TABLE OF CONTENTS.

The White Oak.

OF the Oaks which inhabit the New World, the White Oak (*Quercus alba*) is most akin to the common and familiar tree of all European countries—the Oak of myths and of poetry, of Dodona and Hercynia, the tree which Celt and Briton worshiped, which shaded the Druids' sacred fire, and has in all times been the emblem of strength and longevity. And here in America, when we think or speak in a general way of an Oak-tree, it is the White Oak which naturally most often presents itself to the mind, as the leaves and fruit of this tree resemble more nearly than those of any of our other species the conventional Oak-leaves and acorns with which we have become familiar from childhood.

The American White Oak is a noble tree. In girth of stem and stoutness of branches it is not second to its Old World relative; and there are very few American Oaks which grow over such a wide stretch of country, or are so generally multiplied. The Burr Oak, perhaps, when it has grown under the most favorable conditions, produces timber which is stronger and more solid than that of the White Oak, but there is no American Oak which furnishes universally and over such large areas such a high quality of timber.

As it grows in the dense forests of the Alleghany Mountains, or of the valley of the lower Ohio, the White Oak sends up a tall and massive stem destitute of branches to a height sometimes of sixty or eighty feet, and crowned with a narrow head of comparatively small branches. In less favorable climates or on thinner soil it is a smaller tree, with a shorter trunk and larger branches, which extend laterally in proportion as the individual has found room for their development.

The White Oak owes its name to the color of the bark, which is light gray or sometimes nearly white on vigorous trees, with a surface broken into long, narrow, rather thin scales. The character of the surface is the same on young and on old trees, and only varies slightly in color on different individuals, and, as it is unlike the bark of any other Oak-tree of eastern America, it furnishes the most ready means for distinguishing this tree at a glance at all seasons of the year. The inner bark, as is the case with that of many other Oaks, possesses astringent properties, and has found a place in our materia medica in the form of decoctions.

The wood of the White Oak is very heavy, a cubic foot of dry wood of average quality weighing rather more than forty-six pounds; it is strong, hard, tough and close grained. The annual layers of growth are marked by numerous rows of the open ducts present more or less in all Oak-wood. The broad and prominent medullary rays are silvery white, and make a handsome contrast with the light brown color of the body of the wood.

The leaves of the White Oak when they first unfold are tinged with red and coated with silvery white tomentum. At this time, when the tree is covered also with its catkins of yellow flowers, the White Oak presents a beautiful appearance in the forest, and is perhaps more distinct and attractive than at any other season of the year. As the leaves grow they lose their hairy covering, and at maturity are quite smooth; they are obovate-oblong in general outline, and obliquely cut into three to nine obtuse, mostly entire lobes, which vary considerably on different trees in number and breadth and in the depth of the sinuses which separate them. These sometimes penetrate nearly to the midrib, making the leaf appear almost pinnatifid. The leaves when fully grown are six or eight inches long by two or three broad, and are borne on stout petioles. Late in the autumn, after the leaves of many of the trees with which the White Oak grows have begun to fall, they turn gradually first yellow and orange and then deep vinous red or sometimes bright scarlet. The brilliancy of their autumn coloring is retained for a long time, and, as the leaves die, they turn gradually brown and fall slowly, many remaining on the branches through the winter and until the buds of another year begin to open.

The sterile flowers, like those of our other Oaks, are produced in slender, naked, hanging catkins, which are single, or often several together from the same lateral scaly bud. The male flower consists of a lobed yellow calyx and six to eight stamens with conspicuous yellow anthers. The female flowers, which are composed of a three-lobed sessile stigma and a three-celled ovary enclosed by a scaly bud-like involucre which grows into the cup of the acorn, are solitary or clustered near the base of the shoots of the year. The fruit, like that of all the so-called White Oaks, ripens at the end of the first season. This character best distinguishes these trees from the so-called Black Oaks, which require two summers for the maturity of their fruit. The acorn when fully grown is sometimes an inch long, or often smaller at the north; it is slender, ovoid or oblong, chestnut brown, and enclosed for about one-third of its length in a pale, hemispherical, saucer-shaped cup, which is covered with tubercles at maturity. The fruit is sessile, or sometimes produced on slender stalks an inch or more long, the two forms appearing occasionally on the same tree—a peculiarity also of the Old World Oak.

The White Oak grows from northern Maine, Ontario and the lower peninsula of Michigan to the shores of Tampa Bay, in Florida. It ranges west to western Missouri and Arkansas, and to the valley of the Brazos River, in Texas. In some parts of this great region it forms more than half of the forest-growth. It is especially abundant in the group of states which contain the ranges of the southern Appalachian Mountains and in the valley of the middle portion of the Mississippi River. The White Oak grows on nearly all soils except those saturated with stagnant water. It attains its greatest size on the rich lands of river-bottoms, and produces in such situations its most valuable timber. Mr. Robert Ridgway, whose excellent observations upon the trees of the Lower Wabash and White River valleys, in Indiana, are published in the *Proceedings of the United States National Museum*, records the measurement of a

number of White Oaks produced on different soils. He found that the average trunk-diameter of ten trees growing on bottom-land was 4.59 feet, and that their average total height was 123.60 feet, while of seven trees growing on gravelly uplands in the same region the average trunk-diameter was 2.40 feet, and the average total height only 99.82 feet.

The White Oak was noticed by the earliest botanists who explored the North American flora. Bannister, the English minister, who died in Virginia in 1692, knew it; Clayton, whose Virginia plants were published by Gronovius, remarked on the resemblance of its leaves to those of the English Oak; and Catesby published in 1731, in his "Natural History of Carolina," the first portrait of the foliage and fruit of this tree. It is said to have been cultivated in England as early as 1724, and Michaux, late in the same century, sent great quantities of the acorns and young plants to enrich the forests of France. Such a valuable tree was naturally sought for by European planters, who a hundred years ago were keener than they are to-day in their search for exotic timber-trees. Efforts to grow it successfully in Europe have, however, always failed; and a good specimen of this or of any of the other American species of the White Oak group is probably not to be found there. The reason of this is not easily explained, for nearly all the Black Oaks, especially the Red Oak, the Scarlet Oak and the Pin Oak, grow rapidly and live as long in Europe as they do in this country. Here the White Oak, although it is a difficult tree to transplant, and is best grown from seed planted where the tree is to remain, grows very rapidly, and is one of the most desirable and ornamental of all our native trees for the embellishment of large parks and gardens.

The value of the White Oak from an economic point of view is not easily overestimated. It supplies the principal part of the American oak of commerce, and is very largely used throughout the country in ship-building, in all sorts of construction, in the manufacture of carriages and agricultural implements, for railway-ties, fencing, cabinet-making, the interior finish of buildings, and for cooperage, fuel, etc. For years it has been exported in immense quantities in the form of staves for wine and other casks, for which purpose there is a large and increasing demand for it in Europe, and in California, where no Oak furnishing wood suitable for this purpose grows. There are still great bodies of this timber standing in the United States, especially in western North and South Carolina and in eastern Tennessee and Kentucky and in Arkansas. Railroads, however, are penetrating these Oak-forests, which inaccessibility has thus far preserved from the axe of the lumberman and the settler. Every year the supply is becoming less, and if it is fair to judge of the future of our forests by their past, white oak as a great forest-product must eventually disappear. The time has already arrived when the White Oak is worth preserving. Few of our trees, indeed, better deserve care, especially as a danger more serious even than the axe is threatening to exterminate the White Oak in the very region where it grows naturally in the greatest abundance. The acorns of this tree, like those of the other Oaks with annual fructification, are, unfortunately, sweet, and are, therefore, hunted for and devoured by the hogs which are allowed to roam at will in great bands through the forests of the southern states. They eat the White Oak acorns and pass by the bitter fruit of the Black Oaks, which are, therefore, gradually getting possession of the soil and driving out more valuable species, so that it will be a question of time only, if the pasturage of the southern forests is continued, when their most valuable tree will disappear.

The density of the original forest-covering of eastern America prevented, except in rare cases, the growth of broad-branched, spreading trees such as we so much admire in some of the old forests and parks of England. There are exceptions, however, and fine old wide-spreading White Oaks are occasionally met with in the eastern states. Such trees are those at Waverly, in Massachusetts, which have already appeared in this journal (vol. iii., p. 81), and such is the tree which appears on pages 6 and 7 of the present issue. It is growing on the grounds of Mr. W. H. Fearing, near Jobstown, New Jersey; the diameter of the trunk is six feet at three feet from the ground, and the branches cover a circle 120 feet across. Larger trunks are not uncommon, but such a magnificent expanse of foliage is rare. The tree is fortunate, too, in having escaped mutilation by wind and storm. It has lost no large limbs, shows no dead or dying wood, and is in vigorous health. Altogether the tree is a fine example of what the White Oak can become under favorable conditions, and what character of trees the people who inhabit America three or four hundred years hence will have before their eyes if the present generation of planters plants wisely, and their descendants value trees for what they are worth and bestow upon them the care they deserve.

Dispatches from Washington state that Secretary Noble has asked the War Department for two companies of cavalry to protect the additions to the Yosemite Park and the Tulare Sequoia Reservation from the dangers that beset all Government forests when not under military control. The presence of troops has alone kept the forests and game of the Yellowstone Park from extermination, and no doubt the visible presence of the force of the Federal authority in the shape of armed and uniformed men will do much to prevent wanton destruction of the nation's property by fire and trespass of various kinds. In spite of the smallness of our army and the vast area over which our public forests are scattered, we still feel that these forests would be safer under the control of the army than under any other administration. As matters now stand, the army is the only force that will be likely to represent with any firmness the dignity of the nation against local interest, and against the right which herders and lumbermen, and, in fact, settlers of all kind, feel they have acquired by long usage, to cut or pasture or burn over the woods on the public lands as it may seem for their profit or pleasure to do so.

Old Methods of Preserving Seeds for Transportation.

The *Gentleman's Magazine* for 1760 and 1769 gives some interesting notes on the methods then employed in treating seeds for long voyages. Four methods are described, one as originating with Linnæus, and the other three with John Lewis, Esq., F.R.S.

Mr. Lewis' first method was tried with acorns of the English Oak, and consisted in wrapping the acorns separately in thin sheets of "common yellow bees-wax," warmed so as to be pliable; then adding a coating of "brewers' loam" moistened with a thick solution of gum-Arabic. The acorns were afterward placed in a "chip box," the interstices being filled with dry "house sand," and the box stowed away in a dry cask, from which, after nearly ten months, they were taken out (on arriving at Georgia) "in a state of vegetation, and being set, soon germinated and grew."

Spanish chestnuts were made to retain their germinating power for nearly a year on a sea voyage by pouring a melted mixture of bees-wax and mutton suet over the nuts in an earthen jar; and similarly by using pure bees-wax. Mr. Lewis laments, however, that in one instance, at least, a supply of chestnuts from Spain failed to grow under this process; but he subsequently learned that the nuts had been "thoroughly kiln-dried" to prevent their moulding on the voyage.

The third process tried is similar to the first, with the exception that the nuts were simply wrapped in small sheets of wax. The bottom of the box to contain the nuts was then covered with melted wax to a depth of an inch, and when the wax became partly cooled the nuts were packed in regular layers and the interstices of the last layer filled up with warm, pliable wax; a wooden cover was then secured over all. The acorns thus encased were placed in a dry closet for one year. At the end of this time they were transmitted for examination "to Mr. William Aiton, botanic gardener to Her Royal Highness the princess dowager of Wales at Kew." Mr. Lewis states that in a letter subsequently received from Aiton the

acorns were found to be in a good state of preservation and when planted germinated successfully.

Mr. Ellis remarks that the above methods may suffice for carrying seeds to and from the East Indies, but that they have not been sufficiently tested for larger voyages, and, therefore, recommends "to the curious" the following method contrived by Linnæus, "which has been tried," and, Linnæus affirms, "has never failed":

"Put the seeds in a cylindrical glass bottle, fill the interstices with dry sand to prevent their lying too close together and that they may perspire freely through the sand; then cork the bottle, or tie a bladder over its mouth. Then take a glass vessel so much larger than the one containing the seeds that when the latter is suspended in it there may be a vacant space on all sides of two inches between the two glasses, which must be filled with four-fifths of nitre and one-fifth of equal parts of common salt and sal-ammoniac, well pounded and mixed together. This saline mass, which should be rather moist, will always be so cold that the seeds in the inner glass will never suffer during their voyage from the heat of the sun."

Mr. Ellis concludes with these judicious words: "Perhaps Dr. Linnæus' method will answer the end. I think it worth the trial, especially as he assures us it never fails." To this the editor comments with some warmth: "This seems to be an insinuation to the prejudice of Linnæus' character, the publication of which the reader will the less approve when told that this very method was communicated by Linnæus in a letter to Mr. Ellis in consequence of Mr. Ellis having applied by letter to him for information on this subject."

Washington, D. C. *George B. Sudworth.*

Cranberries in Wisconsin.

IN former issues we have given at some length accounts of the Cranberry as it is cultivated in the bogs of Cape Cod and New Jersey. The following article on the Cranberry in Wisconsin was prepared by Professor Goff and published in a recent number of the *Farmer's Review*:

In several central counties of Wisconsin are extensive marshes, in which the Cranberry-plant is indigenous. From time immemorial the Indians of the country have feasted upon this grateful fruit in its season, and from the first settlement of those regions, farmers, lumbermen and others, at least in productive years, gathered their full winter's supply of cranberries from the spontaneous harvests. But not until the railway had penetrated these wilds did any quantity of the fruit ever reach an outside market, or were the rudest attempts made at improving the marshes, or at introducing the most primitive culture. The crop borne, bountiful in some seasons and very scanty in others, was entirely at the mercy of the elements. When these were favorable the ungathered harvest returned to the soil that gave it by the thousand bushels. But fire or drought or untimely frosts often so far cut off the yield that only the leisurely Indian found time or patience to avail himself of it. It is scarcely more than twenty years since the first systematic attempts were made at improving these extensive marshes, or at gathering the fruit on a commercial scale. A few years previous to 1870 interest began to be awakened in Cranberry-culture in the vicinity of Berlin, in the eastern part of the state, and the more available tracts of Cranberry-land began to be improved in a primitive way by clearing out brush and fallen trees and excavating ditches for the better control of the water. A few years later (about 1873) railroads were extended eastward and west across the central part of the state, which opened up hundreds of square miles of native Cranberry-marshes. The success that had been attained in the neighborhood of Berlin gave a stimulus to the industry in this new field, and soon capital and enterprise began to be attracted there.

From that time to the present the business has shown a gradual, but tolerably steady advance, both in the area cultivated and in the methods, until at last the output of cranberries in the average season amounts to about 5,000 barrels. The greater part of this aggregate, however, is as yet gathered from wholly unimproved marshes. How long this increase will continue it is impossible to estimate. The market for cranberries may be considered as almost unlimited, and if all the Wisconsin marshes were available for improvement the present annual product might be multiplied by thousands. But while one may in places ramble ten miles in a straight line over continuous native Cranberry marshes, the conditions are such that only the areas lying near the railroads can be profitably improved. Owing to the quaggy nature of the soil of the marshes horses are scarcely available either for traffic or labor, and it will only be after the construction of costly roads that the marshes located at a distance from the railways can be utilized. At present the locations adjoining the railroads that are fortunately situated as regards water supply are for the most part in a fair state of improvement.

The methods of culture practiced in Wisconsin are of a much more primitive kind than those in use at Cape Cod and in New Jersey. Very few of the Wisconsin marshes that are considered improved have ever been systematically planted. The "improvements" consist simply in clearing out foreign rubbish and in ditching the ground, so that the water may be under some system of control. Very few of the marshes have conveniences for flooding at pleasure, and the number that have been "turfed" and systematically planted is perhaps still smaller. The "turfing" consists in breaking up the tough sod of the marshes at a dry time, and piling the turf into heaps for burning. This destroys most of the native plants that interfere with the growth of the Cranberry-shrub, and leaves the ground in a smooth condition for planting. The process of sanding the marshes, so common in the east, has scarcely been attempted in Wisconsin. Sand is rarely sufficiently available in the marshes to make the expense warrantable, and it is, indeed, a question if much would be gained by the process. The comparatively few Cranberry-beds that have been planted in Wisconsin have been set with the native plants of the locality. Little attention has as yet been paid to varieties. In the Berlin district a very large and fine bugle-shaped variety is native and has been considerably planted in that part of the state. In the marshes situated in the more western districts this variety abounds to some extent, but is so much mixed with others as to render the separation of the plants a difficult task. I was informed by persons who are familiar with the Cape Cod and New Jersey marshes that nearly all the varieties grown there are to be found wild in Wisconsin.

It cannot be denied that the northern latitude and the consequent danger of early frosts is a drawback to Cranberry culture in Wisconsin. But experience shows that this drawback is by no means fatal to success. In the more improved marshes, where the ground is kept free from grass, and so becomes, to some extent, warmed by the sun, frosts are found to be less injurious than in the wild ones. Where the marshes can be promptly flooded, injury from frosts may be effectually prevented, and some of the other means that have been tried to prevent frost injuries promise good results. One of these, used the past season on the extensive marshes of Messrs. S. & A. S. Mills, at Millsonia, Monroe County, is especially promising and worthy of being described in detail. The hay that is cut during the summer upon the embankments along the ditches is left in small piles, where it partially dries and partially decays. By the time the frosty season arrives this hay is in just the condition to burn gradually, with a great deal of smoke and vapor. But the use of smoke as a preventive of frost is by no means new. The part that is original with the Messrs. Mills is the means used to compel the smoke to drift over the marshes instead of being wafted away by the breezes, as so often happens where this method is tried. A large number of campaign torches are set up at distances of a few yards from each other throughout the central part of the marsh, and as the wet-bulb thermometer gives its frost warning, the grass piles and the torches are lighted simultaneously. The heat generated by the torches is soon sufficient to start an upward current of air at the centre of the marsh, which immediately causes an inward counter current at the surface of the ground. This wafts the smoke, steam and warmed air from the grass-fires around the borders of the marsh inward toward its centre, and the result is that the marsh is hovered over by something of the nature of a thin summer cloud.

While it cannot be claimed that this method of protection from frost has been sufficiently tested, it was used the past autumn on the marshes of the Messrs. Mills with apparently complete success. The torches possess one important advantage over the other means that have been proposed for preventing frost by means of fire, viz., they can be used amid growing crops without in the least endangering them. If it must be confessed that the methods of the Wisconsin Cranberry-growers are somewhat of the slipshod order as compared with the more prim and expensive practice of the Eastern fraternity, it must be admitted that the growers themselves are not lacking in enterprise when the main question is at stake. They have a wide-awake State Association which holds its annual meeting in August to form estimates of the yield and agree upon a schedule of prices. To show that these estimates are more than haphazard guesses, I mention that in the scant cranberry-crop of 1889, the total estimates,

which amounted to something more than 20,000 barrels, were within 16 barrels of the actual output of cranberries for the year, and the estimates of the previous year were nearly accurate. No good reason appears why the cranberry interest of Wisconsin should not, when fully developed, rival any other interest of this progressive state. Already the importance of the industry is attracting eastern capital to some extent, and as new railroads open up tracts of Cranberry-land not yet available for improvement, the business will unquestionably be much extended. The fine keeping quality and color of the Wisconsin fruit is rapidly making for it a place in the markets, while the ease with which the marshes are improved and cared for will render successful competition with the more limited Cranberry-regions of the older states a comparatively easy matter.

Notes on North American Trees.—XXI.

A south Florida and West Indian tree which has often been referred to *Myginda integrifolia* of Lamarck differs in such important characters from the other species of this genus, as Kunth and Grisebach pointed out long ago, that it hardly seems possible to unite it with them without greatly emending the characters of the genus as generally limited to receive it. The unisexual flowers, cup-shaped, fleshy disc, two-celled ovary, suspended ovules and seed, appear to sufficiently distinguish this plant generically; and I should propose for it the name of Gyminda,* the name of a section of Myginda established by Grisebach (*Cat. Pl. Cub.* 55) for our plant.

The genus is an anomalous one with many affinities, as Kunth pointed out, with *Ilicineæ*, from which, however, the prominent cup-shaped disc of the flower and the opposite leaves separate it; while it differs from all the American *Celastraceæ* in its solitary suspended ovules.

A specific name must be found, too, for an examination of the specimen (without flower and with a single fruit only) in Lamarck's herbarium, now in the Museum in Paris, upon which he founded his *Myginda integrifolia*, shows that it is not a Myginda at all but the *Rhamnus ferrea* of Vahl now referred to Condalia by Grisebach, so that *Myginda integrifolia* must become a synonym of that plant. Nothing, therefore, stands in the way of associating with our tree the name of the distinguished botanist Grisebach, who appears first to have understood its peculiar structure and monotypic character. The rather complicated synonymy of this plant as I now understand it is:

Gyminda Grisebachii.

Myginda integrifolia, HBK., *Nov. Gen. & Spec.* vii. 66 (not Lamarck, *Dict.* iv. 368).—De Candolle, *Prodr.* ii. 243.—Grisebach, *Cat. Pl. Cub.* 55.—Sargent, *Bot. Gazette*, xi. 314.—Trelease, *Proc. St. Louis Acad.* v.

M. pallens, Sargent, *Forest Trees N. Am. 10th Census U. S.* ix. 38 (not Smith).

M. latifolia, Chapman, *Fl. S. States*, 76 (not Swartz).—Trelease, *Trans. St. Louis Acad.* v.

There is a form with rather smaller and more broadly obovate, thinner and very glaucous leaves, found in Cuba by Charles Wright (No. 81ª) and distinguished by Grisebach as *Myginda integrifolia glaucescens*. For this *Gyminda Grisebachii*, var. *glaucescens*, would be the varietal name.

The Florida Myginda (Palmer, Key West, 1874, No. 81; Curtiss, No Name Key), referred usually to *M. pallens*, Smith (see Chapman, *Fl. Southern States*, Suppl., 612.—Trelease, *Proc. St. Louis Acad.* v.), turns out to be *M. latifolia* of Swartz, to which, I suspect, Smith's plant also belongs. Professor Wittrock, of Stockholm, has most obligingly compared a specimen of the Florida plant with the type of *M. latifolia* preserved in Swartz's herbarium and finds them identical; and his conclusions are confirmed by a leaf from Swartz's plant with which I have been favored.

C. S. Sargent.

Gyminda, Nov. gen. Celastracearum. Flores dioici. Calyx parvus, tubo brevi urceolato, lobis 4, rotundatis. Discus cupularis, crassus, 4-lobus. Petala 4, rotundata, reflexa. Stamina 4, inter disci lobos inserta; filamentis subulatis, incurvis, excertis; antheræ oblongæ, introrsæ, 2-locularæ, loculis confluentibus, longitudinaliter dehiscentibus. Ovarium, oblongum, sessile, cum disco confluens, 2-loculare; stylus 0; stigma terminale, 2-lobatum; ovula, in loculis solitaria, ab apice loculi pendula; raphe dorsalis. Fructus parvus, obovatus, drupaceous, carne parca, putamine crustaceo, 2-loculari. Semina pendula; testa membranacea, albumine carnoso. Embryo linearis, axilis; cotyledones ovatæ, amplæ; radicula supera, hilo proxima.

Frutex vel arbor glabra. Folia opposita, oblongo-ovata, ad apice rotundata vel emarginata, integerrima, vel crenata, margine crasso revoluto, brevita petiolata, coriacea, sempervirentia. Stipulæ parvæ, caduceæ. Flores bi-bracteatæ minuti, subcymosi, pedunculis, axillaribus, dichatome pauci-floris. Fructus nigrus vel coerulescens. Species unica. Antillana et Floridana.

Gyminda Grisebachii.

New or Little Known Plants.

New Orchids.

Cattleya granulosa, var. Buyssoniana, O'Brien, is a beautiful variety with ivory-white sepals and petals, and the front lobe of the lip rose-crimson, with some yellowish markings. A plant was exhibited by Messrs. Linden, L'Horticulture Internationale, Brussels, at a meeting of the Royal Horticultural Society on October 14th last, when it received an award of merit.—*Gardeners' Chronicle*, October 18th, p. 447, and November 22d, pp. 588, 589, Fig. 116.

Dendrobium × Cassiope, Rolfe, is a very pretty little hybrid raised by Mr. Norman C. Cookson, of Wylam-on-Tyne, from *D. Japonicum* fertilized with the pollen of *D. nobile abliflorum*. The flowers are pure white, with a clear maroon-purple throat to the lip. It can well be compared with *D.* × *euosmum* and *D.* × *endocharis*, two of the most elegant little hybrids yet raised.—*Gardeners' Chronicle*, November 29th, p. 620.

Cattleya superba, var. alba, Rolfe, is a most beautiful pure white variety, discovered and cultivated by Mr. Edward S. Rand, of Parà, Brazil. It is to be hoped that a stock of it will in time appear.—*Gardeners' Chronicle*, November 29th, p. 620.

Cypripedium × Arnoldianum, Manda, is a distinct and pretty hybrid raised from *C. superbiens* and *C. concolor* by Joseph Manda, Jr., of Short Hills, New Jersey, U.S.A. It is said to have flowered when less than two years old, the quickest time on record for a Cypripedium. The flowers are lemon-yellow, with vinous purple nerves on the dorsal sepal, some dark spots on the petals, and some deep vinous purple veins and dottings on the front of the lip. The staminode is lemon-yellow with purple border.—*Gardeners' Chronicle*, November 29th, pp. 632, 633, Fig. 123.

Cirrhopetalum Mastersianum, Rolfe, is a pretty little species introduced from the Dutch Indies by Messrs. Linden, L'Horticulture Internationale, Brussels. It is allied to *C. gamosepalum*, Griff. The peduncles are reddish crimson and the flowers orange-yellow, with brownish crimson lines, except on the upper half of the lateral sepals; the lip is purple-brown.—*Lindenia*, vi., p. 33, *t.* 255.

Kew. *R. A. Rolfe.*

Cultural Department.

Notes on Some Hardy Wild Roses.—I.

In a standard work on Roses, by an eminent authority and pleasant and entertaining writer, the wild type of our Roses is spoken of as "fit only for the road-side." But this statement was made before the general introduction of that exceedingly hardy and handsome species, the *Rosa rugosa*, from Japan, and its still more beautiful white variety known as *Rosa rugosa alba*. A typical Wild Rose may be said to be any single flowered wild species which has not become much changed or modified by cultivation or artificial treatment at the hands of man. Semi-double forms and plants having unusual peculiarities are sometimes found growing wild, but they are exceptional, and, as a rule, abnormal. Although always admired and sought for and furnishing a theme for many a poem and homily, these single species remain comparatively rare in our gardens, being quite supplanted by the vast number of hybrids and other double Roses of artificial origin. But besides their chaste beauty of flower, some of the single species have another recommendation in the bright colored fruit which they show in the autumn, whereas the double flowered garden varieties generally produce no hips.

The Wild Roses are all, apparently, easy of cultivation in good garden soil; but a few may seem more at home and give more satisfaction under exceptional conditions. As a rule, all of them may be safely and exactly reproduced or propagated, according to their kind, by seed. If, however, it is desirable to perpetuate a peculiarity of color, a free-flowering habit, large blossoms, or any other characteristic of any individual plant, it should be propagated by cuttings or layers and not by seed. Some species form new roots very readily,

while others demand a little trouble and care in the production of new plants by division.

Grafting or budding of Wild Roses should be avoided as being of little utility and likely to perplex the amateur.

There has been much confusion and diversity of opinion among different botanists regarding the limitations and the number of natural species of the Roses of the world, some writers reducing the number of species to a score or two, while others have divided them into several hundred specifically distinct kinds. So many of these Wild Roses resemble one another so closely that there seems to be strong grounds for keeping only a limited number of specific names, many intermediate forms being referable to some typical characteristic species.

Some of the largest-blossomed and most beautiful of these single-flowered Roses are not hardy in such a rigorous climate as that of New England, but in our southern states they are or may be perfectly hardy and at home.

Among recent studies of Wild Roses by rhodologists certainly none are more thorough than those by Professor F. Crépin, of Brussels, who has devoted many years to a careful study of this genus. In his classification he divides all the species into a number of groups or sections, chiefly according to the characters and affinities of their flowers and fruit. As already stated, it is not always easy to determine the species of these plants. A student of the American Wild Roses, Dr. G. N. Best, very truly says: "Few plants are more strikingly modified by differences in environment than Roses. Even the younger growths appear quite different from the older, so much so indeed as to cause them to be taken for different species. A knowledge, therefore, of the value of characters is desirable. Quite contrary to what was once thought, the varying degrees of pubescence, glaucousness, glandulosity, and, to some extent, of prickles, possess little diagnostic value, and are to be considered most frequently as accidents of growth depending on peculiarities of soil and location for their development. Not that they are wholly devoid of value, but are so only when taken in connection with characters of the first order. . . . In rank bushes the spines may be stout and curved, in depauperate and slender, straight, and yet belong to the same species. They are frequently absent from bushes to which they normally belong, and this from no known cause." Such variations are liable to become more marked under a long term of garden cultivation, especially in regard to the size and vigor of all the parts of the plants. Where a large number of species are grown together it would seem that foreign pollen must sometimes have an influence on some of the seedlings of an allied species and natural hybrids be the result. In botanic gardens, where pure seed of any good species is desired, it would be well to protect the blossoms from visitations by insects, some of which are industrious collectors of the pollen.

One of the largest groups of wild Roses is that to which the old-fashioned Cinnamon Rose belongs. The single-flowered type of the Cinnamon Rose (*Rosa cinnamomea*) is a native of Europe and northern Asia. It is perfectly hardy where the thermometer registers thirty degrees below zero. The blossoms are of good size, fragrant, and in color like the double-flowered form which has been grown in gardens for centuries. This form has been neglected since the advent of so many finer double garden Roses. In some places it has escaped from cultivation and is found away from any building, covering considerable patches of ground by gradual spreading from underground shoots. *Rosa cinnamomea* is an early flowering species; but one of the earliest, if not the very earliest, of wild Roses to bloom here is *Rosa acicularis*, a species common in northern Europe and Asia and also indigenous in America. This may be made to include the *Rosa Engelmanni* figured on p. 377 of the second volume of GARDEN AND FOREST, or the *R. acicularis*, var. *Bourgeauiana*, as it was first named by Crépin. Under cultivation *Rosa acicularis* is an erect, vigorous bush from six to eight feet high, with stems and branches usually quite thickly covered with rather slender prickles. In this region the first of the large rosy pink flowers often expand as early as the 15th or 20th of May, and the fruit which follows ripens and becomes bright red in the latter part of August. It is a very hardy plant and blooms freely. It does not appear to have given origin to any double garden forms or to have been used much in artificial cross-fertilizing.

Rosa alpina, from Europe, has much the same habit and stature as the last species, and its flowers are hardly distinguishable and seem almost equally early. It is, however, comparatively unarmed and bears very few prickles. A number of double varieties have been derived from this species, and it is said to have been one of the parents of the old climbing, double-flowering kinds known as the Boursault Roses.

Rosa Beggeriana is an Asiatic species, which, although hardy, has not yet shown great vigor or long life here. It attains a height of five or six feet, and is erect, with slender branches which seem insufficiently covered by the foliage. It has slender spines, and the flowering branches are quite smooth and without prickles. The delicate pearly white blossoms are not large, averaging about an inch and a half across, and they are pleasantly fragrant. The fruit is small, round, and dark red in color. The regular blooming of the plant begins about the second week of June, but a few flowers continue to appear throughout the summer, imitating the habit of *Rosa rugosa*. Although the few stray flowers do not make much of a show, the habit may be further developed by selection, and the species is one which may yield some interesting hybrids. Professor Crépin states that there is a double variety of this in cultivation in the gardens of Turkistan.

Arnold Arboretum. *J. G. Jack.*

Pomological Candidates for Promotion.

IF, in the near future, it should seem good to the members of the American Pomological Society to revise its fruit list, with the purpose of amending and enlarging that portion of it allotted to the "best" apples, it would be well that the apple culturists of the continent should begin now to consider the subject, and make known their opinions. It seems to me that the state and provincial lists ought really to be made the basis of the continental list. In this way would be removed the anomaly of a list like the present, which contains so few varieties other than those of the north-eastern states. Surely the south, the west and the Pacific coast ought to be heard from; and even in the north and east there may be apples better entitled to the highest place than some of the present list.

It will be urged that time is required before any variety should be promoted to the highest place. Certainly, time enough should be allowed to permit a majority of the members of the Society to have some adequate knowledge in regard to fruits put forward as candidates for this award. But this need not be very long, when it is so easy in a few years to acquire the necessary acquaintance with such fruits. It must be determined, also, whether high dessert quality alone, without reference to thrift, productiveness and commercial value, is to be sufficient. Some of our finest apples are strictly garden sorts, requiring high culture and special treatment to fully develop their merits. But in these times such a need does not exclude a fruit from commerce. The great improvement which has taken place in our market gardens can be and is being extended to our orchards; and choice varieties, well grown and properly handled, can be made commercially profitable in the hands of competent growers, provided that they join to excellent flavor the other market qualities in a reasonable degree. If, however, a variety is absolutely unprofitable, and cannot be grown except as apricots are grown on our Atlantic slopes, it certainly is open to doubt its admissibility to the list of best apples on the mere quality of the fruit.

It ought to be in order, also, to inquire why sweet apples are excluded from the highest place. We have not excluded other fruits for this cause. On the contrary, sweetness is an acknowledged merit in our grapes, plums, oranges, peaches, strawberries and many other fruits. Mere sweetness, unaccompanied with other definite and acceptable flavor, may not be thought to entitle an apple to the highest place. But a considerable number of our sweet apples possess marked excellence of flavor other than saccharinity, if I may be allowed to use the term.

