuals, for too much heat will give either blind wood or else miserable, deformed buds, while the splendid foliage and flowers produced by many of the market-growers are secured by a careful system of gradual forcing applied to strong, well-rested plants. During mild weather some ventilation will be needed, bearing in mind the fact that the sun's rays are less powerful now than they will be a month later, and therefore but little ventilation will be required to keep the temperature within bounds. Of course, direct draughts should always be avoided. Applications of liquid-manure should be made with caution at this time, too, especially to young plants of the present year's planting, though two-year-old plants in benches and Hybrids in pots will require some such stimulant from time to time.

Cuttings of Tea Roses may be put in at any time during the winter and spring, but, if started now, good stocky plants will be secured for next summer's planting. Only a moderate degree of bottom-heat is needed for Rose-cuttings, and firm young wood, from which a flower has recently been cut, is the best material.

The new Tea, Waban, will doubtless prove a valuable Rose, and certainly it is a beautiful one when well grown, though during the present season it does not seem to strike the popular fancy in some of the larger flower-markets of the country. Fashion seems to favor light pink or rose-pink shades in flowers rather than dark or reddish pink. Of its free-blooming qualities there seems no doubt, but the growth this year is weaker and the flowers smaller than those of its parent, Catherine Mermet. It is quite possible, however, that this condition is due to over-propagation, and that its vigor may be regained after one or two seasons' growth. At present, plants of Waban can, in most instances, be distinguished from those of Catherine Mermet, where the two are planted side by side, by its smaller leaves and thinner wood, but it is very probable that these characteristics may disappear, for some of the flowers of Waban exhibited by its introducer last season were as large as the best flowers of its parent.

A tendency to sport has been developed in Madame Hoste in at least one locality, the sport having been in the form of a fine yellow flower, so deep and distinct from the parent as to match well-colored Perle des Jardins at a little distance. This sport was propagated and tested this season, but I was recently informed by the grower that it proved a failure as a novelty, the young plants apparently having reverted to the original variety.

Souvenir d'un Ami is a handsome old Rose when well grown, though comparatively little used of late years since the larger pink Roses have been more fashionable, but a bench of this variety a hundred feet long and a perfect mass of dark green foliage and long, pointed buds, such as I saw recently, was enough to delight any Rose-grower. The soil in which these plants were growing was light and sandy, and it is quite likely that this had something to do with their unusual vigor.

Holmesburg, Pa. *W. H. Taplin.*

Better Begonias Wanted.

The most enthusiastic admirers of this new race of plants have not gone beyond the truth in praising the brilliancy of these flowers ; a crimson, orange, yellow or white Begonia blossom, four or five inches in diameter, is certainly a remarkable production, when we consider from what it has been developed.

Yet I confess that they seem, to me, to leave much to be desired. I have grown, or seen, the best obtainable varieties sent out by Laing and others, and neither in the untried seedlings sold at a low price by the hundred, nor in the selected kinds which cost half a guinea each, do I find the admirable qualities possessed by the original species. The greater size of the flowers of most of the hybrids is not a merit sufficient to outweigh the entire want of grace which nearly all of these plants display, and their almost total lack of distinctness of habit is a grievous blemish.

Begonia Boliviensis was one of the first species introduced ; its flowers consist of long, lanceolate segments and hang downward. No committee would now give it an award of merit, or even tolerate it upon an exhibition table, but as I saw it last August, growing in a partial shade, bearing abundant foliage as well as abundant blossoms, I thought it much more attractive than a number of hybrids of good quality growing near it.

No tuberous Begonia has finer foliage than *B. Pearcei*, whose leaves of bright green, veined with a much darker shade, have the soft appearance of velvet, and, with the numerous bright yellow flowers, make a plant of great beauty. *B. geranioides* is a species unlike any other, with its tall flower-stems, carrying a mass of snow-white blossoms with yellow stamens, arising from the fresh, green foliage. It comes into bloom later than many varieties and retains its beauty several weeks.

No species can exceed *B. Davisi* in brightness. Excellent for pot-culture or for the open ground, it forms a low, dense tuft of leaves, surmounted nearly all summer by its scarlet

Fig. 97.—A Hemlock Grove in Winter.—See page 601.

flowers. A variety of this has flowers of a shade whose richness is not outshone by the Cardinal-flower. *B. discolor*, or *Evansiana*, has a beauty distinct from all others. Though it endures the sun very well, it is most attractive in the shade, where its large red-veined leaves assume a deep blue-green, and its panicles of pink flowers retain their beauty a long time. *B. octopetala*, on the contrary, does better in the sun. Its underground portion is different from what we find in other species, being a stout, creeping rhizome, which, in the course of a summer, will advance several inches, sending up leaves and flower-stalks throughout the season. This is a giant among Begonias, for its light green, circular leaves are sometimes a foot across—a yard around—and its flower-stalks, rising to the height of thirty inches, bear numerous white, round flowers, the first of which to open are three inches in diameter. This is the only species which ought to be planted before it shows signs of growth. M. Lemoine has hybridized this species with some bright-colored variety, but I have not seen the progeny.

Different from any of these is *B. martiana gracilis*. Its exceedingly numerous flowers are bright rose out-of-doors, pink under glass. If the tip be pinched out when the plant is six inches high, the side branches will be numerous, all stiffly upright, like those of a Lombardy Poplar. *B. Sutherlandii* is a very pretty species, especially if grown in a shady spot. It branches freely, forming a dense round bush, abundantly furnished with leaves of very elegant shape, and with buff or salmon flowers. It appears identical with *B. Natalensis*. *B. Dregii* (syn. *Caffra*) is also a plant of thick bushy form, but with fewer branches than the last mentioned, and with white clustered flowers. These two are useful for cutting, an unusual virtue in the tuberous group.

I have given a brief account of nine species, my design being to show that there is no need of confining ourselves to one form, and that a very ungraceful and awkward one, of tuberous Begonia. There is no reason why each of these types should not be developed (if development be desirable) without losing its distinct character. Begonias might thus be made worthy of a much wider admiration than they now excite.

Canton, Mass. *W. E. Endicott.*

Gall-worms Injuring the Roses.

COMPLAINTS have come to the Experiment Station of a shortness in the hot-house Rose-crop, and a recent visit to Madison, New Jersey, where Roses are grown in quantities for market, convinced me that the trouble was largely due to microscopic worms in the roots of the plants. The affected Rose-plants have a stunted, sickly appearance; they fail to send up strong shoots, and only develop short stems bearing pale leaves. The roots of such victims are much swollen in places, and these knots contain multitudes of minute worms akin to those sometimes found in vinegar, and called eel-worms. Such plants fail, of course, to produce good flowers, and are worse than worthless.

Like all root-pests, these eel-worms are difficult to reach with any remedy, and therefore preventive measures are the only ones that are promising. The worms flourish in a rich soil, and pass from the soil into the plant, and from one plant to another through the soil. It is, therefore, of great importance to have the soil used for potting plants or for the greenhouse-bed free from the worms, and, of course, none but clean plants should be used. The worms are easily killed by heat and cold, and therefore if the soil could be raised to a high temperature, the trouble would vanish. In like manner, soil that is frozen during the winter is less liable to contain the enemy than that which has been protected from the frost. In selecting soil it should, if possible, be that in which no garden-plants have been grown. The greatest trouble with the Rose-plant soil is probably the manure that is used in great abundance by the growers. It is likely that this manure is infested with the worms.

The experiment of raising Roses in a soil where stable-manure is replaced by a judicious mixture of commercial fertilizers is well worth trying. It has been shown, for example, during the present season, that Sweet-potatoes can be grown to great profit without the city manure, that has been the standard source of plant-food among truck-farmers. Also it has been demonstrated that Potatoes thus grown are less liable to the attacks of the various rots and decays so prevalent in many Sweet-potato localities. If the right mechanical consistency for the Roses can be obtained in connection with the commercial fertilizers, it is quite evident that the soil would be under better control and less liable to various infections.

Lime has been found inimical to the eel-worms, and therefore this substance may assist in keeping the plants healthy. The lime may be applied to the surface of the soil and carried down to the roots by the water that is daily applied. With Violets, which are much subject to the root-galls, it has been found that broken mortar, mixed with the soil, has been advantageous. Many of the substances that would be fatal to the worms also injure the tender roots of the Roses and cannot be used.

Those who have Rose-plants now dying from the worms should remove them all at once and burn them. The soil, of course, must be changed before another set of plants is grown, and the greatest care should be taken to reject every plant with root-galls, however small, when the beds are set. With these precautions and the use of lime, about all is done that is practicable, except, possibly, the use of commercial fertilizers in place of manure, but this practice needs to be proved profitable by actual trial among the Rose-growers. The fact that we have had warmer winters than usual during the past three years may have something to do with the overstock of eel-worms in the soil. A good freezing season may help to rid our outdoor soil of them. They are the plague of the garden and orchard in warmer climates, but here are most pestiferous indoors.

Rutgers College. *Byron D. Halsted.*

Notes from the Harvard Botanic Garden.

ARALIA SIEBOLDII.—This fine old plant has long been a familiar object in greenhouses, and its bold aspect is not likely to be forgotten by those who have seen large masses of the plant in the gardens of the milder portions of England and Ireland. As an outdoor plant it is much too tender for this climate, though it would probably thrive in favored locations from Washington southward. It is seen at its best when grown outside, where it develops into a bush from five to six feet high, and as many through, amply supplied with palmate, leathery, deep green, glossy leaves twelve inches across, on stout petioles of a similar length. It bears in summer numerous large clusters of small creamy white blossoms. In this part of the country, however, *A. Sieboldii* is essentially a greenhouse-plant, and with abundant space and liberal treatment it develops into a highly decorative specimen under glass. Where greenhouse space is limited small young specimens are the most useful. These are usually raised from seeds sown in heat, or the young plants obtained by cuttings from the half-ripened stems. Seedlings, however, make the most attractive specimens; but the seeds are not always easy to obtain. When grown to a single stem from one to three feet in height and furnished to the ground, few pot-plants of such simple requirements are more elegant. Repotting is not a frequent necessity, unless it is desirable to increase the size of a specimen. Pot-bound plants are easily kept healthy by the occasional use of weak liquid-manure, but the soil should never become soddened nor thoroughly dry. *A. Sieboldii* is an admirable plant for the dwelling-house, the thick texture and close surface of the leaves enabling them to withstand the dry air of such situations. Such plants derive fresh strength from out-of-door exposure during the summer. *A. Sieboldii* is a native of Japan, and was first introduced to Europe in 1858. It is most generally known under the name given here or *A. Japonica*, but the botanists now call it *Fatsia Japonica*, Fatsi being the Japanese name of the plant. There are two distinct varieties of the species: Variegata, with leaves bearing conspicuous blotches of white, and Aurea, which has a yellow variegation.

CLETHRA ARBOREA.—The Madeiran Clethra, or Lily-of-the-Valley-tree, ranks high among shrubs for the decoration of large conservatories. In lofty buildings dwarf plants can only be used as a fringe to the main groups of large specimens. Big, handsome plants, which need little garniture, are therefore a necessity in many gardens, and *C. arborea* is one that may be depended on for a good appearance. *C. arborea* was introduced to Kew in 1784 by Mr. Frederick Masson, and was formerly very popular in Europe. A half-dozen degrees of frost will not seriously inconvenience it, but the rigorous winters in this part of the country are much too severe for it. However, a well-lighted and airy house which excludes frost affords all necessary winter protection, and in summer a fully exposed position on the lawn will tend to ripen the new growth and produce abundant bloom. The pale green, oblong leaves of the plant are freely disposed around numerous branches, which terminate with large, slightly drooping, paniculate racemes of pure white fragrant blossoms. The inflorescence bears a striking resemblance to a spreading cluster of Lily-of-

the-Valley racemes; hence the popular name. Late summer or early autumn is the flowering season, but it may be retarded and prolonged for a considerable space of time by shading from sunshine. *C. arborea* does not flower freely unless the roots are well confined, and it can be induced to bloom when comparatively small by attention to this peculiarity. Of course, it must be supplied with food in the form of liquid-manure. The foliage soon loses its refreshing green if the soil about the roots is allowed to become dry, and it is the lovely contrast of perfect flowers and leaves which gives the plant its charm. Cuttings of firm young wood root easily in heat.

PHORMIUM TENAX.—This plant, well known as New Zealand Flax, deserves a place among fine-leaved greenhouse plants. It is without stem, and the straight leaves, bright green above and glaucous on the under side, from five to six feet long and two or three inches wide, appear in fascicles, radiating distichously from a common centre like the ribs of an extended fan. The branched scape, bearing insignificant yellow liliaceous flowers, is developed in summer, and exceeds the leaves in length by about two or three feet. The foliage, however, is the most attractive feature of the plant, and especially is this true of the variegated variety. In the latter broad stripes of yellow and white intermingle with the green of the leaves, giving the plant a very pleasing appearance against a dark background. There are several other forms of *P. tenax*, but the species and this variety are perhaps the best for general purposes. Both plants are very easily cultivated, and succeed well in any house from which frost is excluded in winter. In summer they thrive luxuriantly planted out in the garden, but they must be taken up early in autumn. The species makes the most vigorous growth in a rich sandy loam, but soil of a comparatively poor character should be used for the variety, by reason of its inclination to revert to the original green color. A cellar frost-proof and fairly light will answer for the storage of these plants in winter where there is no greenhouse. They are quite at home in porches and entrances at any season of the year, and when grown as house-plants they need no better position. I once knew two specimens which had been grown mainly in a hall-way for fifteen years. One was green, the other variegated, and they occupied twelve-inch pots, without a single change throughout all that time. They were placed outside in front of the house a few weeks in summer, during which time they received frequent doses of liquid manure and a top-dressing of fresh soil. The remainder of the year they spent in the hall at the bottom of a dark mahogany staircase, where they always looked well. No plant except, perhaps, *Aspidistra lurida*, will survive more ill-usage than *P. tenax*. The leaves are stiff, tough as leather, and therefore not easily injured, and they are unusually slow to resent neglect in watering. *P. tenax* was introduced to Ireland by a Mr. Underwood from New Zealand in 1798. It is very common in New Zealand, and its fibre is used by the natives in the manufacture notably of cordage. Considering the interest now taken in Ramie and other fibre-yielding plants by Americans, it is a matter of some surprise that *P. tenax* has not been tried more largely. The fibre appears to be easily separated. In 1822 a company was organized for the purpose of cultivating this plant in Ireland for its fibre, but the project had to be abandoned on account of the slow growth made by the plant under the climate of that country.