Further, it may be questioned whether it should be required that an apple be found "best" in every part of a country so large as this. If growers over a considerable section, or even of a single state, are unanimous in claiming this position for any of their choice fruits it should be allowed. Practically, this was the course taken in making up the present list, which was mainly done when the attendance was chiefly from eastern states.

I have been at the pains of drawing off and classifying carefully the apples rated by Downing as "very good," "very good to best" and "best" in his "Fruits and Fruit Trees of America." A considerable proportion of the apples described are given no rating; and those in the second appendix, though the quality is frequently spoken of, are not rated by this otherwise general system. A few varieties termed "excellent" I have included under the head of "very good," though it might be inferred that they are entitled to a higher rating. I here

append the names of the apples in the two higher lists, "very good to best" and "best," out of which (but not exclusively) I think a considerable number might be taken which are every way equal to some in the Society's list of "best." There are apples in the "very good" (and even in the "good") list which I believe worthy of the highest rank as dessert apples; but I recognize the fact that it is well to be chary in this matter rather than to err in the other direction. I give also the season (Summer, Fall, Early Winter, Late Winter, etc.) and the state where known. The following list comprises Downing's "best": American Golden Russet, W.; American Summer Pearmain, S.; Early Joe, S., New York; Esopus Spitzenburgh, W., New York; Garden Royal, E. F., Massachusetts; Green Newtown Pippin, L. W., New York; Jonathan, W., New York; Melon, W., New York; Mother, E. W., Massachusetts; Newtown Spitzenburgh, W., New York; Yellow Newtown Pippin, W. There are eleven in number, and except two, of which the origin is uncertain, they are all from two states. It is observable that Downing rarely expresses a definite opinion of the quality of fruits with which he is not somewhat familiar.

Downing's "very good to best" follows: Buckingham, E. W.; Canada Reinette, W., Quebec; Cogswell, W., Connecticut; Dyer, F.; Early Harvest, S.; Ellsworth, W., New York; Fall Pippin, L. F.; Fall Wine, F.; Fameuse, L. F., Quebec; Geneva Pippin, L. W., New York; Golay, L. W., Indiana; Grimes' Golden, W., Virginia; Haskell Sweet, F., Massachusetts; Higby Sweet, W., Ohio; Hubbardston Nonesuch, W., Massachusetts; Hunt Russet, L. W., Massachusetts; King of Tompkins, W., New Jersey; Lady's Sweet, L. W.; Long Island Pippin, W.; Mangum, F.; Monmouth Pippin, W., New Jersey; Peck's Pleasant, W., Rhode Island; Pomme Grise D'Or, W., Ontario; Primate, F.; Red Canada, L. W.; Rochester Pippin, W., New York; Summer Rose, S.; Swaar, W., New York; Wagener, W., New York; Westfield Seek-no-Further, W., Connecticut; White Pippin, W.

This list, it will be noted, contains three sweet apples; of one of them, the Lady's Sweet, he says: "We consider this one of the finest winter sweet apples for the dessert yet known or cultivated in this country. Its handsome appearance, delightful perfume, sprightly flavor, and the long time it remains in perfection, render it universally admired wherever it is known, and no garden should be without it." Of the Haskell, or "Sassafras," Sweet, he says, "tender, juicy, very sweet, rich, aromatic."

It cannot be doubted that there now exist many excellent apples of local fame which are not yet on record in our books of pomology. In a number of states there has been no systematic effort made to search out and place upon record the merits of their native apples; while in others where, in time past, lists have been made, varieties old and new in large numbers remain which have never fallen under the notice of pomologists, yet which may possess very valuable qualities. Is it not time that stronger efforts should be made to make our lists and estimates more complete and more exact?

Newport, Vt. *T. H. Hoskins.*

Fig. 1.—The White Oak (*Quercus alba*) in Winter.—See page 2.

The Pompone Lily.

OF the long list of Lilies in cultivation there are but few that are really hardy and reliable for out-door cultivation here in the eastern states, and of those that are satisfactory the greater portion are late-fall blooming kinds. It is also true that the early summer flowering Lilies are fewer still in number and may be easily counted. *L. pomponium* is one of the most reliable of Lilies; it is perfectly hardy in a well-drained, porous soil; the flowering period is June; the color of the flowers is similar to that of *L. tenuifolium*, the Siberian Lily—that is, bright scarlet, with just a tinge of orange—but, while *L. tenuifolium* rarely has more than one flower to the stem and is a most difficult bulb to keep, *L. pomponium* grows three feet high and often has from twenty to thirty flowers to a stem, and these are very fragrant. *L. pomponium* is a native of northern Italy and southern France, but, as before stated, is perfectly hardy. This Lily is often catalogued as *L. pomponium verum* to distinguish it from *L. pomponium aureum* of Dutch growers, which is very similar to it, but has yellow flowers. These flowers are also fragrant, and the plant has much larger bulbs, which are generally difficult to keep. This Lily is known to botanists as *L. Pyrenaicum*, a native of the Pyrenees, and is quite a different plant from the one under notice. It should, perhaps, be added that, after flowering, *L. pomponium* dies down about the end of July, to reappear early the next spring.

While on the subject of early-flowering Lilies, one cannot

refrain from saying a word in favor of *L. Hansoni*, a beautiful Japan species, named after an enthusiastic American cultivator of Lilies with whom this species first flowered. Descriptions of the flower of this Lily differ as to color; we, however, have always found it to be of a bright yellow, with dull purple spots. Its petals are remarkably thick in texture, which makes the flowers very lasting. This Lily also is perfectly hardy and of easy cultivation, and when grown well often attains a height of four to five feet, the leaves being disposed in dense whorls the whole length of the stem. This also is a distinct Lily, flowering in June, lasting long in bloom, and a plant with which we have never had any difficulty in cultivating. On the contrary, the bulbs increase rapidly when established.

South Lancaster, Mass. *E. O. Orpet.*

Dracæna Lindeni.

THIS is one of the most useful foliage plants that has been introduced during recent years. It lasts a considerable time in rooms without injury, and will bear the temperature and conditions of the conservatory from April until October, or longer if the temperature of that structure does not fall below fifty degrees. Although it will bear for a long time shady positions in rooms and in the conservatory, it does much better and lasts longer where a fairly light position can be accorded it. Highly colored specimens are handsome, but poorly colored ones are ordinary in appearance, and in this condition the plant has not much to recommend it. Success in having the plants a good color or the reverse depends solely upon the treatment they receive. Many have been unsuccessful in this respect through growing the plant in too warm a temperature. In a close stove the plant either becomes green or a sickly yellow, and is destitute of those beautiful markings which render it so conspicuous. Plants that are in this condition will, if removed to a lower temperature, soon develop colored leaves. An intermediate temperature appears to suit it best, although it does not grow so rapidly as under stove treatment. This does not matter materially as long as well colored examples can be produced, for if once they are developed they last a considerable time, and in light sunny positions in rooms we have known them to grow and improve. Plants that were taken into the dwelling-house in June are still there, and will last for some months longer in a presentable condition, when they will be cut up for stock.

This Dracæna does not require to be fully exposed to the sun, but it is by no means particular as to the amount of shade. The temperature appears to be the main factor of importance, whether the foliage colors or not. Even if heavily shaded in a moderately low temperature it colors well. We have this season discovered that it is at home even in a late vinery where the foliage was moderately thin and the air admitted liberally. To develop fine specimens they should never have insufficient root room from the time heads or cuttings are rooted. Pot them from time to time, until they are placed into ten-inch pots, if large, well developed plants are needed. This size is none too large, although the plant can effectively be used for decoration in any size down to two-inch pots. We have found it succeed admirably when potted firmly in a compost of fibry loam, sand and one-seventh of decayed manure.

It has been said that this Dracæna cannot be propagated rapidly enough for general purposes of decoration, and this is true if one system, and a general one, only is practiced. After taking off the head, which sometimes flowers after the plants have been root-bound and checked to wait for side shoots, which are produced one by one at intervals of time, is too slow. A quicker way is to cut up the stem into lengths of about three inches and insert them singly in small pots with sand at the base and plunge them in bottom heat. These soon break into growth, and, when large enough, the young should be taken off and re-rooted. By this means numbers are produced in little more time than one or two would be secured from the stem when allowed to break from the top in a natural manner. Plants of this nature when they bear conservatory treatment during the summer are invaluable in assisting to change the character of that structure.—*Journal of Horticulture.*

Fig. 2.—The White Oak (*Quercus alba*) in Summer.—See page 2.

The Hardy Hydrangea as a Decorative Plant.

WHEN walking through village streets one is often tempted to wish that nurserymen had not been so successful in introducing certain plants. A plant may be beautiful or satisfactory in itself, or when properly placed, and yet produce an unpleasing effect on account of its surroundings. A case in point is *Hydrangea paniculata grandiflora*, a valuable and showy shrub, which is pleasing enough when appropriately placed. This shrub is so readily propagated that it has proved a very profitable plant for the grower, and the result is that it has been the most largely distributed shrub of recent years. In certain streets one will find on the average

about every other lawn, large or small, decorated with one or more of these vigorous bushes, and the effect of the great masses of lumpy heads of white flowers in late summer so frequently repeated, is, to say the least, not very pleasing. These plants make rather rapid growth, and one sees many large masses even in small gardens, where they are often the pride of the owner; but, nevertheless, they do not favorably impress some casual passers-by.

My neighbor, who cultivates a small garden, treated this plant to better purpose last summer, and made a most effective group with it in combination with so-called "foliage plants." He struck, during the early spring, shoots about a foot long, of the Hydrangea, which were planted out at intervals near the grass-border and backed by dwarf Cannas and annual Euphorbias. Some low growing Snapdragons or similar flowering plants occupied the spaces toward the front and gave flashes of color during the season. In late summer the drooping heads of the Hydrangea flowered low, and were relieved by the background and surrounding masses of foliage. The whole effect, with glints of color from Cannas and other flowers, was cheerful, but quiet withal and in excellent taste for a moderate sized lawn. Frequent propagation from cuttings would, of course, require more care than many small growers are willing to take, but it would seem that these small cuttings would often be useful in many positions where the large standards were not satisfactory.

The Annual Euphorbia, *E. heterophylla*, to which allusion has been made, is a half hardy annual from Mexico, and it is also said to occur in south Florida. The plant is readily grown from seeds, is about three feet tall, branching, and with deep green, fiddle-shaped leaves. In late summer the bases of the leaves become a bright scarlet color, but only over a small section in the specimens I have observed. Judging from these it is far from being the brilliant and effective plant that was claimed when it was introduced as a novelty in 1889.

Elizabeth, N. J. *G.*

Clematis paniculata.—About the same time that Mr. Orpet had achieved success in grafting this valuable plant, I succeeded in raising over 200 of them from seed, and these have been distributed through the United States. I have always found it to ripen seed freely, but the seed is slow to germinate. It is better to sow it in the autumn, since nearly a year is saved by so doing. Spring sown seeds do not come up in any quantity until the spring following. When once started the plants grow rapidly and bloom at two years old. This Clematis comes perfectly true from seed, indeed this could hardly be otherwise, as no native allied species bloom at the same season. Seedlings, however, vary a little, and among ours is one superior variety. While time is saved by grafting, I yet think that when a species can be perpetuated by seed it is the best way. This is a well known fact with regard to plants from foreign countries having a milder climate, since much is gained in the way of acclimatization. This climber grows rapidly to a height of fifteen to twenty feet; but as the stems are woody and persistent, the lower part of the plant is apt to become bare. I would, therefore, advise pruning some part of it back yearly in order to keep it well furnished.

Wellesley, Mass. *T. D. Hatfield.*

Peaches for Forcing.—One-year-old plants should be obtained now and placed singly in fourteen-inch pots, or in boxes, two or more in each box, protected in some outhouse for two months and then taken into a greenhouse where the temperature is kept not warmer than fifty degrees at night. They will need syringing twice a day, and the top shoots, as soon as they are three inches long, should be pinched back to three leaves. This will give the lower shoots a slight advantage and balance the growth generally. Of course it is understood that the plants have been pruned into shape before planting—that is, the side shoots are to be cut back and the tops reduced one-third. After the growth is completed in the greenhouse they must be removed out-of-doors and water given them in sufficient quantity to keep them from shriveling. Such plants can be brought into the forcing-houses about the first week of November. Peaches require good loam, bone and potash to grow in. If boxes are used they should not be less than a foot deep and a foot wide, and the plants should be set a foot apart—that is, two plants in a box two feet long, and so on. The boxes may be two, three or four feet in length, and I prefer them to pots.

Pearl River, N. Y. *John Thorpe.*

The Best Peaches.—Among the hardier sorts of Peaches, Hill's Chili is of good quality. Morris White and all of this white class are best for canning, and are hardy. Early Rivers endures cold that will destroy many other varieties, while its offspring, Horton's Rivers, is a perfect freestone, although it has its parent's hardiness and excellent quality, with rather firmer flesh. Hynes' Surprise, ripening at the close of the Early Rivers season, is a perfect freestone, and hardy, too, while St. John follows as the earliest yellow sort. Some of these kinds have never failed of a crop even in the most adverse season. Garfield is a new yellow-fleshed Peach of excellent quality and size which promises to become a standard sort.

Geneva, N. Y. *W.*

The Forest.

Forest-policy Abroad.—I.

THE paper which follows was prepared for the meeting of the American Forestry Association, at Washington, last week, by Mr. Gifford Pinchot, and read by him in an abridged form:

The history of the forest has developed itself along similar lines in all the countries of Europe. If we neglect the factors which tended to preserve the European woodlands—factors which have been largely absent in our own country—this history is not without analogy to that of the forests of America. It may be thus briefly summarized:

In early times the demand made upon the forest was small, and the areas cut over easily covered themselves with young growth. The forest renewed itself and maintained its productive power. But as the demand increased the areas cut over increased with it, and the actual re-growth no longer kept pace with the quantity of timber which the forest was called upon to yield. Thus arose the necessity for planting and for a systematic treatment. Again, as the value of forest-land grew higher the separation and demarcation of the rights held by the state, by communes and by private parties naturally took place, and led it in turn to regular systems of forest-protection and management.

All forest-management may be said to rest on two self-evident truths: (1) that trees require many years to reach merchantable size; and (2) that a forest-crop cannot be taken every year from the same land. From the last statement it follows that a definite, far-seeing plan is necessary for the rational management of any forest; from the first, that forest-property is safest under the supervision of some imperishable guardian, or, in other words, of the state.

It would be impossible in this paper even to touch upon the forest-policy of all the nations which might justly claim attention, and I shall refer chiefly to those concerning which I have been fortunate enough to gain some personal knowledge.

To begin with Germany, we find about two-thirds of the forests under more or less complete control of the state. It will not be necessary in dealing with forest-policy in the German empire to treat independently the different states of which it is composed, because one principle lies at the root of forest-policy in each of them, which may be fully illustrated by reference to any one. This principle, special to no country or form of government, holds that "The state is the guardian of all public interests." It is in its interpretation that, for the purposes of this paper, its chief interest lies. From this point of view "public interests" must be taken to mean all interests other than private ones. So understood, this maxim may be said to sum up the forest-policy of nearly all the nations of Europe, as well under republican as under governments of a distinctly paternal character. For its illustration I will describe in few words the forest-organization of the kingdom of Prussia.

Covering an area of some 20,000,000 acres, the forests of Prussia occupy twenty-three per cent. of the total surface of the country. Their ownership—a point of capital importance in relation to our subject—is divided as follows: To the state belong nearly 6,000,000 acres, or twenty-nine per cent.; to towns, village communities and other public bodies, sixteen per cent., and to private owners rather more than half the total area, or fifty-five per cent.

The relation of the state to the forests which it owns is simple and rational. Holding it as a duty to preserve them for the present share which they take in the economy of the nation, the state has recognized also the obligation to hand down its forest-wealth unimpaired to future generations. It has recognized and respected equally the place which the forest holds in relation to agriculture and in the economy of nature, and hence feels itself doubly bound to protect its woodlands. It has, therefore, steadily refused to deliver them to more or less speedy destruction by allowing them to pass into the hands of shorter lived and less provident owners. Even in the times of greatest financial difficulty, when Prussia was

overrun and nearly annihilated by the French, the idea of selling the state forests was never seriously entertained.

But the Government of Prussia has not stopped here. Protection, standing alone, is irrational and incomplete. The cases where a forest reaches its highest usefulness by simply existing, are rare. The immense capital which the state woodlands represent is not permitted to lie idle, and the forest as a timber producer has taken its place among the permanent features of the land. The Government has done the only wise thing by managing its own forests through its own forest-officers.

The organization of the Forest Service is briefly as follows: At its head stands the Department, or, more correctly, the Ministry of Agriculture, which exercises general supervision over forest-affairs through the medium of the Oberlandforstmeister, Chief of the Forest Service. Next in authority is the Bezirksregierung, a council in charge of one of the thirty-five minor divisions of the Prussian state, which has full control over forest-business within its sphere of action. The members of the controlling staff, the Oberforstemeister and Forstmeister, are also members of this council. Their duties lie in the inspection of the officers of the executive staff, of whom there are 681 in Prussia. These officers, styled "Oberförster," are charged with the actual management of the public forest-lands, and it is on them that the security of public interests in the forest chiefly rests. Upon their selection and education the utmost care and forethought are expended.

Space does not permit me to enter into a full description of a system which has produced, perhaps, the most efficient forest-staff of the present day, and, indeed, the subject has been more than once treated in American publications. Briefly stated, their course of training begins after graduation from a gymnasium, with a year of practical work under some experienced Oberförster. Great stress is rightly laid on this year of preparatory work, chiefly because of the vastly greater force and reality which it gives the subsequent theoretical teaching. As one who has suffered from the lack of it, I may, perhaps, be permitted to bear my testimony to the value of the custom, which is, unfortunately, less widely extended than its merits deserve, but which I hope to see one day established in the forest-schools of our land. The young Prussian forester, who has had the good fortune to pass through this preliminary year, next spends two years at a forest-school of recognized merit, such as Munich, Münden or Giessen, and then one year at a university. Then comes the first state examination, which demands, besides a goodly share of theoretical knowledge, large proofs of efficiency in practical detail. It is followed by at least two years of travel and work, during which the candidate, now promoted to the title of Referenda, must take part during five months in the practical administration of a forest-range, and spend four months in the preparation of working plans, besides giving half a year to the active duties of an ordinary forest-guard. At the end of this rather long period of preparation comes the much dreaded final examination, after which the Referenda becomes Forest-Assessor, and is at length eligible for serious paid employment. The actual career of the forester can hardly be said to begin, however, until the appointment as Oberförster, for which the Assessor has no sort of guarantee, and which may delay its coming for from six to twenty years. That once obtained, the chance of promotion lies open, and includes every grade up to the highest. Still, it must be said that as a rule the Prussian Oberförster is wholly satisfied with his position, and very often unwilling to exchange it for one of greater honor and profit. The stimulus which ambition fails to give is supplied by the admirable esprit de corps which pervades the whole body of forest-officers, and forms here, as elsewhere, the best security for the efficiency and healthy tone of the service.

Immediately subordinate to the members of the Executive Staff are the various grades of forest-guards, upon whom the protection of the forest directly and exclusively rests. "The forester" (I quote from the Service Instructions) "must protect the beat entrusted to him against unlawful utilization, theft and injury, and see to it that the forest and game laws are observed. He is charged with the execution of the felling, planting and other forest-work, under the orders of the Oberförster, and he alone delivers all forest-produce to the persons qualified to receive it on receipt of written instructions."

The training of the Protective Staff is provided for with a care which, in any other land, might be thought more suitable for officers of a higher grade, and a period of preparation only less long than that for Oberförster stands before the beginner.

Such is in outline the organization of the Prussian Forest-service. The principles upon which it rests are thus stated by Donne, now Oberlandforstmeister, in a work which carries all the weight of an official document without being actually such. He says: "The fundamental rules for the management of state forests are these: First, to keep rigidly within the bounds of conservative treatment, and, secondly, to attain, consistently with such treatment, the greatest output of most useful products in the shortest time." And again, "The state believes itself bound, in the administration of its forests, to keep in view the common good of the people, and that as well with respect to the lasting satisfaction of the demand for timber and other forest-produce as to the numerous other purposes which the forest serves. It holds fast the duty to treat the Government woodlands as a trust held for the nation as a whole, to the end that it may enjoy for the present the highest satisfaction of its needs for forest-produce and the protection which the forest gives, and for all future time at least an equal share of equal blessings."

Correspondence.

The Holiday Flower Trade in Philadelphia.

To the Editor of GARDEN AND FOREST:

Sir.—The holiday trade of the florists seems to have been satisfactory this season, and as usual it marks a step forward both in quality and variety of the plants and flowers disposed of.

Flowers as holiday gifts are always acceptable, though it must be admitted that American Beauty Roses at $18 a dozen are in the nature of luxuries; but there is so great a variety of other flowers from which to choose that a very pretty box of assorted flowers can always be had for a moderate sum, and these special prices only rule on special occasions.

Probably owing to the bright weather which has prevailed during December cut flowers have been more than usually plentiful, Roses, of course, heading the list since the Chrysanthemum season has waned, and at the present time (December 30th) good flowers can be had of American Beauty, The Bride, Madame de Watteville, La France, Duchess of Albany, Madame Hoste, Catherine Mermet, Papa Gontier, Perle des Jardins, and among the Hybrid Perpetuals, Madame Gabriel Luizet, Mrs. John Laing and Ulrich Brunner, these being considered among the regular stock sorts for forcing. Speaking of Chrysanthemums reminds me that, though the season for these flowers is near its end, yet there are some still in the market, though of rather indifferent quality.

Carnations are in good supply, though first-class flowers with long stems command good figures, and these, like the Roses, may be had in considerable variety. The march of improvement is continued among the Carnations, too, and Philadelphia will show some fine seedlings within a season or two.

Rather out of the common was a wedding decoration during holiday week in which Pansies were the predominating flowers, the bridal flowers being white Pansies, while the maids of honor carried fancy baskets filled with colored Pansies, and the same flower was used as far as possible throughout the house decoration. Some effort was required to secure Pansies enough for such a purpose so early in the season, but the enterprising firm to whom the order was entrusted managed to execute it satisfactorily.

Lilies-of-the-Valley, Roman Hyacinths, Paper White Narcissus and single Daffodils are plentiful, as are also Violets. The latter may always be considered among the favorite flowers, so to speak, and in Philadelphia up to some two or three years past single Violets have been most in demand; but the taste for double ones is rapidly growing, and they will probably supersede the single ones in a few years.

Some sprays of White Lilac are to be had, but these are not forced to any great extent about here, but mostly come from New York.

Smilax continues in demand for greenery, but in fine arrangements it has been displaced to a considerable degree by the graceful and feathery festoons of *Asparagus plumosus*, for, while the latter is much lighter and more delicate in appearance than the Smilax, it is much more lasting.

A few Orchid flowers, mostly Cypripediums and Oncidiums, are to be seen; but these will never be the flower for the million, for few, if any, species are sufficiently prolific in flowers to make them remunerative if sold at a low figure.

Different fashions in the way of sending flowers seem to prevail in different localities. Some florists report a considerable increase in the call for baskets of flowers, while others find boxes of loose flowers in greatest request. Perhaps the

latter way of sending the gift is preferable, as it permits the happy recipients of the boxes the additional pleasure of arranging the flowers to their individual taste.

In plants many sales are reported, a specimen Palm placed in an ornamental pot making an admirable gift, and it is naturally a much more lasting one than cut flowers could be. *Areca lutescens, Livistonia Chinensis* and the Kentias are the favorites for this purpose, and are used in all sizes from four-inch pots up.

Another popular plant is *Dracæna fragrans*, as this also is an admirable house-plant when well grown. Quite a number of young plants of *Araucaria excelsa*, from one to three feet in height and grown in six or eight-inch pots, have been sold during the present season, and charming miniature trees they are too, their light green color giving a very pleasing effect in house decoration. Some early-flowered Azaleas, mostly white, are also among the available plants for Christmas and New Year gifts, and nicely shaped little standards in six or eight-inch pots seem doubly attractive so early in the season.

Holmesburg, Pa. *W. H. Taplin.*

Winter in Los Angeles.

To the Editor of Garden and Forest:

Sir.—Lovers of fruit and flowers find much to enjoy in this favored locality. On my arrival here, November 1st, Muscat grapes were abundant. The season for these is now over, and the market is supplied with three or four varieties of excellent quality from localities further north. On the first of November a limited quantity of second-crop blackberries and raspberries were seen, with a moderate supply of strawberries, which, though not equal to those grown in the east, are exceedingly enjoyable at this season of the year.

Among the fruits which are in season at Christmas-time here are strawberries, fresh figs, guavas, Japanese persimmons, oranges, lemons, limes, apples and pears. Oranges will not be at their best before February.

This morning I gathered fairly good flowers of *Nymphæa Zanzibarensis* and *N. azurea* from my garden and find in bloom Roses, Heliotropes, Geraniums, *Jasminum grandiflorum*, *Plumbago Capensis* and its white variety, *Tecoma Capensis*, *Dahlia arborea*, *Hibiscus Sinensis*, with Ageratums, Abutilons, Fuchsias and Violets. Poinsettias are a blaze of scarlet. In the garden of Mr. J. C. Harvey, an enthusiastic amateur, is a mass of these flowers eight feet high and ten feet through. In another garden I measured one head which was eighteen inches in diameter. In the garden of Judge Charles Silent is a plant of *Bignonia venusta*, covering a space ten by thirty feet, which is now a mass of glowing deep orange color. A somewhat rare plant in cultivation here is *Solanum Wendlandii*, a climber with lovely blue flowers two inches in diameter, in clusters six or eight inches across. A fence about fifty feet long covered from one end to the other with this vine is a charming sight. In the country the farmers are busy with the plow, and the fields are green with springing grass and new sown grain. The season for abundant wild flowers has not yet arrived, though in the foot-hills there still remain a few composites and a remnant of the scarlet *Zauschneria Californica*. In one of my rambles I found the dead stalks of *Delphinium nudicaule*, six feet high, which must have been a fine sight when in bloom.

Los Angeles, Cal. *E. D. Sturtevant.*

Cypripedium spectabile from Seed.

To the Editor of Garden and Forest:

Sir.—In your issue of November 26th there is an interesting note from Mr. Hill, of Fairview, West Virginia, about *Cypripedium spectabile*, in which he notes as one of the probable causes of its being rarely seen in cultivation that it rarely bears fertile seed. On this point perhaps my experience with the same plant would be interesting to those who enjoy the cultivation of our wild flowers.

A few years ago I had in my garden quite a number of these Cypripediums which I had gathered in the woods and transplanted, and which seemed to be well suited with their new home, for many of them grew to be larger plants and flowered better than those I have generally found growing wild. The growth was very strong, and many of the plants bore two blossoms on their spikes. Some of the blossoms of the stronger plants I fertilized, and they produced good seed-pods, which, when ripe and just bursting, I took off and scattered their seeds over the bed where the plants were growing. This planting was done late in the fall, of course, and for the winter a light covering of leaves gathered from the lawn was put over the whole bed. Most of the covering was taken off again in the spring, and the bed was left without disturbance beyond the keeping out of weeds, which were pulled up while yet small.

During the season following this first planting I was not positive that any seeds had started, and more blossoms were fertilized and more seeds sown as before, and in the second season after the first planting I was assured that I had seedlings growing, and had, moreover, two sizes of young plants, the larger being those of the first fall's sowing, which I had not been able to recognize the summer before, and the smaller ones plants that I now knew to be seedlings in their first year.

In this manner I was getting quite a number of seedlings, when, unfortunately, a change of residence obliged me to move my bed of these plants, and all were lost. The care that I had given to these seedlings was very slight, and probably many were lost in pulling out the weeds, and yet I had more than a dozen of them in the second year after sowing; and I am quite sure that with good care and in a good location this plant could be multiplied very rapidly from seed.

Chicago, Ill. *F. J. Le Moyne.*

Periodical Literature.

The most interesting article for American readers in the December issue of the *Kew Bulletin of Miscellaneous Information* is devoted to an account of the production of prunes in the south of France. The prune industry of California is developing enormously, and all that is required now to give California prunes a commanding position in the markets of the world is the adoption of the careful methods by which the French have gained their well deserved reputation in such matters. In this connection the following extracts from the *Bulletin* will be read, perhaps, with interest. They are from the pen of Mr. M. W. Colchester-Wemyss, who has studied with extreme care the prune industry of southern France with a view of ascertaining the possibility of starting a similar industry in England.

"About sixty miles above Bordeaux there falls into the Garonne a fine river which, taking its rise among the mountains of Cevennes, follows a course of some 150 miles, until its junction with the Garonne. This river is called the Lot, and the two rivers together confer the name on the Department known as Lot and Garonne. For several miles along the lower reaches of the Lot, and in the country immediately adjacent to the spot where it enters the Garonne, is produced the fruit known, when it has been specially prepared, as 'French plums.' For over 100 years the industry has been fixed in this locality, and still, with the sole exception of a valley in Servia, there is no other place where the same trees are cultivated. The tree is called 'Prunier d'ente.' 'Enter' is an old French word meaning to graft, and it is simply so called because this particular species was formerly the only plum in this district that ever was grafted. Now there are, practically, no plums other than the 'Prunes d'ente' grown in the neighborhood. Higher up the Garonne, round the old town of Agen and in other parts of southern France, another plum, the 'Prunier commun,' is largely grown, and its fruit treated similarly to that of the 'Prunier d'ente,' but the produce is very inferior and only suitable for stewing; but I believe that nowhere except in the Servian Valley is the true 'Prune d'ente' at present grown; and though many experiments have been made with other varieties, no others have yet been discovered that will yield the established qualities of the 'French plums.' It is rather capricious in its growth, for its area of cultivation does not extend very far from the river bank. It appears to delight in a rich alluvial soil of a rather sandy nature, but which contains a sufficiency of clay to make it very retentive of moisture. The centre of the 'French plum' district may be said to be at Clairac, a quaint little old-fashioned town built on a steep hill-side overlooking the Lot, almost more Spanish looking than French, its houses shaded from the fierce southern sun with wide outspreading eaves and flower-clad balconies.

"In this and the neighboring communes the metayer system is in full operation, and it appears to work well and harmoniously. The owner of the land engages the metayer and supplies all the implements and stock required for the holding; he also keeps the buildings in repair, including the house used by the metayer. The latter finds the whole of the labor except such extra labor as is needed during harvest-time. The

metayer, during the year, has entire control of the farm, and buys and sells, subject, if required, to the consent of the owner. He renders account of all produce from the holding consumed by himself and family, and at the end of the year the balance of profit is divided equally between the owner and the metayer. During the last few years the metayers have fared badly, for the Phylloxera has devastated the vineyards, and sad it is to see acres and acres of land excellent for the growth of grapes, but fit for little else, now deprived of those crops which formerly so well repaid the cost of cultivation. The holdings vary in extent from ten acres to sometimes fifty and sixty, and on every holding in the lowlands are to be seen rows of the 'Prunier d'ente.' The rows are separated from each other by long strips of cultivated land where the mild fawn-colored oxen lazily drag the most old-fashioned and primitive implements over the easily broken soil. The plums are long-shaped, the end to which the stalk is attached being very much the more pointed; color red, deepening into a rich violet as the plum ripens; the skin is extremely tough, without being very thick or hard; the flesh very firm, containing a large amount of saccharine; the specific gravity much less than that of several varieties of English plums with which I made comparison.

"The tree is a very slow grower, requiring ten years to bring it into full bearing, though I saw some trees six years old, very favorably situated, with a fair crop of fruit on them. The fruit also matures very slowly, and is not ripe till all other fruits in the district, apricots, green gages, peaches, have ripened. The plums are picked when just ripe, before the flesh has begun to soften, they are placed on 'claies' or trays, one layer of plums on each 'claie.' The 'claies' are made either of strips of wood or of wicker-work, and are either triangular or round. They are a little deeper than the thickness of a plum, so that when not in the ovens they can be safely placed upon each other. The 'claies' when filled are arranged upon the bottom of the 'fours' or inside the 'étuves,' and the operation commences. Each homestead has a building in which are placed the 'fours' and also the 'étuve,' if the metayer possesses one. The 'fours' are simply like very large ordinary bread-ovens. They are usually built in pairs, each one about ten feet long and four feet wide; they are heated by burning wood inside them; the ashes are cleared out and the 'claies' placed inside. The 'étuves' are closets of variable dimensions, with different appliances for holding the 'claies.' They have a small furnace with pipes underneath the floor for heating. There seems to be a preference for the 'fours,' though the 'étuves' are simpler and more convenient in every way.

"When the fresh fruit is put in the temperature should be about 100 degrees Fahrenheit. When the plums have been inside for about a couple of hours they assume a peculiar puffy appearance. The 'claies' are then withdrawn, the fruit turned by holding an empty 'claie' upside down close over a full one, and then turning them both over. After cooling, the 'claies' are again put into the 'four'; this time at a temperature of about 135 degrees; again withdrawn, turned, cooled, and put in at a temperatare of about 170 degrees; and this operation is continued until the plums have been dried. Some dry more rapidly than others, and they are picked out as they are ready. The more slowly the operation is performed, and the oftener the plums are put into the 'four,' the better will be the result.

"When they are ready the plums are sorted out into various grades, according to the number (30, 35, 40, 45, 50, 55 or more up to about 130) that it will take to make up the French pound, for curiously enough the old French measure is adhered to. They are put into sacks and carried to the markets. Here the merchants come and buy, paying prices varying according to the number of plums required to weigh a pound. Thirty to the pound would be worth about 120 francs the 100 pounds; forty to the pound about 100 francs, and so on down to the very lowest grades, which are not worth more than fifteen francs. The merchants convey the fruit to large, cool, airy warehouses, where it is thrown into bins, and women at long tables are employed sorting over again much more carefully than before. The various grades are then packed separately into casks and are sent to Bordeaux, where the finer qualities are packed carefully in bottles or boxes; the inferior are simply exported in bulk.

"About Agen and in the other districts another tree is cultivated, the 'Prunier commun.' This is a round, violet plum, grown on its own stock. The fruit is prepared in a similar manner to the 'Prune d'ente,' but is very inferior and is only fit for stewing. Enormous quantities are consumed by the peasants in the north and east of France."

Meetings of Societies.

The American Forestry Association.

THE ninth annual meeting of this Association was held at Washington on December 30th, 1890. A summer meeting having been held at Quebec September 2d-6th, the present meeting was primarily for business. At the morning session at the Department of Agriculture members were present from Colorado, Connecticut, Massachusetts, Minnesota, New York, Pennsylvania, South Carolina, Vermont and the District of Columbia. Owing to official duties Governor James A. Beaver, of Pennsylvania, President of the Association, was unable to attend, and Honorable Edwin Willets, the local Vice-President, occupied the chair. The report of the Executive Committee detailed the past year's growth of the Association, now numbering 225 active members, and referred to the increasing popular interest and belief in the necessity of forest-preservation and management all over the country. Attention was called to the work of the New Hampshire Forest-Commission, the movement for a state forest-park in the Adirondacks, the establishment of the Adirondack League Club, the Sequoia reservation and the appeal of the citizens and the Forest-Commission in California. The committee's efforts for national legislation have not yet met with the success that was hoped for last spring when the Special Committee of Congress was appointed to consider forestry-legislation. Legislation on the tariff, the elections, etc., having absorbed the attention of Congress and the public, this committee has not yet reported any of the bills before it; and it would look as if the struggle would have to be continued in the next Congress.

Dr. B. G. Northrop, Chairman of the Arbor Day Committee, presented a report on the increased observance of that day and the practical value of the planting done. Hon. Warren Higley, of New York, described the plans of the Adirondack League Club for practical forest-management on its 93,000 acres of woodlands.

At the afternoon session the committee on resolutions and nominations reported a proposed change in the constitution, adding six members at large to the Executive Committee. This was adopted. The following officers were then nominated and elected: President, William Alvord, of San Francisco; Vice-Presidents, Hon. H. G. Joly, Quebec; Dr. Charles Mohr, Alabama; Dr. M. Riordan, Arizona Territory; Abbot Kinney, California; G. H. Parsons, Colorado; Dr. B. G. Northrop, Connecticut; Hon. C. R. Pringle, Georgia; G. W. Minier, Illinois; C. L. Watrous, Iowa; Professor E. A. Popenoe, Kansas; Hon. A. M. Brown, Kentucky; J. D. W. French, Massachusetts; Professor W. J. Beal, Michigan; Hon. C. C. Andrews, Minnesota; Hon. J. Sterling Morton, Nebraska; J. B. Harrison, New Hampshire; W. A. Stiles, New Jersey; Morris K. Jesup, New York; Professor W. R. Lazenby, Ohio; Herbert Welsh, Pennsylvania; L. D. Davis, Rhode Island; Professor H. A. Green, South Carolina; Professor Charles A. Keffer, South Dakota; Hon. T. T. Wright, Tennessee; W. Goodrich Jones, Texas; Dr. Hiram A. Cutting, Vermont; H. C. Putnam, Wisconsin; Hon. Edwin Willets, District of Columbia; Hon. G. W. Allan, Ontario; Treasurer, Dr. H. M. Fisher, Philadelphia; Recording Secretary, Dr. N. H. Egleston, Washington; Corresponding Secretary, Edward A. Bowers, Washington; Executive Committee at large, B. E. Fernow, H. B. Ayres, Colonel E. T. Ensign, W. G. Pellew, Charles C. Binney, Hon. Warren Higley.

Statements were then made by various members as to forestry interests in their states, and the Association was invited to meet next summer at Denver, Colorado, which invitation was accepted.

The evening session was held conjointly with the American Economic Association at the National Museum. Professor E. J. James, of the latter body, was prevented by indisposition from reading his paper on the duty of Government in regard to forests. Very interesting papers were read by Gifford Pinchot, of New York, who is now studying forestry in Europe, on "Government Forestry Abroad;" by Edward A. Bowers, the new Corresponding Secretary and formerly an inspector of public lands, on "The Present Condition of the National Forests," and by B. E. Fernow, Chief of the Forestry Division, on "The Feasibility of American Forest-administration."

Resolutions were adopted urging the passage of a bill for the reservation and management of the national forests, the proper protection and enlargement of the Yosemite and Sequoia parks, and the state reservation of forest-lands in New Hampshire and New York. Congress was also petitioned to enact the Senate bill for changing the boundaries of the Yellowstone Park without the objectionable amendments added by the House committee.

Notes.

It is said that Orange growers have discovered a process by which an orange picked while green can be colored a rich yellow in forty-eight hours. No doubt consumers will continue to prefer ripe oranges to green ones artificially jaundiced.

Professor Marshall Ward's excellent address on "Elementary Botany in General Education," delivered not long ago at Leeds, England, and recently quoted in our columns, is reported more at length in the *Popular Science Monthly* for January.

The new park system which the City of Montevideo is about to inaugurate under the direction of the distinguished French artist, Édouard André, consists of two parks each of 175 acres, of four smaller parks varying from twenty-five to sixty acres each, of twelve public squares, and of a series of boulevards and broad avenues to connect the old and new parts of the city.

A dwarf form of the Calla Lily (*Richardia Æthiopica*), which was certificated some time ago by the Royal Horticultural Society, is highly commended in the *Gardeners' Chronicle*. It is a seedling, bears a perfect spathe, and is only nine inches or a foot in height. It flowers very freely, has beautiful foliage, and it is so small that it has altogether a different effect from that of the ordinary Calla.

The question as to what time of the year Pompeii was overwhelmed has puzzled antiquarians, but according to the *Gardeners' Chronicle* a late discovery enables us to answer it with some degree of certainty. The trunk of a tree bearing berries has been discovered among the ashes, the berries giving the clue to the nature of the tree, which was the true or Bay Laurel (*Laurus nobilis*). From the degree of maturity of the berries it is, moreover, surmised that the eruption took place in November.

Episcia maculata, a plant of the order Gesneraceæ and a native of British Guiana, first flowered at Kew last summer. In a paper on its floral biology recently published by Professor F. W. Oliver, he says that it is remarkable from the fact that the flowers do not open, as the front lobe of the corolla remains folded back, closing the mouth like a cork. Notwithstanding, its arrangements are for cross-fertilization through insect agency of some sort. The flower is believed to be unique in being thus at once closed and cross-fertilized.

When describing the Mulberry-trees in the province of Ssu-ch'uan, in western China, Mr. Alexander Hosie says: "Here I observed an ingenious device for obtaining young trees from the old. Round a promising branch of a tree a piece of Bamboo about a foot in length, which has previously been divided into two parts along its length, is tied, and the hollow between the branch and the interior of the Bamboo filled with mould. In a short time suckers leave the branch and descend into the mould, and when they are sufficiently developed the branch is cut off and planted, the suckers forming the roots of the young tree."

One of the last papers written by the late Professor Proctor and published in *Knowledge* says (we quote from a summary in the *Popular Science Monthly*): "In all the vegetable world color seems to be in all cases dependent on the requirements of propagation. Thus, where seeds are diffused by animals, as with the berries, we find the fruits brightly colored, to attract the attention of the animal distributors. It will be noticed that when seeds are distributed by the winds, bright colors are not found in the fruit, even though the plant be closely allied to species distributed by animals in which the bright colors are present."

The latest bulletin from the Cornell University Experiment Station gives some account of the Pear-leaf blister, which appears on the leaves in the form of dark reddish spots an eighth of an inch or more in diameter, and are produced by a gall-mite, which has long been known in Europe, but has attracted little attention as yet in this country. The insect is practically invisible to the naked eye, and as it lives within the tissue of the leaves ordinary insecticides cannot reach it. The only promising method of attacking these pests is to prune away and burn the young wood in winter, since it is their habit to quit the leaves as they dry in autumn and collect on the terminal buds, where they remain until spring.

Dr. Byron D. Halsted contemplates the publication of a "Century of Weeds," and hopes to follow it by a second collection showing the seeds of the same species and then to carry on the work until all the annoying and pestiferous plants of America are fully represented in herbaria. American botanists in all parts of the country have been asked to send in lists of the twenty worst weeds in their vicinities, and from their reports the "Century" will be composed. The price has not yet been fixed, but it is expected to be about $8, and Dr. Halsted will be grateful for all words of encouragement, believing that, while the result of his laborious task will be of special value to our agricultural colleges and experiment stations, it will also be of interest to systematic botanists in general.

The last annual report of the Trustees of the Astor Library, in this city, shows that during the year 1889 only 538 readers called for works dealing with agriculture and horticulture, as against 2,748 who called for works on architecture, and 6,762 who desired to study painting, sculpture or archæology. Of students who asked admission to the alcoves for the purpose of more serious research there were fifty-six concerned with architecture, 467 with painting, sculpture and archæology, and only three with agriculture and horticulture. Yet the Library authorities seem to recognize the importance of this department, for while there were fourteen works upon architecture added to the collection during the year and forty-five on the other arts, there were thirty-nine upon agriculture and horticulture. More than half the alcove readers were interested in patents, 5,082 having applied for this purpose, while, with a great gap between, American history came next with 788 students.

Writing of western Pennsylvania in the year 1795 the Marquis De Talleyrand says, in a passage from his "Diary" published in the *Century Magazine* for January: "I was struck with astonishment; less than 150 miles distance from the capital all trace of men's presence disappeared. Wild nature in all its pristine vigor confronted us; forests as old as the world itself; decayed plants and trees covered the very ground where they once grew in wildness; others shooting forth from under the débris of the former and like them destined to decay and rot; thick and intricate branches that often barred our progress; green and luxuriant grass decking the banks of rivers; some large natural meadows; some strange and delicate flowers quite new to me; and here and there the traces of former tornadoes that had carried everything before them. Enormous trees all mowed down in the same direction, extending for some considerable distance, bear witness to the wonderful character of those terrible phenomena." In another passage Talleyrand reports that he saw, "sixty miles from Boston, 6,000 feet of timber exchanged for a bullock."

The *Calcutta Englishman* recently said: "Among the exquisite arts for which the Indian people have long been famous, Sandal-wood carving is one that neither government nor native patronage can rescue from inevitable decay. Parsees have taken up the art in Bombay, and by employing their own methods and enterprise on it have found a market and established a trade, although their work bears no comparison with that of Mysore, the home of the art. The Sandal-wood carvers of Mysore turn out work which is indeed exquisite, and their skill is acquired by slow years of patient practice from boyhood. But the decay of this and other laborious Indian arts is inevitable. The native courts, which used to be the chief patrons of indigenous art, have now the products of all Europe competing for their favor, while, on the other hand, the European markets, which might be open to Indian wares, are impatient of India's tedious methods and stinted supplies. Meanwhile, even conservative India cannot resist the rush of the railway and the whirl of education. Her boys will not sit down for years in one shop without a thought except to perpetuate for generations to come the few and curious ideas of generations foregone. Sandal-wood looks pretty and smells sweet, but the School of Art, with its morning school and its Saturday holiday, is killing the ancient order of Mysore carvers."

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT

ENTERED AS SECOND CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JANUARY 14, 1891.

TABLE OF CONTENTS.

The National Forest-question.

THE perusal of the last annual report of the Secretary of the Interior must make it apparent even to persons little familiar with the forest-conditions which prevail in the western half of this continent that the nation's great forest-inheritance is in serious danger, and that the resources now at the command of the department are entirely inadequate to protect it. How inadequate these are and how great has become the lawlessness engendered by the way offenses against forest-property have always been condoned in this country, appear in the fact reported by the Secretary that the Canadians have actually invaded the territory of the United States at the point where the Rainy River forms the northern boundary of Minnesota for the purpose of cutting and carrying away timber growing on our public domain. Roads have been built into the forest here and a fleet of steamboats equipped to tow the plundered logs to Canadian mills. This is not a more striking instance of the inability of the Government to cope with the dangers which menace our national forests than a dozen others which might be mentioned. Indeed, during the last twenty years the forests of the public domain have been systematically robbed in Minnesota, in Colorado, in California, in New Mexico, and in every state and territory where profit was to be made by manufacturing stolen lumber. This illicit industry has developed populous towns; it has floated ships and equipped mills; and it has ruined and demoralized entire communities who have learned to forget in the looseness of the American principle of forest-management that there was as great a moral offense in stealing a tree from the public domain as in stealing a neighbor's horse. The Government, and not the people, are to blame for the present attitude of the country toward the nation's forests; and the whole theory under which the western lands have been managed is wrong and demoralizing. It may have been perhaps good policy once to give farming-land to settlers at nominal prices, although now that the best land is taken up, the time for doing this has certainly passed; and it is clearly good business for the Government to sell its lands for what they are actually worth in the market.

The conveyance of agricultural land to the settler has always been guarded by law, or, at least, by a semblance of law, and although the system is open to many serious objections, it has had at least the advantage of filling up rapidly large territories. But in the case of the forest other problems have to be met. It was long the principle to allow settlers to cut without restriction such timber as they needed for domestic and agricultural purposes from rough, stony land unfit for farming. Mining companies were allowed to cut all the timber and fuel they needed from the public forests, and railroads were given the same privilege. When men are allowed to go out and cut the timber they need upon land which does not belong to them, they will not be particularly careful how much is cut or how the work is done, and the limit set by personal needs will not always be regarded. Lawlessness and utter disregard of forest-property must be the inevitable result of such a system. The authority given to settlers to supply themselves with timber in this way was taken away some years ago; but now the Commissioner of the General Land Office recommends the enactment of a law repealing statutes forbidding the entry of rugged, stony or other timber-lands unfit for cultivation except under the mining or town-site laws, and allowing settlers to use the timber on such lands which they may actually need to develop the country.

The enactment of such a law as the Commissioner recommends seems to us dangerous and a menace to the best interests of the country. The forests in all the western country, with the exception of those which clothe the shores of Puget Sound, may be divided into two classes; those of the high mountain ranges composed of large and often valuable trees, and those on the rugged and stony land of the lower mountain-slopes and foot-hills. It is from these last, if we understand the purpose of the Commissioner, that the people living in the valleys are to be allowed to cut without control or supervision what timber they require to carry on their farming operations. All these foot-hill forests are stunted and unproductive in comparison with the forests which grow high above them on the mountains; the trees are small and stand at considerable distances apart, and the wood they yield is brittle, crooked and full of knots. To a person accustomed to the forests of Maine or Michigan or Oregon these foot-hill forests must appear worthless and their destruction a matter of no importance. Actually, however, they are as valuable as the forests of any other part of the country. It is their proximity to arable land which makes them valuable, not the character of the timber they can supply. They contain the most available, practically the only, fuel-supply and fencing material for many valleys. When they are destroyed the cost of living on the farms in their neighborhood will be immensely increased, and in some valleys agriculture will not be possible without these forests to draw upon. They are unproductive because the climate in which they grow is not suitable to develop a heavy forest; and if they are cut down or burned they will reproduce themselves very slowly, or not at all. They require, therefore, more careful management than forests growing under more favorable conditions, and unless they are cut systematically, and guarded in every possible way, they will soon disappear not to spring up again.

It is proper that farmers in western valleys should get the advantage which comes from living in the neighborhood of a forest, but they should be compelled to purchase the fee of the forest-land from the Government if they are bound to destroy the forests, or the Government should itself hold such forest-property for the benefit of the whole community, and so manage it that the whole community will get the greatest possible returns from it. This is what Government forest-management means—the care of the forest for the good of all.

The American system, which allows settlers or corporations to go into the forests and help themselves and then

burn up what is left, saves a great deal of trouble ; and the settlers and the corporations like it and are prepared to fight for its continuation. It is, however, an expensive method in the long run, and it can have but one ending—the injury and finally the agricultural ruin of the region where it is practiced.

It appears that 310 cases of trespass on the public forests, involving a loss to the Government of more than three millions of dollars, were reported during the year, although only about a hundred thousand dollars were collected by the Government for losses sustained by the illegal cutting of timber. There are, however, still unsettled claims of this sort for nearly fifteen millions of dollars, from which, probably, a small percentage will in time be collected. But trespasses of this sort do comparatively small damage to the national forest. Their greatest enemies are fire and pasturage. As compared with the damage inflicted by these, the cutting down of a few thousand acres of timber more or less amounts to little. The pasturage of sheep on the Calfornia Sierras has already inflicted untold injury to the finest coniferous forests in the world ; and fires in the western forests seem to be increasing rather than diminishing every year. They are most frequent and most severe in the dry interior region of the continent, where forests are scanty from climatic causes, and where once destroyed they reappear slowly, or not at all. It is evident that any effort to preserve the forests from illegal pasturage will be resisted in the most violent manner by the people of California, and that the spread of forest-fires can only be checked by determined effort of the Government. Apparently it can be accomplished only by the free use of the army as a forest-police, as we have already insisted.

The attention devoted to the forest-question by the Commissioner of the General Land Office and by the Secretary of the Interior in their last annual report shows that the public begins at least to realize the importance of doing something to protect the national forests. This is in itself hopeful ; recommendations are not actions, however, and the outlook in Congress for immediate action in the direction of a national forest-system is not encouraging.

The Pines at Christmas-time.

TWO days before Christmas, while walking among the Pines in search of decorative evergreens, I found several Golden-rods in bloom. They were growing where a new road had been cut through a swamp. The road was narrow, and the thick growth of underbrush and trees on either side somewhat sheltered and protected them. It was the fine thick-leaved species *Solidago sempervirens*. The road had been made during the summer and autumn, consequently the plants had been cut back or trampled down, and as soon as left to themselves they began to throw up flower stems, and although the mercury had gone as low as twenty above zero, yet here they stood, defying the cold, in different stages of growth. Some just starting to send up flower-stalks, others fully developed and not looking much the worse for the freezing. The foliage was specially fine.

Among other Christmas treasures we gathered Holly, Mistletoe, Laurel, and the rich purple, fragrant leaves of the Wax Myrtle, and the large, thick, shining leaves of Magnolia, which have a spicy odor in winter more marked than in summer. And we added the Inkberry as well as the bright scarlet berries of the Black Alder or Winterberry, and long trailing sprays of Smilax covered with clusters of purplish fruit. Small branches of Cedar full of dull bluish berry-like little cones were gathered, and with them boughs of Pine, with its delicious invigorating fragrance. There is nothing more handsome for winter decoration than small branches of Pine, its matted bunches of leaves interspersed with the young cones.

Although we had almost a carriage-load of evergreen treasures, we were still loath to leave the woods on this delightful sunny day with the thermometer at fifty in the shade, and we began to study Pine-trees, of which we have three species—the Pitch Pine (*Pinus rigida*), the Jersey or Scrub Pine (*P. Virginiana*), and the Yellow Pine (*P. mitis*). The Pitch Pine is the prevailing species in the neighborhood of Vineland.

This species, Professor Sargent tells us in his "Catalogue of the Forest-trees of North America," "is found from Mount Desert, Maine, and northern Vermont, to the upper district of Georgia, not extending west of the Alleghany Mountain region," and adds that it grows from forty to eighty feet in height, with a trunk sometimes thirty inches in diameter, and that it grows in the driest and most barren sandy soil as well as in deep swamps. No other Pine looks as well as this in our gardens among our Cedars and Sassafras, Sweet-Gums and Tupelos. When healthy it grows rapidly, and the younger trees are clothed from base to summit with heavy foliage, and the older ones are rugged and picturesque.

But from all appearances, in our region at least, they will soon all be killed by insect enemies. No other Pine, as far as I can learn, is beset with so many foes as this. It is a pitiable sight to see large tracts of young trees standing with brown foliage, killed outright by various insects. The only way that I have saved the young trees in my garden has been by the most persevering vigilance. One of the most destructive things I have found was the larvæ of a small Tortrix-moth (*Retinia frustrana*), which mines into the terminal buds and young shoots. On some of the trees, when I first found the creatures, there was scarcely a terminal shoot that did not hold from one to five of these destructive larvæ. They are completely hidden while at work, and soon destroy the twigs by eating all except a thin shell which is so brittle that it will crumble to pieces when handled.

My trees were badly crippled by their work, but by the third summer after finding them, I so diminished their numbers that the trees are again growing and looking well. There is no way of killing these larvæ after they have become established in the twigs except by hand picking. But I have found that the moth will not deposit her eggs on the twigs after they are well dusted with Pyrethrum powder. I use a small bellows while the twigs are damp with dew, and apply the powder after each rain.

Another destructive creature is the larva of the White Pine Saw-fly (*Lophyrus abbotii*), which eats the foliage. These larvæ live in colonies and soon strip a twig entirely of its leaves, and move on to the next, destroying every leaf as they go. But I can manage these creatures much more easily than the Tortrix-larvæ. I slip a pan beneath the twig and soon jar them all into it. I have no idea how many broods there are in a season, as I find them all summer long. And even as late as the middle of November I was surprised to find a colony feeding on one of my Pines, after they must have been frozen and ought to have been dead !

Although this creature is called the White Pine Saw-fly, it likes our Pitch Pine very much better. I have small White Pines growing in the vicinity of the Pitch Pines, but as yet the former have never been disturbed by the Saw-fly larvæ, nor by the Tortrix-moth.*

But these two insects are not the ones that have killed our Pines in the wood. This has been done by the larvæ of beetles, an account of which I must leave for another article.

Vineland, N. J. *Mary Treat.*

Winter Flowers in Oregon.

ON Christmas-day I counted some half dozen plants, mostly common weeds, blooming here in one of my neighbor's gardens. They were mostly plants which had not perished in the annual drying up of such things here in the latter part of the summer, which is our dry season. Their lives had been preserved because they chanced to grow in an irrigated and cultivated enclosure.

They were: The May-weed (*Anthemis Cotula*), the Shepherd's Purse (*Capsella Bursa-pastoris*), the Heron's-bill Geranium (*Erodium cicutarium*), the Mouse-ear Chick-weed (*Cerastium viscosum*), a Lupine (*L. micrantha*, var. *bicolor*), the black Mustard (*Brassica nigra*), the common Knot-grass (*Polygonum aviculare*) and *Boisduvalia densiflora*.

The last is without any common name here so far as I know. It is a near relative of the Godetias, Clarkias, etc. The small flowers are borne in a long, close, densely-leaved spike or in short lateral spikelets, and they are rose-colored or purplish. It is found only in moist ground. A smaller species, *B. Torreyi*, which blooms in the summer at the same time with this, I find on dry ground only.

The pretty little white and bluish purple flowers of the Lupine mentioned are out in the spring before those of any other Lupine here, and may be seen long after other larger and later-blooming plants of this genus have dried up and died. The Heron's-bill Geranium is the common forage plant, the "Filaree" of California and Oregon. The Shepherd's Purse,

*Figures of both these insects may be found in Bulletin No. 7 of the "United States Entomological Commission" under the title of "Insects Injurious to Forest and Shade Trees," by A. S. Packard, Jr., M.D.

the Chick-weed and the Knot-grass are the well known plants growing nearly everywhere in cultivated grounds.

But the first and only true wild flower of the season that I have seen as yet was a blossom of our little wild Strawberry plant, which I found early in December (I have found a number of them since). This plant, being a perennial, never wholly dies, and here it always renews its growth at the beginning of the rainy season. Indeed, I have known the ripe fruit to be gathered in November from plants growing wild in the pastures. If the winter be a mild one it will flower sparingly all the winter season; but it does not usually come into active blooming until about the middle of March, and April is its most floriferous season. But by that time many other species of plants, some of which are not as yet out of the ground, will have strewn the ground—literally covered it in many places—for a month or more with the prettiest wild flowers.

If the weather continues mild, in January we shall have the little Buttercup (*Ranunculus occidentalis*, var.?) which is so abundant here in the spring. It loves the upland or moderately dry ground, and in March and April large tracts of such land will be yellow for a time with its bright flowers. Its blooming period will culminate about the middle of April, or perhaps a little earlier; but it will continue to bloom more or less until nearly midsummer. The pretty little *Dentaria tenella* will also make its welcome appearance in January. By February it will have become abundant.

Crocidium multicaule, a very interesting little plant, because of its blooming so abundantly and so early in the season, will also be sure to be found. It has a little yellow blossom at the top of the slender stem, which usually is only three to four or five inches high. These little plants are gregarious, if such a term may be applied to plants, and are nearly always found occupying little patches of ground by themselves, which they render yellow when in flower. The plant belongs to the Composite family; and so the little blossom is composed of several very small individual flowers collected into a capitulum or head, the whole surrounded by an involucre of scales, which to persons not botanists gives it the appearance of a single flower. These Crocidiums always occupy warm, dry, sunny places.

In moist places, those who are looking closely for wild flowers will at this time be pretty sure to find our dainty Nemophila (*N. parviflora?*) in bloom. This little plant is also very frequently found in the timber where the ground is moist and shady, for, as its name implies, it loves the woods.

In or near the timber, where the ground is moist and shaded throughout the year, may nearly always be found *Synthyris rotundifolia*, whose cordate, crenately margined leaves are an interesting feature of these woods the year round. Its flowers are a light violet color, in clusters near the ground. In all mild winters *S. rotundifolia* blooms abundantly in January and February; I have even found it in flower before this time of year. It continues to bloom, of course, until late in the summer.

Peucedanum utriculatum, a small umbilliferous plant with yellow flowers, is also among our earliest plants to bloom. These humble plants spring up soon after the rains begin; and they have been growing now for some weeks. A Luzula, or Wood-rush, will probably complete the list of herbaceous plants found in bloom here during the winter months.

Among the trees, the Alder (*Alnus rhombifolia*) will be in bloom early in February, or in January if the winter be mild. The Hazels will follow closely after and then the Manzanitas and some of the early Willows. Nuttallia and the Snowberry will by this time be leafing out; and in early March the Dodecatheons, the Erythroniums and other large and handsome flowers will open in abundance, and our true season of flowers will begin.

Wimer, Ore. *E. W. Hammond.*

Flowers and the Perfume Industry.

M. THOMAS GRIMM describes in the *Petit Journal* the method by which, in the districts of Cannes and Grasse, enormous quantities of perfumes are annually made from the flowers grown in those neighborhoods. He estimates that something like 62,000 acres are given up to the growth of flowers between the right bank of the Var and the chain of the Estérel. At one of the largest perfume factories of Grasse, M. Grimm found that the three principal operations in the making of perfumes were the preservation of the odor of the flowers by distillation, by enfleurage and by exhaustion. The last named process, which is applied chiefly to Roses, is perhaps the most important. It consists of submitting the petals of the flowers to the action of heat in broad deep pans heated by steam and filled with a mixture of lard and beef-fat. When the Rose has yielded up the whole of its essence, the contents of the vessel are placed in horse-hair sieves, and the so-called pomade which runs out under pressure is again placed in the receptacle with fresh Rose-petals. This operation is three or four times repeated, in order that the fat may be thoroughly saturated with perfume. The product is not sold in this condition as perfume, since it is far too strong smelling. It is treated as a kind of "stock," from which most of the perfume is afterward extracted by means of alcohol, and the residuum is used as a basis for pomade or toilet soaps, according to the degree of aroma that may remain.

The distillation of flowers is still conducted by aid of the time-honored machine called the "Florentine Receptacle." This apparatus collects not only the water distilled from the flowers, double, triple or quadruple, according to the number of distillations, but also the essential oil, which is the very quintessence of the perfume. Ten thousand pounds of fresh Rose-leaves will provide only one pound of this essence; but only half that quantity of Orange-flower leaves is required to make a pound of essence. There are some flowers which will not yield up their essence to what is called the hot method of manipulation. Among them are the Violet, Mignonette, Jessamine and Heliotrope, and these have to be treated by a very delicate process; the petals are brought into contact with wool saturated with Olive oil, and then the perfumed oil is very carefully expressed. Nearly every operation connected with the making of perfumes requires to be performed very rapidly, since the value of the product depends in great measure upon the perfect freshness of the materials. The flowers are picked by women shortly before dawn, are immediately cleansed, and piled up in great heaps in the workrooms, which themselves need to be very carefully chosen, since they must be spacious, well aired and shielded from direct sunlight. That which M. Grimm visited satisfied these conditions admirably, being the crypt of an ancient Capuchin monastery.

Such is the rapidity with which the work has to be done, that if all the flowers used in the making of perfumes came to perfection at the same time it would be impossible to accomplish it. Happily, that is not the case. The season begins with the Violets, on January 15th, and they are gathered until April 15th. In the Commune of Grasse alone from 290,000 to 300,000 pounds of Violets are manipulated during these two months. The Jonquils flower in February and March, and furnish 30,000 pounds to the perfume factories of Grasse. The crops of Orange-flowers and Roses are the most important of all; this harvest begins on April 20th and ends on May 31st. The neighborhood of Grasse produces annually 3,800,000 pounds of Orange-flowers and 2,000,000 pounds of roses. Mignonette, which is gathered from May 15th to the end of June, yields a crop of 50,000 pounds. The Jasmine, which yields 300,000 pounds, and the Tuberose, which gives 150,000 pounds, are gathered from July 20th to October 10th. Then comes the Cassia, with its concentrated, penetrating and almost violent perfume, which begins to flower in October and finishes at the moment when the Roses begin. No mention has been made of Lavender and Rosemary, because, although they are cultivated to perhaps a greater extent than any other flowers, they are chiefly treated throughout the south of France by nomadic distilleries which move about from canton to canton.

Notes on North American Trees.—XXII.

42. *Reynosia latifolia*, Griseb. This small Florida tree has been referred (Gray, *Bot. Gazette*, iv., 208) to the *Rhamnus lævigatus*, Vahl ("Symb.," iii., 41), the *Ceanothus lævigatus*, DC. ("Prodr.," ii., 30), and if the correctness of this reference could be satisfactorily established the proper name of the plant would be *Reynosia lævigata*. The identity of these two plants, although possible, is certainly doubtful. Vahl's description is short and unsatisfactory. The leaves of Rhamnidium are usually opposite, while those of his plant are described as alternate without any reference to their being emarginate at the apex, a pretty constant character in nearly all the species of Rhamnidium. Professor Trelease, who has examined Vahl's herbarium at Copenhagen (*Proc. St. Louis Acad.*, v., 364), was unable to find the type of *Rhamnus lævigatus*; so that as long as this uncertainty remains it will be safe to retain Grisebach's name as he wrote it.

Reynosia is referred by Baillon ("Hist. Pl.," vi., 82) to Condalia. It differs, however, from the plants of that genus in the thinner and much less prominent disk of the flower, in the thinner wall of the stone of the fruit, and in its longer radicle and ruminate albumen; and in habit and in its unarmed branches. Baron Eggers, in his characters of the genus Reynosia ("Vidensk. Medd. fra nat. For. Kiobenh.," 1877, 3), describes the flower with five (0?) cucullate, unguiculate petals inserted on the margin of the disk between the lobes of the calyx. I have been able to examine the flowers of *R. latifolia* only; these show no trace of petals, nor do we find the margins of the cotyledons recurved and subcontorted as described by Eggers. The stigma is as often three as two-lobed.

43. *Condalia ferrea*, Griseb. This common West Indian and Florida tree has already been referred to no less than six distinct genera, in none of which it seems properly to belong. The last reference, that of Grisebach, to Condalia, made probably because, like Condalia, it has no petals, certainly cannot be sustained. The completely two-celled ovary, exalbuminous seed filled with the thick and fleshy cotyledons, remove it from that genus, which it does not resemble in its unarmed branches, and large opposite, persistent leaves. The distribution of this plant is quite different, too, from that of Condalia, which is not represented in the West India flora. The structure of the seed is that of Zizyphus, which is sometimes destitute of petals, but the pinnate venation of the leaves and the unarmed branches make it undesirable to unite it with that genus. Nothing remains, then, but to consider our plant the type of a new genus, or to refer it to the Brazilian genus Rhamnidium, enlarged by the addition of a section with apetalous flowers to receive it. This, on the whole, seems to be the best disposition to make of our plant, Reisseck's genus (Martius, *Fl. Braz.*, xi., 194) having been already extended by Grisebach (*Cat. Pl. Cub.*, 32) to include a group of West Indian shrubs very similar to our plant in habit and inflorescence and in the structure of the fruit, although, unlike it, provided with petals. The leaves of all the West Indian species are coriaceous and persistent without the prominent veins which characterize the Brazilian species, while the leaves of these last are apparently deciduous, at least in the case of two of the species. The walls of the stone of our plant are thick and crustaceous, but not more so than in one or two of the West Indian species now referred to this genus; and the branchlets are thickly beset with lenticels, a character common to all the species of the genus.

The oldest name of our plant is that of Vahl (*Symb.*, iii. 41, t. 58), who published an excellent figure of it; so that, if it is referred to Rhamnidium, it becomes *Rhamnidium ferreum*.

Rhamnidium was placed by Bentham & Hooker in the "Genera Plantarum" in the tribe *Rhamnæ*, in which the fruit is described as dry or drupaceous, with three (rarely two to four) indehiscent or two-valved cocci or stones. The fruit of Rhamnidium is, however, a true drupe, with a single one to two-celled stone, and seems rather to belong with the *Zizyphæ* and to follow naturally after Condalia.

C. S. Sargent.

New or Little Known Plants.

A Hybrid Calanthe.