Cambridge, Mass. *M. Barker.*

Calanthes.—The season of these useful and brilliant Orchids has come around again, and we are more pleased with them than ever. The various tints of coloring of *C. Veitchii* contrast finely with the white varieties of *C. vestita*, *C. rubra* and *C. occulata*. A few plants set in between good specimens of *Adiantum Farleyense* in the warm greenhouse have an excellent effect. They take the eye at once, and give the house a bright appearance while they last, which few other plants can surpass. For cut flowers these Orchids are among the best. Not many spikes of *C. Veitchii*, with fifty flowers and buds on each, with Asparagus plumosus, say, for green, are needed to make a centre-piece for a dinner-table that ought to please the most fastidious. Florists ought to find profit in growing Calanthes; they increase rapidly, are no more trouble than Roses; they come into flower mostly after Chrysanthemums have faded and gone, and would be valuable for the holiday trade. They require an even temperature when in growth of not less than sixty-five degrees at night and ten to fifteen degrees higher in the daytime. They grow best in a fibrous loam, with a little thoroughly decayed cow-manure and a sprinkle of sand to keep the mass porous. The pots should be half-filled with potsherds, for thorough drainage is essential. The plants will bear feeding with liquid-manure after the fleshy roots have penetrated all through the compost and the young bulbs begin to form. They must be shaded from bright sun, and the long flower-stems carefully kept down from the glass.

A hundred plants in bloom at once, with fifty flowers and buds on many of the stems, present a beautiful appearance, and such a display can be seen now in the conservatories of Mrs. J. W. Lasell in this town.

Whitinsville, Mass. *W. S.*

The Forest.

The Subjection of Torrents by Reforestation of Mountains.—III.

CORRECTIVE WORKS.

THESE may be considered as barriers, drains and rectifications of the bed.

The barriers, whether of dry masonry or of hydraulic mortar, of timber or of living wicker-work, all have, as an object, the enlargement of the section in such a manner as to ultimately permit the establishment of a fixed and definite bed, preventing all erosion, and giving a solid support to banks otherwise unstable. Their deposits may be used to build up the old bed, by forming a series of stairs across the channel, and thus reducing as much as possible the great first cost of dams. These secondary works, judiciously employed, may even be retained among the greater works which it will be necessary to maintain continually, and thus reduce the number of the latter. The dams of the first class, besides this principal function, have the effect (1) of breaking by the falls they produce the rapidity of the water-flow, and preventing a sudden concentration in the main channel or in the river to which the torrent is tributary, and (2) of holding back above them the coarse material which formerly was carried into the valley below.

In addition to important works of the first class constructed in the principal bed of a torrent, there are placed in all its branches a series of rough barriers of rip-rap, so that the whole upper basin is under control before a specific correction of the channel is undertaken below. The value of this method, both as regards economy and safety, has been sanctioned by nearly twenty years' experience.

The number of important works of the first order, their forms and their dimensions depend upon the special character of the torrent under consideration, and it sometimes happens that the most powerful torrents require fewer great engineering works than certain others of an inferior development.

So far as the rough barriers are concerned, experience has shown that in many cases they may be widely spaced, especially in those places where the deposits are of rocky material. In certain ravines the deposits have a slope of twenty-five to the hundred, now held in place by vegetation. The little wicker-work dams in the small ravines can only be employed where the slope is less than one to five. Covering the bed of the channel with branches, or even with trees, piled two or three meters thick, with the tops up-stream, has been substituted where the slope is steeper. This system, in use about eight years, has quickly furnished most valuable results in the immediate correction of gullies.

Drainage, cautiously tried at first, has assumed a great development during the past ten years, since its effects have proved so striking in some torrents. These drains are superficial and much ramified. They were first tried with the object of giving the waters from melting snows or torrential rains a rapid and immediate flow toward mains on the line of the greatest slope, but they proved of greater and more permanent value than their projectors had dreamed. The earth, formerly unstable, wherever a corrected bed had first made the base firm, was found quickly safe from saturation, and the forestation of the bank or of the slope could at once be proceeded with. Conclusive experiments have been made during the past few years over an area of about 5,000 acres, which are to-day dry and solid.

The practice of rectifying the beds of torrents after a preliminary treatment has been largely developed, especially where the transverse profile of the torrent presented a suitable width and the longitudinal profile a pitch not exceeding twelve or fifteen to one hundred. The treatment consists of ranging at the foot of the banks rocks which will ward off the current and thus form a good defense for the shore. The new bed once outlined thus, is fixed by means of rude walls of large blocks, tending to guide the waters in the desired direction and checking all erosion, whether lateral or longitudinal. This very economical method requires continued attention for a

number of years, for which a force of well-trained men is needed.

The extinction of a torrent once accomplished, the complete reforestation of the treacherous basin will have the result of transforming this once-destructive agent into a beneficial mountain brook. After this it will be possible to decide upon the works which it may be necessary to retain and keep in order. For the rest it will suffice to open a free passage for the water through their centre, and to take up the differences of level by a series of small rough sills extending across the new bed, while the alluvium will soon be covered and fixed by a vigorous forest-vegetation. In this way the torrents are reconstructed into clear and harmless mountain streams.

I shall now cite some examples of forests treated by the adopted method.

THE TORRENT OF BOURGET.

This torrent empties into the Ubaye just above Barcelonette. The crests of the mountain from which it flows rise to an altitude varying from 2,900 to 3,000 meters, while its foot has an altitude of only 1,200 meters. The first operations began in 1870 with the reforestation of all the stable lands of the basin by sowing and planting *Pinus Cembra* in the higher region—that is, above 2,400 meters of altitude; *Larix Europea* and *Pinus montana* in the middle region, between 1,700 and 2,400 meters, and finally of *P. Sylvestris* in the lower region, between 1,400 and 1,700 meters. Woody vegetation has now taken possession of all the basins formerly denuded, and the young forest which has been absolutely created is increasing from year to year.

The unstable lands have been fixed by a series of corrective operations begun in 1872. The source of the torrent is at an altitude of 2,936 meters, and the profile of its bed is divided into three well-marked sections. The upper section, the catch-basin of the torrent, is 2,100 meters long, with an average pitch of 54 to 100. In this section the rock is hard, and the banks relatively stable. The middle section, constituting the drainage channel, flows exclusively through Jurassic marls, where the torrent erodes at will, and causes most disastrous washes by undermining banks and starting land-slides from the principal slopes. The length of this section is 1,764 meters, and it has an average pitch of 26 to 100. The third section, formed by the cone of detritus, has a length of 1,283 meters. It is more nearly level, and has an average pitch of 9 to 100.

The principal works of correction have been confined to the second section. Altogether they required the construction of twenty dams of masonry varying from 3 to 8 meters high. The subjection of the Bourget has been assured for more than nine years by a young forest of 988 acres, which occupies the upper basin. This result has been attained in fourteen years.

Botanical Exhibition of the Appalachian Club.

To the Editor of Garden and Forest:

Sir,—The Appalachian Mountain Club has just held in its rooms in Boston an exhibition of plants prepared as herbarium specimens. As such exhibitions are none too common, a short notice of it may be of general interest.

The specimens were all mounted, with the exception of a few cryptogams—Lichens and the like. As many as possible were displayed on the wall, but a great number had to remain in genus covers, owing to the unfortunate lack of available wall space. This insufficient space necessitated covering the walls almost from floor to ceiling in order to make even a partial display of the collection, and therefore fully one-third of the plants shown were so hopelessly "skied" that it was impossible to examine them except with an opera-glass. A botanical specimen is not like a picture, where distance often lends enchantment to the view. It needs to be examined closely, if at all.

Of three rooms occupied, one was devoted to a large collection of Ferns from various parts of the world; another was filled with a collection of plants from California, supplemented by a set of colored outline drawings, an excellent adjunct to an exhibition of this nature. In the third room was shown a miscellaneous collection of flowering plants, Mosses, Lichens, Hepaticæ and Algæ. Altogether, there was enough material to occupy for some time the attention of any one interested in botanical subjects, and many visitors availed themselves of the privilege here offered.

It may seem ungracious to be critical in regard to such an informal exhibition, and yet it may be of service to point out a few defects. Much pleasure and instruction can be gained from such exhibitions, while, as object-lessons, their value is beyond question. But, of course, the work must be carefully planned and carried out if these desirable results are fully achieved.

In this case the whole exhibition displayed a lack of system. Some attempt had been made to arrange the plants in different genera, especially among the Ferns. The whole result, however, gave the impression that a number of people had been working each on a different plan. The genera appeared and disappeared in a most provoking manner, and many an important genus seemed wholly unrepresented, unless, perhaps, in the regions near the ceiling or somewhere in the genus covers. Mixed with the general collection, but without any general plan, appeared several special collections that it was desired to keep together, and altogether it was difficult for an observer to find any special plant without assistance.

It may well be questioned whether a local exhibition of this kind should not give a local collection the place of prominence, and admit other plants only in the form of special collections, as seems to have been actually done in the case of the California plants. Visitors are likely to be more interested in the plants of their own part of the country than in stray specimens and insufficient collections from here, there and everywhere. A good general collection is much beyond the scope and attainment of any small exhibition of plants, and a poor one serves more to gratify idle curiosity than to give instruction. It would, therefore, seem better to have some definite purpose to accomplish, such as showing the flora of a special region, or special plants for some marked object. From this point of view, the exhibit of our poisonous species of Rhus (under glass), together with some of the plants most resembling them, was most commendable. The wonder is that some one did not also make a special exhibit of our plants poisonous to the taste.

Unfortunately, it must be said that some determinations were open to suspicion, some were questioned, in many cases there were no names at all, in many more no specific name was given, and in a few cases the common English name of the plant seems to have been thought sufficient. Such errors could be avoided by providing for a careful inspection of all plants contributed under the supervision of some one of recognized botanical standing.

Again, there was too much disregard of ordinary care in preparing and mounting the specimens. Many of the labels lacked neatness; different varieties of a plant were mounted upon the same sheet, and in some cases not only two or three different plants were mounted together, but a whole flower-garden with not even a label to guide the observer through its mazes.

In spite of these manifest short-comings every visitor must have been impressed with the great promise that this venture gives, and must have felt grateful for the perseverance shown by the club in its first attempt. The more undertakings of this kind we have the better. If properly conducted, they can do great good by arousing a healthful and practical interest in our native flora. May this exhibition, therefore, be but the beginning of many in the years to come.

The Acorn Crop near Chicago.

To the Editor of Garden and Forest:

Sir,—In the issue of Garden and Forest for October 21st information is requested about the acorn crop in different parts of the country. Having been closely studying the Oaks of this vicinity for some time, the fruit has received a good deal of attention on account of its importance in the determination of species. Hence any great change in its amount, and particularly any failure, would have been observed. But no failure has been noticed, though in the case of the Bur Oak, which is more immediately concerned, it has seemed less productive than usual the past season. Besides this, the forests are supplied with the White Oak, Swamp White Oak, Red Oak, Black Oak, Scarlet Oak, Yellow Chestnut Oak, Shingle Oak and a hybrid of the last with the Black, or Scarlet Oak, much like *Quercus Leana*. These are all of whose presence I am certain, or familiar with in this region. All have been carefully studied, and, with the exception of the last two species and the hybrid, are abundant or common, though the Red Oak and Swamp White Oak are more restricted in their habitat than the other common kinds, and not so generally met with. On all biennial-fruited Oaks the acorns were very abundant last fall, as they are nearly every year. The annual-fruited kinds have seemed to me more changeable and uncertain in

their crop, though I recall no complete failure in any of the common species.

A year ago a group of the Yellow Chestnut Oak (*Q. Muehlenbergii*) practically failed. The trees are small and occupy a limited area. Some of the leaves having been found to bear a strong resemblance to those of *Q. Prinus*, the acorns seemed necessary in order to be certain of the species, and very diligent search on every tree revealed but three or four, just enough to determine the point. The past season plenty of acorns were seen on several of the same trees, as was the case with some in another locality where I had not met with them before.

On some of the Scarlet Oaks the acorns have been exceptionally abundant. Small trees, developing from stool shoots ten to twenty feet high and standing in open places, were so covered with fruit as to suggest a different kind, and were doubtfully identified at first. The acorns were borne in bunches, being massed upon the crowded twigs and near the ends of the branches, and the specimens were sufficiently exceptional to merit a place in my herbarium with the descriptive note made at the time, "Remarkable for the number of their acorns." Small trees of their habit are very handsome, from their compact rounded top, glossy leaves deeply divided into narrow lobes, and fruit grouped in bunches.

Another fact relating to the acorn crop here deserves a passing notice. It is the large percentage injured or destroyed by the Nut-weevil. Fully fifty per cent. were tenanted by the grub or had been abandoned after the meat was eaten out. Having traversed a good many miles of Oak forest, more particularly to find out what might be reliable characteristics of *Q. tinctoria* and *Q. coccinea*, for their forms must either cross or blend imperceptibly, acorns were everywhere taken in hand and examined in various ways, so that the destruction was seen to be very general. The case was even worse with the Shingle Oak and the hybrid, fully three-fourths of the latter, gathered for planting, having to be rejected. Other kinds were not examined so carefully or extensively, but as far as they were observed they were very badly affected, the Red Oak, of the biennial-fruited species, evidently being the least injured. It shows what havoc the Nut-weevil could work with the profits of an acorn crop, if it should be taken as an economical product, as it may be where mast forms an article of food for domestic animals.

Englewood, Chicago, Ill. *E. J. Hill.*

Uncommon Varieties of Apples.

To the Editor of GARDEN AND FOREST:

Sir,—Some time ago one of your correspondents asked why farmers and orchardists insisted upon planting so few kinds of Apples to the neglect of other and, in some cases, better varieties, and urged planters of new orchards to get out of the old ruts and introduce a little new blood. Well, the trouble is not wholly with planters. As a matter of fact, it is extremely difficult to get trees of any except the old and approved sorts, for which, perforce, there is a steady demand, since a farmer must either take these or nothing.

For example, this fall I wanted to set out a little orchard of winter Apples, and, bearing in mind your correspondent's suggestion, I searched the "Fruit Garden" and the "American Fruit Culturist," the best authorities I know on the subject, for new kinds. One of those selected was Cogswell, a Connecticut fruit, which seemed exactly what I wanted. Then began a hunt through the catalogues, which I procured from half a dozen of the largest nurseries in the country. But not one of them sold Cogswell. Another Apple I wanted was Winesap, but one of the largest nurseries in western New York could only undertake to supply twenty-five trees. Bailey's Sweet was another kind which they could not furnish at all, although it was included in their catalogue. I have had the same experience with other varieties, and one evident reason, therefore, why we planters don't go outside of the old lists when selecting trees is, that the nurserymen have no other kinds to offer.

Another Apple I would like to try, principally for its color, is Arkansas Black, which is very highly commended in a recent report of the Agricultural Bureau; but I can find no trace of it in the catalogues at hand. The same is true of Princess Louise, which has been highly spoken of as a substitute for the Snow Apple.

By the way, can any of your readers state anything definite about the new Apple, Palouse?

Recent Publications.

Sharp Eyes: A Rambler's Calendar of Fifty-two Weeks among Insects, Birds and Flowers. By William Hamilton Gibson; Illustrated by the Author. New York: Harper & Brothers, 1892.

The quotation with which Mr. Gibson prefaces his book says: "In good soothe ye are all blinde except thy minde and eie do see in harmonie. . . . Verily, there be those who see not though they doe looke, who, having eies of great bowinge, yet walk abroad in staringe blindness." In the introductory chapter we find another quotation,

> We're made so that we love
> First, when we see them painted, things we have passed
> Perhaps a hundred times, nor cared to see,

and by these two borrowed statements the purpose and character of Mr. Gibson's volume are well explained. He has tried to put what his own sharp eyes have seen before his readers, rightly believing that in this way their own will be sharpened to their lasting future delight and improvement. The many little chapters which the book includes—one for each week throughout the year—were written, he explains, in reply to letters received during ten years or more, chiefly from young students of natural history who had been interested by his previously published works; and they were first printed in the pages of a young people's journal. Nevertheless, the book is not for young people only. It is for all those who are still young in knowledge of the world of nature, and it will be pleasant reading even for students of a more serious sort than Mr. Gibson professes himself to be. Following his pretty and suggestive calendar from year's end to end, even the practiced, sharp-eyed naturalist may find some facts that are new to him, or have been observed in a novel way; and if this is not the case, even so he may find pleasure in living a while outdoors at second-hand when corporeally cooped up in a city's streets.

A good deal of gentle sentiment is mingled with Mr. Gibson's recording of minute, evanescent or more obvious phenomena; but this, of course, increases the value of his book to beginners in the gentle art of attentive sauntering. The best results of a developed keenness of sight are a developed intelligence and a developed heart; and, showing how the sights of the outdoor world led him to pretty, tender, fanciful and sometimes poetic thoughts, Mr. Gibson will help to awaken a similar capacity in his readers. Natural history, in the true sense of the term, cannot, of course, be learned from such a book; but it should inspire one with a desire to learn something at least about some one branch of it, and even if this does not result, it cannot but increase the reader's sharpness of vision and consequently his daily pleasure in existence. Mr. Gibson has been wise in recognizing this as the character of the service which could be rendered with a scheme such as he adopted; he has been wise in not trying to cram his pleasant talks with scientific terms, or to dwell upon such interesting and beautiful sights as can be discovered only by a closeness of sustained observation amounting to strenuous study. He shows us such things as we all may see any day in the woods and fields, if we use, in a simple, natural and easy way, the eyes that nature has given us. Yet he has been equally wise in giving the scientific names of the plants and living creatures he mentions. The insertion of these names will not bother the most careless reader, while they will greatly help the reader who may desire to follow a subject further. For, it is hardly needful to explain, common names vary so much in different parts of the country that it is often hard to identify a plant by their aid alone.

"Sharp Eyes" is a large octavo, beautifully printed, prettily bound, and profusely illustrated with photogravure reproductions of wash-drawings in Mr. Gibson's well-known, graceful, delicate and charming if not very vigorous manner. It is a very attractive volume for a holiday gift; but it surpasses most books of this sort by having genuine value as a volume to read. Perhaps it will not often be read through from end to end. More likely it will be taken up now and again for the sake of two or three of its little chapters. But this merely means that the pleasure it gives will be more prolonged, and that its influence in sharpening the mind as well as the eyes will be all the greater for frequent renewal. In the city it will be a charming reminder of the country, and in the country a charming incentive to outdoor enjoyment.

Notes.

In the Philippine Islands, canary seed obtained from *Phalaris Canariensis* is ground and made into a most palatable bread, which is in common use among the people there.

A Cocoa-nut tree that weighs six tons is to be transported, it is said, from Honolulu to a public park in San Francisco.

In Ferguson's "Information Regarding Ceylon," it is stated that one of the Palms of the island, the so-called Palmyra Palm, can be used for five hundred different purposes.

A remarkable Orchid, says the *Revue Horticole*, could recently be seen at the château of M. Pauwells, at Bosterlaer. It was a plant of *Oncidium divaricatum* bearing a flower-stem ten feet in length and no less than 784 flowers.

The bark which annually scales off the thousands of Plane-trees in Paris is carefully collected and sold, at one franc for seventy-five pounds, to the manufacturers of colors and chemical products. When boiled, it also furnishes a very astringent decoction, which is useful in compresses on wounds, burns and chilblains, and even on the bites of venomous animals.

At his recent visit to Philadelphia, Mr. John Thorpe secured for the Columbian Exhibition the promise of some large specimen Palms from the collection of Mr. G. W. Childs, and also some rare specimen plants from Mrs. Baldwin. Some of the large Ferns and Palms in the park conservatory, which were placed there during the Centennial Exhibition, will also be forwarded to Chicago.

A late number of the *Gardeners' Chronicle* contains a full account of the Orchids to be found in the British branch of the United States Nurseries at Hextable, Swanley, Kent. The Cypripediums are accorded the place of honor, which they also hold in the collection of Messrs. Pitcher & Manda at Short Hills. A Chrysanthemum-house, one hundred feet long, was reported as making a gorgeous show, and the white Carnation, Lizzie McGowan, came in for special commendation.

The Linnean Club, of whose good work in securing a park for the town of Jamaica, Long Island, we have already spoken, has arranged for a course of six illustrated lectures on plants and vegetable life, to be given by Dr. Morong, of Columbia College, under the University extension plan. The lectures will begin in January, and they will be followed in the spring by lectures on some branch of practical horticulture. These lectures are open to the public at a nominal price, and it is hoped that they will stimulate the growth of a public sentiment favorable to the objects which the club was organized to promote.

We have received several letters from growers of Carnations in various parts of the country in relation to the rust which was referred to in our last number by Professor Halsted. In some cases sulphate of copper has been used with good results, but in other cases, where, perhaps, the solution was too strong, it ruined the plants. There seems to be a great difference in varieties as to susceptibility to the fungus. On some varieties the fungus has not yet appeared at all, although they are growing by the side of infected plants. In one letter the varieties Annie Webb and Florence are spoken as nearly rust-proof. It would be interesting to have a list of the varieties which seem to be the least easily affected. We hope to publish in an early issue some further particulars in regard to this disease.

"Few of our native trees," says a writer in *Meehan's Monthly*, "have odoriferous wood like the sandal-wood of the islands in the Pacific Ocean; but a few of the coniferæ of the Pacific Slope have sweet-scented woods. The fine church at Metlakatla, built by the civilized Indians of Alaska, is as fragrant as if incense were continually floating through the air, from the wood of the great Arbor-vitæ (*Thuja gigantea*), of which it is built. *Libocedrus decurrens*, found further south, is known as 'Incense Cedar,' from its fragrance. The Yellow Cypress (*Cupressus Nukœensis*) and the Monterey Cypress (*C. macrocarpa*) have also scented wood."

Writing of the great Banyan-tree in the Botanical Gardens at Calcutta, Bishop Hurst says, in his "Indika," that the central trunk is fifty-one feet in girth, and that many of the one hundred and seventy smaller trunks have reached considerable size. "The process of cultivating the tendency of the Banyan to multiply itself," he adds, "is highly interesting. A slender root-like shoot is thrown out from the lower side of one of the branches and grows rapidly downward. Its lower end terminates in a small tuft of delicate rootlets, ready to strike into the ground as soon as they reach it, but, at the same time, presenting a tempting morsel to any goat which may pass beneath the tree. For the double purpose of protecting from the goats the slender stem which is to develop into a large trunk in a few years, and also of encouraging its growth, it is encased in hollow bamboo and fastened to the ground. It very quickly finds its way down the dark little cavity in the bamboo, and when once it becomes rooted in the earth its career is fairly begun, and it becomes the one hundred and seventy-first trunk in the vast system called the Banyan-tree."

The tenth annual meeting of the American Forestry Association, to be held at Washington on the 29th and 30th of this month, promises to be one of especial interest. Papers will be read by Mr. B. E. Fernow, Chief of the Forestry Department; President Adams, of Cornell University; Gifford Pinchot, of New York, and J. D. W. French, of Massachusetts. There will be a special meeting in the afternoon of the first day, in which the Executive Committee on the Establishment of National Reservations will report, and the Secretary of the Interior and the Commissioner of the General Land Office will be present and take part in the discussion. The meeting also will be attended by Senators and Representatives who have expressed an interest in the matter. President Harrison has assured the friends of forestry that he will give the broadest construction to the law which authorizes him to set apart these reservations, but it is well known that the mere act of reservation will accomplish but little unless it can be followed by the establishment of some rational administration of the territory. It is therefore proposed to memorialize the President and recommend further reservations, and also to recommend further legislation for their future management.

"If we were to make a suggestion independent of the architectural merit of the various buildings," said a recent editorial note in the *American Architect and Building News*, referring to the constructions proposed for the World's Fair at Chicago, "it would be that the Horticultural Hall . . . would probably be the most useful of all as a permanent structure. Even now, all our large cities contain enthusiastic horticultural societies which hold frequent exhibitions in the largest halls they can hire, and find their exhibitions crowded with people." The great success of the recent Chrysanthemum show at the Madison Square was then described, and the writer continued: "In fact, all over the country, Rose shows, Chrysanthemum shows, fruit shows, Orchid shows, winter flower shows, summer flower shows, spring bulb shows, Azalea shows and Rhododendron shows, and so on, follow each other in rapid succession, and the universal complaint made with regard to them is that no place can be found large enough to show all the good flowers that are offered, and accommodate, at the same time, the people who wish to see them. For Chicago, the Columbian Horticultural building would give exactly what is needed, and in exactly the right place, and it would add very little to the cost of the structure to make it permanent. It is to be remembered, also, that a building of this sort can be used for many other purposes besides exhibiting flowers."

Professor H. L. Bolley, of the North Dakota Experiment Station, has just issued an interesting bulletin on the Potato-scab, giving the details of experiments, which confirm his previous work and that of Professor Thaxter in Connecticut. There seems no longer room for doubt that the cause of the disease is a bacteroid fungus. It also appears that seed-tubers affected by this scab will produce a diseased crop, and that seed-tubers free from the diseased germs will produce a healthy product in any kind of soil, provided only that the soil itself is free from the germs. The germs of the disease can probably be killed without injuring the growth of the Potato, if the seed-tuber is treated with a solution of corrosive sublimate of the proper strength. But, after all, the disease-germs will remain in the ground, from crop to crop, for at least five years. Of course, it follows that when seed-tubers free from the disease are planted upon new ground the crop will be healthy, but this land will only remain free from disease so long as uncontaminated seed is planted there. Care also should be taken as to the kind of manure used, for the refuse from infested plants will certainly contaminate it, and implements which have been used in infested soil should also be thoroughly cleansed before they are used in the uncontaminated land. Professor Bolley has also discovered that Beet-roots have been attacked by a plant-parasite which is apparently identical with that which causes the scab of Potatoes. The affected Beets which were examined came to the station from various parts of the state, but in every instance, so far as could be ascertained, they had been planted on land where potatoes had been a previous crop. The disease on the Sugar Beets appears to be more extensive than it ever has been in the Potatoes. It seems also that the Swedish Turnip, Carrot and the roots of Cabbage are affected by the same disease. It now becomes of interest to know whether this scab of Potatoes is a disease common to all root-crops.

GARDEN AND FOREST.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, DECEMBER 30, 1891.

TABLE OF CONTENTS.

The Old Age of the Year.

THE mildness of the recent season has made the usually cheerless month of December a period of enjoyment. Sunny skies and a warm temperature enduring until the holiday season have rendered outdoor employments not only possible, but agreeable, even during the very shortest days of the year. Fortunate are they who have taken advantage of this opportunity to complete the delayed tasks which properly belong to autumn. The unfrozen ground has permitted the transplanting of trees and shrubs, although late labor of this sort is of doubtful propriety. The planting of trees in autumn should be completed early, so that the roots may have time before deep freezing to throw out feeders to supply the moisture which drying winds absorb from the limbs all winter long. On the other hand, every hour has been well spent which has been devoted to the preparation of the ground for spring-planting. Large spaces deeply-trenched for trees will have time to settle and solidify during winter, and give a firm basis and compact feeding-ground for young roots. Recently worked soil, with its open air spaces, is not in the proper mechanical condition to receive the roots of a tree, and it is hard to bring it to the required firmness by ramming or tramping. The late December, too, has been an admirable time for studying plantations already made, for after the leaves have fallen it is easier to decide which trees should be removed or pruned. The weather has been unusually favorable for all pruning operations, whether undertaken to rejuvenate old trees or improve unsightly ones. It is yet in order to cover beds of Lilies or other plants which enjoy a protective mulch which does not exactly keep them warm, but insures a uniform temperature and guards against the alternate freezing and thawing which injures their cell-structure.

But even after all thought of work is over a stroll down the sunny paths of the garden of an afternoon has a charm of its own, although the bare twigs have lost their summer beauty. A few hardy plants still show fresh green foliage, and on many shrubs the berries hang, to give a flash of color here and there. The grass is yet green or a soft golden brown, and the trees with their grace of bare outline, the variety of tint and texture shown in their bark and the delicate tracery of their interlacing branches against the sky, are quite as attractive as at any other season. The twittering of a few lingering birds, the soft odor of the Firs and Pines, the mildness of the air, delude us into hoping that this second Indian summer may hold over into another year. But the most seductive of these days are often the precursors of wild storms, and one wakes after a moonlit evening of delight to find the ground white with snow, and a lowering sky bending over the frozen earth.

The old age of the year is treacherous. Chill and paralysis attend it, its days are brief, its nights are long. In storm and darkness it creeps to its end. However it may put on the semblance of life and warmth, death and icy cold are at hand, and the last leaves are dropping into its open grave. It is the period of retrospect, the time for getting rid of the cast-off garments of the past, and clothing ourselves afresh for the coming of the New Year. But if the last week of the old year be a reminder of disappointments, there yet lingers in it that hope which is freshly born with its lengthening days. Though the sap be chilled in the branches of the trees, it still stirs in the trunks and warms the roots, and prepares in silence the new growth. The old leaves help to protect and nourish the young shoots; from death issues life; and so the great unending cycle sweeps on, explaining to us that all is but change. End there is none, only rest and new birth, the burial of the seed and the resurrection of the plant, the sorrow of evening and the joy of the dawn, the passing of the old year and the happy birth of the new. This lesson of the garden and the forest is a lesson of comfort and cheer. It upbears the mind in failure, and encourages it to renewed effort and to patient waiting for results. The seed shall not fail to bear fruit, even if long hidden from view in the bosom of the earth, which buries but to nourish, and destroys but to bring new life.