IN the report of the Boston Chrysanthemum Show, on page 566 of the issue of Garden and Forest for November 19th, 1890, appears a reference to a new seedling Calanthe. The specimen in question was exhibited by Mr. Richard Gardner, gardener to Mr. Cornelius Vanderbilt, of Newport, Rhode Island, and it was awarded the silver medal of the Massachusetts Horticultural Society. The seedling, as stated in the report, is the result of fertilizing *C. vestita rubro-oculata* with the pollen of *C. Veitchii*. It was raised in the garden of Mr. Pierre Lorillard, at Jobstown, New Jersey, by Mr. Gardner in 1882. The pseudo-bulbs, in the development of which it is extremely prolific, are larger than in either parent, very broad at the base, tapering gradually to a small apex, and have never shown the jointed formation characteristic of *C. Veitchii*. The plant differs from *C. Turneri*, a species from Java to which it has been compared in this latter particular, and is superior to it in other respects. With the exception of being a trifle wider, the leaves bear a strong resemblance to those of the male parent. The racemes are shorter than in *C. Veitchii*, not so erect, and yet with a less conspicuous arch than the inflorescence of the seed parent, and they are produced more freely than in either parent. The larger flowers, with a more even spread to the parts, are arranged as compactly as those of *C. Veitchii*, the color being of a purer white than in *C. vestita rubro-oculata*, with a larger, though less dense, blotch of a reddish tint at the base of the lip. The illustration on page 17 is reproduced from a photograph of the raceme of the plant exhibited in Boston.

Some time ago a representative of the Messrs. Sander & Co. purchased a portion of the stock of this Calanthe, and sent a plant of it to Dr. Reichenbach with the suggestion that it be named after Mr. Eyerman, of Easton, Pennsylvania, well known as a collector of choice Orchids; but Dr. Reichenbach died before he had published any description or name of the plant, which is now locked up in his herbarium. Specimens have been sold at auction, however, under the provisional name of *C. Eyermanii*.

Mr. Gardner has another promising hybrid Calanthe which is also the result of crossing *C. Veitchii* and *C. vestita luteo-oculata*, but in this instance the latter is the male parent. Here the flowers resemble those of the pollen parent in color, but the white is the purest I have yet seen in a Calanthe, and the yellow of the eye is beautifully delicate. In all other respects this plant resembles *C. Veitchii*. But a correct estimate of its good qualities can hardly be given yet, for, although raised at the same time and place as the other hybrid, the plant, having passed through many vicissitudes, is still small.

There is in existence another hybrid Calanthe, *C. Sedeni*, which claims the same parents as the so-called *C. Eyermanii*. It was raised by Mr. Seden at the well known London establishment of Messrs. James Veitch & Sons. In color the flowers resemble those of *C. Veitchii*, and they show an appreciable improvement in size. I am not aware, however, which is the pollen parent in this case, but, in view of Mr. Gardner's experiences, it is probable that *C. Veitchii* was the seed-bearer. Perhaps the experts of the Veitchian establishment can throw some light on the matter.

Cambridge, Mass. *M. B.*

Foreign Correspondence.

London Letter.

Cattleya Warocqueana.—I have received the following note from M. Lucien Linden, Director of *L'Horticulture Internationale*, Brussels:

"I read in the Garden and Forest for November 26th a note by you on *Cattleya Warocqueana* in which that new introduction is referred to *C. Gaskelliana*. I have too often had occasion to recognize the fairness and courtesy of your criticism in that journal to think of complaining of your judgment with respect to this Cattleya, but I would like to call your attention to the fact that some of the best judges have recognized in *C. Warocqueana* the *C. labiata autumnalis*, a view confirmed by the time of its flowering and the form of its flowers; also that the numerous varieties of *C. Warocqueana* that have flowered with us, of which some have been exhibited in London, are much superior to the best forms of *C. Gaskelliana*. I can also assure you that *C. Warocqueana* comes from a locality very far removed from the habitat of *C. Gaskelliana*."

I have not seen among the plants of *C. Warocqueana* exhibited by M. Linden at the meetings of the Royal Horticultural Society any that could be considered identical with the autumn flowering *C. labiata*, now called *C. labiata vera*. The opinion that such might be the case was discussed by the Orchid connoisseurs at the meetings of the Royal Horticultural Society, but obtained no support. By the side of M. Linden's *C. Warocqueana* were exhibited plants of *C. Gaskelliana* (which, of course, is also a variety of *C. labiata*), and the opinion of those qualified to speak on this subject was as I expressed it in the note in Garden and Forest to which M. Linden refers—namely, that whilst there was no clear line of separation between *C. Warocqueana* and *C. Gaskelliana*, the plants of the former shown by M. Linden were better forms than any yet seen of *C. Gaskelliana* as introduced seven years ago. As already stated by me, some of M. Linden's flowers

were not unlike those of *C. speciosissima*, now called *C. Luddemanniana*, which blooms in October. Certainly I have seen in *C. Warocqueana* forms of most exquisite beauty, quite as striking and attractive as any of that section of the Labiatæ group to which it belongs. The geographical point referred to in M. Linden's note cannot be taken for much alone, as the distribution of *C. Loddigesii*, of *C. Dowiana*, with its subvariety *aurea*, and of *C. superba*, indicates. Slight variations are certain to occur in different localities. It is only in the case of Orchids that these slight differences are seized upon as good specific characters.

A HYBRID STANHOPEA.—The first hybrid in this genus has been raised in Germany by a Mr. Weber, who crossed *S. oculata* with *S. tigrina*, the result being a hybrid intermediate between the two parents and inferior to *S. tigrina*. The Stanhopeas are all interesting and good garden plants, but they do not find much favor in England. This may be partly owing to the fugacious character of the flowers, although they last quite as long as the flowers of many popular Orchids. Such species as *S. tigrina*, *S. insignis*, *S. platyceras*, *S. grandiflora*, *S. Devoniana* and *S. Bucephalus* are worth a place in every good collection. They are very easy to cultivate, they bloom annually, their flowers are large, fragrant and richly colored, whilst structurally they are more remarkable than most Orchids. A picture of Mr. Weber's hybrid is given in the December number of *Gartenflora*.

CYMBIDIUM TRACEYANUM.—This plant was sold by auction last week, and realized seventy-five guineas. It was bought by Mr. Sanders, of St. Albans, who sent a flower to Kew for determination. Mr. Rolfe considers it is only a variety of *C. Hookerianum*, the *C. grandiflorum* of Wallich. The only difference between the type and this high-priced plant is one of size, the flowers of the latter being nearly an inch wider than those of the former, which are five inches in diameter. Here is an instance where size makes a difference of seventy guineas in value.

FLORISTS' FLOWERS.—The editorial remarks in GARDEN AND FOREST (iii., 569) with reference to the "improvements" made by florists in the size and form of flowers are endorsed here by all except those who consider grossness of quality in a flower the acme of perfection. What is perfection in a flower? To some florists it is rank heresy to speak disparagingly of double flowers or big flowers or over-formal flowers. The bigger or more double a flower, the better it must be. The late Mr. Hibberd used to say, "Let this class go their own way; they have their own ideas of perfection, and in their efforts they do an enormous amount of good work which is easily separated from the bad." Even double and huge-flowered Begonias have a special interest as showing the wonderful power to vary inherent in all plants, which requires certain simple conditions to bring it out. Mammoth turnips and cabbages are only a few examples of what cultural skill will achieve when its aim is to produce size. It is only when size is repulsive that objection is strong. With regard to double flowers I am of the opinion that except in a few cases they are less attractive than their single-flowered progenitors. The Carnation, the Chrysanthemum, the Gardenia, the Almond, and, of course, the Rose, are the exceptions.

Fig. 3.—A Hybrid Calanthe.—See page 16.

QUERCUS TINCTORIA.—Mr. Anthony Waterer has forwarded some leaf-branches of his "Knap Hill" variety of what he calls Scarlet Oak. He also states that "the leaves are still hanging thick upon the trees." As this was written on December 17th, after a fortnight's severe frost and fog, it is clear that Mr. Waterer's Oak is an unusual one. *Q. tinctoria* as represented at Kew has been leafless for some time. Of course there is a great difference between these Oaks as grown on the poor gravelly soil at Kew and in the famous Knap Hill Nursery, where the soil is exceptionally deep and rich and the situation sheltered. At the same time it is risky to attempt to name an Oak of this character from leaves alone. The rich chocolate crimson of the leaves of Mr. Waterer's Oak, together with their persistency in frosty weather, give it an exceptional value, in England at any rate. After comparing the leaves with specimens with the help of Mr. Nicholson I am driven to own that the Knap Hill Scarlet Oak may be *Q. tinctoria* or *Q. coccinea* or a hybrid, or something else. [The Knap Hill Scarlet Oak is *Quercus coccinea*.—ED.]

London. *W. Watson.*

Cultural Department.

Notes on Some Hardy Wild Roses.—II.

Rosa blanda is a very hardy Wild Rose, belonging to the Cinnamon Rose group, which is found more or less commonly throughout the north-eastern part of North America. The type is a dwarf plant, rarely growing more than three feet in height, and probably hardly averaging over two feet, and it is particularly distinguished by having its stems wholly unarmed or bearing very few prickles. The leaflets are usually large, and the flowers, which appear a week or ten days later than those of *Rosa acicularis*, are also above the average in size, fragrant and of a bright rosy color, and often borne singly. The large, roundish, dark-red colored fruit, with persistent sepals, is often brightly conspicuous as it hangs just above the snow along road-sides in its native habitat, notably in the valley of the St. Lawrence River. In its natural haunts it seems to prefer rich rocky soils.

Little seems to have been done to improve this plant from the gardener's point of view, but on account of its large blossoms and unarmed habit it may be made a parent of some useful hybrids. As this species extends westward it seems to become more variable, several varietal and specific names having been given, which are considered as simply forms or varieties of *Rosa blanda* by other authors. Some of these plants are characterized by having more numerous flowers, in corymbose clusters, and by their prickly stems.

Rosa Nutkana, a native of the Rocky Mountain region and the Pacific slope from northern Utah to Alaska, appears in cultivation at the Arboretum as an exceedingly strong, stout-stemmed species, growing from six to eight feet in height. The stems bear a few strong recurved spines, which are often very broad at the base, so that they are almost triangular in shape. On many plants there are few or no prickles, and the flowering branchlets are perfectly smooth. The first flowers appear at about the same time as those of the last species. They are usually solitary, and average about two inches or more in diameter, and are of a delicate pale, pinkish red color.

The erect habit of this species, its thick, clean stems, which attain a height of three or four feet without branching, and its comparative freedom from spines, may make it a desirable plant to form tree-like or standard bushes upon which to bud or graft other garden varieties, as is often practiced upon the Dog Rose in Europe. *Rosa Nutkana* does not spread from suckers, and it is perfectly hardy in this latitude.

What has been classed as *Rosa pisocarpa*, a species from California and the Pacific coast region, appears very variable in habit under cultivation. Sometimes the plants are moderately tall and bushy, while others have stems as high as those of *R. Nutkana*, but not so coarse and stout. The spines are more abundant, though very much smaller, and prickles are numerous. The flowers are not so large, and are usually of a much deeper color than those of *R. Nutkana*, and the fruit is small and globose. There is some confusion as to the limitations of *R. pisocarpa*, as well as of a number of other western species of Rose which are too little known by botanists and in cultivation to give any idea of their value.

Rosa gymnocarpa, whose habitat is also the western side of the continent, is a slender, sometimes long stemmed, species, which, although it lives through our winters, does not yet appear to be sufficiently vigorous and enduring to be very satisfactory here. The flowers are rather small, of the usual pale rose color, though forms with white flowers are found. It seems to be more closely allied to the Asiatic *R. Beggeriana* than to any other species in cultivation.

Rosa rugosa also belongs to the Cinnamon group of Roses, with one or more species of which it appears in gardens to have exchanged pollen, which has produced forms intermediate between the two parents. Some of these have been sold as *Rosa rugosa*, a fact which is to be regretted, because these plants are generally much inferior and less beautiful in foliage and flower than the typical species. *R. rugosa* and its white variety easily rank among the most beautiful of the very hardy Roses in cultivation; and, either for its thick glossy foliage, or on account of its flowers, which, under good cultivation, expand four or even five inches across, or for the sake of its large rich red fruit of late summer and autumn, it is a desideratum for any garden. It is one of the hardiest species, and will stand twenty-five degrees or more below zero without any apparent injury. It may be called a perpetual blooming Rose, for although it has only one regular period of profuse flowering, it continues to bear blossoms as freely as a Hybrid Perpetual until checked by frosts. This species is now being used in hybridizing with others in the hope of obtaining even better Roses than any we now have.

So far, the double flowered forms have, as a rule, proved less interesting than the single blossomed type. There is much variation in the depth of color of the flowers of different plants, those having the deepest purplish red blossoms being the best. The white form is very desirable. The prickly character of the whole plant is objectionable, but it is exceeded by the dense and formidable covering of prickles which protect the stems of *R. Kamtschatica*, a species closely resembling *R. rugosa* and possibly only a variety of it.

It has been stated by some writers that the thick, rugged, dark green foliage of *Rosa rugosa* was not liable to attack by the usual Rose-injuring insects. This is not the case, however, for the Rose-slug (*Selandria rosæ*), the Leg-Hopper (*Typhlocyba rosæ*) and other insects sometimes attack it quite freely, but the thick, leathery character of the foliage serves to make equally serious invasions less noticeable than in other thinner leaved species. The flower-buds of this, and some other wild Roses in the Arboretum, are often destroyed by a well known and widely distributed red-colored snout-beetle (*Rhynchites bicolor*), which eats holes into the buds, and whose larvæ live within and destroy the fruit.

Arnold Arboretum. *J. G. Jack.*

Winter Pears for Market.

THE Anjou pear I regard as the queen of winter pears for the table. It possesses all the virtues of a perfect pear, being rich, vinous and melting, with keeping qualities not excelled by any pear of its season. It is large, of pleasing shape, fragrant, and when fully ripe of a warm straw color. Coming into market when all fall pears are gone, it may be kept from November until March. As a market fruit it is always in ready demand wherever known, and brings the highest price, $5 to $6 per bushel for fine selected fruit. The tree is hardy, vigorous, not subject to blight, does not overbear, and hence requires little thinning, while few inferior fruits are seen on the tree.

Anjou does well as a standard or a dwarf. It should be planted in well-prepared, rich, dry ground and kept under the best cultivation, enriching it every year alternately with a moderate dressing of well decomposed stable manure and hard-wood ashes. A thin sprinkling of salt during winter is also beneficial. Pruning is very important to keep up the vigor and health of dwarf trees and also to prevent overbearing. Dwarf trees that have been maintained under proper cultivation, and have been properly pruned, may be seen producing excellent crops of fine fruit after a half century of existence. Most of the dwarf Pear-orchards throughout western New York are neglected in most, if not in all the above requirements, and therefore their lease of life is short and unsatisfactory.

The Winter Nelis is one of the finest winter pears, and a great favorite in eastern markets. The fruit is of medium size, melting, and possesses a rich aromatic flavor. For a dessert pear in respect to size, color and quality it has no superior among winter varieties. Its season is from December to March. Winter Nelis should be grown on Pear stock, or double-worked on dwarf stock, White Doyenne being the best tree for double working. A slender grower, in order to obtain bearing trees within a few years, it should be top-grafted on good-sized, vigorous trees. It often overbears, and requires thinning, otherwise the fruits prove inferior in size and quality. Indeed, too much stress cannot be laid upon the necessity of thinning, not only with pears, but with all other kinds of fruit.

By all who have tasted the Josephine de Malines when well grown and ripened this will be pronounced one of the very best late-winter pears. The fruit is medium to large, the pink or salmon-stained white flesh, melting and of a delicious rose aroma. This succeeds either as a standard or dwarf. Its season is from January to April. Owing to its moderate, irregular growth, it is little propagated in nurseries, and on this account is not much disseminated.

Lawrence, largely grown in some sections of our state, is held in high esteem by those who prefer sweet pears. The fruit is medium to large, melting and of pleasant flavor. Its season is from December to January. The tree is a moderate grower and very productive.

Clairgeau is the largest and most attractive early winter pear in cultivation, and always commands the highest price. The fruit is very large, pyriform, yellow and red, with its red cheek usually very highly colored, nearly melting, and keeps till January, the tree being a good grower and an abundant bearer. This is a very valuable market pear.

I have thus briefly referred to the best winter market pears that have come under my observation. Others might be added, but none, all requisites considered, equal to those specified. This is applied to winter market pears solely.

The pear for market and the pear for the amateur are two different matters. And yet, while the list might be increased in the latter case, where quality is the main consideration, it would be, nevertheless, difficult to name any finer winter pears for the table than Clairgeau, Anjou, Winter Nelis and Josephine.—*George Ellwanger in Popular Gardening.*

Bartell's Dewberry.

ONE of the most encouraging phases of pomology in this country at the present time is the progress we are making in improving our native fruits. Within the past half century many valuable varieties of the native Grape have been developed, and as the result our markets are now abundantly supplied with this delicious fruit. The tender foreign Raspberry has been supplanted by hardy native varieties, and the same may be said of the Gooseberry. In the north-western states improved varieties of the native Plum are gradually coming to the front and give promise that plums of good quality may soon be grown in our coldest states. The Crandall Currant seems to be a step forward in the development of a new species that may yet prove valuable, and the dwarf Juneberry and Buffalo-berry are beginning to receive attention. The garden Blackberry, now a valuable market fruit, appears to have been entirely developed in this country, and of more recent introduction to culture is the Dewberry, which, if we may judge from its best showings, gives promise of developing into one of our most delicious and productive small fruits.

It is only within a few years that the cultivation of the Dewberry seems to have been attempted. The earliest mention I have seen of any attempt of this kind was in the *Massachusetts Ploughman* in 1882. This was before the introduction of any named variety so far as I know. Within the past few years the Lucretia and Bartell's Dewberries have been rather extensively advertised in nurserymen's catalogues. But not all of the testimony from those who have tried them has been favorable, though occasional reports have been very flattering.

My experience with the Dewberry at Geneva, New York, was quite unsatisfactory. The variety tested was called Mammoth, and it proved a decided failure. But in the summer of 1889 I saw a small plantation of Bartell's variety on the grounds of Mr. H. C. Adams, of Madison, Wisconsin, that at once established my faith in the possibilities of this fruit. I was informed that the most productive season had passed at the time of my visit, and that the berries which I saw were inferior in size to those gathered a few days earlier. But at this time the vines were fairly well loaded with fruit of larger size and more attractive appearance than the finest blackberries, and, to my taste, altogether superior in quality. There is a juicy, melting quality in the dewberry that is scarcely equaled by any other fruit of my acquaintance.

Fig. 4.—Bartell's Dewberry, natural size.

The fact that the Dewberry is prostrate in its habit of growth is a decided objection to it in climates where winter protection is unnecessary. But in regions of severe winters the ease with which the plants may be covered is a partial recompense for this fault. It is said that a plantation once started is eradicated from the soil with considerable difficulty, which, if true, is an additional objection to the plant in cultivation.

I consider Bartell's Dewberry worthy of trial by all who are interested in testing new fruits. Mr. Adams, who is an extensive grower of Blackberries, has found this variety more profitable as a market fruit than any Blackberries he has grown.

The accompanying illustration is made from a specimen taken after the height of the fruiting season had passed. It would not have been difficult to have found larger fruits and much larger clusters at an earlier date.

University of Wisconsin, Madison. *E. S. Goff.*

Notes from Wellesley.

Reinwardtia trigynia and *R. tetragynia* are old-fashioned winter-flowering greenhouse plants now blooming here which deserve more general cultivation. They belong to the Flax family, and are nearly related to the typical genus Linum, to which they have sometimes been referred. Their habit is semi-shrubby, flower clear yellow; and although the petals are fugacious the flowers are produced in such abundance as to remain showy for five to six weeks during December and January. Old plants may be divided yearly, but cuttings taken from non-flowering shoots make neater plants.

Streptosolon Jamesonii, the handsome greenhouse evergreen, is the only species of the genus, and was sent out as *Browallia Jamesonii* many years ago. It is still a comparatively uncommon plant. I have grown it for two years, and had almost come to the conclusion that it had little to recommend it, until recently I saw two fine trained standards in a neighboring greenhouse. I had grown mine planted out, and so treated they made coarse, rambling plants which never flowered well; but treated as standards, continuously in pots, the growths are shorter, they can be better ripened, and the beauty of the plant is increased by their taking a graceful, weeping habit. The flowers are orange yellow, borne in elegant panicles at the ends of the branches, and they last for a long time. Propagation is by cuttings in early spring; they root easily. This plant requires a good rich loam and abundance of water during the growing and blooming season.

Daphne Indica is not so frequently met with as it should be. It is almost indispensable in any conservatory for the odor of its flowers. Although having handsome bright green foliage it is an ungainly plant no matter how it is grown, but wherever the flowers are, in view or out of sight, their presence will be felt. It is propagated by cuttings or grafting. Cuttings of half ripened growths taken off with a heel and inserted in sand without bottom heat are pretty sure to root, although they may take two months to do it.

Clematis indivisa is a rare and pretty white flowering greenhouse climber from New Zealand. Mr. Harris has trained it to the roof of the Odontoglossum-house, in company with Lapagerias, which position seems to suit it exactly. Though not so handsome as many of the summer-blooming species of the northern hemisphere, it is yet a very interesting plant.

Lachenalias are not now required to fill the position they once did. They are remnants of the time when it was customary in all large places to have a house for South African plants alone, from whence they come. They are still grown because of a dislike to discard anything really good. The genus is here represented by two of the best, *L. tricolor*, and its variety, *Nelsoni*, the latter raised by the late Mr. Nelson, of Alborough, England, an amateur who made a specialty of these charming bulbous plants. In appearance they somewhat resemble a Squill, with mottled leaves and pendant waxy bells of yellow, red and green in mixture. It will not do to force them; their growth is slow, beginning about September, the blooming season in a cool greenhouse being February. In England, Mr. Ingram, of Belvior Castle, uses the common *L. tricolor* for bedding purposes, keeping the plants over winter in a cool frame, where their blooming season is retarded until March and April. They increase freely by bulblets produced naturally, and blooming the second year.

Wellesley, Mass. *H. G.*

Work of the Season.

THE great variety of work now pressing in the many departments of the garden makes this one of the most interesting periods of the year to the in-door cultivator. Among the tender-foliaged plants, such as Marantas, Dieffenbachias, Alocasias, Begonias, and others of like character, the increasing power of the sun will be felt, and light shading will be found necessary, though this should be applied with judgment, as over-shading is fully as injurious to most plants as is the other extreme. The use of one of the many different shading materials, such as muslin, burlap or other cloth, or that formed of light wooden strips linked together so that it can be rolled up in cloudy weather, is undoubtedly the best system of shading, but as such appliances add considerably to the running expenses of a place, they are frequently supplanted by cheaper devices, and among these naphtha and white lead, mixed to about the consistency of milk, and applied either with a brush or syringe, is one of the most serviceable. Even whitewash will give good results, except for the fact that it removes the paint from the wood-work wherever it is applied. In the Palm-houses little or no shading is required so early in the season, except for some of the soft-leaved species, such as Calamus, Verschaffeltia, and most of the Geonomas.

If one could only secure perfect glass for glazing the houses there would be less need for early shading, but one imperfect square of glass may ruin several fine plants in a few hours, and it is therefore best to be on the safe side. And speaking of glass brings to mind the fact that some of the large Rose-growers are now using second quality of French glass in preference to first quality American glass, on the ground that there are fewer imperfections in the French glass and consequently less injury is done to the foliage beneath it, while the cost of the two qualities quoted is about the same.

Where the early forcing of flowering plants is practiced this operation will now be under full headway, and it will be necessary to give proper attention to every detail. With Lily-of-the-Valley one of the necessary conditions for successful early forcing is to allow the pips to freeze thoroughly before they are brought into heat. This fact is so well recognized by large commercial growers that they secure this condition by means of cold storage houses; this arrangement, though costly, rendering them independent of the weather.

For Tulips, Narcissus, Hyacinths and other Dutch bulbs the freezing process is not essential, and as these may be brought into flower with moderate heat they are naturally among the most popular and satisfactory plants with amateur cultivators.

A succession of *Lilium Harrisii* and *L. longiflorum* should be arranged, as the former may be had in flower by Thanksgiving-day, and by successive lots a supply may be kept up until spring. *L. longiflorum* will not force as early as *L. Harrisii*, but from the latter part of February or beginning of March and onward this exquisite Lily may be enjoyed in all its pure-tinted loveliness.

Other easily forced spring flowers are the Indian Azaleas, among which the old Fielder's White and also Alba are of the easiest to manage, though Deutsche Perle and Flag of Truce may also be brought in early, and are far superior in flower to the first named. Among the host of colored Azaleas, Madame Vander Cruyssen is by far the best for early work, while Charmer, a large-flowered, dark pink variety, is also good, but is not quite as shapely a grower as Madame Vander Cruyssen.

Some Genistas will also be brought in from the cold-house from time to time in order to continue a supply of their graceful racemes of bright yellow, and it is well to remember also that the present is a good time to put in cuttings of these useful plants, in order to secure strong, stocky young plants for next winter. Rose-cuttings, and also those of Carnations, Bouvardias and similar stock for next season, should now be provided, while the time for sowing seeds of a multitude of plants for summer bedding is at hand. The usual complaint at this time is lack of space for some of these very necessary operations, but it should be borne in mind that drawn up seedlings seldom make satisfactory plants, and it is therefore wisest to limit the varieties in accordance with the space at command. If Ferns are grown this is also a good season in which to sow spores, from the fact that the growing season for most of the exotic species is now about to begin, and in fact in many cases has already begun, and seedlings started now usually make more progress than when sown later.

Holmesburg, Pa. *W. H. Taplin.*

Orchid Notes.

Cœlogyne cristata.—This is an old favorite with Orchid-growers, and it makes a host of new friends for itself every year. It is very beautiful at this season, the graceful racemes of pure white flowers, with conspicuous marking of yellow in the lip, being produced in great profusion from the base of the most recent pseudo-bulbs. Where there are a number of plants a succession of bloom may be maintained from the middle of December to the latter end of February by confining to a lower temperature those whose flowering it is desirable to retard. They may be returned to the normal conditions as occasion demands. The plant loses somewhat in some hands by being too severely dried off after the growing season. During the blooming period it is far from uncommon to see the flowers associated with pseudo-bulbs much shrunk and withered, and leaves of unhealthy hue. It is true that a smaller quantity of water is demanded when the growth has been perfected, but the supply should not be withheld so far as to cause this condition. There is nothing to be gained by this rigorous treatment. The flowers appear just as freely in the company of plump pseudo-bulbs and rich green leaves, and, as a matter of course, the plants are then much more pleasing to the eye.

Maxillaria picta.—Some other species of the genus Maxillaria are better known than this one, and their superiority entitles them to much more general attention than they receive. It is a plant very easily managed. It is a native of Brazil and was introduced to Europe in 1832. The ovate pseudo-bulbs are slightly compressed, furrowed and clad with ragged brownish sheaths. They support two or three sharply pointed ligulate leaves, from twelve to fifteen inches in length, leathery, and dark green. The scapes emerge from the base of the pseudo-bulbs formed during the previous spring and summer. They are from six to nine inches in length, and each bears a single flower about two inches in diameter. The petals are smaller than the sepals; and both petals and sepals are incurved and have their margins turned slightly backward. The interior surface is dark orange with irregular brownish blotches, and the exterior creamy white, becoming greenish at the base, with numerous spots and patches of reddish purple. The sepals are further marked on the outside with a line of the latter color which traverses one-third of their length from the base. The lip is broader than the sepals and about half their length, creamy white, marked on the upper surface with reddish purple spots and with lines, which are most numerous toward the margins. The column is reddish purple and very conspicuous. The flowers are produced with great freedom during November and December, and they are powerfully fragrant. It is the odor, rather than the color, size or form of the flowers, which renders them attractive and pleasing. The plant thrives best in pots or pans, with ample drainage material, rough peat fibre and growing sphagnum. Abundance of water is required during the growing season, but afterward the supply may be slightly diminished with advantage. A constant intermediate temperature gives very satisfactory results.

Saccolabium giganteum.—Among the numerous Orchids now in bloom it would be difficult to find one more stately or one in which the colors of the flowers are more exquisitely blended. It is a plant of erect habit, the stem being well furnished with bold strap-shaped leaves about twelve inches in length, unequally notched at the apex, and of dark green color, with parallel lines conspicuously paler. The pendulous axillary inflorescence is about as long as the leaves, and it takes the form of a cylindrical raceme four inches through at the widest part, tapering slightly toward the tip. The flowers are sweetly fragrant, each an inch across, and densely packed on five-sixths of the peduncle's entire length. The sepals are elliptical, white, with pale purple spots, and the petals elliptic-lanceolate and like the sepals in color. The lip is dilated and trilobed at the apex, the lobes turned upward, bright purple, with lines of a darker tint on the upper surface and lilac tipped with purple beneath. The column is greenish white, marked with purple at the base and in front. This species succeeds best in pots, as do most of the large-growing Saccolabiums, with crocks and rough pieces of charcoal and sphagnum on the surface for the roots. The plant delights in a hot, moist atmosphere and frequent applications of water during the growing season. To promote abundant flowering it is necessary, however, that the roots and air be maintained in a somewhat drier state, and that the temperature be slightly reduced in winter. But even then sufficient water should be given to prevent the smallest degree of shriveling. Free exposure to light, but strict shading from brilliant sunshine, even at the dullest period of the year, are essential for securing luxuriant foliage.

Cambridge, Mass. *M. Barker.*

Anchusa Italica.—The Italian Alkanet, as it is called, is a member of the Borage family, and is also known as *Anchusa azurea* and *A. paniculata*, both of which names are descriptively correct, as the flowers are borne on tall panicled stems and are of a bright shade of blue. If we except the Larkspurs there are few hardy plants that possess this peculiar shade of blue; and, as the plant under consideration flowers in early summer and lasts long in perfection, its value is considerable, as it is quite hardy and also a true perennial. The Anchusas are among the easiest of perennials to raise from seeds, for these germinate as readily as those of most annuals, and as seeds are freely produced it is obviously the best means of propagation. There are several other Anchusas, but our own experience is limited to the above and to *A. Capensis*. This last species is said to be a tender biennial; but we have found it perfectly hardy in that the abundant seeds, produced rapidly, germinate around the parent plant, survive the winter and flower the following season in profusion for three months. The flowers, however, are small in comparison with those of *A. Italica*. It is a well known fact that bees are partial to many Boraginaceous plants, and to the genus Anchusa in particular. *A. Capensis* is eminently suitable for sowing in places where it can be left alone to take care of itself, as in a wild garden. The Alkanet of commerce, a deep red dye, is the product of *A. tinctoria*, a dwarf species of spreading habit.

South Lancaster, Mass. *E. O. Orpet.*

The Forest.

Forest-policy Abroad.—II.

WITH respect to the second class of forest-property, that belonging to towns, villages and other public bodies, it is again impossible to speak for the whole of Germany, except upon the broadest lines. The state everywhere exercises oversight and a degree of control over the management of these forests, but the sphere of its action varies within very wide limits. Even within the individual states it does not remain the same. Thus far, however, the action of the Government is alike, not only throughout Prussia, but in all parts of Germany. It prevents absolutely the treatment of any forest of this class under improvident or wasteful methods; nor does it allow any measure to be carried into effect which may deprive posterity of the enjoyment which it has a right to expect. How far the details vary may be gathered from the fact that while in the Prussian provinces of Rheinland and Westphalia the village communities manage their own forests, subject only to a tolerably close oversight on the part of the controlling staff, in the former Duchy of Nassau, now Prussian territory, their share in the management does not extend beyond the right to sell the timber cut under the direction of the Government Oberförster, the right and obligation to pay for all the planting and other improvements which may be deemed necessary, and the rather hollow privilege of expressing their opinion. But however galling so extensive an interference with the rights of property may appear, it is none the less unquestionably true that in France, as well as in Germany, the state management of communal forests lies at the root of the prosperity of a very large proportion of the peasant population, and the evils which have attended its withdrawal in individual cases are notorious. While, on the one hand, villages whose taxes are wholly paid by their forests are by no means rare, on the other, the sale of communal forest-property in certain parts of Germany in 1848 has been followed with deplorable regularity by the impoverishment of the villages which were unwise enough to allow it.

The relations of the state to the third class of forests, those belonging to private proprietors, are of a much less intimate nature. The basis of the relations is, however, the same. To quote again from Donner, "The duty of the state to sustain and further the well being of its citizens, regarded as an imperishable whole, implies for the Government the right and the duty to subject the management of all forests to its inspection and control." But this intervention is to be carried only "so far as may be necessary to obviate the dangers which an unrestrained utilization of the forest by its owners threatens to incite, and the rights of property are to be respected to the utmost consistently with such a result." Prussia, of all the German countries, has respected these rights most highly, and the Government exerts practically no restraining influence except where the evident results of deforestation would be seriously dangerous. Here it may and does guard most jealously the woodlands which have been called in general "protection forests," of whose many-sided influence so much has of late been said and written in America.

The state leaves open a way of escape for the private proprietor who finds himself unwilling to suffer such restriction of his rights for the public good, and shows itself willing to buy up areas, not only of Protection Forest, but also of less vitally important woodlands. On the other hand, it is ready, with a broadness of view which the zeal of forest-authorities sometimes unfortunately excludes, to give up to private ownership lands which, by reason of their soil and situation, will contribute better to the commonwealth under cultivation than as forest. In this way the forests, whose preservation is most important, are gradually passing into the hands of the state; yet the total area of its woodlands is increasing but slowly.

The policy of state aid in the afforestation of waste lands, important through their situation on high ground or otherwise, is fully recognized, but the absence of considerable mountain chains has given to this branch of government influence very much less prominence than in the Alps of Austria, Switzerland and France, where its advantages appear on a larger and more striking scale.