In another column of this issue will be found an interesting account of the nursery of Mr. George W. Vanderbilt, near Biltmore, North Carolina, together with a sketch of the proposed forest and arboretum so far as their plans have been matured. This enterprise is wholly of a private character, and the account seems to have been prepared for a magazine of local circulation to meet the natural interest in the undertaking which has been manifested by Mr. Vanderbilt's neighbors. We reproduce it, however, because the matter is of more than local importance, and because this is the first authentic publication that has been made of the scope and purpose of the work. The establishment of a nursery containing such a variety of woody species is of itself an event of the first importance to all intelligent lovers of trees; and if the arboretum project is carried out upon the lines indicated, it will become an institution of world-wide usefulness. Of course the project now is only a promise, and the realization of its possibilities in full measure can only be attained after years of patient study and labor, of study and labor, too, organized and directed and controlled by the broadest knowledge and the most thorough training which the age can furnish. The conception, however, is a noble one, and it is encouraging to be assured that the foundations of the work have been laid with intelligence and care. The almost unparalleled richness of the southern Appalachian region in species of trees and shrubs, and the number of exotics which would thrive on the banks of the French Broad River, warrant the belief that a collection of unrivaled interest and value could be established there, while the grandeur and beauty of the natural scenery of western North Carolina must prove an inspiration to any artist of

creative genius who is entrusted with the landscape design.

As we have said, this is a private enterprise purely ; and yet the span of a human life is so short when compared with the possible life and the ever-growing influence of a well-ordered arboretum, that the project can hardly be conceived of in any other way than as a great institution, or, rather, in connection with the forest and other features of the plan, a cluster of institutions, devoted to special science and art. Indeed, it cannot fail to be a centre of educational influence in forestry, arboriculture and landscape-art, so long as it has any lusty life, whoever may direct it. Looking, therefore, at the enterprise in its essential relations to popular education in science and art, we may be allowed to express the hope that provision will be made to ensure its perpetuation. It is not often that men of wealth and public spirit find so worthy an object for their generous impulses.

Notes of a Summer Journey in Europe.—III.

BEFORE leaving Geneva for Pallanza, on the other side of the Alps, a short excursion was made to some of the villages along the northern shore of the lake, and opportunities were found for a ramble through some of the vineyards which cover every hill-side. To persons always accustomed to the prevailing American mode of pruning Grape-vines by leaving one or more long stems and training them to high trellises, the system practiced here at first seems strange. The old portions of the plants look like stumps, generally not more than a foot above ground. At the top of the stump are from two to four short arms, two or three inches in length, and from each of these arms one or two shoots are allowed to grow and bear from one to three bunches of grapes. At pruning-time these shoots are cut back to the stumps again. In some vineyards the stumps appeared old, and were entirely moss-covered, the moss sometimes being as much as an inch and a half thick. Some rather small stumps were said to be at least thirty years old. The vines are usually tied to slender stakes about four feet in height, the tying material being simply one or two stalks of Oat-straw or other Grass-plant, with the ends tied or made fast by a neat twist. So diminutive do these vines appear in comparison to those trained on our system, that from a distance or from a train they seem more like Peas or Tomato-stalks trained to stakes.

The vines are planted quite near together, and, apparently, hand-labor is entirely depended upon in the cultivation of these vineyards. Indeed, toward the upper end of the lake, anything but careful hand-labor would be impossible on account of the great steepness of the hill-sides, which are faced with stone walls supporting terrace upon terrace, so that the soil cannot be washed away. The situation is exceedingly favorable for Grape-culture ; every foot of land fit for it is made use of, and one is impressed with a sense of thrift and economy in such intense cultivation. At Nyon some rather weedy vineyards were noticed, and laborers were busily hoeing out such weeds as Mustard, Chickweed, a pretty flowering but pernicious Bindweed, or Convolvulus (*C. arvensis*), Potentillas with long runners, and Canada Thistles, the latter in full bloom.

The dreaded Phylloxera has apparently not yet gained a foothold here, and the vines generally seemed very healthy. They had not long ceased flowering, and the little grapes were mostly just well-formed (July 21st). Many of the bunches were infested by little lepidopterous larvæ, or caterpillars, one or more of which attack a bunch. They spin little silken tubes, within which they live separately, and generally accomplish the destruction of a considerable portion of the cluster of fruit.

After leaving the lake, and on proceeding toward Brieg, on the Simplon Road, Apple-trees and orchards become more common, and are usually found in land which is kept in grass. Our common Locust is thoroughly naturalized, and grows as rampantly as a weed all along the railway. Above Brieg, on the Simplon Road, the Walnut-trees were bearing no fruit, the young tips and blossoms having been destroyed by frost. The mountain-sides were still covered with flowers, most noticeable among them being several kinds of Campanulas. On descending toward the Italian frontier, the native Clematis (*C. Flammula*) becomes conspicuous everywhere, strongly suggesting our own Virgin's Bower. Farther down in the valleys the Walnut is again abundant. The young walnut fruit is here much destroyed by lepidopterous larvæ, which cause the immature nuts to drop during the summer, the injury being analagous to that caused by the codlin-moth among apples.

As soon as we cross to the Italian side of the Alps and get to the region about Lake Maggiore, we find the treatment of the Grape-vines to be very different from that practiced around the Lake of Geneva. Here the vines are allowed to grow long, as we are most accustomed to see them, and they are trained to tall poles or trellises, or very commonly to living trees. The tree most selected for this office is the common Field Maple (*Acer campestre*), a species which does not generally grow to a very large size. Most of the branches are removed, only enough being left to keep up the life of the tree. The removal of the branches allows the sun and air to have free access to the vine, while its living support has at least the advantage of not needing frequent renewal ; although, on the other hand, it must take considerable nutriment from the ground, which should otherwise be appropriated by the vine. The practice is one which will hardly commend itself to thrifty cultivators.

The main object of my excursion south of the Alps was to visit some of the gardens at Pallanza on Lake Maggiore, particularly the gardens and nurseries of the Messrs. Rovelli. The rows of thrifty specimens of our great Southern Evergreen Magnolia, planted here as a street and shade tree, at once indicate that Pallanza enjoys a climate peculiarly favorable for trees and other plants of warm, temperate regions. Handsome high hedges and immaculate clipped walls of what is called *Elæagnus pungens* showed how thoroughly acclimated is this Japanese species, which we have not yet been able to grow well where the temperature is liable to go a good many degrees below zero of Fahrenheit.

The nurseries of the Messrs. Rovelli are not kept as an exhibition or show-place, in the popular sense of the term ; but, although no studied attempt is made to produce landscape or floral effects, there is much to please and repay any one who may be able to spend a few hours there.

The greatest interest in the place rests in the fact that here we find large, characteristic, and often handsome specimens of a great number of rare trees, shrubs and other plants which the firm propagate ; so that the visitor who personally goes to this nursery with the intention of purchasing may obtain a fair idea of the size, effect and other characteristics which his plants may develop when they attain to a good age and large proportions. Conifers and other evergreens are most largely represented among the arborescent plants, and we find here such well-grown specimens of Pines and other trees as are rarely seen in the collections which the average traveler is likely to visit.

One of the rarities of the garden and an object of special pride is a handsome specimen of the so-called Chinese Golden Larch (*Pseudolarix Kæmpferi*), which is as much at home in this mild Italian climate as it is when subjected to the extremes of heat and cold, which it endures so well in the vicinity of Boston. This specimen produces fruit biennially, and the seed is allowed to fall and germinate beneath the tree, as greater success in procuring young plants is obtained in this way than by any artificial sowing which has been tried. The ground was covered with thousands of young seedlings, whose light-green foliage formed a complete and very pretty covering.

A specimen of the Monterey Cypress (*Cupressus macrocarpa*), at forty years of age, has a trunk three feet in diameter, and makes a handsome tree ; and, besides other large Cypresses, here also are good representatives of the Sequoias (*S. sempervirens* and *S. gigantea*), the first ninety feet high, while of the latter a curious pendulous form was pointed out as one of the novelties of the nursery.

A specimen of *Cryptomeria Japonica*, from fifty to sixty feet high, is the finest I saw anywhere. This has not yet proved hardy enough to thrive well at the Arnold Arboretum. A large specimen of the rare and beautiful Californian *Abies bracteata* thrives here, and produced fruit some years since. The very long, sharp-pointed leaves, which are white beneath, and the curious long-bracted or porcupine-like cones make this one of the most distinct and remarkable species of the genus. Another curious tree is *Keteleeria Fortunei*, long considered by many botanists as an Abies, and known as *A. Fortunei*. Its right to a distinct generic name now appears to be well established. This species is a native of south-eastern China, and is only hardy in warm temperate or sub-tropical regions. It may truly be called a very rare tree outside of its native habitat, the Messrs. Rovelli having the largest and finest in cultivation. This individual tree has a trunk two feet in diameter, covered with a curious corky bark resembling that of the Cork Oak. Although it produces cones in

abundance, it has not, owing to lack of pollen, produced perfect seed. It is propagated by grafting on stock of the common European Silver Fir (*Abies pectinata*), while a limited number of own-rooted plants are also produced by fastening rings of damp sphagnum to the branches in the same manner that many greenhouse-plants are rooted. Among other Firs were fine examples of Nordmann's and the Cilician Fir. The first is well known as being quite hardy at Boston, while the other is somewhat more tender. *Cunninghamia Sinensis*, *Podocarpus Chilina*, *Fitzroya Patagonica* and Araucarias (fruiting) were some of the other most interesting conifers noted, and which we are accustomed to see only as pigmy plants in greenhouses.

Reference to the Pines should not be omitted, for a number of fine examples are to be seen here. *Pinus Canariensis*, an insular species from Teneriffe, seems to be a favorite and does well, and a Himalayan species (*P. longifolia*) attracts attention by its curious long-leaved foliage. Among our American species we find here the Californian *P. insignis*, one of the most ornamental Pines in cultivation, but, of course, not hardy in our northern gardens, and the Long-leaved or Georgia Pine (*P. palustris*), which is not more enduring, although some of our nurserymen have led many amateurs into buying it. Of several Mexican Pines, one of the prettiest is *P. patula*, while another long-leaved one appears to be a form of *P. Montezumæ*.

Several species of Palms prove quite hardy in the open air. Among these the most interesting and remarkable is a specimen of the beautiful Coquito Palm (*Jubæa spectabilis*), of Chili, forty or forty-five years old, twenty feet in height, and with a trunk almost three feet in diameter. An example of *Cocos australis* was in flower, and the Japanese Fan Palm seemed quite at home. Quite a variety of Bamboos have been brought together, some of them being twenty or twenty-five feet high. One of the specialties of the establishment is the cultivation of Camellias, of which there are a great variety growing in the open air, while their near relatives, the Tea-plants, are to be seen growing beside them.

Much more is to be seen here than can be well indicated in these notes, and any one interested in the fruits of warm temperate regions will also find much to study. Twelve or fourteen varieties of the Japan Persimmon (*Diospyros Kaki*) are grown, and the fruit is said to be gaining in popular favor.

An old friend was noted in the herbaceous Asiatic Lespedeza, which, in a particularly warm spot, was expanding its very first flowers (July 23d). This pretty, rosy purple flowered, leguminous plant is apparently no more shrubby at Pallanza than it is in our northern gardens, where it blooms in the autumn. Unfortunately, it is most widely known as *Desmodium penduliflorum*, a name which should no longer be kept up, as by its botanical characters the plant is a true Lespedeza.

Arnold Arboretum. *J. G. Jack.*

George W. Vanderbilt's Nursery.

AN article under the above title appears in the December number of *The Lyceum*, a magazine published in Asheville, North Carolina. We have made allusion to it in our editorial columns, and herewith reproduce the greater portion of it. It was prepared at the request of the editor of *The Lyceum* by Mr. Frederick Law Olmsted, whose name is a guarantee that it is authoritative.

1. It is intended that the greater part of the estate with which the nursery is connected shall be occupied by a systematically managed forest, constituted mainly, at least, of such trees and bushes indigenous to the region as are likely to be of commercial value. This forest will be in a large part formed by the improvement, through thinning and otherwise, of the present young "second growth," but considerable spaces, now bare of trees, or the trees on which are unpromising, will be planted. The extent of the forest is to be fully 4,000 acres.

2. Roads will be carried through the forest, in the laying out of which the motive of convenient transportation from its different parts will be modified by regard for picturesque interest, and the immediate borders of a part of these roads are to be planted with the object of gradually forming more interesting foregrounds than might otherwise be presented to view from them.

3. It is proposed to make a plantation, three or four miles in length, along the borders of a certain series of the forest-roads which will contain a few specimens, suitably classified and arranged for study, of each of the native trees of the region, and of all other trees that can be obtained from any part of the world with a reasonable hope that they will flourish under the conditions of climate and soil of the locality. This will be "The Arboretum"; in effect an Experiment Station and Museum of living trees. It may be hoped to be of considerable national value, as the trees acquire their mature character, perhaps fifty years hence.

4. It is intended to gradually form in some of the glens of the estate, passages of local scenery resembling those naturally occurring in many similar situations in the mountain-regions of North Carolina, of which the more notable constituents are lustrous smooth-leafed evergreens, such as the Rhododendrons and Kalmias, Ilexes and the Leucothoe. In the glens there are occasional partly flooded or water-soaked areas, in or on the edges of which grow Cane, Bullrushes, Sagittarias and other aquatic forms of vegetation, mostly herbaceous. With masses of such evergreens as have been indicated above, it is designed to associate a comparatively small number of foreign bushes of a generally similar, glossy, evergreen character, by the introduction of which, if it can be successfully accomplished, greater variety and grace of form and vivacity of tint, and, at points, more complex intricacy of effect may be obtained than if the planting were to be confined strictly to natives. Also the attempt will be made to naturalize a few foreign plants, as, for instance, certain Bamboos, Nelumbiums and Nymphæas, each having qualities of its own, differing from, but to be pleasingly associated with, those of the native aquatic and water-side plants.

In the nursery there are now under propagation, or already in cultivation, young trees and bushes for each of the four above-stated purposes. Of such of these as are designed to be used either directly, or as stocks for propagation, for the Arboretum, there are two or more examples each of four thousand two hundred species and varieties. Of the different species of Rhododendron, Kalmia, Leucothoe, Andromeda, Ilex, Laurus, Osmanthus, Aucuba, Abelia and other smooth-leafed evergreens collected or otherwise obtained with a view to the fourth class of plantations above defined, there are now in the nursery, or planted on the banks of Ram branch, 20,000 plants, not including those intended as ground-covering, such as Ivies, Evergreen, Loniceras and Running Roses, Hypericum, Periwinkle, etc., of which the present stock is about 100,000. Among the Rhododendrons there are two examples each of four hundred hybrid varieties, mostly the result of crossing the Catawba Rhododendron, growing naturally on the high mountain-tops of North Carolina, with others largely obtained from the Alpine regions of Europe and from the Ural and Himalayan mountain of Asia.

All of the plantations described are intended, as they come to maturity, to have a natural aspect, and to stand in harmonious and modestly subordinate relations with the general landscape of this region of country. There will be a small space of "kept grounds," near the dwelling of the proprietor, which, for the most part, will be laid out formally, with a view to domestic convenience and correspondence with the buildings, consequently, with a clearly defined demarcation from the natural landscape. There will be but little space given on the estate to what are commonly called "ornamentals," and none to the exhibition of mere curiosities, eccentricities or rarities of vegetation. There is, consequently, little in the nursery of special interest from a gardening point of view. Its stock of trees and bushes of merchantable size now numbers about 100,000; of seedlings and cuttings propagated on the grounds during the last year, about 500,000. Some of the stock having been brought long distances (part from southern Europe, part from Japan) and delayed on the passage, is not at present looking very thrifty, but after the next winter's rest is expected to fully recover.