In closing this brief sketch of forest-policy in Prussia it may be proper to refer briefly to the erroneous ideas of German

forest-management which have crept into our literature. They have done so, I believe, partly through a desire of the advocates of forestry to prove too much, and they injure the cause for which we are working, because they tend to make forest-management ridiculous in the eyes of our citizens. The idea has arisen that German methods are exaggeratedly artificial and complicated, and the inference has not unnaturally been made that forestry in itself is a thing for older and more densely populated countries, and that forest-management is inapplicable and incapable of adaptation to the conditions under which we live. It is true, on the contrary, that the treatment of German forests is distinguished above all things by an elastic adaptability to varying circumstances which is totally at variance with the iron formality which a superficial observation may believe it sees. It is equally true that its methods could not be transported unchanged into our forests without entailing discouragement and failure, just as our methods of lumbering would be disastrous over there; but the principles which underlie not only German, but all rational forest-management, are true all the world over. It was in accordance with them that the forests of British India were taken in hand and are now being successfully managed, but the methods into which the same principles have developed are as widely dissimilar as the countries in which they are being applied. So, forest-management in America must be worked out along lines which the conditions of our life will prescribe. It can never be a technical imitation of that of any other country, and a knowledge of forestry abroad will be useful and necessary rather as matter for comparison than as a guide to be blindly obeyed. Under these conditions I do not believe that forest-management in the United States will present even serious technical difficulties. It only asks the opportunity to prove itself sound and practical.

Switzerland is a country where the development rather than the actual condition of forest-policy may best claim our attention. The history of forestry in the Swiss republic is of peculiar interest to the people of the United States, because in its beginnings may be traced many of the chracteristics of the situation here and now, and because the Swiss, like the Americans, were confronted by the problem of a concrete forest-policy extending over the various states of a common union. The problem has been brilliantly solved, and not the least important result of its solution is the fact that the people of Switzerland have recognized the vast significance and importance of the forests in so mountainous a country, and a full and hearty appreciation and support of the forest-policy of the Confederation is found in every nook and corner of the land.

The history of the forest-movement in Switzerland has not yet been fully written. I may be allowed to quote from an unpublished sketch of it by Professor Landolt, who, more than any other man, has contributed to make that history of which he writes. As the example set by a republic to a republic, as the brilliant result of the work of a few devoted men, crowned by a public opinion which they created, and rewarded by the great and lasting blessing which they have brought to their country, our country can find no worthier model, no nobler source of encouragement and inspiration.

"Soon after the middle of the last century," begins Professor Landolt, "certain intelligent, public-spirited men of Zurich and the canton of Bern (which then included Waadt and a great part of Aargan) turned their attention to the situation of agriculture and forestry in Aargan. Their object was to gain a knowledge of the conditions involved, and their surroundings, and to remove the most pressing evils.

"In the years between 1780 and 1790, the cantons, following the lead of Bern, succeeded in appointing forest-officers, whose first task was to become conversant with the actual management of the state and large communal forests, and to make suggestions for their future treatment. Partly at this time, partly earlier, a large proportion of the state forests and a few communal forests were surveyed, and a few of them were marked off into compartments on the ground, a measure of vital importance to conservative management.

"The appointment of state forest-officers is to be regarded as the beginning of regular forest-management. Great numbers of forest-regulations bearing on the most various subjects, tree-planting among others, had been promulgated in former centuries. They had been often renewed, but without forest-officers they could not be enforced.

"Until about 1830 forestry in the less mountainous parts of Switzerland developed slowly, but still in a satisfactory manner. The mountain forests, however, with few exceptions, were in complete disorder. But the following years brought new life not only into politics, but also into national economies, and the status of the forest, which last was materially improved by the floods which spread in 1834 over the greater part of the Alps. The damage which they caused was so severe that the philanthropic and scientific societies set themselves the task of searching out the cause of inundations, which became more frequent as time went on. They concluded that it was to be found largely in the improvident destruction of the mountain forests. To the fear of a wood famine, which had hitherto been the chief incentive to the advancement of forestry, there was now added another, which, if not wholly new, still had been formerly little insisted on. It was the influence of forests on rainfall and the phenomena of nature in general. The societies did not fail to direct attention to this question, and with excellent result. The less mountainous cantons, with imperfect legislation, made new laws, or amended and completed the old ones, looked after the appointment of foresters, and took the organization of the felling, planting and care of their timber seriously in hand. But the chief gain lay in the fact that the mountain cantons applied themselves to the work."

Taken as a whole, forestry has made satisfactory progress as regards legislation, the improvement of forest-management and the increased number of forest-officers, since about 1840. In 1865 the Swiss Forest-school was established (as a fifth department of the Polytechnicum at Zurich), and "provision was thus made," says Professor Landolt, "for a forest-staff of our own, educated with special reference to our own conditions."

The Swiss Forestry Association was founded in 1843. Through frequent agitation, and by setting forth what action was necessary, it has rendered great services to the cause of forest-protection. It has moved successfully, among other things, for the foundation of a forest-school, the examination of the higher mountain forests, the passage of a new forest-law and the correction of the torrents.

In 1854 Professor Landolt called the attention of the Association to the investigation of the mountain forests. In 1858 the Federal Assembly appointed a commission of three men with authority to study and report upon the Swiss Alps and the Jura in regard to geology, forestry and police regulations bearing on water supply. From the appearance of the final report of this Commission in 1861 the improvement of Swiss forestry has been kept steadily before the Confederation. In 1875 a federal forest-inspector was appointed, and a year later the first Swiss forest-law was passed. This law does not extend to the whole of Switzerland, but only to the Alps and the steeper foot-hills. More recently attempts have been made by the Cantonal Government and the Forestry Association to extend its influence to the Jura or to the whole of Switzerland, but the need of such action is not yet clearly apparent.

The passage of the federal forest-law was followed almost everywhere immediately by the appointment of trained forest-officers, and all the cantons whose forest-legislation was defective amended or completed it.

"Our forest-laws," Professor Landolt goes on, "are intended to work more through instruction, good example and encouragement than by severe regulations. This method is somewhat slower than one which should involve more drastic uneasiness, but the results achieved are the more useful and lasting. Our laws require the same treatment for the forests of the state, the communes and other public bodies."

The oversight of private forests is less strict. Their owners may not reduce the area of their woodlands without the consent of the Cantonal Government; they must plant up the land cut over which is without natural growth, and they are bound to take proper care of the growing stock, but they are not held to a conservative management. In "protection forests," on the other hand, the timber that may be cut by private owners is marked out by Government officers, so that reckless lumbering may be prevented. The regulations which look to the formation of new protection forests must also be conformed to by private proprietors, or they must allow themselves to be expropriated. In these matters the Confederation and the cantons work in unison. The consent of the Federal Assembly is necessary to the clearing of private land in protection forests.

It hardly needs to be added that the present condition of forestry in Switzerland is admirable. Systematic forest-management has probably been known there as long as anywhere in Europe, and nowhere can finer individual examples be found. I have seen nothing, even in Germany, which seemed to me so workmanlike as the management of the Sihlwald, a forest belonging to the city of Zurich; and I am the bolder in my opinion because the Sihlwald (Garden and Forest, iii., pp. 374, 386, 397) has been called the most instructive forest of Europe by, perhaps, the most experienced forester of the present day.

New York. *Gifford Pinchot.*

Correspondence.

Tuberous Begonias.

To the Editor of GARDEN AND FOREST:

Sir.—Not every one who is familiar with the species and has watched the marvelous development of the hybrid Begonias will agree with all the views expressed in a recent article, entitled "Form in Flowers," in GARDEN AND FOREST. "Spoiling the flowers" is a familiar cry to the reader of horticultural literature, and we have had the same warning and very much the same arguments over all florists' flowers which those who are deploring the fate of the Begonias are now advancing. "Nature gives us the Ramanas and the Cherokee Rose, the florist produces Paul Neyron." So runs the complaint, and it seems a severe arraignment till the florist finds time to remark that besides Paul Neyron, his art has also produced La France, The Bride, Catherine Mermet and others which seem to have been overlooked in the course of the argument.

While there are certain ill defined canons of taste recognized among people of intelligence, yet practically we all decline to believe that anything which gives us pleasure has no beauty. I have no desire to enter into an unprofitable discussion on the beauty of form or the lack of it in the new Begonias, but simply wish to call attention to the conception of "Nature's Begonia," on which the argument is based. The type as Nature designed it, we are told, is a low dwarf plant with weak peduncles and small, drooping flowers of somewhat irregular outline. But taking the entire family of tuberous Begonias, of which there are about a score of species in cultivation, the combination specified is on the whole a rather rare one. The rule, if there is one, among the very diverse habits of these plants, is that the dwarf ones have stiff flower-stalks and the tall kinds weak ones, while there seem to be at least as many flowers of regular as of irregular shape. But most of our hybrids have been made from *B. Boliviensis*, *B. Pearcei*, *B. Veitchii*, *B. Davisii*, and in a smaller degree from *B. rosæflora* and *B. Clarkii*. *B. Boliviensis*, a tall plant, is responsible for the weak peduncles appearing so frequently in the hybrid Begonias, especially in the double varieties, the first of which were derived from that species. From a cultivator's point of view a flower on a low plant which has a peduncle so weak as to allow it to lie on the ground like a boy's sucker is not very desirable, and after supplying one's wants for hanging baskets, etc., such varieties are usually discarded by careful growers. There does not seem to be any inherent objection to trying to secure seedlings of the Davisii type with dwarf habit and fine flowers on stout, erect stems. We could hardly have too great an abundance of such pure colors, and if the flowers are sometimes rather large, this fault would regulate itself, for under ordinary treatment they are generally but little larger than those of some of the types. No doubt many inferior forms have been sent out, for every plant produces a salable tuber, and the margin of the florist is so small that he cannot be expected to throw away a plant so readily marketable. But after all, instead of assailing the hybridizer for lack of taste, why not encourage him in the production of what is new? Suppose some of the seedlings are not beautiful according to some ultra-Japanese standard, many of them will be sufficiently wayward and whimsical to suit the hyperæsthetical, and many more will delight those whose tastes are less highly educated, who can endure a regular flower and even admire a double Camellia.

Now is a good time to get some seed of one of these naughty hybridizers, for if sown at once they will commence to come into bloom in early June. The culture from seed is of the simplest. Use light soil, sow thinly on the surface and cover pan with glass. They will germinate in a fortnight, and even in the seed-leaf stage will stand considerable neglect. They should be dibbled out when small and kept growing at not too high a temperature. One can scarcely have too great a stock of these plants either for the garden or greenhouse.

Flatbush, L. I. *Quis.*

[If our correspondent will take the trouble to read again the article on which he comments, he will find not a word in disparagement of hybridizing. What the article maintained was: That increased size alone is not necessarily improvement; that a certain irregularity of outline which is pleasing in small flowers may be disagreeable when exaggerated in larger ones; that stiff perpendicular stems with a flower at the top, face upward, is no improvement on the graceful drooping habit of most Begonias, and that in many plants (not all) the single natural flowers are more beautiful than those which have been doubled by the gardener's art. "Quis" admits that "many inferior forms have been sent out," and we agree with him that the grower can hardly be expected to throw away marketable tubers. And yet it is well to insist now and then that flowers are not always beautiful merely because they are new or big or perfectly double.—ED.]

The Owl and the Sparrow.

To the Editor of GARDEN AND FOREST:

Sir.—Your pleasant correspondent, Charles Naudin, has some interesting notes on the *Stryx passerina*, a bird of whose existence I may as well confess my ignorance. The suggestion of any process which promises to aid in the extirpation of that admitted pest, the English sparrow, is alluring, but in avoiding Charybdis we often fall upon Scylla, and it occurs to me that our pigmy friend, who is, to quote Mr. Naudin's description, "a ferocious and well-armed bird," who "not only exterminates the sparrows' nests, but drives them away entirely by its presence alone from any locality," is a party to be respected certainly, but distrusted as to his ability or willingness to draw the line at English sparrows. I think your correspondent, who praises him possibly not too highly, would hardly care to "seal to such a bond" as would guarantee his discriminative powers in this respect. Like the writer, there are doubtless a few of your readers whose suburban experience, having a retrospect of something over half a century, includes, among other pleasant memories, recollections of countless mornings in years long past, which in one respect at least answered to Milton's beautiful description as "Sweet, with charm of earliest birds." That these are now mainly matters of reminiscence is largely due to the thoughtless and unfortunate introduction of the English sparrow. The diminished ranks of the native inhabitants of our orchards and hedge-rows are ill-conditioned to face a new marauder of the type Mr. Naudin describes, and it would seem to be the part of prudence to keep the Atlantic between us and the fierce little Chevêche until we are better informed as to his preferences and limitations. While we admire his valor, we may fairly question his discretion, and before making further reckless ventures we ought to be well assured, as between the English sparrow and the Chevêche, that this is not a case where "bad begins and worse remains behind."

West Roxbury, Mass. *W. H. C.*

[We have received letters containing the same warning from several correspondents, and should be glad to hear from others who have some knowledge of the habits of the Pigmy Owl.—ED.]

Recent Publications.

Outings at Odd Times. By Charles C. Abbott. New York: D. Appleton & Co.

Dr. Abbott has found another felicitous title for this latest addition to his series of out-of-door books. He saunters through upland and meadow, along woodside and brookside, to discover in every well-tramped highway and byway a freshness that never fails in the familiar forms of lowly life. The oftener he strolls among the familiar scenes where he has so often invited his readers to accompany him, the more thickly throng the surprises among the shrubs and weeds, the reptiles and insects, the birds and "small deer," for one who has eyes to detect them. And what Dr. Abbott sees he can weave into a narrative so entertaining that reading it is the next best thing to actually watching and witnessing in detail the modest events in the history which Nature keeps making day by day all the year long.

The book is so much in the vein of its predecessors that what has been so often said of their scope and quality will answer as a characterization of this one, and yet it differs somewhat in its flavor from the rest, and particularly from the earlier volumes of the series. It is less distinctly descriptive of our humble relatives and their ways and not so photographic in its delineation of what is seen. It is more contemplative. It treats the reader to musings on the more general laws of Nature. It is more subjective, too, and depicts the mood of the observer as often as the object mirrored in his mind. If, therefore, the reader finds fewer facts recorded he may detect more poetry; and since the book is not advertised as having merely or mainly a scientific value, he will not complain, and he may find the change not disagreeable.

Notes.

Small trees of *Araucaria excelsa* are largely used now in table decorations for large dinner parties.

Foreign journals state that the whole stock of a new Rose, Mamam Cochet, which last autumn was introduced by Charles Verdier, has been sold by him to an American, whose name is given as Mr. Ernest Asmus.

At Lafayette College, Easton, Pennsylvania, free tuition in road-building is now offered to one student from each county of the state. The instruction will be given by professors in the Engineering Department of the College.

A Stevia possessing an agreeable aromatic odor has been introduced to European horticulturists by Herr Dammann. It is a perennial, which grows only to a height of fifteen inches, is a strong bloomer, and is said to be more beautiful than any in common cultivation.

The annual report of Dr. J. A. Lintner, State Entomologist of New York, has been published, and as usual it is an important contribution to economic entomology. The illustrations are excellent, the index is complete, and the elaborate bibliography adds greatly to its value.

At the meeting of the Ohio State Horticultural Society a new Grape, raised by Mr. T. V. Munson, and said to be a cross between Lindley and Delaware, was pronounced very promising. The Colerain, a pure native seedling of the Concord type, and Nectar, a seedling, raised by the late Mr. Corywood, were also commended.

Professor Lazenby bagged some sweet cherries last year just after the fruit had set, and kept them covered until they were ready to pick. The fruit developed in this way was larger and heavier than that which remained uncovered, the skin was more tender, the general appearance particularly fresh, and the color notably brighter.

The *Bulletin of the Torrey Botanical Club* says that at a recent meeting of the club Miss Stabler "reported a peculiar growth of aërial roots in Swamp Maple as noticed by her at Great Neck, Long Island. The trees in several instances were decayed ten or fifteen feet above the ground, and roots one and a half inches in diameter had been sent out from above through this decayed growth to the ground, fifteen feet below."

Monsieur André, already distinguished by his explorations of the South American flora, made last year at the time of his visit to Montevideo an extended botanical excursion into northern Uruguay to the borders of Brazil, where virgin forests of the greatest interest were traversed, and where many trees were found of first-rate ornamental value for the future plantations of the parks and public gardens to be laid out in Montevideo under his direction. Among these there are many, he writes us, capable of embellishing the gardens of southern Europe. The results of these explorations are soon to be given to the public.

Professor George Lawson, of Halifax, in a private letter calls attention to the interesting fact that *Rhododendron Catawbiense* is likely to become naturalized in Nova Scotia. "It is nearly twenty years ago," he writes, "since I imported a few hundred Rhododendrons from Edinburgh. Many died; but all of the Catawbiense blood survived and have grown enormously. They seed very freely, and spontaneous seedlings are now seen peering out of mossy banks at long distances from my grounds. *Quercus sessiflora* is also spontaneous here with the Rhododendron from acorns of trees planted about the beginning of the century."

A "Hay Palace," recently built at Momence, Illinois, is described as being 206 feet in length and 166 feet wide in the centre. "The main hall is 103 feet in diameter, flanked on the four sides with wings. A circular gallery eighteen feet wide sweeps entirely around the main hall. The walls are built of baled hay, with just enough baled straw to make a pleasing contrast in shading and color. The primary object of the exhibition is to make a display of the varied products of eastern Illinois and western Indiana, which will include products of the farms, factories, forests, mines, quarries, and of the arts, domestic skill, and the accomplishments of the people of the district in music, oratory and manual training. A special feature is the display of the latest tools in haying machinery, and implements for ditching, laying and making tile, and road machinery."

A correspondent of the *American Architect and Building News* says: "Baton Rouge received its name from an enormous Cypress-tree which stood upon its site early in the eighteenth century, and out of which a certain carpenter once offered to build two boats of sixteen and fourteen tons respectively. The Cypress of Louisiana has bark of a reddish hue, grows to a great height, and is bare of branches excepting at the top. Naturally this particular Cypress was recognized among the pioneers and settlers as a landmark, and 'one of the first travelers who arrived at this locality,' says Le Page du Pratz, an old chronicler, 'exclaimed that this tree would make a fine stick' (a walking-stick for the Titans, presumably), 'hence the name of Baton Rouge (Red Stick), given to this place.'" The reference in this account is, of course, to the Bald Cypress (*Taxodium distichum*).

A writer in the *Illustrirte Gartenzeitung*, of Vienna, while disputing the excessive claims recently made for certain so-called "weather plants," points out the fact that a modest degree of power in forecasting atmospheric changes is possessed by a multitude of common plants. Among these he cites *Gallium vernum*, whose pleasant fair-weather odor becomes strong and pungent at the approach of rain; *Carlina vulgaris*, whose leaves close before rain; *Calendula pluvialis*, which predicts rain when its flowers remain closed after seven in the morning; *Oxalis acetosella*, which closes its leaves at the approach of rain or cold; *Lapsana communis*, which keeps its flowers open in the evening if it is to rain the following day, but closes them if fair weather is coming; *Draba verna*, which droops its leaves toward the ground before rain; and *Alsine media*, which predicts a clear day if its flowers open about nine o'clock, and a second one to follow if they remain open as late as four in the afternoon.

In his "Three Years in Western China" Mr. Alexander Hosie says: "Between Ch'ung-k'ing and Ch'i-chiang Hsien, the first city of any importance on the southern road to Kuei-chow, there are a number of factories for the manufacture of the ordinary coarse Chinese paper. . . . There is an entire absence of machinery for washing and shredding rags; there are no troughs of pulp, chemicals for bleaching, resin for watering, wire moulds for receiving and drums for firming the paper as it comes from the pulp-troughs. Bamboo-stems and paddy straw are steeped with lime in deep concrete pits in the open air and allowed to soak for months. When nothing but the fibre remains, it is taken out and rolled with a heavy stone roller in a stone well until all the lime has been removed. A small quantity of the fibre is placed in a stone trough full of water and the whole stirred up. A close Bamboo mould is then passed through the mixed fibre and water, and the film which adheres to it emerges as a sheet of paper, which is stuck up to dry on the walls of a room kept at a high temperature. The sheets are afterward collected and made up into bundles for market."

Mr. T. S. Brandegee distinguishes, in the November issue of *Zoe*, a new Poplar of Lower California under the name of *Populus Monticola*. It inhabits the high mountains of the Cape region in the extreme southern part of the peninsula, growing along streams and following down the cañons toward the warm lowlands. Young trees have a smooth, light colored bark similar to that of the Aspen, but it becomes very rough on old specimens. At elevations of five thousand feet it is rarely more than twenty feet high, but at lower altitudes it becomes a large tree nearly a hundred feet high, and is a favorite support for the wild Grape-vine. The wood is described as light red in color, and is said to be used in making furniture. The new growth is densely tomentose. The leaves are round-ovate, with a short point, variably sinuate-crenate or dentate, silky-pubescent upon both sides, especially upon the veins, with terete, white-tomentose petioles; the stipules are linear and the bud-scales white-silky; the capsules are ovate, densely white-silky tomentose, two to three-valved; styles usually two, united at the base, each with two narrow divisions. The disk is small and nearly flat; scales minutely sinuate-dentate, nearly glabrous. "This tree is known by the name of 'guerigo' to the inhabitants, who distinguish it from the common one of the fields and gardens called by them 'alamo.' The leaves and flowers appear in February, and in October all have fallen, a season of growth usual in Alta California, but very different from the ordinary habit of the plants of the Cape region of Baja California, where most of the vegetation comes forward with the summer and fall rains at the time when the cottonwoods are losing their leaves and appear to be preparing for a winter, which, however, never comes."

TABLE OF CONTENTS.

The Proposed Widening of the Drives in Central Park.

IN his recent message Mayor Grant, of this city, declares that the question of widening and improving the drives in Central Park is one which demands immediate attention. There is nothing novel in this suggestion. The necessity of widening and straightening and leveling the roads of the park has often been urged by persons who assume that these roads were made primarily for pleasure-driving. But it should never be forgotten that the only excuse for the existence of such a park in such a situation is to furnish an opportunity for rural and sylvan recreation to an urban population. The scenery is the park. The drives were constructed to enable those who visit the park in carriages to enjoy the scenery just as the paths are laid to make these refreshing prospects available to those who come on foot. As has been often stated, the walks and drives are not essentially the park any more than knives and forks or glass and china are the essentials of a dinner. They are simply the means of making the park accessible and available.

There have always been persons who have insisted on the necessity of a Rotten Row, a place of gallant and festal promenade, just as others have felt the necessity of a speed-road for those whose delight is in fast trotters. No doubt both of these objects are desirable in themselves considered, and so are many others that could be named, but that is no reason for confiscating the park, or for condemning a portion of it to any such purpose. If it had been originally intended to provide a place where the wealth and fashion of the city could meet for social greeting and the display of equipage, no man in his senses would have chosen as the field for such assemblage these rugged ledges, which have since been transformed into rolling meadows and grassy dales. Some level, open space would have been selected for such a promenade; and now that the city has borrowed and spent $10,000,000 for the avowed purpose of creating the scenery of the park, it would be a breach of trust, as well as a wild extravagance, to sequester a portion of the park and devote it to alien use. These millions have been spent to develop the park in accordance with one motive; that is, in its construction and maintenance the original design of furnishing pastoral and reposeful prospects has been adhered to. Any attempt now to adapt the park to another and quite a different motive, to transform it into a display ground for stately processions, or a place for pleasure driving, would not only destroy the original intention, but signally fail to fulfill the new purpose. The result would be a spiritless compromise between two, or rather several, designs; for the men who drive fast horses and those devoted to athletic sports, not to speak of the botanists and zoologists who want gardens and the militia who desire more parade grounds, and the rest, will all insist with equal justice that their claims should be recognized.

It will be urged, as it always has been, that the roads can be widened without affecting the value of the landscape; but a little study of the ground will show that any expansion of the wheelways, besides increasing the already large ratio of gravel to grass, would not only displace and separate essential elements of the landscape, but would destroy many of the finest trees and most effective of the rugged and rocky passages in the park. The planting was, of course, adapted to roads of the present width, these roads were adjusted to the contours of the ground, and the modeling and planting of the road-sides are an integral part of the design. The widening would not only mean the destruction of slopes and banks and ledges that have been beautified with the growth of thirty years, which could not be replaced in a shorter time, but the sweeping away of trees, groups of shrubs and vine-covered rocks would open the views in front which are now masked by projecting ledges and masses of foliage, and thus destroy that charm of surprise which a winding course now ensures. Not to speak, therefore, of the immense expense of widening the roads, an expense which would include almost a complete reconstruction of the drainage system of the park, any considerable addition to the graveled roads or curtailment of the verdurous elements on either side of them would mean the destruction of the scenery which gives the park its value.

The wheelways are now ample to fulfill the purpose for which they were designed, and no park drives could be more free from obstruction. The transverse, sunken and hidden roads by which traffic can be carried on across the park, besides the numerous bridges and archways which have been so planned that it is possible for persons on foot to reach any portion of the park without crossing a carriage track, are devices which have demonstrated the foresight of the designers and more than doubled the efficiency of the wheelways. And finally, if they could be widened with no injury to the essential value of the park, this would do nothing to relieve congestion of the drives at certain points and at certain periods. As a matter of fact, whenever a roadway is widened to make room for crowding carriages this will only mean, at the point selected by fashion for a festal promenade, another file of carriages, and the throng will be more dense and impenetrable than ever. This is not a probable theory merely; it has proved true in actual practice. The promenade ground of fashion has been shifted more than once in both London and Paris within the memory of men still living, and when a wider space was made for the increasing number of vehicles the exclusives deserted it for a narrower road.

The truth of the whole matter is, that the park roads are of a width which is ample for the purpose they are meant to serve. They cannot be enlarged without serious defacement of the beauty of the park and the practical destruction of elements which constitute its unique charm and value. Even if the area of gravel should be extended at so great a cost, it would do nothing to relieve any temporary crowding of vehicles at special points which is complained of. When the throng is greatest on the East

Drive even now the equally attractive West Drive is comparatively vacant, and if after years of labor the capacity of the East Drive were doubled it would probably be deserted for Riverside or some other carriage road. The system of drives and bridle paths which are in process of construction, and are to connect Central Park with Morningside and Riverside, and which can be completed in two years, ought to offer accommodation for all who ride or drive for pleasure until the extensive park areas further north are made ready for the growing city. In this great system of roads there can be found better opportunities for those who drive for the sake of driving, or for the display of horses and horsemanship, or of dress and equipage, than can be afforded in the narrow limits of Central Park, which, it should be remembered, will soon be a down-town park. Those who visit this park on foot will multiply much more rapidly than the visitors in carriages, and if it is to serve its highest purpose for the refreshment of this thronging population, its character as a rural retreat must be preserved.

The first issue of the *Gardeners' Chronicle* for the year is a jubilee number devoted largely to a commemoration of the fiftieth anniversary of that journal's first appearance. Founded by Dr. Lindley and Sir Joseph Paxton, its policy has always been directed by men of accurate knowledge and scientific temper. Its trusted correspondents have been among the foremost of skilled cultivators and recognized authorities in the sciences related to horticulture. During its life of half a century its influence has tended to elevate and dignify the art of horticulture, not only in England, but throughout the world, and it was never more worthy to command respect than under its present management. Our venerable cotemporary is to be congratulated on the possession of so honorable a history, while its future is bright with the promise of ever increasing usefulness.

A correspondent of the *Northwestern Lumberman*, in a recent issue of that journal, describes, with the aid of an illustration made from a beautiful photograph, a small tract of virgin forest on the northern slope of the Adirondack mountains. This picture gives some idea of what these forests were before their ruin had been largely effected by irresponsible management. The tract in question consists of 1,748 acres of land, and is situated in the town of Duane, on the banks of Deer River. It is supposed to contain not less than 10,000,000 feet of pine, and the trees, as they appear in the illustration, stand close together, with tall, straight, beautiful shafts. The Pines are mixed with Spruce and hard-wood-trees, and lie in clusters on the ridges. The trees are sound, running as high as forty or fifty inches on the stump. From the northern slope of the Adirondacks it is safe to say, this writer remarks, that two-thirds of the original Pine has been cut away, although in the central portion of the wilderness large tracts are yet untouched. In the south-west corner of the wilderness are dense forests of Spruce with some Pines scattered through them. These forests, however, are now being invaded by operators on a large scale, and their ruin is only a question of time. The most extensive lumbering now being done in the northern Adirondack region is on the San Regis River, spruce and pine being cut indiscriminately. Logging railroads, as they are understood in the west, are not, however, in use, the rivers being generally depended on to float the logs to the mills.

Methods of Quickening the Germination of Seeds.

It is almost always desirable to hasten the germination of seeds, not only that plants may be obtained more quickly, but also that their long exposure to the enemies which exist in the soil and destroy them, or many of them, if seeds are allowed to remain in the ground too long before germinating, may be avoided. As a general rule, the fresher seeds are, the quicker they germinate, and, with the exception of the cases here enumerated, it is desirable to sow, as far as possible, the last seeds to ripen on any given plant. The exceptions are :

First. Where double flowers are desired, as in the case of Zinnias, China Asters, etc.

Second. Where plants are likely to be ruined by an excess of growth at the expense of heading, such as in the case of Lettuce, Cabbage, etc.

Third. Where plants are liable to produce leaves at the expense of flowers and fruits, as in the case of Tomatoes, Cucumbers, Melons, etc.

Other things being equal, seeds preserved in their natural envelopes up to the time of planting germinate much better and more quickly than those which have been washed and preserved without covering, even if kept in paper or cloth bags in a dry, equable temperature. With few exceptions, all seeds with fleshy coats should be preserved in their natural covering as long as possible. When their natural covering is removed, if the planting-time has not come, it is always safe to place the seeds between layers of fine sand containing at least ten per cent. of humidity, and so preserve them from direct contact with the atmosphere. Seeds of the Grapevine washed and dried at the time the fruit ripened, and then placed in bags and sown the following spring, germinated only in the proportion of eight to ten to the hundred the first year, while others did not germinate until the second or third year. The plants produced by these had the seed-leaves nearly always blotched with white. A part of the same seed preserved in their pulp to the end of December, and then placed in sand until the sowing-time, germinated much more quickly and in the proportion of seventy-five to eighty in a hundred. The same precaution is necessary in the case of various large oily seeds, such as the seeds of Oaks, the Tea-plant, the Camellia, Laurels, Chestnuts, Beeches, etc., which lose in a large part their power of germination if preserved during the winter in bags, and require to be sown as soon as ripe, or, at least, to be preserved in sand, and so prepared for germination when the time for sowing arrives. This is the best method, too, in the case of seeds with bony, hard covering, which germinate slowly, such as the seeds of the Olive, and of most of the Rose family, nut-bearing plants, etc. There are also a number of vegetable seeds which take a long time to germinate, such as those of the Parsnip, Carrot, Sugar Beet, Parsley and Tarragon; these are improved by being placed in layers of sand before planting, although their germination can be hastened by more active treatment. Many systems are in use for this purpose among gardeners. Sometimes good results are obtained by mixing seeds of this character with fine soil, and then, after placing them in a pot or sack, plunging them for some time into hot water. Others soak such seeds for a longer or shorter time, varying from six to forty-eight hours, in tepid water, to which is added a little salt or chlorine. Some gardeners soak Carrot and Beet seeds in liquid manure for two or three days before sowing them. All such methods are generally good if they are carefully used.

I have read of certain Indian fakirs being able to cause seed to germinate in a few minutes with a little powder, which they sell afterward to an astonished public without disclosing their secret. They are probably very skillful prestidigitateurs, and their process consists in changing the seed rapidly.

I do not recommend the method of hastening germination which consists in plunging seeds into water strongly impregnated with potassium or caustic soda. The strength of these salts is so great that if a Coffee-seed is dropped into a solution made with them, germination takes place at the end of a few hours; but seeds so treated, instead of continuing to grow, perish when they are transferred to the soil.

It is said that electricity stimulates germination. Experiments which I have made in this direction have only given moderate results, although I recognize certain results which make me suppose that with proper appliances electricity would be a powerful and efficacious means of making old seeds or seeds with hard and bony coatings germinate quickly.

I have secured the germination of seeds in half the ordinary time by plunging them during a period varying from six to thirty-six hours, according to the hardness of their coats, in water to which was added one-tenth of its volume of the liquid ammoniac of commerce.

Any process which facilitates the transformation of the starchy parts of the seed into glucose and renders it assimilable by the embryo, favors its development and hastens germination. Air, humidity and heat being the indispensable agents for this, it only remains to select the substances best suited to aid these agents in their work. That which appears to me the best is ammoniac. In practical application it is best applied in the form of fresh horse-manure or horse-manure refreshed with horse-urine, which should be used either mixed with other substances or alone, and which for this purpose should be

placed in a bed in a warm greenhouse. I have caused in this way the germination of Pear and Grape-seeds, nuts, Plum-stones, Almonds, the seeds of the Coffee-tree, of Palms, Sugar Beets, Peanuts, Fraxinella and other seeds of slow germination in half the time needed to secure the germination of the same seeds sown in the ordinary condition. In the case of Beets, Beans, Lupins, and other plants of the Pulse family, the use of heated soil produces the most deplorable results on account of the rapid development of the cotyledons, which results in the breaking and destruction of many embryos when the seeds are treated in this way. For all such seeds it is recommended to immerse them for six or eight hours in slightly-heated water, which softens the coating of the seed and facilitates the exit of the germ.

There are certainly many additions to make to the examples I have cited, my object being simply to indicate methods of making experiments through which, perhaps, results may be reached which will be of use to future generations of gardeners.—*J. B. Weber in the Revue Horticole.*

—Mr. Duncan has been much more successful than with the exterior. The latter is not altogether pleasing in outline, and its various parts seem to lack harmonious proportion and unity, while the interior is harmonious, appropriate and imposing. But when he actually undertakes his task, Mr. Duncan will have time to study his exterior in a way that was impossible before the competition, and the result will no doubt be more satisfactory.