The entire undertaking looks to results that can be fully realized only after many years, and, except to a botanist, its value lies in its promises and experiments rather than its actualities.

New or Little-known Plants.

Spiræa discolor, var. ariæfolia.

THE panicle of flowers of *Spiræa discolor*, var. *ariæfolia*, figured on page 617, is from a photograph of a specimen grown during the past summer in the Arnold Arboretum, where it bloomed better than it has ever done before, no doubt owing to the comparative mildness of the past two winters and to a moderate amount of winter protection given to it. Perhaps, also, it is one of those plants which are apparently hardier after they attain a considerable age. Although one of the most beautiful of all the Spiræas, it

unfortunately is not, or, at least, has not proved sufficiently hardy so far to always withstand our New England winters without some shelter or protection. On this account it is rarely seen here as it cannot be planted with any assurance of giving satisfaction. It is not impossible that hardier strains may yet be procured from higher altitudes or colder latitudes. Its native habitat is mainly west of the Rocky Mountains, where it is said to range from southern California northward through Oregon and Washington and into British Columbia at least as far north as the forty-ninth degree of latitude.

This variety was originally described as a separate species under the name of *Spiræa ariæfolia*, and as such it is still commonly known in catalogues and collections. Later botanists have relegated it to the rank of a variety of *S. discolor*, an apparently extremely variable species, as there is at least one other distinct botanical variety (var. *dumosa*) recognized, which, being less northerly in its distribution, is not so hardy as the form under consideration.

Under cultivation and favorable circumstances this Spiræa becomes a large shrub ten or twelve feet high and as much as fifteen feet in diameter. The branches are slender and covered by a very minute pubescence. The bark is at first light gray in color, but after the second year it is dark brownish gray. When young it is marked by minute longitudinal ridges, which become obsolete with age. The foliage is usually so abundant that the stems are well covered.

As the name denotes, and the figure shows, the leaves have the outline and pinnatifid lobing which gives them some resemblance to the leaves of certain forms of the European Beam-tree (*Pyrus Aria*), but this character is common to the other variations. They vary from one to two or three inches in length, and are usually quite densely covered on the under surface with a close grayish pubescence.

In this latitude the blossoms usually begin to open in the last days of June or early July, and flowering is continued for about three weeks.

The individual blossoms are small and of a pale greenish white color, so that the whole panicle has a rather dull white effect. The large loose feathery, much-branched panicles are produced at the ends of the shoots, and are frequently very much larger than shown in the figure. They are borne in as great profusion as the panicles on a well-grown *Hydrangea paniculata*, and, in a manner, are almost as effective, though lacking their pure white lustre.

The odor of the flowers has been described as that of Sweet Birch, but it is as strongly suggestive of honey, with perhaps a faint hint of Chestnut-blossoms which renders them not entirely agreeable to many people.

Seed is freely produced, but it is not easily separable or distinguishable from the chaff or remains of the withered flowers, which are so persistent that they still adhere when the leaves have fallen. Plants may either be reproduced from seed, or more speedily by layers, or from cuttings of green wood started in sand under glass. They do not spread much from underground shoots. It was early introduced into European gardens, and was brought to England in 1827. Wherever it is hardy it is deservedly much esteemed; and it is particularly valuable because it blossoms at a later season than the vast majority of shrubs.

Although we have spoken of it as a Spiræa, it should be noted here that the late C. J. Maximowicz, in his monograph of the Spiræas, places *S. discolor* under a separate genus, the generic name proposed being Holodiscus, which was first used as a subsection of Spiræa. He removed it entirely from that genus, as he considered that it was related to the Potentillas, and that it was also allied to the Raspberries by its two pendulous ovules.

Maximowicz did not recognize the varieties of *S. discolor* as they are designated in botanical works, and, besides these, he also included one or two other plants which had been described as species and whose range extends through Mexico and as far south as Guatemala.

With the present tendencies toward creating and more sharply defining genera, it is not at all unlikely that the classification of Maximowicz will come to be universally accepted, and that our plant may finally be known as *Holodiscus discolor*, or, if there proves to be sufficient difference to warrant keeping up the varietal name, as *H. discolor, ariæfolia.* Indeed, the name Holodiscus is already in use in some botanical gardens, and is taken up in Coulter's "Manual of the Botany of the Rocky Mountain Region."

Arnold Arboretum. *J. G. Jack.*

New Orchids.

Aërides Lawrencæ, var. Amesiana, Sander.—A robust and handsome variety, with short, rigid dark green leaves, and the purple tips of the sepals and petals broader than usual. It is said to be like a dark-colored form of the variety Sanderiana in the flower, but to differ in habit. It was introduced by Messrs. F. Sander & Co., of St. Albans.—*Kränzlin, in Gardeners' Chronicle*, October 3d, p. 393.

Cypripedium Godefroyæ, var. luteum, O'Brien.—A very pretty variety, with the ground color of a clear soft primrose-yellow, and the spotting pale rosy lilac. It appeared in a batch of the ordinary form in the collection of Messrs. Hugh Low & Co., of Clapton.—*Gardeners' Chronicle*, October 3d, p. 393.

Cypripedium × Enfieldense, Hort.—A handsome hybrid, raised in the collection of A. J. Hollington, Esq., Forty Hill, Enfield, by Mr. Ayling, from *C. Lawrenceanum*, crossed with the pollen of *C. Hookeræ*. It is like an improved *C.* × *marmorophyllum*, in which *C.* × *barbatum* takes the place of *C. Lawrenceanum*. The leaves are much like those of the two parents. The dorsal sepal is very broadly ovate and subacute, stained and nerved with purple on a light green ground, paler toward the margin. The petals are deflexed and much like those of *C. Hookeræ* in their bright purple color, but not quite so broad near the apex. The lip and staminode are intermediate in character.—*Gardeners' Chronicle*, November 7th, p. 546.

Phajus maculato-grandifolius.—This is a handsome hybrid, raised by Mr. Seden for Messrs. James Veitch & Sons, of Chelsea, from *P. grandifolius*, crossed with the pollen of *P. maculatus*. It has the general habit of the mother plant, but the leaves are rather thinner than those of that species, and have a few yellow spots as in the pollen parent. The spike is nearly three feet high, with the flowers about as large as those of *P. grandifolius*. The sepals and petals are yellow, with a slight coppery tinge, and the lip yellow at the base, with its infolded front lobe chestnut-red, and some lines of the same color extending to the base of the lip. It was awarded a first-class certificate by the Royal Horticultural Society on November 10th last.—*Gardeners' Chronicle*, November 14th, p. 591.

Foreign Correspondence.

London Letter.

Bulbous Plants.—Among the species of Crinum cultivated at Kew there are several which usually flower in winter. The following are in bloom now, and will continue so until the end of the month: *C. angustum.* This is one of the handsomest of the large evergreen tropical species. It forms a specimen as large almost as the *C. Asiaticum*, figured early this year in Garden and Forest, the thickness and length of the stem-like neck of the bulb and the width and length of the fleshy bright green foliage being very similar to what I described in that species. In the flowers, however, *C. angustum* is much more attractive, each flower being fully six inches across. The segments are narrow and recurved, and they are colored rich deep crimson, paler on the inside. There are as many as thirty flowers in a single head, and they open in slow succession. The species is a native of Mauritius and the Seychelles, whence it was introduced to Kew seventy years ago. I do

not see any difference between this and *C. amabile*, which is also now in flower at Kew. They are alike in all characters, and on turning to Mr. Baker's description of these two species in his "Amaryllideæ" I perceive that both descriptions are essentially the same. There is, however, the difference in geographical position, that called *C. amabile* being a native of Sumatra. *C. Hildebrandti* is another species in flower twice already this year. It is a pretty pot-plant, and not too large for the ordinary shelf in the stove. It was sent from Johanna Island, off the south-east coast of Africa, in 1875, to Berlin, by the collector Hildebrandt, and a few years later to Kew by Sir John Kirk. Although found at an altitude of 3,000 feet, it suffers from cold if kept in an ordinary greenhouse. *C. bracteatum* is

Fig. 98.—Spiræa discolor, var ariæfolia.—See page 615.

evergreen species, and one which is very easily kept in health in a stove. It has a neck a foot long, is almost leek-shaped in fact, with strap-shaped leaves eighteen inches by two inches. The flowers are borne in an erect head on a scape a foot high, and are remarkable for the length of the tube, which is from six to eight inches long, and perfectly straight. The segments are three inches long, narrow, spreading and recurved; pure white. We have had this similar in general characters to *C. pedunculatum*, but does not grow to so large a size. It has a short thick neck, broad fleshy leaves, and a flattened scape a foot long, bearing numerous pure white flowers two inches across. The stamens are reddish. Originally from the Seychelles, but now well known in cultivation in the tropics. *C. pedunculatum* is quite as large as the common *C. Asiaticum*, the only difference between the two being in the size of the

flowers and in the number of ovules. They are both noble stove-plants and very easily grown. They may be planted in borders in warm houses, but grow equally well in pots. They like an abundance of water at all seasons. *C. giganteum* has recently been figured in Garden and Forest, so that I need only mention it here among those which are in flower now. It blooms twice or three times annually.

Callipsyche is a small genus of Amaryllids which is represented in gardens by two species—namely, *C. aurantiaca*, a native of Ecuador, at an altitude of 8,000 feet, and *C. mirabilis*, from the Andes of Peru. The former is now in flower in a stove at Kew. Although not possessed of much attraction in the shape or color of the flowers, yet the plant is decidedly interesting, and well worth a place in a collection of stove-bulbs on account of the peculiar form of the flowers. The bulbs and leaves are similar to those of Urceolina, while the scape is erect, fistulose, two feet high, and bears an umbel of a dozen yellow flowers, which spread horizontally, and are tubular, two inches long, with the stamens protruding three inches beyond the recurved tips of the segments of the corolla. The flowers remain fresh on the plant about a month. The treatment for this plant should be the same as for *Urceolina pendula*.

Eucharis grandiflora (*Amazonica*) is, of course, in flower now. We find that by treating this plant as if it were a tropical Daffodil, or, in other words, giving it plenty of water at all times, a rich loamy soil, not too much sunshine and not too frequent disturbance at the root, never, in fact, so long as it is doing well, it will flower twice or thrice annually, keep free from the mite (Rhizoglyphus) and behave itself exactly as a good stove-plant should. Many cultivators fail with this and the several other species of Eucharis through subjecting them to a process of alternate high-feeding and starving, which may answer for some bulbs, such as Hippeastrums, some Crinums and Nerines, but which is quite opposed to the nature of Eucharis.

Nerines.—Except *N. flexuosa* and *N. Munselli* these are now all over, and the plants are in full-leaf growth. Our chief difficulty with these beautiful bulbous plants is owing to the absence of sunlight in winter, when they are in full growth. In America the Nerines ought to become general favorites, your bright sunshine, even in the depth of winter, being favorable to their growth. In Ireland, especially in the Glasnevin Botanic Gardens, in the Scilly Isles, in Baden Baden, and even so near London as Windsor, Nerines are a success, but they do not grow satisfactorily in any garden which is within reach of London fogs. Given a fair amount of sunlight in winter, and Nerines will prove most valuable greenhouse-bulbs. They grow from November to May, rest from then to October, and then push up their gorgeous and elegant flowers.

Bomareas.—These are not bulbous, but they are Amaryllids, and they are in bloom now. I propose to send shortly a series of notes on this genus for publication in Garden and Forest. In the mean time I may call attention to three of the best of them, which Professor Sargent saw in flower and admired at Kew this week. They are *B. Carderi*, *B. Caldasiana* and *B. frondea*. The first of this trio has scandent stems from eight to twelve feet long, clothed with broad leaves and terminal umbels of flowers as large as those of Lapageria and of similar texture. Their color is rich rose with conspicuous spots of brown on the upper part of the segments, the inner segments being greenish white. I have seen an umbel of flowers on this species which measured two feet in diameter and contained over fifty flowers. *B. frondea* has stems eight feet high, lanceolate, dark green leaves five inches long, and terminal umbels of rich golden yellow flowers, with a few spots of brown. The head formed by the flowers is suggestive of the umbel of *Alstrœmeria aurantiaca*. *B. Caldasiana* has broader leaves than the last-named and looser umbels of flowers, which are shorter than in *B. frondea* and colored a deeper yellow, with larger spots of brown on the upper half of the segments. This species and *B. Carderi* have not been out of flower since June. They are planted in a shallow bed at the south end of a sunny greenhouse, their stems being trained against the roof, from which the flowers hang gracefully.

Lachenalias are pushing up their flower-spikes and promise to make a fine show presently. The perpetual flowering *Cyrtanthus Mackeni* is as attractive now as it was in June. Its near ally, *C. lutescens*, ceased flowering about a month ago.

The first of the Hippeastrums to bloom is the sturdy and really useful *H. aulicum*, the variety known as *superbum* being better than the type. I like this plant because of its evergreen nature and its vigorous free-flowering habit, characters which unfortunately do not belong to many of the species or varieties of Hippeastrum.

London. *W. Watson.*

Cultural Department.

Strawberry Notes from Wisconsin.

Among the more progressive market-growers, the Warfield is the most popular variety at the present time. It was given the first place at the last meeting of our state horticultural society, and in our trial grounds at the experiment station it proved decidedly more productive than any other variety tested. Its rich glossy color and its firmness, coupled with remarkable productiveness, are its specially valuable qualities. We have several varieties, however, that yield fruit of better size and quality. The appearance of the berry is sufficiently like that of the Wilson to permit the two varieties to be packed in the same case without detection unless by the expert, a fact which makes the latter sort popular as a fertilizer for the Warfield.

The Haverland was second in productiveness on our grounds. In color, this berry is decidedly inferior to the Warfield, though it averages a trifle larger. In quality there is little difference.

Lady Rusk has proved disappointing. It is fairly productive, but the fruit is irregular in shape, inferior in size, and poor in quality. In firmness it does not surpass the Wilson or Warfield.

Shuster's Gem was only fairly productive, and the quality is inferior. Edgar Queen was productive and promising. General Putnam has value as a family variety, the berry being large and of good quality, but its color and softness do not commend it for market.

Our finest early variety was the Van Deman, which gave its first ripe fruits three days before any other. A peculiarity of this sort, if we may judge it from the past year's record, is that it ripens the bulk of its crop very early, several days before any other variety tested. This, with its other good qualities, will probably give it a place as a market variety. It is of fine color, firm enough for a near market, fairly productive, and of good average size and quality. Though ripening first, its crop held out through the entire strawberry season. This, together with the fact that its flowers are perfect, should give it especial value as a family variety.