Meanwhile, the chief interest for the readers of GARDEN AND FOREST will be with the scheme in its entirety rather than with the design of the monument as a work of architecture narrowly so-called. The site where it will stand is one of the most commanding which could be found near any city in the world, and this is to say, of course, that especial care ought to be given to its environment and approaches. To place a building, however fine in itself, on this elevated bank, in the centre of a noble driveway and close above a mighty river, and not to give architectural accent to these surroundings, would be to throw away an unrivaled opportunity. Even were the place

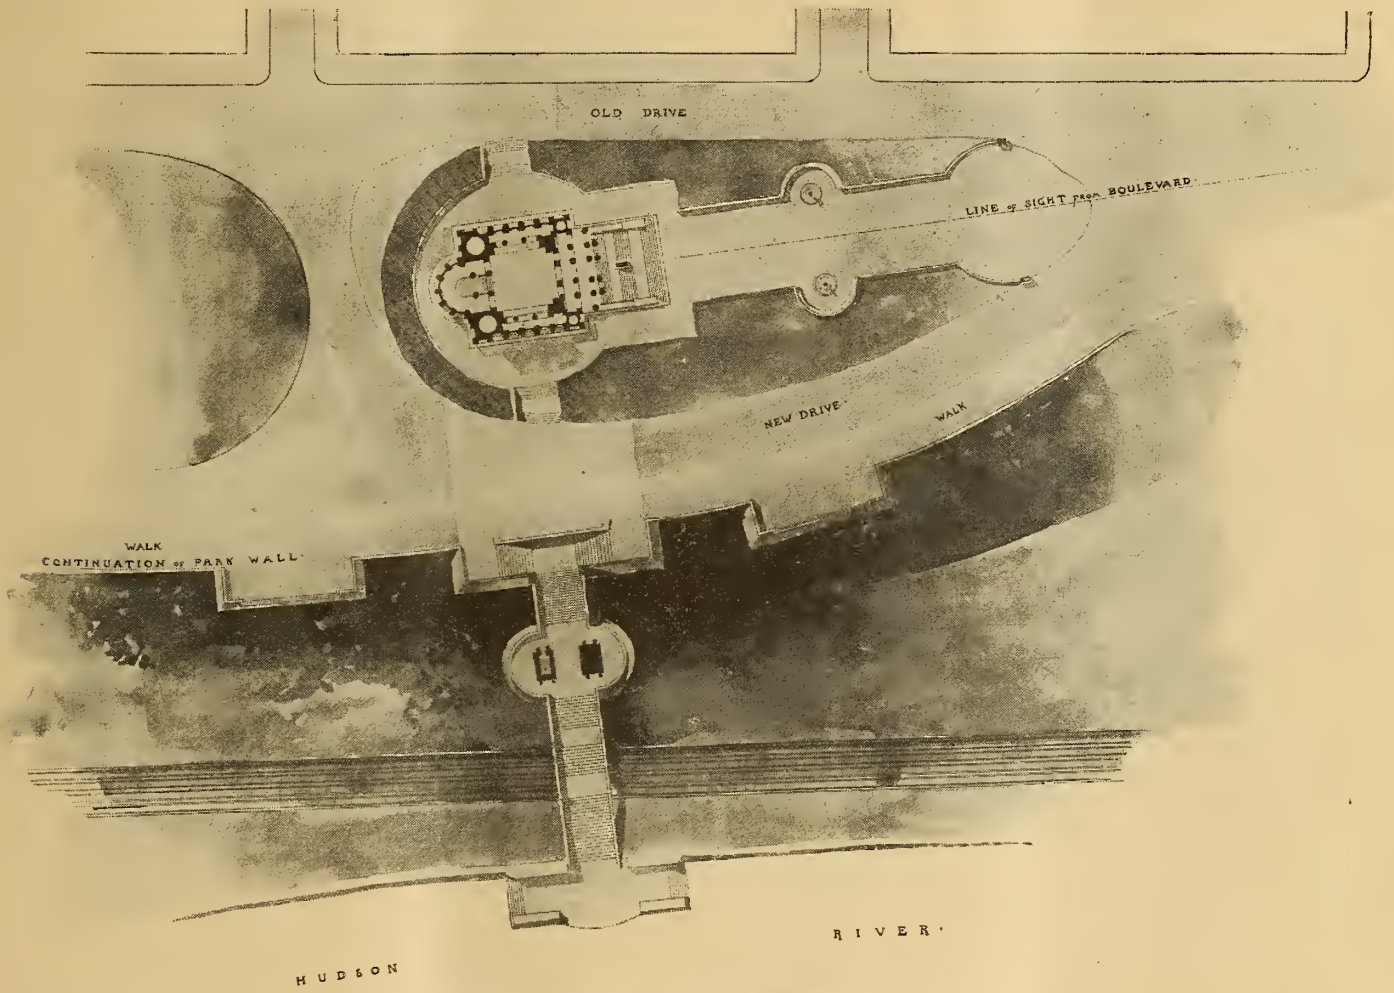

Fig. 5.—Ground Plan of the Proposed Grant Monument, Riverside Drive.

The Grant Monument for Riverside Park.

THE competitive designs for the monument to contain General Grant's tomb which were exhibited a few months ago have lately been shown again with the annual exhibition of the Architectural League in this city. It has recently been decreed by Congress that the hero's remains shall not be transported to Washington, so it is probable that, if sufficient money is subscribed, the memorial will be erected on Riverside Drive by Mr. John H. Duncan, whose design was selected, last autumn, from among those just referred to. Some of the architect's drawings (of course, on a greatly reduced scale) will be found on this and the following page. These drawings also included a large plan, a section and an elevation of the monument proper; but from the three offered a general idea with regard to the effect of the monument can be gathered. To do justice to the design the interior of the building should be shown, for here—in an arrangement which recalls, but by no means imitates, the tomb of Napoleon in the Invalides at Paris still a bare hill-side to which no artist had given his attention, and the future estate of which was still in doubt, the architect ought to consider its possibilities in his design, and, in conjunction with a landscape-gardener, ought to prescribe some extensive scheme of treatment. But an artist has already here been at work, and has laid out the noblest driveway in the world, and to ignore these preparatory labors would be doubly unintelligent. Yet, so far as could be seen from their designs, no adequate thought was given to the surroundings of the monument by any of Mr. Duncan's competitors. Of course, all of them had borne in mind the elevated character of the site, the free approaches to it, and the fact that it will be well seen from a great distance to those who shall come by land or water. But none of them seems to have felt the necessity for uniting the building to its environment in an integral way, or the desire to improve so rare an opportunity for extended and varied architectural effort. Mr. Duncan, however, has done this; and despite the superiority of his monument (in its interior at least) to that of any of his rivals,

it is not improbable that his sketches for its surroundings largely influenced the committee in their choice.

It will be seen that he has not placed the tomb quite parallel with the river-bank, but somewhat diagonally, in order to make it face the line of the Eighth Avenue Boulevard. The way in which this driveway forks, so as to afford a direct approach to the tomb and an encircling road as well, seems very intelligent, and the great flights of steps, crowned by an equestrian statue, would rise with excellent effect from the terrace. Access to the outer terrace is afforded to persons on foot by the short lateral flights of steps, while carriages would turn in front of the tomb or drive around it. But the most ingenious and interesting part of the scheme is that which shows the way in which access from the upper level to the river is supplied, meeting the practical end of allowing visitors to approach directly from the landing-stage at the river's edge, and the artistic end of bringing the river itself into the scheme and doing the best that could be done to conceal the intrusiveness of the railway. It has been objected, that the great stairway will have a ladder-like effect and ought to be very much wider. Possibly it might, to good advantage, be somewhat wider; yet, on the whole, the objection hardly seems well taken, and is apparently inspired by the inability of unaccustomed eyes to read an architectural elevation rightly. The lateral view certainly does not suggest a ladder-like effect, nor is it probable that a full view of the actual structure would do so, whatever the drawing might suggest to untrained eyes. Of course the effect is bridge-like, but the structure will be a bridge and ought to look like one. The various terraces and flights of steps and the triumphal arch which stands midway up can hardly be judged in reproductions so small as those given here. But a general idea of the scheme is all that it is proposed to give, especially as it is probable that only its general idea is as yet fixed in the architect's own mind. It may be explained, however, that the retaining wall will be masked at its base by plantations of trees; that the spaces on either side of the tracks will be laid out in a harmonizing way, and that broad zigzag driveways, which are not suggested in these hasty sketches, will ascend from the river level to the high ground on either side of the stair, supporting it to the eye and greatly increasing its dignity and the coherence of the whole design.

Of course much more money will be needed for a comprehensive design of this sort than for an isolated monument. But Americans are slow in giving money only when not convinced that they will receive its value in return, and whatever the sum they may here spend, they will get its value only if the surroundings of the monument are well considered. Mr. Duncan's design for the tomb itself shows how a portion of it may, with good effect, be built in the beginning to contain the sarcophagus, while the remainder is left for future execution. But the ultimate success of the enterprise is more important than the immediate enshrinement of the sarcophagus; and, therefore, it would seem the better plan to spend the first installment of money upon the approaches, retaining walls and terraces. Build these, and before long the tomb will surely be built. But build the tomb first, and who knows how long we may have to wait for the approaches, since the public so faintly appreciates the necessity for placing a building well even when it takes real interest in the building itself? Unless this building is fittingly placed, it will discredit us as a people incapable of valuing a magnificent opportunity; and to be fittingly placed means that it must be united with some such wide architectural and landscape-gardening scheme as Mr. Duncan's drawings suggest. It is fortunate that an architect has been selected who has shown himself capable of realizing the true nature of the problem.

Plant Notes.

Some Recent Portraits.

In the issue of the *Gardeners' Chronicle* published on the 27th of December there is a figure of the cones of the Colorado Silver Fir, *Abies concolor*, produced on a tree growing in the Knaphill Nursery, Woking, and possibly the first which the Colorado tree has produced in cultivation. Cones described as brown and as purple, both produced at Knaphill, presumedly from different trees, are represented, the tree bearing the last being mentioned as variety *violacea*. The color of the cones, however, is hardly a sufficient fixed character upon which to establish even a variety. In the forests of Colorado green cones and purple cones are produced on trees standing side by side, and undistinguishable except in this one particular. It is not at all an unusual thing to find among conifers individuals of the same species producing cones of different colors. This occurs in the case of the Mountain Hemlock, *Tsuga Pattoniana*, whose cones are sometimes dark purple and sometimes green; and also in the case of *Abies lasiocarpa* (the *A. subalpina* of American botanists), which, on the eastern slopes of the Cascade Mountains, in Washington Territory, produces green and dark purple cones. It is not known even in the case of these species if the same tree produces permanently the same colored cones or whether they are not in some years green and in others purple. The English custom of considering the White Silver Fir of the California Sierras, which we in this country call *Abies concolor*, distinct from the Fir of Colorado, is hardly tenable from a botanical point of view, desirable as it may be in garden nomenclature, and it is certainly not supported by the botanists who have had the opportunity to observe this tree growing from one end to the other of the immense territory it inhabits.

In this connection may be mentioned the exceedingly curious and interesting Silver Fir discovered on the San Francisco Mountain, in Arizona, by Dr. C. Hart Merriam, already noticed in these columns. The leaves might well be taken for those of *A. lasiocarpa*, although much longer than those which this tree produces in Colorado and New Mexico. The bark, however, is very distinct from that of any of our American Abies, and is composed of a thick, corky, compressible layer of small compact cells, the surface of the bark being nearly pure white. This structure of the bark is so unlike that of our other Abies that it would seem to indicate a distinct species, although this cannot be determined until the cones are seen.

There is a charming portrait of the Copper Austrian Briar Rose in *The Garden*, of London, of December 27th, 1890. The Copper Briar is one of those old-fashioned flowers which graced and enlivened our grandmothers' gardens, but which in these days is very rarely seen, in this country at least. It is a native of southern Europe, and was cultivated three centuries ago in England. Mr. George Paul, the well known

English Rose-grower, contributes to *The Garden* the following note with regard to this plant, which we should be glad to see more generally cultivated here:

"It is best grown as a dwarf, though I have standards in my garden which flower freely, but the slender leafage and short time of flowering hardly render them nice-looking objects for the rest of the year. As dwarf bushes they succeed admirably, growing in any good light soil, either on their own roots or worked on Briar or Manetti stocks; indeed, I think the stock gives an additional root power, and so leads to stronger and more vigorously pushed-up shoots, the flowers being produced along the full length of the last year's suckers or shoots. Good suckers are very valuable, and give the finest blooms. The small wood should, on pruning in March, be cut closely into the two-year-old wood, the strong wood be left long, and these shoots be bent over in the shape of a bow, or they may be pegged down parallel with the ground their full length.

"So far this Rose has not given, to my knowledge, any hybrid progeny. It has been tried at Lyons, and Lacharme had it freely planted on the wall upon which he seeded his Roses, no doubt with the hope of the pollen effecting natural hybridization, but no seedling of his which I have seen showed any signs of hybridization. In its native home I believe it seeds freely.

"As a rock plant it is effective, and should have a sunny southern exposure to ripen the wood. In common with other Roses, the riper the wood the better it flowers. In saying that no hybrids had been produced, I do not forget Harrisoni and Persian Yellow, which are probably double forms of this variety, Persian Yellow being probably an introduction as a double form from eastern gardens, as *R. sulphurea* also was."

New or Little Known Plants.

Viburnum molle.

THIS handsome plant is closely related to the common and familiar blue-fruited Viburnum or Arrowwood of the northern states (*Viburnum dentatum*). It is a tall shrub, with stout stems growing sometimes fifteen or eighteen feet high, and slender branchlets, beset when they first appear, like the petioles and flower-cymes, with stellate pubescence. The leaves, which are borne on rather slender petioles, are broadly oval or ovate, conspicuously crenulate-dentate, and softly pubescent, especially on the lower surface. They are often four or five inches long by nearly as much broad. The flowers differ from those of *V. dentatum* in their more prominent calyx-teeth, while the blue fruit is larger than that of that species, more pointed by the persistent style and rather more oily.

*V. molle** grows on some of the islands of Massachusetts (Nantucket, Martha's Vineyard and Naushon) and extends southward to Florida and Texas. It has been cultivated for a number of years in the Arnold Arboretum,† where it is perfectly hardy, and where, like many of the North American Viburnums, it is a valuable and exceedingly ornamental plant, well worth a place in any collection of hardy shrubs. *C. S. S.*

New Orchids.

CYPRIPEDIUM INSIGNE, var. MACFARLANEI, Rolfe, is a beautiful yellow variety, much like the variety *Sanderæ* in color, but quite different in shape. The dorsal sepal is much narrower and with a smaller white area, the petals narrower, but the bract much longer. The plant is in the collection of R. H. Measures, Esq., of Streatham.—*Gardeners' Chronicle*, December 6th, p. 655.

CATTLEYA REX, O'Brien, is described as a beautiful Cattleya, somewhat resembling *C. Dowiana*, var. *Imschootiana*, in the shape and color of the flowers, but with long, thin pseudobulbs, and the leaf about a foot long. It was introduced by Messrs. Linden, L'Horticulture Internationale, Bruxelles. I have not seen it.—*Gardeners' Chronicle*, December 13th, p. 684.

CYPRIPEDIUM × ANTIGONE, Rolfe, is a most elegant hybrid, raised by Mr. Seden in the establishment of Messrs. James Veitch & Sons, of Chelsea, from *C. Lawrenceanum*, fertilized with the pollen of *C. niveum*. It is much like the former in habit, but the flowers are white, variously nerved and veined with light purple, thus more nearly resembling the pollen parent, though tolerably intermediate in shape. The leaves are very handsomely variegated. It received a first-class certificate from the Royal Horticultural Society on November 11th last.—*Gardeners' Chronicle*, December 20th, p. 716; also November 15th, p. 570, and November 22d, p. 602.

CYPRIPEDIUM × DORIS, Rolfe, is a pretty hybrid raised in the collection of N. C. Cookson, Esq., of Wylam-on-Tyne, from *C. venustum* fertilized with the pollen of *C. Stonei*. It has retained largely the characters of the mother plant, the influence of *C. Stonei* being unusually small. A second plant, however, is said to show more of the Stonei character. It received an award of merit from the Royal Horticultural Society on November 11th last.—*Gardeners' Chronicle*, December 20th, p. 716; also November 15th, p. 570, and November 22d, p. 602.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

London Letter.

FERTILIZERS FOR ORCHIDS.—The interesting experiments made by Mr. Moore on his Orchids at Glasnevin were referred to a few weeks ago. I refer to them again for the purpose of showing how similar results to those obtained by Mr. Moore have been arrived at by a grower in the south of England, Mr. Spencer, gardener at Goodrich Court, in Rosshire, who writes: "I gave all our Cypripediums, except *C. niveum* and its allies, a dressing in June of Jensen's fish guano, which they took to amazingly. They have also received several doses of manure water from the stable tank, and they show their appreciation of it by the darker color of the foliage and robustness of health generally. As an example, I may mention *C. Spicerianum*, of which a plant purchased six years ago, when it was in a small sixty pot, is now in a twelve-inch pot and recently carried seventeen flower-scapes, bearing a total of thirty-two blooms, thirteen of the scapes carrying each a pair of flowers, one three flowers, and three one flower each. I think this is a proof of the good that results from feeding well these plants when growing. I also use manure for *Cœlogyne cristata* with good effect. Although I have not ventured yet to directly apply manure to Lælias, Cattleyas and similar Orchids, I see no reason why it should not prove more or less beneficial for them and for all Orchids if applied with discretion. Meanwhile, I take care to keep the atmosphere of the houses impregnated with ammonia by means of frequent dampings down with stable drainings. This must make a difference to all the plants with roots exposed to the air, such as Vandas, Oncidiums, etc. We shall in time, perhaps, get to grow many Orchids as fat as we now grow Cockscombs and Hyacinths."

CHRYSANTHEMUM MRS. BEAL is the best by far of all the white late-flowering varieties, at any rate it is superior to any other at Kew. It makes a nice shapely plant, the flowers are large, particularly elegant in arrangement of florets, and of the purest snow white, without even a suspicion of green in them. If I wanted a large quantity of a particularly pleasing white flower for Christmas decorations I should grow a good many plants of this Chrysanthemum.

MRS. ALPHEUS HARDY is proving something of a failure here as a decorative plant; the flowers are rarely even respectable in form, often they fail to open regularly, and when open they are curious merely. All this, too, notwithstanding the most careful treatment, such as, if given to any other variety, would never fail to produce first-rate plants.

The Official Catalogue of the National Chrysanthemum Society (centenary edition) has lately been issued. It contains a careful, interesting paper on the history of the Chrysanthemum by Mr. Harman Payne; a bibliographical list; select descriptive lists of the best exhibition kinds in each of the ten sections into which Chrysanthemums are now divided; a general alphabetical list with synonymy, and a list of new unvouched varieties. The raiser's name and year of distribution are given with each of the recognized kinds. Altogether the book contains much useful information, and will interest both growers and admirers of the Chrysanthemum. Its price is one shilling, and it is sold by E. W. Allen, 4 Ave Maria Lane, London.

STATICES are among the most useful of winter-flowering plants; they grow and flower freely, they are fog-proof, and the dull winter weather does not appreciably affect them. Then

* *Viburnum molle*, Michaux, "Fl. Bor. Am.," i., 180.—Gray, "Syn. Fl. N. Am.," i., 11.—Watson & Coulter, "Gray's Man. N. States," ed. 6, 218.
V. scabrellum, Chapman, "Fl. S. States," 172.

† There seems to be considerable confusion with regard to the correct determination of *V. molle* in collections. It has been received at the Arboretum from the Parsons Nursery at Flushing as *V. lævigatum*, and also as *V. Nepalense*; and the *V. pubescens* of the Kew Arboretum (No. 1104) is not Pursh's plant of that name, but *V. molle*.

their blooms remain fresh so long that some people even grumble at them on that account. Now, when all the usual winter flowers are either destroyed or damaged by bad weather, the Statices are conspicuous for the bright blue, purple and white of their flowers. I fancy these plants have gone out of fashion; at any rate, one sees and hears little about them; and yet they are first-class greenhouse plants, which with a little management may be had in bloom not only in December, but almost the whole year through.

The Weather.—The effect of the dark, foggy, cold weather of the last three weeks has caused the destruction of many herbaceous in-door plants, of almost all flowers, and much work by gas-light all the day through. It appears as though gardening in winter will soon be practically impossible in the vicinity of London.

Apples.—The scarcity of English apples this Christmas has enabled dealers in American apples to "make hay." Thousands of barrels of American kinds found ready and remunerative sale in London last week; for instance, Newtown Pippins sold readily at forty-two shillings a barrel, while the poorest samples fetched twenty-four shillings a barrel wholesale.

Onions.—The finest samples of English onions that I have seen were exhibited lately at a meeting of the Royal Horticul-

Fig. 8.—Viburnum molle.—See page 29.

harm to even sturdy-leaved, hard-wooded plants. I have never seen anything so disheartening as the winter-flowering Begonias, Acanthads, Bouvardias, Salvias, Poinsettias, Reinwardtias, Camellias and Azaleas are in London gardens now. Some of these plants have lost every leaf, and the flowers have withered before opening; others are blotched and disfigured as though they had been frozen. Orchid-flowers have faded almost as soon as they opened, while some have dropped when the buds were quite small. At Kew we have suffered very much, but in the nurseries at Chelsea and other places nearer the city the damage is even greater than here. Plants which have hitherto resisted the poison of the fogs have been terribly damaged by the continued absence of anything approaching sunlight. Day after day we have been compelled to

tural Society by Mr. Deverill, of Banbury, in Oxfordshire, the raiser of some first-rate sorts. "Deverill's Pedigree Onions," as he calls them, are remarkable for their size, firmness and flavor. Bulbs weighing two pounds each are easily grown from Deverill's seeds on good rich loam. One variety, called "Ailsa Craig," is the largest, heaviest and handsomest onion ever raised in England. The flesh is white, very mild in flavor; the bulb comes quickly to maturity, is a good keeper and weighs from two to three pounds. Mr. Deverill exhibited a bushel or so of this variety, and the bulbs, of a pale straw color, looked like large turnips. The cultural directions for obtaining these fine results are given by Mr. Deverill as follows:

"The soil is a heavy blackish loam, resting on red clay, and it receives a tremendous dressing of stable manure in the

month of October, and, if the weather is dry, a good coat of salt; the ground is then trenched two feet deep and left until the spring, when a top dressing of soot is applied. In March or April the ground is raked and made ready to receive the Onions, the seed of which was sown the last week in February, in boxes, then hardened off, and planted the first week in May, in drills eighteen inches apart, seven inches being allowed from plant to plant. There are two rows of Onions, then a path two feet wide and two rows of Onions again, and so on. The beds are top dressed with well spent manure, and several doses of soot are sown broadcast during the season; the beds being well watered in dry weather, thoroughly soaked between the rows, the two-foot path between each two drills being very convenient for the purpose.

"This method of cultivation produced the finest bed of Onions ever grown in the United Kingdom. Hundreds of bulbs could be picked weighing from a pound to a pound and a half each, and scores from two pounds to two and a half pounds. A dozen bulbs scaled twenty-eight and a half pounds, and six bulbs fifteen and three-fourths pounds."

Cultural Department.

Notes on Some Hardy Wild Roses.—III.

THE pretty little Burnet or Scotch Rose, the type of which is known to botanists as *Rosa spinosissima* (or *R. pimpinellifolia*), has been so long and so much cultivated that innumerable forms and variations of it are now grown. It appears to hybridize naturally and easily with a number of species of Roses belonging to other groups, so that many of the forms classed under *R. spinosissima* in catalogues are in reality mixtures with other species. The erect, though dwarf, and much branched habit of the plant; the very numerous prickles of unequal length with which its branches are armed, and the generally small leaflets, serve as a rule to distinguish these Roses from any others in cultivation. As it grows wild in its native habitats in Europe and Asia, the Burnet Rose seldom exceeds a foot or a foot and a half in height, and its rather small flowers are borne singly, and are either white or pink in color. In cultivation the plants attain a height of from two to three feet. While many double flowered forms have been developed, those with single blossoms, of varying sizes and shades of color, are none the less beautiful. One of the prettiest of these in the Arboretum has flowers of a very delicate pinkish white color, which expand from two to two and a half inches across. The flowers of these Roses appear early in the season, and they continue to bloom for two or three weeks, and are followed in August and September by large, solitary, almost globular, and very firm hips, conspicuous by their purplish black, or sometimes deep red, color, which also extends down the somewhat thick and fleshy fruit-stalks. As the foliage of this species is good and persists late, it is often useful for massing in clumps in shrubberies.

Any peculiar form of this Rose must necessarily be propagated by cuttings or layers or other modes of division; seeds cannot be depended on to come true to the character desired.

Although the single-flowered Yellow Eglantine Rose (*Rosa lutea*) has been in cultivation for centuries, it still appears to be one of the rarest of wild Roses in northern American gardens. This may be partly accounted for by the fact that it does not seem sufficiently hardy and enduring under ordinary circumstances to make it popular. Nevertheless it will do well in sheltered situations, and its large single yellow flowers are quite as interesting and beautiful as those of any double yellow Rose we ordinarily meet with. Besides the deep color of this Rose there are the variations, which are of a deep coppery, lurid red or scarlet hue on the upper side of the petals and yellowish beneath, giving to them an unusual or unique place in the genus. Although the flowers are less enduring than those of the double Yellow Harrison, or the handsome, but troublesome and generally unsatisfactory, Persian Yellow, they are quite as attractive as either of these double Roses when growing side by side with them in the garden, and are well worth a little space in any collection. While the little Scotch Rose is generally noted for its more or less rounded or compact habit under cultivation, the Yellow Eglantine is disposed to become straggling, and requires to be carefully trained, and judiciously, but not too severely, pruned. Plenty of warmth and sunlight and moisture are essentials to its successful cultivation. As there is little likelihood of confusing the foliage and flowers of this with other species, it may sometimes be budded or grafted to advantage upon other kinds suitable as stocks.

The Sweet Briar Rose (*Rosa rubiginosa*), or Eglantine, as it is also sometimes called, is one of the few examples where a single or primitive Rose has taken and held a place in gardens, although its popularity has, no doubt, been partly owing to the peculiar sweet-scented and agreeable fragrance given off by the foliage when rubbed or bruised. This odor originates in the rusty-colored glands which cover the leaves and buds and which suggested the name of the Rusty-leaved Rose for this plant. It is one of those species in which long cultivation and selection have produced many modifications and well established variations. Around it may be grouped a number of others generally described as distinct, but which are hardly separable as species from the horticulturist's point of view. Some of them are deficient in the true Sweet Briar fragrance, and relationship to the Dog Rose (*R. canina*) and other species may sometimes be indicated. *R. micrantha* hardly differs from the Sweet Briar except in the size of its flowers and fruit; and others closely allied go under such names as *R. graveolens*, *R. Belgradensis*, *R. Caballicensis* and *R. agrestis*. The flowers of some of these are white, others are rose colored; and they are generally, although not always, followed by an abundance of bright red fruit, which remains conspicuous throughout most of the winter. *R. rubiginosa*, var. *echinocarpa*, as it grows in the Arboretum is a very robust plant with flowers of a bright rose color, which expand over two and a half inches across, and some of whose stamens become transformed into petals, showing the tendency toward the double forms which have already been evolved from this species. The Sweet Briar has escaped from gardens and become naturalized in many of the older settled localities in America, from Nova Scotia and the St. Lawrence Valley to the southern states. Gardeners have occasionally found it of value as a stock upon which to bud some kinds of our garden Roses.

The Sweet Briar appears to be, more than any other species, subject to large mossy-looking deformations or excrescences on its stems and branches. These are caused by a gall-making insect (*Rhodites rosæ*), of which a considerable number, occupying separate cells, are to be found in each mossy cluster. They naturally interfere somewhat with the free growth of the plant, and where they occur in such abundance as to be annoying the galls may be cut from the bushes in winter and burned, for the insects do not leave them until the following spring or early summer.

The Dog Rose (*R. canina*) has also become spontaneous in some parts of this country. There are a large number of plants, mostly found in Europe, to which varietal or specific names have been given, but which bear more or less affinity to the typical Dog Rose. The principal use which has been found for this Rose is as a stock upon which to bud or graft many of our finest garden kinds, as thus treated they give better satisfaction than when grown on their own roots or upon other stocks.

The Red-leaved Rose (*R. rubrifolia*, a name which Professor Crépin now replaces by the older *R. ferruginea*), a native of some parts of Europe, is perhaps more curious and odd than really beautiful, the dark pinkish or purplish red leaves contrasting strongly with the foliage of other species. The plant grows five or six feet in height, and produces numerous rather small flowers, which are hardly distinguishable from the leaves in color. When not too freely used this Rose may be so planted among other green-foliaged plants in shrubberies that it will give a pleasing effect and variety. It is still uncommon in this country; but it will be found perfectly hardy in exposed situations, even where the temperature falls to twenty or thirty degrees below zero.

Arnold Arboretum. *J. G. Jack.*

Rose Notes.

AUTUMN BLOOMING VARIETIES.—No variety surpasses the old Souvenir de Malmaison as an autumn bloomer. In many of the northern states, where our winters are a constant succession of hard freezing and complete thawing, this and many other out-door Roses are so crippled by the sudden changes as to have little chance to show us their best points. They may often be seen in really fine form in localities of extreme cold, but this is where they are not subject to these trying thaws; in both situations, however, a judicious winter protection, which allows a good circulation of air about the plant, will usually be found of great benefit.

In the milder climate of England and in the more favored areas of our own country, especially in the Ohio Valley and southward, the Malmaison, with Sombreul for a lovely companion, are beautiful beyond description. Cave Hill Cemetery, at Louisville, is a garden of Roses, and it is seldom seen to greater

advantage than when these two fine varieties, with Hermosa for a modest third, are in the full flush of their autumn bloom. Not a stray Rose here and there, but Roses in the greatest profusion and on every side.

Of the hybrid Teas, La France is often noticeably beautiful in the autumn; but this entire section of the Rose family, notwithstanding that it contains some of our most delightful varieties, is rendered almost unfit for out-door planting in the north, owing to its susceptibility to the ravages of that dreaded disease, Black Spot. I cannot refrain from calling attention to a near and lovely relation of La France, the Viscountess Folkestone. One of the late Mr. Bennett's pedigree seedlings, it is not surpassed in beauty by any Rose extant. There are many locations through our middle states where it winters finely, and seems a Rose absolutely without fault. The flower is of grand size and the most finished form; the texture is like satin; the color is white, shading to a soft flesh tint at the base of the petals, giving it a bright illumined appearance.

Madame Willermoz (Tea).—This beautiful Rose was introduced by Lacharme in 1845, but has become badly confused in our country with Madame Denis, which it much resembles. Wherever the Tea Rose flourishes Madame Willermoz is seen in perfection, a beautiful flesh-white flower of rounded, symmetrical form, set in large leathery foliage of great beauty. Lettie Coles, an exquisite sport from Madame Willermoz, is very popular in our country, as it deserves to be; it is identical with the latter save in color, which is soft China pink of varying shades.

Dr. Grill (Tea).—This is a comparatively new Rose (1888, I believe), and must be classed among tender Teas until a more complete trial out-of-doors shall entitle it to a better position. For the conservatory it is a most beautiful variety, the color being coppery yellow, with rosy reverse shadings. The outer petals are large and shell-shaped, and enclose a full double centre of short petals of very brilliant color. It is a strong, free grower.

Richmond, Ind. *E. G. Hill.*

The Cultivation of Native Orchids.

THE hardy native Orchids, as a class, are not as easily grown as most other wild flowers. Almost all of them grow in situations and conditions quite unlike those offered by an ordinary garden. Many of them, in fact the majority, are bog-plants, and when transplanted into an unmodified garden soil, even though they may flower for one season, do not acquire strength for a second year and soon die. Those which do not grow on bogs often grow where the conditions are similar to those of a bog, and some of these will flourish in soil which, though not wet, never becomes perfectly dry.

The Cypripediums, or Lady Slippers, are perhaps the most desirable of the family, and, except *C. acaule*, are the easiest to manage. If not planted on a bog they need a specially prepared soil, and to give them this, good drainage, shade and plenty of peat or leaf-mould are necessary. Let it be well and deeply mixed into the soil. For *C. spectabile*, which is the queen of Lady Slippers, and also for the little Ram's Head Lady Slipper (*C. arietinum*), it is quite important that the roots do not come in contact with a gravelly or sandy soil, as this seems not to agree with them. Therefore, when planting in such soils, in addition to the peat already mixed in, enough of the pure peat should be used to surround the roots. The two yellow Cypripediums—*C. pubescens* and *C. parviflorum*—are the least particular about their location; but even they delight in the leaf-mould, and will do enough better to pay for applying it. There seems to be considerable difficulty in establishing *C. acaule* in cultivation, though the soil selected for it may be almost exactly like that in which it is found growing wild. One reason for this may be that the foliage is sensitive to gravel or sand, and, when planted without a mulch, the heavy rains spatter the soil over its leaves, which seems to poison them. No doubt this is one reason why a good many other plants do not prosper in cultivation which might do so if this were prevented. It is well known to farmers and gardeners that this is very injurious to the leaves of Beans, and for this reason they never hoe them when their foliage is wet. In very light sandy soils heavy rains alone so injure the foliage of some varieties of bush Beans that they cannot be successfully grown, and in such soils pole or running varieties are often preferred, because their foliage is held up above the reach of the soil even in the hardest showers. Naturally most plants have sufficient mulch around them to prevent this. The buds and ground about them covered with leaves, grass or moss prevent the soil from getting onto the foliage. *C. acaule* often grows on bogs, yet is more frequently found on higher ground, especially in Pine-woods. Mr. Edward Gillett has had the best success in growing it when mulched with Pine-needles. This would seem to be a natural covering, and if planted in the fall and the buds covered by an inch or more of this mulch, they would readily penetrate it in spring, and when unfolding after, no particles of the soil underneath could reach the leaves.