Our finest late sort was the Eureka, which proved much more productive than the Gandy, while equal to it in all other respects. The Jessie succeeds admirably with some growers, while it is disappointing with others. At its best it is a remarkable variety, the plants being very productive of fruit of the largest size and superior quality. On our own grounds it has done only fairly well. The old Wilson still holds its own with a few market growers, notably J. M. Smith, of Green Bay. Where vigor has been maintained in the plants, and high cultivation is given, it must be confessed that this old stand-by has few superiors.

Perhaps it should be added that the comparative earliness or lateness of different sorts may depend considerably upon the weather during the strawberry harvest. If the weather is dry at the commencement of the strawberry season maturity in the earlier sorts will be hastened. If abundant rains fall after a few pickings have been made, the later sorts may take on a new growth, which will delay their maturity considerably. This was well illustrated on our own grounds the past season. Dry weather prevailed until the majority of our varieties had commenced ripening, when abundant rains followed, and the maturity of the later sorts was considerably postponed. Owing to this the strawberry season was considerably prolonged, berries having been gathered for the table during an entire month.

University of Wisconsin. *E. S. Goff.*

The Hellebores.

THESE plants are the best of their season, and they are not much inferior to the choicest afforded by the garden at any time of the year. Helleborus is a genus of perfectly hardy, herbaceous perennials, with or without stems, varying in height from six to twenty-four inches, with deciduous or persistent palmate or pedate leaves, and inhabiting Europe and Asia. The common names, Christmas and Lenten Roses, are given on account of the season when the flowers of the two sections appear; but, of course, they are not Roses, but members of the Buttercup family. The popular name, Christmas Rose, Christmas Herb, or Christ's Herb, originated with the Dutch, Rose having probably been substituted for Herb from the resemblance of the flowers to those of a wild Rose.

According to the "Genera Plantarum" of Hooker and Bentham, there are ten or twelve species. Mr. J. G. Baker, however, in the monograph of the genus which appears in the *Gardeners' Chronicle* for 1877, recognizes only six species, and classes other forms as variations of two of these distinct types, or species closely allied to them.

H. lividus is a pretty Corsican species, with flowers of a bright greenish color, known in gardens since 1710. A variety, Integrilobus, differs slightly from the type in the foliage. Both flower in spring. *H. fœtidus* is a large species with decorative, persistent foliage, producing large panicles of greenish flowers, margined with dull purple, during the early months of the year.

The Black Hellebore (*H. niger*) is the best of all the species, and a first-rate garden-plant. This is the true Christmas Rose, a very variable plant common to central and southern Europe, and first introduced into England by Gerard in 1596. The typical form is from six inches to a foot high, the pedate, coriaceous leaves on stout petioles, which proceed from a spreading underground stem, as do the erect scapes, which, during the autumn and winter months, bear from one to three cup-shaped, pinkish white flowers about three inches in diameter. The variety Altifolius, or Maximus, is the largest and most handsome, the pure white flowers, suffused with pink externally, from four to five inches across, and at their best in November and early December. *H. niger angustifolius* is an extremely floriferous sort, a trifle smaller than the type, flowering in October and November, and of pure white color. This variety is the best for forcing and pot-culture generally. Madame Fourcade is an excellent pure white form of *H. niger*, blooming in November and December. In the variety Major the blossoms are like those of Altifolius, but somewhat smaller, and developed in December and January. Riverston's variety has large pure white flowers, which are borne in great abundance during November and December. Only a few days ago I picked a large cluster of flowers from a plant of this variety in a Massachusetts garden. The leaves were a trifle ragged, but the large pure white flowers were in excellent condition. The blooms of the variety Rubrus are of a charming pale reddish tint, large, and expand in January. This is a free-flowering variety, very distinct and useful, being the only Christmas Rose with red flowers. *H. niger vernalis* (*Caucasicus*) is another handsome kind which blooms in January, the flowers being large, pure white, tinged with rose externally, and delightfully fragrant. Several other varietal names are given to alleged forms of *H. niger*, but the characters of the plants thus distinguished, excepting one known as Variegatus, which has leaves of green and white, coincide so markedly with those of the kinds already mentioned that it is sheer folly to perpetuate them.

H. viridis has ornamental foliage, and is sometimes grown on that account. The flowers are bright green, from two to three inches in diameter, and produced in spring. It is a native of Western Europe, and is said to have escaped from cultivation in some parts of our eastern states. The following are ranked as sub-species of *H. viridis: H. Bocconi*, a form from the mountains of Etruria, in cultivation ten or fifteen years, flowers green and agreeably odorous. *H. cyclophyllus*, a green-flowered, Grecian plant, unknown in gardens; *H. graveolens*, a Hungarian form, with greenish flowers, tinged with purple; *H. intermedius*, a native of Austria, flowers green and purple; *H. luxus*, also from Austria, with pale green flowers; *H. purpurescens*, the last and by far the best of the group, which, with *H. Bocconi*, are the only forms really deserving general attention. The former bears large, deep, purplish flowers of large size, and has been admired in gardens for seventy years; *H. orientalis* is a Grecian species, introduced about 1839. It is about eighteen inches high, and produces white flowers, with purple margins in late spring. A comparatively large number of sub-species are built on this plant as the type. Among these are *H. abchasicus*, with greenish purple flowers, and cultivated in European gardens for a quarter of a century; *H. Antiquorum*, a beautiful form, with pale purple flowers; *H. atrorubens*, a very desirable kind, with large flowers of deep purple color; *H. Caucasicus*, with pale green flowers, and wholly distinct from the *H. Caucasicus* (*vernalis*) of the niger group; *H. Colchicus* is from Asia Minor, and one of the best of the entire genus, with large and abundant rich purple flowers; *H. guttatus*, an attractive plant from the Caucasus, having flowers pure white, spotted with purple; *H. odorus*, a native of Austria, bearing numerous green and fragrant flowers; *H. Olympicus*, bearing in winter white flowers tinged with green, and *H. pallidus*, a similar plant.

The Orientalis group contains, in addition to the above, numerous varieties, and some plants which are presumably hybrids of the Viridis and Orientalis sections. The finest of these are, Apotheker Bogren, large, rich reddish purple; Frau Irene Heinmann, bright purple, with reddish spots; Gertrude Jekyll, very fine pure white; Leichtlini, white, spotted crimson, and Punctatissimus, pale purple, freely marked with spots of a much darker shade. It is evident that *H. niger* and *H. orientalis* yield nearly all the plants of the genus which are of value in gardens. These, at any rate, will be found satisfactory to ordinary growers, and the others can be added for investigation and experiment. The student and hybridizer will find in the Hellebores a wide field for interesting work, and all who cultivate plants for their beauty alone will be agreeably surprised with the results of any extra attention given to them.

Cambridge, Mass. *M. Barker.*

The Cranesbills.

THESE plants have always been of peculiar interest to me, the rarer forms always possessing great charms; few hardy perennials combine more handsome foliage, with showy flowers borne in profusion, or are more easily grown. They are in no sense weedy, and do well in almost any soil and in all exposures. They must not be confounded with the tender Geraniums, which properly belong to the genus Pelargonium.

Geranium sanguineum is one of the oldest cultivated species; its dark red flowers are borne continuously through the summer and into late autumn, and show to advantage against the dark green, handsomely cut foliage. The variety Lancastrænsis has light pink flowers veined with deeper color. *G. Endressii* has light green, nicely cut foliage and clear pink flowers, but unfortunately it is a little tender here. The double form of *G. pratense*—one of the oldest of old-fashioned flowers—is really a showy plant, and gives an abundance of bloom up to the late summer months. The flowers are very double and deep purple in color.

G. peltatum is especially noteworthy in its foliage, for, though the flowers are freely borne, they are of secondary consideration. *G. Ibericum* is very choice, with deeply cut and fringed foliage and showy open panicles of deep violet flowers, an inch or more across and veined with purple. It makes a bush one and one-half to two feet high, producing an abundance of flowers throughout July and August, and the variety Platypetalum is richer in the color of its flowers than the type, and the whole plant is not quite as large in growth. With us it is a freer bloomer. Some time since I imported a plant as *G. Londesii*, and it has proved the best in my collection, forming a large, self-supporting broad bush, three feet high, and heavily enveloped in late July with open, flat panicles of light blue flowers, fully an inch and a quarter in diameter and handsomely veined with purplish violet. It is very distinct from any other species that I have, both in foliage, flower and habit. I have doubts, however, as to the correctness of its name.

G. Wallichiana is of prostrate, trailing habit, with light green, palmate foliage and deep red flowers, borne sparingly all summer. It is a desirable plant, used as a trailer, and its Himalayan habit lends peculiar interest to it.

Fertilizers for Tomatoes.

YOUR remarks on Fertilizers for Tomatoes interest me. I have become satisfied that the difficulty with Tomatoes in this latitude, where they are, as a rule, very unsatisfactory in midsummer, is very largely due to the general impression that heavy manuring is not good for them, especially the heavy use of stable-manure. A large part of the benefit of well-rotted stable-manure in a hot climate comes from the abundant carbonaceous matter mixed with it, which tends to keep the soil from baking hard in the summer heat, and pre-

serves moisture. I have been particularly struck with the success of an old negro, a porter in a mercantile house in Raleigh, in growing Tomatoes and keeping them up all through the summer. So I sought him out and asked about his method of cultivation. "Well, boss," said he, "I'se jess got a bit of a gyarden to 'muse myself moonlight nights. I keeps a pig and some chickens, and saves their manure, and my boy scrapes up the hoss droppin's on the road, and we gits rich dirt and mixes it all up in a compose pile ready for spring. Den, in April, when I sets out my Termatter-plants, I digs a big hole for every one of 'em and fills it mos' full ob dat compose. De holes is ober a foot deep. On de top I puts some of de sile, and sets de plant right in de middle, wid a stout stake alongside ob it, and ties de vine up to it; and it jess grows and grows, and keeps a-growin', an' I cuts off de side shoots as soon as I see de blossom on 'em. Dat's all, boss. Dem plants jess keep a-growing', and I cuts out de old straggly stuff now an' then, and has fresh shoots an' Termatters all de time." There is a lecture on Tomato culture! Such heavy manuring may not do everywhere, but in this climate of alternate deluges and droughts the old colored man's plan works well, and will be tried in my own work next season. I am not sure, however, that it is advisable here to train the plants off the ground. Close training to one main stem exposes this stem too much to the sun and makes it short-lived. I am inclined to believe that better success will be had here from vines sprawling on the ground, and shading with their foliage not only the stem of the plant but the ground as well. I have abandoned varietal tests of Tomatoes, and will, hereafter, study modes of culture and development.

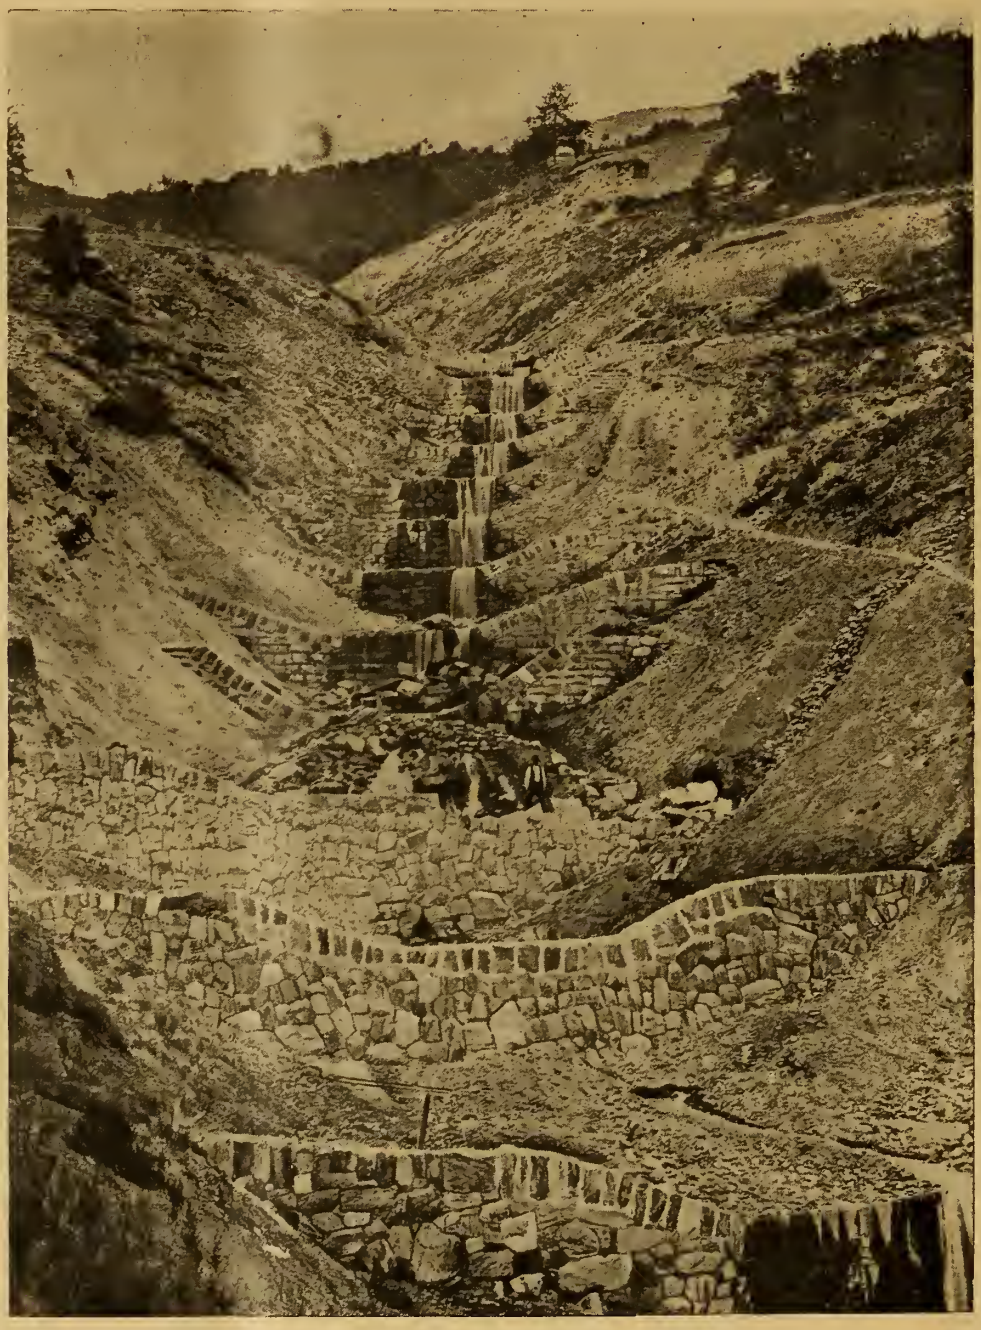

Fig. 99.—Corrective Works in one branch of the Torrent of Grollaz.—See page 621.

Dwarf Callas.—About two years ago there appeared in the *Gardeners' Chronicle* a cut of a new dwarf Calla, which created considerable interest among gardeners and florists, inasmuch as it was doubted whether its dwarfed character could be perpetuated. That it is a genuine novelty has been fully proved by a local florist, who imported a number of bulblets last spring. The bulblets were very small, scarcely averaging the size of a pea. About ninety per cent. of the importation lived, and some have now reached the blooming stage. There is every probability of its becoming an important winter-blooming pot-plant. In a six-inch pan it makes an elegant specimen, and it would prove of great value for the decoration of the dinner-table. The plants I saw were single crowns with twelve fully developed leaves, one open spathe, and two others in the process of development, and the whole plant was not more than ten inches high from the soil. The spathes had six to

eight inches of clear stem, the expanded portion measuring two and a half to three inches across, thus making one of the neatest flowers possible for boutonnières.

Any one who knows how to grow the common Calla need have no trouble growing this. A light soil, with abundance of well-decayed manure, is preferable, with enough drainage to allow water to flow off quickly. The best plants I saw were growing on a bench near the glass, in a temperature of fifty-five to sixty degrees, and with a light shading even in December. Others were growing in a cooler house, quite exposed, in a drier atmosphere, but did not appear to thrive so well, and were dwarfer, or stunted. The bulblets as they appear about the crowns may be taken off as soon as they develop one or two leaves, and as they need no ripening they will grow at once into neat plants. I believe good marketable plants with one spathe could be grown in five-inch pots.

Violas.—I lately picked, from under a slight covering of Pine-needles, a bouquet of these in yellow and blue. Unprotected, they would have been all withered by frost; but why are they not oftener seen in gardens? They are hardier than Pansies, and will almost take care of themselves. But they become ragged with age, and so it is better to transplant a few of the seedlings, which can always be found about an old bed. They bloom all summer long, and nothing is neater for shallow dishes.

Wellesley, Mass. *T. D. H.*

The Forest.

The Subjection of Torrents by Reforestation of Mountains.—IV.

THE TORRENT OF RIOU-BOURDOUX.

THIS torrent, classed among the incurable ones, and famous for its devastations, was the most powerful of all those which raged in the French Alps. Starting from mountain crests at an altitude of 2,900 meters, it rushed into the Ubaye 1,800 meters lower, after a course of three and a half miles with an average pitch of 30 to 100. Its catch-basin is rimmed with ridges of tertiary rock, and at an altitude of 2,400 meters it enters the black Jurassic clays. Thus the Riou-Bourdoux, while yet near its source, rushes through deeply cut banks. It receives numerous affluents, most of which are justly entitled to be ranked as torrents already formidable. All these affluents flow between banks cut nearly perpendicularly to a depth sometimes of 100 meters, absolutely bare, bluish black in color and sinister in aspect. Fifteen years ago the Riou-Bourdoux was in full activity, steadily cutting under the foot of its banks and starting land-slides over enormous areas on both shores, which tended to join each other from opposite sides, but were quickly separated by the torrent, which, hollowing out its bed between them, carried into the valley prodigious quantities of material.

The mouth of its "channel of erosion" is found some 1,500 meters above the Ubaye, where the torrent spreads out over an immense cone of débris, the base of which is crossed by the national road from Montpellier to Coni. The area of the cone, nearly 600 acres, presents a most desolate aspect, without a trace of vegetation. With each great storm the wash flows over the cone, spreading now over one side, and again over the other. The national road is only a trail across the débris, ceaselessly covered with débris, so that large sums are annually absorbed merely to keep it in passable condition. Such was the situation in 1875, at the time when the works of restoration were declared necessary for the public good.

To-day the torrent is tamed, and, thanks to operations carried out along a definite line and with persistent energy, we are masters of the entire upper basin, where over 3,000 acres of restored forests occupy the degraded lands. The affluents are corrected, the bed is rectified in the channel of erosion, and after next year the subdued torrent will flow like a peaceful brook through a definite bed prepared on its cone, leaving an area of 593 acres to be restored to agricultural use.

In this instance especially was the suppression of the torrent a public benefit. It meant the rescue from certain ruin of the territory of an entire commune; the assured existence of a vigorous population on the frontier; the protection of a rich valley against deposits which are a destruction to arable lands, security to the threatened city of Barcelonette, and an open highway over the only road to France, an important point in connection with national defense in a notable part of the Alpine frontier.

THE COMBE OF PÉGUÈRE.

The ravine opens out at an altitude of over 2,000 meters on the east side of the mountain which overlooks the health resort of Cauterets. Long ago subdued by the vegetation which protected its catch-basin entirely, this gorge had again assumed activity, which increased as its basin was more and more denuded by the habitual passing of flocks of goats and sheep.

In 1884 the danger became more serious; the security of the thermal springs of Rallière and others was threatened, travel over the international road from France to Spain became dangerous, and the safety of Cauterets seemed threatened.

The alarm among the people in the valley was great, and their authorized representatives hastened to lay their grievances before the Minister of Agriculture.

The peak of Péguère, composed of granitic rock, presented this peculiarity, common in all the neighboring mountains of the same group, that on the crests the rock is broken in all directions, sometimes to very great depths. The walls of the ravine furnish a striking example of this; they are formed of blocks of all dimensions, with sharp outlines produced by the dislocation of the primitive rock, and with deep crevices between them. They are surrounded by sandy earth and placed in a most threatening state of instability. The least disturbance, the action of gravity alone, may start a movement among these rocks, but water especially brings on the great disasters. In winter, it filters in abundance into innumerable fissures, congeals there, and splits the rock in every direction. In spring, with a sudden melting of snow or with heavy rains the sands which fill the spaces between the blocks are washed away by the waters, and, equilibrium once broken, the movement begins. The blocks thus started leap down the smooth steep slope, dashing themselves to pieces, and sometimes bombarding the establishment of Rallière or that of Mauhourat with their fragments. Such a destructive force tends to increase more and more, and would soon threaten the town of Cauterets if measures prompt and energetic enough to subdue it were not taken.

This state of affairs is shown in the report of the survey made in 1884 by the foresters called upon to undertake the work of suppression. It was stated in the first report that in dry times the sands flowed into the hollows of the valley like sand in an hour-glass; the wind lifted it in clouds; in times of rain it was borne away by the waters. There was no rest in this ravine; incessantly some pebble starting dislodged larger blocks, which, like avalanches, descended with a terrible crash, shivering the rocks which they struck, and tearing the earth and trees as they bounded along.

The most intrepid mountaineers would only venture to cross the mouth of the Combe on a run, while into its depths they never thought of penetrating, so constant was the peril from falling rocks, which the slightest touch might dislodge.

Of course no work could be done here during the bathing season, the operations were restricted to the first days of spring or the last days of autumn. The construction of a system of walls on such a steep slope was not practicable, on account of the expense which their great number and size would involve.

The problem consisted essentially in retarding the motion of the more or less earthy sands, which keep the blocks in unstable equilibrium. Observation of the local climate, together with the nature of the soil, furnished a very simple and economical plan of solution. The plan was: (1) To clear the slopes of all loose blocks whose fall seemed imminent; (2) To reclothe, as far as possible, all the sands with a mantle of vegetation formed by plats of grass, and to calk, so to speak, all the spaces between the rocks considered reasonably firm; (3) To construct retaining walls of dry rock wherever the accumulated rocks left no chance for the grass to support itself.

This operation would leave no work of man visible except the retaining walls; the remainder would be transformed into a mountain sod, from which would emerge here and there portions of the protected rocks.

The execution of the work was exceptionally difficult; the necessity of working in the Combe only at rare times in order to avoid all danger to the thousands of bathers at the springs below; the total absence of roads and paths in the steep slopes; the lack of workmen accustomed to the perils which were to be constantly faced; the distance which it was necessary to transport sods; the danger from dropping the smallest stone in building the walls, lest it start an avalanche of rock; the lack of all shelter for the workmen; the difficulty of procuring water; constant dangers to the lives of the workmen—all these were discouraging conditions. But the workmen, following the example of their chiefs little by little, grew courageous and confident, and finally conquered all opposition.

The result of the first five campaigns exceeds the most san-

guine hopes, and the Combe has been subdued without damage or accident.

CONCLUSION.

The problem offered by the laws of 1860 and 1882 is now solved. Facts have abundantly proved that the solution is neither long nor costly, and that it is only necessary to aid nature by a series of small measures judiciously conceived and carried on with system and persistence.

The 579 square miles of forests recently created in the three regions, whether by the state or by communities and individuals, insure quiet for the future, and demonstrate by their vigorous growth how empty were the allegations of the politicians, who in 1860 ridiculed the possibility of reforestation. The task, indeed, is hard and thankless. It is on the most desolate mountain-heights, or in the depths of gorges, which they alone penetrate, that the foresters do their work quietly, often in face of public indifference, or even the hostility of selfish interests.

I can recall no nobler mission than theirs. Surrell was right when he said: "I dare to predict that the usefulness and the grandeur of this work will one day be recognized, and that it will have a place of honor among the great enterprises which will signalize this epoch throughout all coming time."

[A series of heliographs were shown at the Paris Exposition which vividly illustrated the magnitude and difficulty of the work of the French foresters in their campaigns against the torrents. Copies of many of these pictures have been exhibited at some of the meetings of the American Forestry Association, and some of them are now to be seen in the National Museum at Washington. Mr. Fernow, Chief of the Bureau of Forestry, has had plates made of some of them, and it is to be hoped that they will be published in a future Government report. On page 620 we give an illustration of a series of corrective works on the torrent of Grollaz, which will explain itself. The denudation of the mountains here was comparatively recent, and the Grollaz has only been a dangerous torrent in late years. In 1880 it had become a constant menace to the wagon-road between France and Italy and to the Mont Cenis Railroad, and at one time it seemed certain that the railroad would have to be moved to the other side of the arc, to which the Grollaz is tributary. But the steep-banked, narrow gulch, through which vast quantities of mud and stones were carried after every rain, is now a broad open bed. Its steepness is all taken up by the falls of the dams, and it carries no waste into the valley below. When the banks are covered with forest, the torrent will be definitely extinct. Of course, only a small portion of the engineering work can be seen in this picture, but the result of it all is, that not only are the road and the railroad safe, but canals for irrigation have been dug from the different levels made by the dams, and the Grollaz is now enriching the very fields from which it had once driven their owners.

We are indebted for the picture from which our illustration is made to Mr. Gifford Pinchot.—Ed.]

Correspondence.

In the Shore Towns of Massachusetts.—IV.

To the Editor of Garden and Forest:

Sir,—Marshfield formerly had a common. In earliest times it was the Training-field. The town ran a public road through it, and a religious society has a perpetual lease of a part of it as the site of its chapel. During recent years various persons have obtained permission to build horse-sheds on the remnants of the common, and there is not much of it left for future appropriation. Mr. Seth J. Ventress, who was born in this town, learned to lay brick and stone as they should be laid in structures that are to abide and endure, and he came to know more than anybody else about bakers' ovens and how to build them. He had $40,000 when he came to die a few years ago, and left $10,000 in trust to build Ventress Memorial Hall here, within three-fourths of a mile of the meeting-house, for a town-hall and public library. Daniel Webster's grave is in this town, and it is visited by thousands of the summer people. His birthplace, in the town of Franklin, New Hampshire, is not marked in any way.

Kingston has no park or common, or rights on the shore. Duxbury has a town-landing, perhaps two of them, not used. The Standish monument is here. It stands on the slope of a hill, because the top, the right place for it, could not be bought for this purpose. The Monument Association owns a small area around its base. It should be considerably extended and improved, and made a convenient and attractive place of resort for great numbers of people. This region is full of interesting local history and historic places.

Plymouth keeps its old Training-green, or some of it, a scant acre now. There is a tract of perhaps five acres around the great statue of Faith, and a small area about the celebrated Rock, down by the water-side. Coles Hill, where a few of the first burials were made, is a small, steep hill-slope just above the Rock, and is used as a park or place for seats for those who wish to contemplate the Rock and enjoy the view of the water. Burial Hill, five or six acres, is practically a park, and has many visitors. There are few interments now.

The great possession of Plymouth is Morton Park, 150 acres of unsurpassable woods, lying along the shores of Billington Sea. It has been described in your pages in more graceful prose than my pen can write. Mr. Morton seems to know every tree and every inequality of surface in the park. The city ought in time to own the shore lands entirely around Billington Sea. Plymouth is a very large town. It is eighteen miles across it, from the Kingston line to that of Sandwich. This great region is mostly woods, and is well watered. People say that a man can camp by a different lake every day in the year in this town, but I did not have time to camp by all the lakes or to count them. It is an enchanting region for summer residence, and people are finding it out in increasing numbers. There will be thousands of summer dwellers on these beautiful lakes in a few years. Every acre outside Morton Park is a private holding. Intelligent men here say that the permanent reservation of a strip of woods on each side of the public roads would greatly improve them. As much of the land is valued at twenty-five cents an acre for taxation, it would probably not be difficult to make a public holding of a belt a few rods wide on each side of all the principal public roads. This would give to great reaches of country much of the aspect and character of a park.

The method of keeping the public records of the town has been brought to a wonderful degree of accuracy and convenience. To the student of civilization these records are among the chief attractions of the place. The Pilgrim Society has an interesting collection of furniture, implements and other articles used by the early inhabitants. It is a valuable instrument for awakening and fostering interest in local history, and influences working to this end are much needed in the shore towns.

Sandwich has no town holding of any kind for a place of public resort. The Sandwich Glass Company had a small common near the glassworks, with large trees and seats for the operatives. It was a pleasant and valuable resting-place for them, but the company has gone out of business and the common is uncared for. There is a piece of remarkably interesting scenery near the road from Sandwich to Mashpee. It is a vast wooded hollow, or deep valley, which happens to have just the right proportions to be impressive. It ought to be defended from forest-fires, and its sylvan beauty perpetuated. There is no place of public resort in Bourne, and the boys of this town say they have no right to meet anywhere out-of-doors for athletic exercises, amusement or mutual improvement. Playing ball along the public highway causes complaint and is dangerous to persons passing, and if the boys assemble in a field or pasture they are warned away as trespassers. The boys think there should be a Town Field, or public playground, and some of the leading citizens take the same view of the matter. Intelligent men here feel much interest in the law relative to preserving ornamental and shade trees on the highways of the state. It is Chapter 196 of the Acts of 1890. The people here say their roads would be much better if the trees along the road-sides were left standing; that the highways are often injured, and all their beauty is destroyed by widening them unnecessarily; and that when they are straightened, and the old curving lines are abandoned, the scenic interest and value of the region is impaired, and the drives are rendered unattractive. Half-way between Buzzard's Bay Station and Bourne are the remains of an old trading-post, which was established here in 1627. The old cellar-pit and its walls are still, to a great extent, unchanged, but the land has been sold recently, and is likely to be improved, and this interesting monument of early commercial activity will probably soon be destroyed.