There are other Orchids, seldom seen except in bogs, which may be treated like the Cypripediums on upland soils and made to prosper. Such Habenarias as *H. tridentata*, *H. hyperborea*, *H. dilatata*, *H. blephariglottis*, *H. lacera*, *H. psycodes* and *H. fimbriata* have flourished on higher ground than their natural habitat in soils which were prepared for them. Artificial bogs seem the most natural place for them in cultivation, but it is not necessary to discard them entirely if no bog is to be had.

Calopogon pulchellus, a natural bog plant, usually growing with *Pogonia ophioglossoides*, is frequently found on upland in wet or moist sand, and may be grown in garden soil, treated like the Habenarias, but *Pogonia ophioglossoides* and Arethusa do not flourish except in bogs. They may be grown in pots, but require the same conditions as on a bog.

The delicate and charming little Calypso, planted in moist, dark soil in autumn, and protected during winter with a few leaves, will come out thrifty in the spring and bear perfect flowers. After the flowering season is past, however, during its dormant season, which is from early June until the middle of October, comes the most critical time for this plant. The cool and dark Cedar-swamps, where it is found in New England, afford during the hot summer months just such surroundings as the bulbs need, surroundings not easily copied in a garden. But I believe if the right mulch is applied, one which will protect it from the heat and keep it always moist, and then removed at the time the fall growth begins, even this may be grown and flowered more than one season in a cool nook of the garden.

Aplectrum hiemale (Putty-root) is one of the easiest Orchids to transplant. Though by no means common, it can be relied on to live if fairly treated. A fine chip dirt, used as a heavy mulch over the bulbs, in moist, well-drained soil, is at once the best food and the surest protection for this plant.

The Habenarias, such as *H. bracteata*, *H. Hookeri* and *H. orbiculata*, which grow on drier soil in rich woods, require less care in their treatment. They seem to take readily to cultivation if well developed roots are used in setting. These species when taken up in flower do not mature their buds in a new place so well as the Cypripediums.

One of the hardest Orchids to establish in cultivation is the common *Orchis spectabilis*. It must have a moist, shady place, with perfect drainage. Leaf mould and sand is the best mixture for it. Only the strongest roots should be used in setting, and a mulch of something like fine leaves over the roots will be useful in protecting them from the severe cold and to keep the soil from the leaves in spring.

Southwick, Mass. *F. H. Horsford.*

Oxalis floribunda.

THE genus Oxalis has almost disappeared from the catalogues. Why this should be so is hard to say, for many of the species are highly ornamental, of neat, compact growth and easy culture.

O. floribunda is one of the group having thick, fibrous roots and a stout fleshy body which begins as a round tuber and grows upward into a short succulent trunk, generally with a few tuberous, almost globular, branches at the top when the plant gets old. I consider this species a very desirable one for either winter or summer flowering, and of the innumerable seedlings which spring up around the old plants have made a selection of several very distinct and pretty varieties. The typical form is red of a shade inclining to rose; and this was the first which I obtained many years ago. My original plant had blossoms with narrow petals, overlapping hardly any, if at all. Ninety-nine per cent. of accidental seedlings will have that undesirable form which I have heard called "mill-wheely," but I found one about five years ago whose petals overlapped almost to the very circumference, making a beautiful round blossom about the size of a silver dime.

I have, of course, kept this variety, and have sown its seed whenever I could get it, which is a matter of chance, for the seed-vessel of Oxalis opens with a snap when ripe, scattering the seed far and near. I have thus obtained a beautiful white flower as round and perfect as the parent. When the sun shines this kind is as bright and pretty as can be imagined. Another seedling is bright lilac; a very distinct kind, not so perfect in shape as the

others, but somewhat larger and well worth growing. Still another is a bright pink, with wavy edges; I consider this one the best of all.

I have not yet succeeded in getting a very good two-colored sort, though I have a variety whose flowers are white with a pink tip to each petal, and another with rose-centered white blossoms. These are both too narrow in petal to be perfectly satisfactory. A pink one, whose color is altogether different from the pink one mentioned above, is also not quite to my liking; still I keep them, hoping to get, some time, good shape in connection with these colors.

I am best pleased, however, with a hybrid raised from *O. floribunda* type fertilized by *O. articulata*, a species of similar style of growth which flowers in August, bearing perfectly circular blossoms of a light mauve color. This hybrid, which is, as far as I know, the only one in existence, has the ever-blooming habit of the pistillate parent and its comparatively small flowers. These are of a deep shade of red, with a distinct bluish tinge. The shape is equal to that of the staminate parent, whose influence is also apparent in the foliage.

If the varieties of *O. floribunda* are grown continually in a pot they will blossom twelve months in the year, but in a few years the roots will be so crowded that the flowers will fall off in size, and the plant will probably become infested with red spider. I prefer, therefore, to plant them out in the garden in May, where they will be objects of beauty on every sunny day, growing finer and finer as the season progresses, getting too large before winter to be covered by a half-bushel measure. At the end of October they should be dug up, the foliage and flowers sheared off close to the stump. As many of the lumpish branches as are wanted for winter blooming should be broken off and potted singly in five-inch pots. They will strike root and develop leaves and flowers in a very short time, and, either on brackets or hanging baskets, will give their owner great pleasure until the following May, when they should be planted out.

If it is desired to keep any of the plants dormant through the winter they may be carried through successfully by packing them in damp moss or earth.

Canton, Mass. *W. E. Endicott.*

Cypripedium Fairieanum.

Cypripedium Fairieanum may be reckoned among the dwarf-growing kinds, its bright green, oblong-acute leaves not being more than three to five inches long, and about an inch broad in the widest portion, while the pale green, slender hairy scapes seldom exceed four to six inches in height and bear a single flower. The latter measures about three inches from the tip of the upper sepal to the point of the slipper, so that it cannot be considered a large flower. But what it lacks in size is made up for in beauty, and this fact is universally acknowledged. The upper sepal is almost oval in outline, with a slightly ciliate wavy margin, the upper portion of which is turned in to the front on each side. The ground color is creamy white, tinged with pale yellowish green at the base, and longitudinally traversed by rich purple stripes, which form a beautiful net-work on each side, giving the plant one of its most charming features. The lower sepal is much smaller, pale green and veined with dark purple. Perhaps one of the best descriptions on record of the petals is that they resemble the horns of a buffalo, being first bent down and then curved upward. They are oblong-acute, and have the wavy margins densely fringed with blackish shining hairs. The surface is pale yellowish white, striped lengthwise with thin purplish lines, which, however, form bands, owing to contiguity, near the margins on the apical portion. The small, neat-looking pouch is pale green washed with brown, and has a few conspicuous dark purple veins, which give off smaller ones on each side, while the creamy white, inflexed basal lobes form a strong relief to the several purple spots with which they are decorated.

Like *C. superbiens*, the subject of this note is remarkable inasmuch as its native country is unknown, and is merely conjectural, notwithstanding that it is stated in the *Flore des Serres* for 1857 that *C. Fairieanum* was received from Bhotan. But it has never been found in that region, and all the plants in cultivation have been propagated from the first few plants which reached Europe. This event occurred in 1857, or perhaps earlier, but the first notice of *C. Fairieanum* was by Sir W. J. Hooker, who received flowers from Mr. Reid, of Burnham, Somerset, and Mr. Parker, of Holloway, and had a figure prepared for the *Botanical Magazine* (*t.* 5024). The specific name commemorates Mr. Fairie, of Liverpool, who exhibited the plant at a meeting of the Royal Horticultural Society in 1857, when Dr. Lindley named it after him. It has been stated also that *C. Fairieanum* was supposed to have been sold at the London auction rooms with a miscellaneous collection of Orchids imported from Assam, and it was in this way introduced to cultivation. It is naturally very scarce, and will no doubt require many years of careful propagation to render it in any way a common plant.

It will be found best to grow this species in a house not too warm nor too cold—in fact, what is technically termed "intermediate." The temperature in winter may vary from fifty-five to sixty degrees Fahr., and about ten degrees more in the summer months, gradually raising by a degree or two until the warmest period is reached, and again gradually decreasing as the cold winter months approach. Small, well drained pans which can be suspended near the glass appear to be the most fitting receptacles in which to grow *C. Fairieanum*, and the compost may consist of rich, rough peat and fresh sphagnum. As to watering and ventilation, the gardener must, of course, exercise his own judgment in these matters, giving greater or less supplies of water according as the plant shows an inclination to grow vigorously or to rest, and air to strengthen the growths when there is no danger of creating any great or sudden fall in the temperature by cold and piercing draughts.

Isleworth, London. *John Weathers.*

The Mignonette Disease.

IN a large house devoted almost entirely to the growth of Mignonette I lately observed thousands of plants struggling to come into bloom, but lamentably failing because of a fungous parasite which was preying upon them. The whole expanse of Mignonette had a sickly appearance, for the lower leaves were either entirely dead or badly spotted. The Fungus sends its fine threads through the substance of the stem and leaf and shortly they come to the surface in certain places, the green of the normal leaf disappears and soon upon the white spots dark specks are produced. These are due to the formation of multitudes of spores, and as they are carried away by the wind when dry, or by the water when wet, the disease is spread from plant to plant.

Last year the section of Vegetable Pathology of the Department of Agriculture at Washington had this disease under investigation, and the results have recently been published in its annual report with a colored page plate. Therefore, for the Mignonette-growers now suffering from this trouble, some of the facts of that investigation, together with the remedies that proved effective, are here given in brief. The Fungus doing the mischief has been known for twenty years or more, and was named *Cercospora resedæ* in 1870. The Cercosporas are, many of them, serious enemies to growing crops, but, as a rule, are within the reach of remedies when taken in season. The Fungus itself is entirely microscopic, and only becomes noticeable when it has killed a portion of the tissue it is feeding upon. It, therefore, is not reasonable to hope that any substance can be applied that will restore the lifeless spots of a leaf to health. The chief point is to check the further spread of the disease and permit the dead portions to be superseded by new healthy ones. The spores, for example, are all borne upon short stalks that project from the surface of the diseased parts, and are therefore within easy reach of a fungicide. In like manner these spores must fall and germinate upon the surface of the plant; therefore, the coating over of the surface of diseased and healthy plants at the same time kills the spores before they have become desseminated and destroys others that may have reached the healthy plants and are possibly beginning to germinate and penetrate the substance.

It was found that while the ammoniacal solution of carbonate of copper checked the spread of the disease, the Bordeaux mixture was the most successful. This made in the ordinary way and sprayed upon the bed liberally about once per week saved the plants when they were not so far gone as to appear worthless at the outset.

Any Mignonette-grower whose plants are suffering from the disease can test the efficacy of the Bordeaux mixture by omitting to spray certain portions of his beds, and in that way be an experimenter for himself.

Rutgers College. *Byron D. Halsted.*

Acacia pubescens.—This is one of the best of a large genus, and should be grown wherever space can be afforded. It is now in flower at Wellesley College, and in the gardens of Mr. H. H. Hunnewell there are two very large specimens, measuring nearly, if not quite, ten feet in diameter, which will make a magnificent display in about a month, with their long,

drooping, panicled branchlets covered with small, globular, sulphur colored flowers, filling the air with a delicious fragrance. Some Acacias are difficult to propagate by cuttings, and I believe this is one of them. They are, however, easily raised from seed, and seedlings invariably make the best plants. Acacias make roots rapidly, and quickly fill whatever space is allotted to them. When they are finally placed in tubs as large as can be conveniently handled, frequent top-dressings of rich soil will keep them in good condition for many years. They may be kept in symmetrical form by a little yearly pruning after the flowering season, which is the time for cutting out crowding branches.

Wellesley, Mass. *H. G.*

Clematis paniculata.—In urging the advantage of grafting as a means of propagating this plant it ought to be said that the stock used is merely a vehicle to carry the scion during the infancy of the plant. When grafted plants are set out care should always be taken to place the point of union beneath the soil, and an examination at the end of the first season's growth will soon show that *Clematis paniculata* has thrown out a quantity of its thick, thong-like roots, and that the foreign root is already superseded and speedily becomes of little or no use to the plant. Mr. Hatfield says truly that *C. paniculata* varies considerably when raised from seed, and I have seen seedling forms with a distinct variegation or venation of the foliage, the centre of the leaves being distinctly marked with blotches of a lighter green. And yet it is difficult to imagine anything more beautiful than the typical plant as a perfectly hardy climber.

South Lancaster, Mass. *E. O. Orpet.*

The Forest.

Forest-policy Abroad.—III.

In France, which stands with Germany at the head of the nations as regards thoroughness of forest-policy, the large extent of Government and other public forests is in excellent condition. The training of French foresters, and, to some extent, the treatment of French forests, differ widely from those which distinguish Prussia, as indeed the genius of the people would naturally lead us to expect. That this training extends over two years instead of the six to eight spent by the Prussian candidates, cannot but make the task of national forest-administration seem lighter, especially in view of the admirable, and very often the wonderful, results which the French forest-officers have achieved. Perhaps their most brilliant work has been accomplished in the correction of the torrents in the Alps, Pyrenees and Cevennes, in the course of which over 350,000 acres have been rewooded under difficulties which seem almost insurmountable. Of the total cost to the French Government, some 50,000,000 of francs, about one-half was consumed in engineering works whose direct object was to make the replanting of the drainage areas of torrents possible. "The forest thus restored to its natural place is alone able," says an eminent French authority, "to maintain the good, but precarious, results of the works of correction in the waterways themselves." The disappearance of this forest, in the first place, may be traced, in most cases, directly to mountain pasturage, and the whole story of reboisement in France is full of the deepest interest in comparison with the past history and probable future of our mountain forests.

Perhaps the closest analogy to our own conditions in the magnitude of the area to be treated, the difficulties presented by the character of the country and the prevalence of fire, and the nature of the opposition which it encountered, is to be found in the forest-administration of India, and that in spite of the tropical climate with which it has to deal. The history of the movement is comparatively fresh, and the fact that many problems remain as yet unsolved will scarcely detract from the interest and sympathy with which we may be led to regard it.

Systematic forest-management was begun in India about thirty-five years ago, under difficulties not unlike those which confront us now. An insufficient or a wrong conception of the interests involved, the personal bias of lumbermen, the alternating support and opposition of the men in power, were the chief obstacles with which it had to contend; and against them were pitted the splendid perseverance and magnificent administrative powers of one man. The victory was brilliant, conclusive and lasting, and India has to thank Sir Dietrich Brandis for benefits whose value will go on increasing from age to age.

"History has proved," says Dr. Schlich, "that the preservation of an appropriate percentage of the area as forests cannot be left to private enterprise in India, so that forest-conservancy in that country has for some time past been regarded as a duty of the state. Of the total area of Government forests, which may perhaps amount to some 70,000,000 of acres, 55,000,000 have been brought under the control of the Forest-Department. Of this area 33,000,000 are so-called reserved state forests—that is to say, areas which, under the existing forest-law, have been set aside as permanent forest-estates—while the remaining 22,000,000 are either protected or so-called unclassed state forests. These areas together comprise about eleven per cent. of the total area of the provinces in which they are situated. Rather more than half the area, or about six per cent., are strictly preserved and systematically managed forests."

The formation of these reserved state forests was the first step in systematic forest-management, and it was carried out along lines which are typical. The forest-areas were first selected, following standards which cannot be enumerated here, then surveyed and demarcated on the ground, and finally established as reserved state forests by an act which provided, first, for the presentation, within a certain time, of all claims against the state forests as demarcated; secondly, for their hearing and definite settlement; thirdly, that no prescriptive rights could accrue in reserved state forests after their declaration as such under the act; and, fourthly, for the special treatment of forest-offenses.

These forests have been gradually brought under simple, but systematic, methods of management, which aim at effective protection, an efficient system of regeneration and cheap transportation, the whole under well considered and methodical working plans. The forest-staff charged with carrying these plans into effect draws its controlling officers from England, but the executive and protective work is done by natives, since they alone are equal to the physical labor in so warm a climate. The results of this enlightened policy are conspicuous, not only in the great fact that the forests yield, and will permanently yield, the supply of timber and forest-produce which the population requires, but also in the beginning which has been made toward regulating the water-supply in the mountains, and in the increasing capital value and annual net revenue of the state forests. This last has reached the verge of half a million sterling, and it is believed by the men best fitted to judge, that the forest-revenue will increase at least four times during the next quarter of a century.

There are two other facts resulting from the forest-policy of India which are of special significance to us as citizens of a country where any interference by the Government with private rights would be so vigorously resented, and where private enterprise must consequently play so conspicuous a part: First, a body of efficient and experienced officers of all grades has gradually been formed in the state forests whose services are available for the management of private forests, and of communal forests when the time shall come to form them; secondly, the example set by the well-managed state forests and the steadily increasing revenue which they yield have induced native and other forest-proprietors to imitate the state. The trained foresters, without whom so laudable a purpose must fail, are at hand, and the whole situation argues most favorably for the future prosperity of the country.

It has been impossible to do more than glance at the chief points of forest-policy in a few of the many lands which teem with interest in this respect. I would gladly have called attention to Austria, where an excellent forest-service upholds the general principles which we have seen exemplified elsewhere, and to Italy, where the sale of government forests, forced on the state by the pressure of financial necessity, is beginning to bear evil fruit. A circle of lands around the Mediterranean might have been cited to instance the calamitous results of deforestation, and from some of them still further proof might have been adduced to show at what a cost such errors must be repaired. But the countries which have distanced us on the road toward a rational forest-policy might better have claimed our attention.

Without confining ourselves to Europe, where we might have stopped to glance at Sweden, whose Government has recognized its obligations as a forest-proprietor, and where even Russia could have shown us the beginnings of conservative forestry, we might have found in Japan an organized forest-administration, with a forest-school at Tokio. Cape Colony has an efficient forest-staff, thanks to which the Government is in receipt of a net revenue from the management of its forests, and Natal has recently engaged a German forest-officer to take charge of its interests in that line. Victoria has a reserved state forest, and New South Wales, Queensland and Tasmania have followed her lead in the appointment of

forest-officers. New Zealand has taken the examples of the colonies of eastern Australia, and Ceylon, Java, the Fiji Islands and others have made steps in the right direction.

Dr. Schlich's statement of the destructive tendencies of private forest-ownership in India might with equal truth have been made as a general proposition. It is the salient fact which the history of the forests of the earth seems to teach; but nowhere have the proofs of its truth taken such gigantic proportions as in the United States to-day. Even in Germany, where the state has done its utmost to surround them with every possible safeguard, the wood-lands of private proprietors are steadily decreasing both in area and in quality. A second great fact, which is of equal and immediate significance to us in America, is that the countries which have been successful in forest-preservation have been so along the lines of forest-management. The first and most evident function of the forest is to produce wood, and no scheme which leaves out of account the imperative and legitimate demand for forest-produce is likely to meet with the support of a people as practical as our own. The forests which are most profitably used are the forests which are best preserved. These truths have never had the currency with us which their importance has deserved, and as a result we have been hastening along a road whose end is painfully apparent. We are surrounded by the calamitous results of the course that we are now pursuing. In fact, it seems as though there were almost no civilized or semi-civilized country in either hemisphere which cannot stand to us as an example or a warning. To this great truth they bear witness with united voice: The care of the forests is the duty of the nation.

New York. *Gifford Pinchot.*

Correspondence.

The Owl and the Sparrow.

To the Editor of GARDEN AND FOREST:

Sir.—GARDEN AND FOREST for December 24th, 1890, contains a letter from Charles Naudin, in which he recommends the introduction into the United States of the European Pigmy Owl, or *Chevêche*, the scientific name of which he gives as "*Stryx passerina*, Linnæus." *Strix passerina* of Linnæus (1758) is the *Glaucidium passerinum* of modern authors, while *Strix passerina* of Gmelin (1776) is at present known as *Carine noctua*.

It is not quite clear which species is really meant, but this matters little so far as the proposed scheme of introduction is concerned, both species inhabiting France, and both feeding largely on small birds, particularly such species as make their nests in holes or cavities. It is not likely that the introduction of either of these small owls into the United States would go far toward reducing the numbers of English sparrows; while, on the other hand, the experiment might be fraught with most unfortunate results.

Our little wrens, bluebirds, titmice, and other species which nest in crevices, holes and artificial houses erected for their use in the vicinity of dwellings, would be destroyed as well as the sparrows.

One of our native owls—namely, the little Screech Owl (*Megascops asio*)—has taken up its residence in many cities and large towns infested with sparrows, and has learned to feed upon these pests in great numbers. Its presence may be encouraged without incurring the risks attendant upon the introduction of exotic species. The importation of exotic birds, with a view of setting them at liberty in our own land, should always be regarded with suspicion, as likely to be followed by disastrous results.

Department of Agriculture, Washington, D. C. *C. Hart Merriam.*

The Madroña in Winter.

To the Editor of GARDEN AND FOREST:

Sir.—Among the broad-leaved evergreen trees of the Pacific coast none are handsomer perhaps than the Madroña (see illustration in GARDEN AND FOREST, iii. 515), and it is peculiarly bright and beautiful here during the winter months. Unlike the Ash, the Alder and the Maple, the Madroña is found in the driest and sunniest localities upon the hill-sides as well as in the denser forests along the foot-hill streams. Even on these drier ridges, where the forest is more open, the Madroña is quite abundant, and always forms a charming feature of the landscape. Especially is this the case in the winter, when the bright green of its leaves are in pleasant contrast with the sombre hues of the huge conifers of this region, or with its leafless neighbors among the deciduous trees. But in the denser forests of mingled evergreen and deciduous trees along the foot-hill streams the Madroña is most abundant, and here in the dim light, where the rich and varied foliage of evergreen shrubbery hangs above a living carpet of moss and trailing plants, its presence wonderfully increases the charm of it all. Its large, handsome leaves are of the glossiest green. Its great, almost naked, branches are clad in the daintiest and closest fitting bark, soft, velvety, smooth and conspicuously clean, a garment scarcely thicker than writing paper, and ranging through a variety of colors, from almost pure white through the most beautiful and delicate shades and tints which I can only describe as drab to pea-green, yellow-green and buff to cinnamon and red.

Here the Madroña, the type of all that is loveliest in sylvan life, is so abundant, that with its leafy wealth on every hand, we are made to believe, even in the winter months, that by some magic we have been transported to some semi-tropical land. *Berberis Aquifolium*, the handsome Holly-leaved Mahonia, with us called Oregon Grape; *B. nervosa*, the low Oregon Grape, the prettiest little plant, perhaps, of its genus; *Micromeria Douglassii*, the sweet-scented yerba buena; *Linnea borealis*, the pretty little Twin-flower, known and loved the world around; *Whipplea modesta;* Synthyris; *Gaultheria Shallon*, the Salal; *Chimapila umbellata*, the Prince's Pine, and a host of other evergreen, shrubby and trailing plants, lend the charm of their bright foliage to this deception.

Wimer, Ore. *E. W. Hammond.*

Periodical Literature.

In the *Popular Science Monthly* for January we find a biographical sketch of Dr. Elisha Mitchell, who deserves to be more widely known to American lovers of nature than we believe to be the case. Dr. Mitchell was born in Connecticut in the year 1793, was graduated from Yale College in 1813, and, after being licensed to preach by the Theological Seminary at Andover, accepted, in 1818, the post of Professor of Mathematics in the University of North Carolina, at Chapel Hill, in that state. Here he remained until the end of his life, a period of thirty-nine years, being transferred, however, in 1825 to the chair of Chemistry, Mineralogy and Geology. These facts imply great breadth of learning, which indeed he possessed; but natural science was his favorite study, and, though not a titular professor of botany, he was an enthusiastic and accomplished botanist. One of his biographers has said that "when he died he was known in almost every part of North Carolina, and he left no one behind him better acquainted with its mountains, valleys and plains; its birds, beasts, bugs, fishes and shells; its trees, flowers, vines and mosses; its rocks, stones, sands, clays and marls. Although in *Silliman's Journal*, and in other periodicals less prominent, but circulating more widely nearer home, he published many of his discoveries concerning North Carolina, yet it is to be regretted that he did not print more and in a more permanent form." It would doubtless have thus appeared that he knew, and perhaps justly estimated the worth of, many facts which much later investigators have proclaimed as their own remarkable discoveries. But the information that he gathered was for his own enjoyment and for the instruction of his pupils. On these he lavished, to their utmost capacity for reception, the knowledge that he had gathered by his widely extended observations, and had stored up mainly in the recesses of his own singularly retentive memory." In the extracts from his note-books and the comments of his friends, which are given in the article from which we quote, it is interesting—in these days of perhaps excessive specialization—to read how all the natural sciences went hand in hand in his mind and his daily labors. In one memorandum book he wrote, when preparing for a journey: "Objects of attention—geology, botany, height of the mountains, positions by trigonometry; woods, as the Fir, Spruce, Magnolia, Birch; fish, especially trout; springs; biography," and so on. And among his baggage he notes "two barometers, a quadrant, a vasculum for plants and a hammer for rocks." Of course a man whose energies, no matter how great they may be, are thus widely spread, can rarely reach the highest eminence in any one branch; but in a little known and interesting region, where scholars and explorers were few, such a many-sided absorber as Dr. Mitchell was especially able to do good service to science, and his own pleasure must have been infinitely greater than that of the most devoted specialist. His most noteworthy claim to remembrance was his service in ascertaining the exact altitude of the highest peak in the Appalachian range, that peak of the Black Mountain in Yancey County, North Carolina, which is loftier even than Mount Washington. It was at first generally known in the

neighborhood as Mount Mitchell or Mitchell's High Peak, although after his explorations in 1844 this name was attached to another, which is rightly "Party Knob." Prompted by controversies with regard to the justness of his calculations and the exact peak whence they had been made, Dr. Mitchell made a fifth ascent of the mountain in 1857, and then lost his life, probably falling in a storm into the pool where, some time afterward, his body was found, at the foot of the falls now called by his name. A year later his remains were removed from the graveyard at Asheville and buried beneath the Balsam Fir whence his famous observations had been taken on the very top of the highest peak of the mountain. His name was definitely given to this peak by the United States Geological Survey of 1881–1882, and there his monument, a simple shaft twelve feet in height, will long stand on the most elevated spot in eastern North America.

We may add that Dr. Elisha Mitchell, or Professor Mitchell, as he is more often called, should not be confounded with Dr. John Mitchell, a Virginian botanist of earlier date, for whom his correspondent, Linnæus, named our pretty Partridge-berry.

Notes.

It is stated that Mr. Ruskin maintains a Cherry-orchard solely for the benefit of the birds on his estate.

In a late bulletin issued by the New Jersey Agricultural Experiment Station, Professor Halsted describes nine distinct kinds of Fungus which attack the Sweet Potato and cause it to rot.

An olive-oil factory is soon to be built in Sonoma County, California, by a company which now has sixty acres of six-year-old Olive-trees and is planting 700 acres more. The plant will cost $250,000.

The leaves of *Daboisia Hopwoodii*, an Australian shrub, are chewed by the natives in the same way that the leaves of Tobacco are chewed, and bid fair, it is said, to become a rival to Tobacco. They contain an alkaloid, piturine, which is identical or closely related to nicotine, the action of the two being in every respect identical.

The newest Oxalis, which was introduced to the trade in Europe by Herr Dammann, is *O. sensitiva*, and, says a foreign periodical, "is even more beautiful and interesting, as regards its foliage, than *Mimosa pudica*. The finely cut leaves are in almost constant motion, and fall together at the slightest touch. They form charming frills around the clusters of yellow flowers." Like the common Oxalis, this is a wood-plant, which can easily be cultivated even in shady localities.

The *Revue des Sciences Naturelles Appliquées* says that among the food-producing plants valued in Abyssinia, but elsewhere unknown or little prized, are: *Coleus tuberosus, A. Rich.*, which has fleshy tubers resembling the potato in taste, although not in shape, and is grown at an elevation of from 6,000 to 7,000 feet above the sea; *Brachystelma lineare, A. Rich.*, which grows in moist shady situations in the valleys and furnishes large fleshy tubers; *Campanula esculenta, A. Rich.*, the roots of which are eaten, and *Cyanotis Abyssinica, A. Rich.* (*Commelina hirsuta, Hochst.*), which is also a tuber-bearing plant.

Some of the lessons drawn by the *American Agriculturist* from the immense crops of Potatoes grown in competition for the prizes offered by that paper are: That cutting the seed-potatoes into sets with two eyes each gives most general satisfaction; that large or medium sized potatoes are best for planting; that the sets should be slightly sprouted before being planted, although they should be cut before the sprouts have started; that planting should be delayed until settled weather; that placing the sets directly upon stable manure is bad practice, and that concentrated commercial fertilizers are better as a rule than stable manure.

The December issue of Hooker's *Icones Plantarum* is devoted to figures and descriptions of Indian Orchids of the genera Dendrobium and Bulbophyllum, the descriptions being supplied by Sir Joseph Hooker, who is now engaged in studying these plants for the Flora of India. Of the species included in this part only *Dendrobium Moulmeinense* is of garden interest, all the others being supplied with small and inconspicuous flowers. *D. Moulmeinense* belongs to the same group as *D. dixanthum* and is a native of the same country, differing, however, from that species in its more slender stems, pendulous habit and deeper fimbriation of the lip.

The Directors of the Madison Square Garden Company announce a grand competitive Chrysanthemum show, to be held on November 1st, 1891. The company offers $1,500 to be given in prizes, and a large number of ladies well known in society are aiding the project by their influence, as well as by liberal contributions to the prize fund. Nowhere in the country are Chrysanthemums grown in greater perfection than in the neighborhood of this city, and it is to be hoped that next autumn a display will be made which will at least equal in merit the shows in Philadelphia and Boston, not to speak of a dozen less important places. The managers of this enterprise are to be commended for this seasonable announcement of their plans.

The Northern California Citrus Fair is now in progress at Marysville, and here there are to be seen displays of oranges, lemons and other semi-tropical fruit, grown in places which have the same latitude as St. Louis or Kansas City. No protection of hedges has been given to Orange-groves, and growers declare that their losses from frost have been no heavier than they have been in Los Angeles or San Bernardino. One of the singular features of the fair is the presence of beautiful oranges from the foot-hills of Placer County, once the foremost mining county of the state. Old mining ditches and flumes have been repaired and are now used to irrigate orchards. If the original gold-hunters could return they would be amazed to find their old prospecting grounds transformed into groves of tropical fruit.

The London *Telegraph* said not long ago: "An individual living in the Department of Aveyron, France, struck by the high price at which mushrooms were being sold in his district, conceived the idea of fabricating the delicacy out of turnips. He cut the turnips into rounds, dried them, and, after giving them a dab of the paint-brush, disposed of them to unsuspecting customers as the genuine article. For some time he drove a thriving trade, but, unluckily for him, he one day sold a batch to a gourmet who was not so easily to be taken in. Indignant at the trick played on him, the gourmet brought an action which has just resulted in the condemnation of the mushroom-manufacturer to two months' imprisonment. It was in vain that he pleaded that he had enabled his fellow citizens to regale themselves on a vegetable which they regarded as a good specimen of the mushroom at a cost far below that commanded by the real article. Vain, too, were his efforts to demonstrate that his mushrooms could be consumed without entailing disastrous consequences on lovers of the delicacy. The court turned a deaf ear to his specious arguments, and has allowed him two months' leisure to meditate on the error of substituting dried turnips for honest mushrooms."

In an interesting article on Anemones, published in the December number of the *Illustrirte Gartenzeitung* of Vienna, Dr. Carl Mueller says of *Anemone coronaria* that it grows in western and southern France, in Italy, Dalmatia, Turkey, Greece and the Levantine countries, as well as in Algiers, but then explains that one thinks of it especially as the characteristic flower of Palestine. Here, he says, "it as commonly grows wild as about Smyrna and in Asia Minor, spreading far and wide as the most beautiful of spring blossoms, growing on chalk soil along the edges of shrubbery. We cannot wonder that it was already in ancient times a favorite of the inhabitants and excited in poetic minds sensations such as can only be excited by surprising beauty. '*I am the Rose of Sharon and the Lily of the valleys*,' sings the first verse of the second chapter of Solomon's Song, and there can be no doubt to-day what is here meant by the Rose of Sharon. It was an American, Fiske P. Brewer, who decided this question, *Narcissus Tazetta*, which likewise grows in Palestine, having previously been considered the Biblical flower. This gentleman, according to the *Edinburgh Review* of 1886, while traveling in the year 1859 from Jaffa to Ranleh, came upon a place where a considerable expanse of ground was half covered with brilliant red flowers. At the sight of them some of his native companions immediately exclaimed 'Roses of Sharon'; and, when he inquired about the name, he was told that the Anemone was there universally so called. In truth it would not be easy otherwise to speak of a Rose in Palestine, for native Roses do not exist there—at least not where they would justify the association of the Plain of Sharon with their name. Wild Roses are found in Palestine only on Lebanon, or where, here and there, *R. centifolia* is cultivated for the production of attar, as in the Wadi-el-Werd (Rose-valley) near Hebron. According to Ebers and Guthe, in their 'Palestine,' the translations of the Bible often use the word Rose where there is no warrant for understanding by it a true Rose. The Roses of Persia and Media were not introduced into Palestine before the Grecian period."

TABLE OF CONTENTS.

The "Sauce" of Architecture.

AN architect who has studied in Paris, and, unlike many of his American brethren whose opportunities have been as good, has learned to appreciate the interest and importance of landscape-gardening and its vital connection with architecture, said, not long ago: "Yes; all French architects feel as I do, and in the studios they call landscape-gardening 'la sauce de l'architecture.'"