There has been considerable successful tree-planting in Barnstable. I walked about a piece of woodland which was planted

by its present owner, and which has long yielded valuable annual crops of timber for fuel and other purposes. It begins to look really forest-like. The Pitch Pine (*Pinus rigida*) is the tree which has been chiefly planted in this region. There are no considerable public holdings for places of resort in Barnstable. Old citizens say the town formerly held several hundred acres of town or common land, but that these tracts were seized by various persons who lived on them till they gained title by occupancy.

Yarmouth had, in earliest times, a little reserve, or common field of clay for making brick for the people. It was much used long ago, but not in recent years. A few years ago the town voted to fill it in and fence it, and it is now a pretty bit of common, with trees and grass, perhaps an acre in extent. There was formerly a town-landing on Bass River, but it was sold a few years ago. In early days Yarmouth granted portions of her common lands to various persons who were to retain these holdings as long as they "improved," that is, used them. These titles were not intended to be transferable to other citizens, but to revert to the town if the first holders should leave the lands. But the persons to whom the grants were made sold their rights, or claims, to others, who transferred them in turn, and the town's title was ignored. The town appointed a committee of lawyers and others to inquire into the matter. They reported that it did not appear to be worth while for the town to undertake to assert title to these lands. Bass River, between Yarmouth and Dennis, yielded $600 to each town, last year, from the sale of the right to the herring fishery.

Dennis is a beautiful town, full of quiet, satisfying scenery. There is a Cedar-swamp here, with unusually large timber. The "Old Whaling Ground" on the shore is an interesting town-holding. The editor of the *Register*, in Yarmouth, who has a remarkable knowledge of the local history of the region, told me that the Old Whaling Ground belongs jointly to the towns of Dennis and Yarmouth, as it was a common, or town, possession when the two towns were one. There is a very old Indian burying-ground on the shore of Scargo Lake, in Dennis, about an acre in extent. The town fenced it last year. The title is in the two towns, Dennis and Yarmouth. The Indians buried here were of the Nobscusset tribe. There is no park or common in Dennis belonging to the town. An acre or more around Liberty Hall, owned by an association, is called the Park. It is not, at present, much used or cared for.

There is a pretty little circular green near the church in Brewster, which belongs to the parish, and is, possibly, a fragment of the ancient Training-field. There is a town-landing on Cape Cod Bay, perhaps 200 feet of shore-line, at the end of a street. The town owns a herring or alewife brook, and appoints an alewife committee at the annual town meeting to catch the fish and dispose of them. Formerly the fish were abundant, and the town would often have 300 barrels of alewives a year. A family of eight persons would then have a right to a barrel of fish, and could buy more at thirty or forty cents a barrel. The committee now sells the fish to anybody who wants them. The gross catch is small of late years, not worth more than $100 usually. The population is decreasing, but it is likely soon to receive considerable annual reinforcements of summer inhabitants.

There is a green of perhaps an acre and a half in front of Pine Grove Seminary, in Harwich, the gift of Mr. Sidney Brooks, principal, and former owner. The town owns Herring River, from Long Pond to the ocean, about six miles, and has recently sold the fishing right for five years for $615 a year. Three citizens bought it to enable them to control the water for the benefit of their Cranberry-fields. Some of the people wish the town to sell the public fishing right once for all, finally and entirely—that is, to relinquish and extinguish this particular holding. There are many fine trees along the streets in the villages of this town.

Chatham appears to be the most easterly point in the state. There is no common or park. The town probably has a right in the long beach, but it has not asserted it lately. The marsh-hay was formerly sold by the town every year. There is a very old cemetery; the title is in the town. It has not been very well cared for. Some valuable materials for local history have been lost by the deaths of several old inhabitants within a few years. Champlain was here in 1606, I believe, and had some rough experience. He broke his rudder, probably on Pollock Rip, and found it difficult to make a landing. The Indians helped him, but afterward he had a fight with them, and two of his men were killed. He called the place Port Fortune, and set up a cross on the shore. Some of the people here know the place, approximately at least, and it would be well to mark it in some way The shore region here is interesting and attractive, and the summer people are crowding in. The depth of the water along this part of the coast is constantly changing, and the wariest navigators meet surprises. One of the great chart-makers of the world lives here, and his fame is known in all littoral countries.

Boston, Mass. *J. B. Harrison.*

An Indian Orchard.

To the Editor of Garden and Forest:

Sir,—When the whites settled in Oneida County, in the centre of New York state, they found there an Apple-orchard owned by the Tuscaroras. It was long known as the "Old Indian Orchard." The trees were set without the least consideration of order, and they numbered several hundred. The sorts were varied, and did not correspond to the cultivated fruits, but were evidently seedlings from those in cultivation. We have now at least one of these, known as the "Indian Rareripe," grafted about the state. It is a large, excellent, handsome, early-autumn Apple. It was the best mid-early fruit we had before the advent of Porter and Gravenstein and Strawberry. Whether other sorts from this source are still propagated I cannot say.

The Tuscaroras reported that the orchard was on their land when they came from the south to join the Iroquois League. This is possible, but not probable. It was certainly planted somewhere near 1715 or 1720, when they reached their northern home. They had come into close contact with the whites in Carolina and Virginia; and it is most likely that they obtained the seeds of them and brought them north and planted as soon as they reached here. At any rate, the Indian orchard and the arrival of the Tuscaroras are two events that closely coincide. Had the orchard been planted by the Indians already here, it is unaccountable that they did not have more such plantations. But the Kirkland orchard, of which I own the remnant, planted in 1791, was the only other plantation of Apple-trees in central New York in the last century.

Were the Indians in any sense horticulturists? We have been compelled lately to give over our early classification of them as strictly hunters and fishers. They were fond of agriculture. The Mohicans and Iroquois, as well as the southern tribes of Cherokees and Choctaws, were accustomed to raise large fields of Potatoes, Maize, Tobacco, Pumpkins and Squash. Those who lived far enough southward cultivated Cotton, which they wove for clothing. It was an article of traffic, as well as Tobacco and Corn. Not having suitable tools, they adopted the plan of burning over a tract of land and using it for a garden. This was sufficient preparation for Corn, vines and Tobacco, but would have been valueless for the European grains.

The fruits repeatedly spoken of by the early visitors and colonists are Strawberries, Mulberries, Raspberries; but all these are mentioned invariably as growing wild. This is not to be wondered at, when we remember that our own people did not to any extent cultivate the Strawberry and Raspberry until toward the middle of the present century. Fifty years ago we relied for these and for Grapes almost wholly on wild vines. In Brown's "Genesis of the United States" will be found letter after letter going over the fruits with which the Indians regaled their visitors, or enumerating those found on the river-banks and in the villages. Invariably all fruits are spoken of as wild. This admirable work carries us into direct contact with original documents. Bancroft, in his "Native Tribes of the Pacific Coast," makes it clear that the western Indians also were entirely deficient in the arts of horticulture. Fruits of the Rose family were always wild. So we come very certainly to the conclusion that our Indian orchard came from seed procured from the whites, and was not the result of artificial improvements, or of selection of a natural sort fostered and taken advantage of by the aborigines. Such other orchards as were found in the west were of a date not anterior to 1700, and were the result of proximity to white people. The Wild Apple of America has not been the parent of any of our choice fruits; but we can invariably trace all our choice stock back to a parentage from Europe. The earliest imported seed was of Pippin, Pearmain, Bellefleur, Gillfleur and Swaar, and the blood of this early parentage can be traced in all the best fruits we now cultivate. The Spy, Wagener, Jonathan, Spitzenberg, Fameuse, Rhode Island Greening, Newtown Pippin are children or grandchildren of the well-known imported roots. Most of our early orchards were from imported seeds.

It seems clear that we have not given the Indians sufficient credit as land-tillers, but yet we cannot compliment them with any truth as horticulturists. Still, the fact that the Indians pre-

ceded the whites with their own rude arts of fruit-growing is interesting. The first orchard planted by the Six Nations, probably by the Sixth Nation, or Tuscaroras, anticipated the work of missionary Kirkland by about seventy-five years. The chief matter of lament is that we have not more minute records of the trees, the apples and the uses made of them. But we have at least one sort, and it should be kept as a historic landmark. If others have data either to corroborate or add to controvert my opinion, I shall be glad to know it. I believe no tree of the original Indian orchard remains. I hope to sustain in life one or more of the trees planted by Kirkland until the close of this century. That will make them one hundred and nine or ten years old.

Those who know the abundance of rich berries in all wild sections will not wonder that the Indians never saw any advantage in growing them in gardens. The Plum was their best large fruit, and was enormously abundant on all the river-banks and forest-edges.

Clinton, N. Y. *E. P. Powell.*

Notes.

Dandelions are blooming to-day on many of the lawns in this city and its suburbs.

In his *Plantes Potagères*, M. Vilmorin figures sixty-six varieties of wheat with clearly distinguishable charcteristics; but in the Agricultural Museum at Poppelsdorf, in Germany, no less than six hundred varieties are exhibited.

Mr. A. H. Church, in his "Food-grains of India," says that the millets constitute a more important crop in India than either rice or wheat and are grown more extensively, being raised from Madras, in the south, to Rajputana, in the north, occupying, in all, about 30,000,000 acres.

California during the year just closing has produced a more valuable crop of fruits and vegetables than in any previous one. Some of the statistics of shipments are 30,000,000 pounds of oranges and 78,000,000 pounds of other green fruits, 72,000,000 pounds of dried fruits, 47,000,000 pounds of raisins and 78,000,000 pounds of canned goods.

Fruit-culture, which is now a very important industry in Bohemia, is said to have been first practiced there on a very large scale at the beginning of the present century by French immigrants who had been driven from their homes by the Revolution. The results of their industry and their love of natural beauty are also to be traced in many of the parks which adorn Bohemian towns.

Colonel Pearson has expressed a fear, in an article prepared for this paper, that the copper mixtures used as fungicides may have a deleterious influence on the soil. Mr. Frank T. Shutt, chemist of the Dominion Experimental Farm, writes to the *Canadian Horticulturist* that the copper which reaches the ground from properly conducted spraying is so minute in quantity and insoluble in nature that no fear need be entertained that it will poison vegetation.

At a recent exhibition of the Royal Horticultural Society Baron Schrœder showed a two-flowered plant of the beautiful *Cypripedium insigne*, var. *Sanderæ*, which was unanimously awarded a first-class certificate. It differs from all other varieties of *C. insigne* (of which we have about twenty named) in having flowers of a uniform shining, soft yellow color, without spots anywhere, while the upper part of the dorsal sepal is pure white. We may look upon this as the nearest approach to an albino Cypripedium yet discovered.

One of the most famous and fatal poisons used in Japan, according to the *Inland Printer*, is obtained from the Bamboo. The young shoots of the cane, when they first push through the ground, are covered with fine, brownish hairs, which, under the microscope, appear to be bayonet-like spikes of crystals of silex, infinitely sharp and hollow. Small quantities of these hairs, administered daily in the food, bring on ulceration of the whole alimentary canal, simulating malignant dysentery, which eventually causes death.

In a paper prepared for the American Pomological Society, Professor Massey says that throughout all the coast region and the lower part of the Oak belt of North Carolina, the Fig produces good crops with literally no cultivation. Some attempts are now being made to raise figs for commercial purposes. In Halifax County one grower last year marketed his crop, from five acres of Figs, in a fresh state in strawberry-boxes, and realized a very profitable return. With modern facilities for canning and evaporating, there is no reason why Fig-culture cannot be made profitable in all the coast region of North Carolina.

The San Francisco correspondent of the New York *Tribune* recently wrote: "Allen Kelly, who has just returned from an inspection of the forests of the Sierra Nevada, declares that the only way for the Government to save the timber-lands from destruction is to withhold all mountain timber-lands now unsold and make a series of reservations from Shasta to the new Sequoia Park. All the high Sierras about the Yosemite must be reserved soon or the timber will be ruined. As it is, the timber is becoming so thin on these high plateaus about the Yosemite that the snow melts rapidly, and most of the water-falls in the famous valley are dry by midsummer."

As an illustration of the general law under which nature seems to avoid hybridizing, Professor Bailey cites the instance of the great genus Carex or Sedge, which occurs in great numbers and many species in almost every locality in New England, and in which the species are particularly adapted to intercrossing by the character of their inflorescence. Even between species of this genus but few undoubted hybrids occur. Among 167 species and prominent varieties inhabiting the north-eastern states, there are only nine hybrids recorded, and all of them are rare or local, some of them having been collected but once. Species of remarkable similarity may grow side by side for years, even intertangled in the same clump, and yet produce no hybrid.

Writing of Haidarabad, the capital of the Nizam's dominions in the Dekhan, in southern India, Bishop Hurst says, in his recently published "Indika": "The garden of the Nizam is public. . . . I never tired of wandering through its labyrinths enjoying its delightful fragrance, and examining the endless variety of its plants. Every art which these cultivators of flowers in India have arrived at by the experience of centuries is here employed, by rich designs in colors, by succession of flowering shrubs, and by a happy combination of large shrubs and the smaller plants. All the more delicate plants are in pots, and need to be watered every day. There are six millions of potted plants alone, to say nothing of the multitude of larger ones."

According to the *Pittsburgh Dispatch*, Mr. Arras, an engineer in the Government service, states "that the beginning of the end has come, so far as the White Oak in Pennsylvania is concerned. The Government lately gave a contract in this city for some square White Oak timber, of a size that a dozen years ago could have been found in the hard-lumber yards hereabout in an hour's time. After a persistent search the contractor threw up his contract, stating that he could not fill it. It was then given to another and, at the end of a fortnight, he reported that he had secured all but two pieces, and that they were not to be had. Mr. Arras then got the order modified, and, as changed, it was filled, after all the log-rafts lying in the river had been inspected."

To a correspondent who inquires which are the best varieties of the Carnation to use as house-plants, we would say that there are no varieties which can be classed among good window-plants. The Carnation is nearly hardy, and it loves pure air and a cool temperature too well to be a successful window-plant in the ordinary sense of the term. A temperature no higher than fifty-five degrees is best suited to it at night, and this is cooler than most living-rooms in American houses. The atmosphere is too dry for the healthy development of many plants, and as the Carnation especially rebels against such surroundings, other plants had better be selected. Of course, where there is a sunny window in a cool, well-aired room, some Chrysanthemums will do fairly well.

Dr. E. Lewis Sturtevant sends some interesting extracts from a translation from an Arabic treatise on agriculture and horticulture, which was published in the twelfth century in Seville. From these extracts it appears that in Moorish Spain as early as the twelfth century, of cucurbitous plants alone there were cultivated Cucumbers, Melons, Water Melons, Gourds and Benincasa for food, and the Colocynth was grown for medical purposes. The Pumpkin had not yet appeared. They show also that many varieties of each of these plants were in ordinary use, and these varieties are carefully described. In the cultural direction it is said that if the seeds of the Melon and Cucumber are soaked in honey the fruit will be of a sweet and pure savor; if in vinegar, in a certain way they become acid. If Cucumber-seed is soaked in fresh milk the fruit will become sweet. It may be added that this opinion is found also in Latin authors.