Now, a Frenchman's idea of the importance of a sauce is very different from our own, and one must know Parisian dinners and Parisian cooks to appreciate the full import of the phrase. Nevertheless, taking it in its highest potency, we are inclined to utter a mild protest against it. A truer simile would suggest the difference between an article of food which is cooked or prepared in any way and one which is raw. In any case where landscape-architecture might help the sister art (which means in every case except that of a building on a closely covered city street) there is as much necessity for its service as for the service of fire upon meat. A building badly placed when it might be well placed and surrounded is worse than ungarnished, it is incomplete. Moreover, in most cases, the way in which it should be placed and surrounded is not an open question for the architect to decide as he will. It is a question decided largely in advance by unalterable facts and settled canons of taste, and these the landscape-gardener is better fitted than the architect to understand. Take the instance of a country house. If the domain is small there will hardly be more than one spot where it can be set and one way in which its entrances and chief rooms can be arranged for convenience and good effect, and success here is involved in the arrangement of the grounds, as well as in that of the building. The architect cannot safely design the house without studying its relation to neighboring streets and structures and to the character of its own site, and then call in the landscape-gardener to add a "sauce" that will make it attractive. If he does this the owner is apt to find his chief windows looking where they should not look, and his entrances placed where they will necessitate inconvenient approaches, and these in their turn spoiling the grounds by preventing the best arrangement of lawns and gardens. If the domain is larger the problem is only more complicated, and more likely, if improperly attacked, to result in error and loss.

Not long ago an architect who stands high in popular repute was asked to design a large country house in a picturesque situation a mile or two from a New England town. Being unfamiliar with the spot, yet feeling obliged to begin his work in winter, he took a flying trip from his office in another city, drove up to the house of a friend in a sleigh, and asked for guidance to his client's property. There, walking about for just a quarter of an hour, he decided upon the site, turning a deaf ear to his friend's remonstrance that the view was so noble it ought to be carefully considered, and that it could not be considered when the trees were leafless, and the little lakes, so immensely important in summer, were blotted into the solid ground by a universal sheet of snow. To-day the house stands where no one would think of placing it who meant to live in it and had the slightest feeling for the beauty of nature. No garnishing, though supplied by the greatest landscape-gardener who ever lived, could now change this ruined estate into a fine one. Only a few miles from this is another large country house which, apparently for the sake of having it well seen from the highway, has been placed on the summit of such a steep rise in the ground that the carriage approach has been carried to the highway by a grade so heavy and a turn so sharp that even skillful drivers run danger of disaster every time they traverse it.

Nor should these be thought extreme cases. They could be matched by a thousand others of every-day occurrence. At every step, in every part of the country, we see what might have been fine places spoiled by the placing of the house, and even fine houses robbed of their right effect, because their builders thought of nothing beyond the conspicuous placing of the structure. Not every picture shows to best advantage when hung in a bright light in the centre of a wide field of wall, though a picture is an independent work of art. This a building never is; yet we constantly see proof that an architect thinks his structure will look best when most boldly shown from a hill-top or some exposure where no plantations can screen it from the road. It is a fatal mistake to think of the house as something independent of its surroundings. Even when its aspect has been more wisely considered, questions of prospect have often been forgotten. Or else the view from the piazzas and windows has been borne in mind while the aspect of the house from a distance has been neglected. To consider both together means a wider range of view than most of our architects take, and to secure excellence in both (which often necessitates a compromise involving some sacrifice in both directions) a power of foresight is demanded and a degree of skill which only a study of the art of landscape-gardening can give.

In our country hardly any one but professed landscape-architects has studied this art at all, while in France some knowledge of it is regarded as essential to architects. Here, therefore, the architect will do well not to trust himself, but to ask for the help of his brother artist. And, of course, he must ask it in advance, and not when his own labors are ended. We should be glad if all American architects were convinced of even as much as is expressed by the careless studio phrase we have quoted—if all could feel about sauces as Frenchmen do and then really be convinced that landscape-gardening is the "sauce of architecture." But this would only be a half step in the right direction. Happier still will be the time when they will realize that a building and its surroundings are one and indissoluble, that they must be considered together from the very outset, and that the claims of the one should never be unduly pushed to the unfair detriment of the claims of the others. There may be cases when a mere "sauce" of ornamental planting after architectural completion will serve. But almost always the work to be

executed can be rightly executed only in some way determined in advance by causes which must be studied according to the canons of landscape-art as well as of architecture. Very often the only choice will be whether a building of this character is to be placed on a given spot; with that determined, the one right way of treating both house and site will be prescribed by conditions which the architect cannot ignore; or if he does, no subsequent dressing by a landscape-gardener can redeem or even mask the error. And when a choice is possible between different good methods of planning and treatment, still this choice must be preliminary to the architect's action and should not be made according to his lights alone.

A Vase of Chrysanthemums.

AS a contrast to the group of Chrysanthemums of a single sort which we published some weeks ago (vol. iii., p. 397), we now present on page 43 a picture of a vase in which five flowers, each of a different kind, have been placed. We do not consider the arrangement entirely fortunate, as the weak stems of the two on the right of the picture hardly harmonize with the sturdier bearing of the others. But it will at least serve as a hint of what may be accomplished by thus contrasting specimen flowers of different forms and colors. It is often said that the best way to arrange Chrysanthemums, and, indeed, most kinds of flowers, is in groups or masses of a single kind. Certainly this advice is good, because eminently safe. So long as excessive crowding is avoided a really unbeautiful effect can hardly be produced with flowers of one kind with their foliage; moreover, it is always easier to find an appropriate place and background for such a group than for one of varied colors, and our readers hardly need to be told again that the beauty of a vase of flowers depends as much upon its proper environment as does the beauty of a painting. Nevertheless, safety is not the only, nor always the highest, aim even in arranging flowers, and too close an adherence to the generally excellent practice of massing may deprive us of occasional effects whose beauty, depending upon harmonious contrasts, is especially striking and individual. Feeble painters, we may say in explanation, are apt to win success by using a simple scheme of color and attempting no vivid contrasts, and great painters constantly do the same; but occasionally a great painter will boldly put the most strongly contrasted tones together—even upon occasion scarlets and crimsons—and produce a more striking sort of beauty by the harmony he wins from them. And so with flowers we may well at times exercise our taste in trying to produce a harmonious group with strongly contrasting blossoms. In our picture, for instance, the uppermost flower is of the deep yellow variety called Kioto; the central one is G. F. Mooseman, whose color is a dull crimson within the florets and a light brown without; the one to the left is a pure white blossom of Mrs. Langtry; the upper one on the right is a pink Mrs. Fottler, and the one beneath it is a bright yellow named Gold. Those who can command a variety of Chrysanthemums will do well some day to repeat this arrangement with the same flowers or others of similar colors. It requires care to make a coloristic success of such a group; but if the result does not suit them they will at least have a starting-point for an interesting series of experiments which may result in some other varied arrangement of entire and surprising beauty.

Muskau—A German Country Park.

THE River Neisse flows with no great rapidity from its source in the highlands which divide Germany from Austria to its meeting with the Oder in the plains south-east of Berlin. Its total length is perhaps one hundred miles, or about that of our New England Merrimac or Housatonic. In the lower half of its course it traverses an exceedingly sandy region, out of which the river has carved a shallow and crooked valley. Occasionally a cheerful meadow lies along the stream, but the banks or hills which bound the valley, and all the uplands beyond, are covered with a dismal and monotonous forest of Pines. The region has few natural advantages and little natural beauty.

In 1785, in the moated house of the Count or Lord of a part of this forest-country, was born a boy who was destined to work a wonderful revolution in the scenery of his native valley, and by so doing to awaken throughout Germany an interest in designed landscape which is still active and growing. This boy, Ludwig Heinrich Hermann von Pückler, became a restless youth, who first attempted at Leipsic the study of law, then tried and abandoned the military life, and finally declined to enter even the civil service of his country, because, as he said, "my liberty is too dear to me."

At the age of twenty-one he set out on a round of travels which occupied four years. He saw Vienna, Munich, Switzerland, Venice, Rome, Naples, southern France, Paris and the lands between, for all his journeying was done either on foot or on horseback. In 1812 he was cordially received by Goethe in Weimar; and in the following year, under the Duke of Saxe-Weimar, he was military governor of a post in the Netherlands. When peace was established he made his first visit to England, where he saw the landscape works of Brown and Repton; and in 1815, his father having died, he at last turned homeward to his Standesherrschaft of Muskau, on the River Neisse.

There is every reason to believe that the idea of improving the surroundings of his home and village had been cherished by Pückler during all his wanderings. His letters show his intense interest in both natural and humanized scenery; and they make it evident that the sight of the great works then lately accomplished in England had only made him the more eager to begin the arduous task he had set himself.

This task was nothing less than the transformation of the almost ugly valley of the Neisse into a vale of beauty and delight; and the great distinction of his idea lay in the fact that he proposed to accomplish this transformation not by extending architectural works throughout the valley—not by constructing mighty terraces, mile-long avenues or great formal water-basins, such as he had seen in Italy, at Versailles and at Wilhelmshöhe—but by quietly inducing Nature to transform herself. He would not force upon his native landscape any foreign type of beauty; on the contrary, his aim was the transfiguration, the idealization of such beauty as was indigenous.

In the picture galleries of Europe he had seen the first-fruits of the young art of landscape-painting. In common with the painter he had found in the study of the beauty of nature a source of pure joy which the men of the renaissance had failed to discover. Somewhere and somehow he had learned the landscape painter's secret, that deepest interest and finest beauty spring from landscape-character—character strongly marked and never contradicted. In England he had seen this truth illustrated by actual living landscape, for Repton's parks were simply the idealization of characteristic English scenery.

Accordingly we find Pückler, on his return to Muskau, intent upon including in one great landscape-scheme his schloss, his village, his mill, his alum works and all the slopes and levels which enclose them—intent upon evolving from out the confused natural situation a composition in which all that was fundamentally characteristic of the scenery, the history and the industry of his estate should be harmoniously and beautifully united.

One circumstance greatly favored the happy accomplishment of his design—namely, the very fact that he had to do with a valley and not with a plain or plateau. The irregularly rising land skirting the river-levels supplied a frame for his picture; the considerable stream, flowing through the midst of the level, with here and there a sweep toward the enclosing hills, became the all-connecting and controlling element in his landscape. Well he knew that what artists call "breadth" and "unity of effect" was fully assured if only he abstained from inserting impertinent structures or other objects in the midst of this hill-bounded intervale.

On the other hand, his difficulties were many and great. To restore the unity of the river-level just mentioned he had to buy and remove a whole street of village houses which extended from the town square to the mill. To perfect the levels themselves required the removal of the wild growth from many acres and the cultivation and improvement of the soil. To carry the park lands completely around the village, so as to make the latter a part of the perfected scene, and to otherwise rectify the boundaries of his estate, required the purchase of some 2,000 morgen of land. Moreover, the hill-slopes behind the village, where the Count particularly wanted a background of rich verdure, were so barren they would hardly grow even Pines, so that these and many of the other upland slopes of the estate had to be improved at much cost and trouble.

In the valley the pre-existing but confused elements of breadth and peace and dignity were to be developed and enhanced. In the thickets of the lowlands and along the bases of the hills were found many large Oaks and Lindens which helped much to give character to the intervale. In the upland

regions the original tangle of knolls, dells and glades was to be made still more pleasantly intricate by opening the wood here and closing it there, and by breaking and fringing the original Pine-forest with a great variety of appropriate trees and shrubs. This work of introducing more cheerfulness and variety proceeded gradually with the happiest results. To-day the crooked ways which follow the hidden dells in the woods are as charming in their way as is the central valley of the Neisse, while the roads which lead along the edges of the heights and command views of the valley are the most delightful of all. It would be difficult to make choice between the view from the low-lying schloss over the quiet meadows to the semicircle of hills beyond the river and the reverse view from these hills looking across the stream and the intervale to where the turrets of the schloss and the long row of village roofs lie close together under the edge of the dark woods which crown the western range of heights. When his thirty years of pleasant toil were passed Pückler tells us he was one day showing his results to a very intelligent and discriminating lady of his acquaintance who told him "very modestly" that she had little knowledge of the art of designing parks, and that she could recall many scenes grander and more picturesque than the one now before her; "but here," she said, "what strikes one first and gives one most delight is the repose which pervades the whole scene"; and the Count adds that no praise ever pleased him more.

The plan, see page 41 (for the original draft of which I am indebted to Dr. Carl Bolle of Berlin), must serve to explain the general arrangement of the estate. Within the park are included not only the chateau and its gardens, pleasure-grounds and appurtenances of all sorts, but also the very ancient castle hill, the old schloss of the Count's more immediate predecessors, the close-built village of Muskau, with its churches, schools, shops, etc., many acres of plowed land owned and cultivated by the villagers with other acres farmed by the Count, a Pine-woods hotel and sanitarium, an arboretum and nursery, a woodland cottage called "the English house," used as a holiday resort by the townspeople, a large grist-mill, an alum mine, the ruin of the oldest church in Lausitz, and more than one ancient grave-yard. In most directions the park has no definite boundary. It flows into the ordinary Pine-forest on many sides, and in several directions the country roads are "parked" for many miles.

Always keeping in mind his general scheme, Pückler was occupied during thirty years in extending his works and developing the details. At the end of that time he suddenly sold his creation! Muskau passed to Prince Frederick of the Netherlands. He who had become Prince Pückler-Muskau was obliged, like many a landscape painter, to confess himself a victim of his love of beauty. In his zeal for his art he had outrun his resources. At the age of sixty he retired to his lesser manor of Branitz, where he wrote his invaluable books and passed a peaceful old age, varied by many journeys and many visits to the country-seats of friends. He died in 1873.

All Germany has long held him in high honor. In England, the "Letters of a German Prince," as the translation of his "Briefe eines Verstorbenen" was entitled, passed through several editions, and remains to this day the best foreign delineation of the England of his early manhood. His essays on landscape were long since translated into French, and it is to be hoped that they may yet appear in English, for they contain a very clear presentation of the elements of landscape design, as well as many lively descriptions of his work at Muskau.

The significance, for us Americans, of this work at Muskau is very obvious. To be sure at least one-third of our great country is so arid that luxuriant vegetation must depend on irrigation; and, where this is the case, a pleasure-ground becomes an oasis to be sharply marked off from, and contrasted with, the surrounding waste. Spanish models will help us here. But the other half of our continent presents verdurous scenery of many differing types, from the rocky Pine-woods of Quebec to the Palmetto-thickets of Florida. Throughout this varied region there is a woeful tendency to reduce to one conventional form all such too meagre portions of the original landscape as are preserved in private country-seats and public parks. What shall check this tiresome repetition of one landscape theme? When shall a rich man or a club of citizens, an enlightened town or a pleasure resort, do for some quiet lake-shore of New England, some long valley of the Alleghanies, some forest-bordered prairie of Louisiana, what Pückler did for his valley of the Neisse? He preserved everything that was distinctive. He destroyed neither his farm nor his mill nor his alum works; for he understood that these industries, together with all the human history of the valley, contributed to the general effect a characteristic element only second in importance to the quality of the natural scene itself.

Our countrymen are beginning to manifest an appreciation of landscape-painting; let them show the genuineness of their appreciation by preserving and enhancing the beauty of the actual landscape in which their lives are passed.

Boston. *Charles Eliot.*

Plant Notes.

Lyonothamnus asplenifolius.

THE following note is extracted from an interesting account of this tree contributed by Professor Henry Chapman Ford to the *Bulletin of the Santa Barbara Society of Natural History:*

"In the summer of 1885 Mr. Barclay Hazard, of Santa Barbara, during a visit to the island of Santa Cruz, noted a new and peculiar shrub or small tree, and called the attention of the fact to Professor E. L. Greene, of the California University. During July of the following season (1886) Professor Greene visited the island and found Mr. Hazard's discovery to be a new species of Lyonothamnus, and later, in the *Bulletin of the California Academy of Sciences*, described it under the name of *Lyonothamnus asplenifolius*.

"In 1888 Mr. Brandegee found the same species on the island of Santa Rosa, but he states that 'the trees were small and often distorted by the wind.'

"Professor Greene found it growing in a hundred fine groves distributed up and down the thirty miles of the northern slopes of Santa Cruz. He speaks of specimens often as high as thirty-five or forty feet, and says: 'No other small tree of our coast equals this in grace of form and beauty of foliage. The flowers, too, are quite showy in their season, the larger corymbs often measuring a foot in diameter,' adding that 'the wood, close-grained and hard, was called iron wood by the men of the island.'

"As early as 1875 the writer was informed of the existence of this 'iron-wood' and vainly endeavored to procure specimens at the hands of sailors and others frequenting the island.

"It was not until this season (1889) that opportunity offered a personal inspection of the growing trees. In a recent visit to Lady Harbor Dr. Yates and myself climbed the precipitous slopes near, and upon the rocky ridges we found large groups of Lyonothamnus, obtaining specimens of the wood, bark, leaves and corymbs of seed capsules, which were shown at a late meeting of the Society. The trees were in clumps of from five to fifteen individuals, and of different diameters, ranging from a half inch to six or eight inches. The outer bark is deciduous, parting in tough strings from the trunks of the larger specimens, leaving the inner portion rich in reddish brown color. The beautiful Fern-like foliage seems to be deciduous, yet the tree may not be entirely bereft of leaves at any time. The flowering season having passed, deprived us of judging of their beauty. The trunks are quite straight, the branches springing from them somewhat in whorls at regular intervals. We noticed no seedling specimens, yet it is probable that other localities might furnish them.

"Examples of the wood of various diameters were obtained. It is exceedingly close-grained, hard, and of similar specific gravity to many tropical species. Specimens are in the process of seasoning with a probability that the wood will prove susceptible of taking a high polish with fine color. Notwithstanding its great weight proportionate to the size, it is said to be quite brittle when green. When seasoned it has long been a favorite wood for handspikes used by the sailors and others who have knowledge of its strength.

"The *Lyonothamnus asplenifolius* adds another singularly beautiful tree to our already long and desirable list that should be introduced in ornamental planting. Its showy flowers, rare foliage and general novelty should make it a favorite wherever planted. Its propagation by seeds ought not to be difficult, as they are produced in profusion.

"It belongs to the order *Saxifragaceæ*, and is the first tree of the family that has yet been discovered in North America, most representatives of the order being herbs or shrubs."

In a personal letter from Professor Ford he adds: "I am satisfied that the close-grained wood of this tree may become a rival of Turkey Box-wood for fine wood engraving. It possesses certainly the advantage over that wood of being obtainable in much larger blocks. Beautiful paper knives, with finely carved handles, have been wrought from it; but I have no doubt that it would serve for the manufacture of tool-handles and for various articles in turnery, as it can be made to take a high polish."

New or Little Known Plants.

New Orchids.

Lælia anceps, var. Thomsoniana, O'Brien.—Described as an exceptionally large and brightly colored variety, near the variety *Amesiana*. The segments are delicate blush-rose, and the lip very darkly colored. It appeared in the collection of W. J. Thomson, Esq., of St. Helens, Lancashire.—*Gardeners' Chronicle*, December 20th, p. 716.

Cypripedium × Leeanum, var. giganteum, Rolfe, is an exceptionally large form, raised by Messrs. Heath & Son, of Cheltenham, from *C. Spicerianum* fertilized with the pollen of a large form of *C. insigne*. The dorsal sepal is over two and three-quarters inches in diameter, and the petals two and seven-eighths inches long, and barely under an inch across near the apex.—*Gardeners' Chronicle*, December 20th, p. 718.

Cymbidium Tracyanum, Hort., is a large and showy Cymbidium which I believe to be a variety of *C. grandiflorum*, Griff. (*C. Hookerianum*, Rchb. f.), with the sepals and petals striped like a dark-colored *C. giganteum*. It agrees in other respects. The flowers are five and a half inches in diameter. It was exhibited by Mr. H. A. Tracy, of Twickenham, at a meeting of the Royal Horticultural Society on December 9th last, when it was awarded a first-class certificate. A few days later the plant was sold for seventy-five guineas to Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, December 20th, p. 718; also December 15th, p. 702.

Masdevallia Schroederiana, Hort.—This pretty little Masdevallia, described on an earlier page of these notes, is figured in the *Journal of Horticulture*, for December 25th, p. 557, Fig. 74.

Rodriguezia Fuerstenbergii, Kränzlin, is a lovely species allied to *R. Leeana*, Rchb. f., with pale rose sepals and snow-white petals and lip, the latter with a golden yellow blotch and eight lines of the same color on the disc. The flowers are two inches long. It appeared in the collection of Count Fuerstenberg, of Donaueschingen, from an importation made by Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, December 27th, p. 746.

Cypripedium × Eyermanianum, Rolfe, is a distinct and pretty hybrid raised in the establishment of Messrs. F. Sander & Co., of St. Albans, between *C. barbatum grandiflorum* and *C. Spicerianum*, the latter believed to be the pollen parent. As in many other cases, it presents a curious combination of the characters of the two parent species. It received an award of merit from the Royal Horticultural Society on November 11th last.—*Gardeners' Chronicle*, December 27th, p. 746.

Cypripedium × Deboisianum, Ch. de B.—A hybrid raised by Messrs. Edm. Vervaet & Co., of Mont St. Amand, by crossing *C. venustum* with the pollen of *C. Boxallii atratum*. It received a certificate of merit from the Société Royale d'Horticulture de Gand, and from the Chambre Syndicale des Horticulteurs Belges.—*Gardeners' Chronicle*, December 27th, p. 747.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

London Letter.

Low Temperatures for Tropical Plants.—The minimum temperature that a plant will endure with impunity cannot apparently be arrived at without actual experiment. The temperature of its wild habitat affords little or no assistance upon this point. It frequently happens that one of two plants from a given locality will bear exposure to severe frosts, while the other cannot endure even a degree or two. Instances of this nature are common among the plants from New Zealand, the Cape and Japan. We sometimes laugh at the apparent absurdities committed by our grandfathers in growing the Chusan Palm, *Aucuba Japonica*, *Sophora Japonica*, *Ginkgo biloba*, *Areca sapida* and many more in greenhouses, or even stoves, from a belief that they required such treatment. But in all these cases it has been only after experiments extending over a long period, or by accident, that the "hardiness" of these plants in England has been discovered.

The cold weather of the past month here, coupled with dense fog at times so black as to almost produce darkness, has necessitated exceptional treatment for many in-door plants. It is an established axiom in horticulture that the intenser the light, the higher the temperature may be, within reasonable limits, with advantage, and of course the converse of this is equally sound. When, therefore, the day is almost as dark as the night, we make it the rule to keep the temperature of the houses the same for the day as for the night. Consequently, the temperature in the large Palm-house at Kew has during the past cold, dark weather been kept regularly at about fifty-five degrees, and on several occasions it has even fallen to fifty degrees, while scarcely once has it risen to sixty degrees. In very severe frosts, especially if accompanied by cold wind, more harm is done by the hard firing necessary to keep a temperature of, say, sixty degrees, than by the five degrees lower temperature. It has been proved at Kew that stove plants generally in winter are happiest when kept in a minimum temperature of from fifty-five to sixty degrees, with a fairly dry atmosphere. The plants in the Palm-house include such intensely tropical subjects as the Durian, Cocoanut, most of the Palms from Mauritius and the Seychelles, Pandani of many kinds, in fact, representatives of nearly all of the most tropical forms of vegetation. The minimum temperature that such plants are called upon to endure when in a wild state is, according to Humboldt, seventy degrees. Yet, in glass houses in England it has been proved that they will bear a temperature as much as twenty degrees below this without apparently suffering in the least. It is possible that many of them would bear even more than this. We have proof of the hardier nature, hitherto unrevealed to horticulturists, of some of the tropical genera of Palms, such as Caryota, Oreodoxa, Seaforthia, Cocos and Chamædorea, which have endured in the large temperate house at Kew a temperature of from forty to fifty degrees for about three weeks.

Landscape-gardening.—Mr. William Morris, poet and socialist, has contributed to the *New Review* for January a paper on "The Socialists' Ideal in Art," in which he points out the relations of art to society. Art, he says, "is kept alive by a small group of artists working in a spirit quite antagonistic to the time; and they also suffer from the lack of co-operation, which is an essential lack in the art of our epoch. . . . Nor have they any position or power of helping the public in general matters of taste. For example, in laying out all the parks and pleasure-grounds which have lately been acquired for the public, as far as I know, no artist has been consulted, whereas they ought to have been laid out by a committee of artists; and I will venture to say that even a badly chosen committee (and it might easily be well chosen) would have saved the public from most of the disasters which have resulted from handing them over to the tender mercies of the landscape-gardener." Mr. Morris goes on to declare that "art as it is cannot build a decent house, or ornament a book, or lay out a garden, or prevent the ladies of our time from dressing in a way that caricatures the body and degrades it." Evidently Mr. Morris holds the belief that whatever is, is wrong, except, perhaps, socialistic views. Art in the garden is like art in most things, and what is perfection in one man's eyes is sometimes abominable in another's. There are, of course, many gardens which are so badly constructed as to offend even the common eye, but it is as ridiculous to blame the landscape-gardener for these as it would be to blame painters for all the bad pictures and poets for all the trash called poetry that one meets with everywhere. A landscape-gardener should be an artist, or he has no just claim to his title; his training must be at least as strict and his taste as good as that which makes a landscape-painter. It seems to me, therefore, as absurd to set painters to make good gardens as to expect landscape-gardeners to make good pictures with oil and canvas. There is surely a great deal more in the making of a garden than the disposition of walks and beds and lawns. A knowledge of the material to be used in its composition must be of first importance, and a man who is not a gardener cannot be expected to possess this. Probably the opinion of a committee of artists on the plan of a garden or on the garden when made might be of some value to the landscape-gardener, but the latter, if possessed of the true principles of garden architecture, would, I fancy, produce a much finer garden than any committee of artists, however well selected, that did not include a landscape-gardener among them.

Tritonia and Freesia.—In an interesting article on Tritonias, by Mr. W. E. Endicott (p. 600), a statement occurs at the end which, if correct, is of considerable biological interest. It is this: "Some years ago I hybridized the white form of *Freesia refracta* and *Tritonia crocata*. Singularly enough the resulting plants bore flowers which were Freesia pure and simple, though the Tritonia was the seed parent." Mr. Endicott's contributions to your paper are so careful and accurate that I hesitate to express any doubt of the trustworthiness of the statement here quoted. Freesia and Tritonia are so different that I cannot understand how what Mr. Endicott records could have occurred. The Tritonia has large, orange-colored flowers with broad refracted segments, and they are produced on tall

branching scapes; whereas in Freesia the flowers are tubular, curved at the base, the segments as broad as long, and, in the variety mentioned by Mr. Endicott, pure white save only a small blotch of yellow in the throat. Moreover, the scapes are much weaker than in *Tritonia crocata*. A cross between these two plants would be most interesting. Has Mr. Endicott any plants of the hybrid he raised?

Cultural Department.

A Winter Campaign Against Insects.

THERE is time for a good many odd jobs during the winter in the garden and orchard, or even in the grove, where that is supposed to be kept in order, and no such odds and ends of time can be better employed than in a systematic campain against insects. In orchards usually infested by the tent caterpillar, especially if the trees are young or small, every twig should be examined against the sky for egg-masses. These encircle the twig, making an apparent swelling from half an inch to an inch in length, and are brown, smooth and glistening as if varnished. They look as though a disc of cobbler's wax had been flattened out to about the size of a half dollar and an eighth of an inch thick and then stuck round a twig of suitable size. These egg-masses when once recognized are very easily seen, and should be gathered and destroyed. The little caterpillars hatch in the spring and begin the formation of their tent, usually on the twig that bore the egg-mass. Gathering the eggs will of course prevent the formation of nests, and this is easier than to destroy the nest when once formed.

All dead wood should be removed, and trees that are badly infested by borers should be cut down and the wood burnt. If it is left, even in the wood-shed, the borers will still come to maturity, emerge at the proper time, and nothing has been gained. The Oak-pruner (*Elaphidion villosum*) sometimes infests Apple-orchards to a considerable extent. The usual habit of the larva is to bore in the branches, and at the approach of winter to girdle these inwardly to such an extent that a good high wind will break them and they fall to the ground, the larva remaining in the fallen wood and there completing its transformations. By gathering and burning all fallen twigs and branches, of course all contained insects are destroyed. Where there are Oaks on the grounds or in a grove the fallen branches should be also carefully gathered, not only for the benefit of the orchard, but for that of the Oaks themselves. Dead wood of all kinds should be destroyed. Many bark-borers and wood-borers get into young Oak and Hickory where a fire has been over the ground, and all such material should be cut and burnt. Loose bark on old trees should be removed, and the trunks thoroughly brushed with a stiff broom, which will clear the crevices of many cocoons and pupæ of the codling moth and other pests. A clean, smooth, healthy bark offers little or no chance for concealment, and other locations on rubbish, old fences, anything, in fact, on which shelter is obtainable, are selected by the insects, and these should be either removed or cleaned. A good coat of whitewash, thoroughly put on, will destroy much of the insect life hibernating on fences. It should be put on between board and post where the joints are loose, or between the rails on a fence of that description. Sheds in which produce is stored should be treated in the same way, that is, they should be thoroughly cleaned and whitewashed, and so also should cellars. A liberal use of whitewash is to be recommended not only for the insecticide effects which it may have, but because it offers a very poor resting-place for many Fungus-spores which are the cause of much of the rot and decay in fruit or produce-sheds.

Where ornamental, especially dwarf, Willows are grown, on lawns or gardens near New York, Jersey City and Newark, they should be carefully examined. There has been introduced within a few years last past a weevil, *Cryptorhynchus lapathi*, which works in Willow-twigs and branches much in the same way that the White Pine-weevil works in the leaders of so many of our ornamental conifers. The Newark collectors tell me that in some localities every Willow-copse is infested, and Mr. Machesney informs me that a Kilmarnock Willow in the grounds of a friend has been totally ruined by this beetle. It works preferably in the smaller twigs and branches, burrowing in considerable numbers, in much the same way as does the *Pissodes strobi*, and making much the same sort of cells when the larva is full grown. Wherever the presence of this insect is noted treatment should be radical, and every infested branch or twig should be burnt. The insect will undoubtedly spread and should be carefully watched. Badly infested trees, where they are small, had better be cut and burnt; larger trees should be cut back into sound wood as early as it can be safely done.

Arbor-vitæ hedges are especially subject to bag-worm attacks, and these should all be picked off and destroyed during the winter. The bags contain the egg-sack, and every sound bag means 200 or 300 larvæ early the next spring. Not only Arbor-vitæ, but other hedges and a large number of other plants and trees, are attacked. Willows are sometimes almost defoliated, and Poplars are favorites. As the larvæ do not usually wander from the tree on which they hatch, clearing a hedge or tree during the winter means practical exemption from attack in summer.

The caterpillar of the White Marked Tussack Moth (*Orgyia leucostigma*) is a great pest, especially in city gardens and streets. It is recognizable by the bright red head, shining like sealing-wax, and by the thick hair tufts on the back. These caterpillars pupate in a thin cocoon on the tree trunk, on fences, under the sills of windows, on the sides of weather-boarded houses, and, in fact, everywhere that a projection offers even a suggestion of shelter or a hold for the cocoon. The female moths are wingless, and on emerging cling to the outside of the cocoon, upon which they deposit their eggs, covering them with a pure white frothy mass, which hardens and becomes brittle, preserving the eggs from damage during the winter. These egg-masses are easily seen, and should be gathered and destroyed. In Albany, a few years ago, Mr. W. W. Hill induced some of his neighbors to unite with him in gathering the egg-masses on their premises and on the trees in front of their houses; and their trees were the only ones on the avenue that escaped defoliation. Trees that are badly infested with scale insects can be sprayed with the kerosene emulsion during the winter, and most or all of the scales destroyed. There is no foliage to interfere, and every twig and branch can be reached. The emulsion, too, can be used much stronger than is possible at other seasons of the year; the scales are more certainly penetrated and the vitality of insect or egg destroyed. One part of the emulsion to nine parts of water is both effective and safe.

It is in parks and gardens that these winter campaigns can be most successfully carried on. Cleanliness everywhere is of vital importance. Health is as essential to plants as to man to enable them to resist the attacks of insects and of Fungi. Therefore stimulate weaklings where possible, and where they do not respond destroy them. They offer a favorable soil for Fungus attack and a direct invitation to insects. Where these are once established on failing plants the healthy are in constant danger.

The Cracking of Fruits and Vegetables.

THE cracking or bursting of fruits and vegetables during growth or at maturity is often a source of considerable loss. A better understanding of the causes of this trouble might enable us in some cases to use preventive measures. At present it must be confessed that the subject has been too little investigated. It is plain that all instances of cracking cannot be referred to a single cause, and it is quite possible that in some cases the real source of the affection has not been suspected.

In certain vegetables, as the carrot and kohl-rabi, as well as in the potato-tuber, the cracking appears to be the result of a second growth that occurs after some maturing of the tissues has taken place. When a period of dry weather, which tends to premature ripening, is followed by abundant rain, a new season of growth often begins. But the outer layers of cells being no longer capable of growth, the formation of new cells in the cambium region of the vegetable or tuber necessitates a rupture of the outer part, precisely as the formation of a new layer of wood causes ruptures in the bark of trees. The only preventive we can at present propose is the harvesting of the crop before the second growth has gone sufficiently far to cause the rupture.

The cracking of ripe apples upon the tree in wet weather appears to be due in some cases, at least, to the absorption of water through the skin. Ripe apples immersed in water will often absorb enough of the liquid to burst the skin in a few hours. This process has been ascribed to an osmotic action between the juices of the fruit and the water. In an experiment, however, there was no evidence that osmosis had taken place. After soaking an apple in distilled water for several days, during which the flesh cracked nearly to the centre, the water gave no evidence of containing glucose, and showed

only the faintish acid reaction. The preventive in this case is to gather the fruit as fast as it matures.

The cracking of apples and pears during growth is generally due to the Fungus parasite (Fusicladium) that causes the scab upon these fruits. It is, indeed, the advanced stage of this disease. The preventive is to spray the trees early in the season and at intervals thereafter with a solution composed of one and an eighth ounces of copper carbonate dissolved in one quart of aqua ammonia and diluted with twenty-five gallons of water.

The cracking of ripe tomatoes in wet weather is probably due, as in the case of ripe apples, to the absorption of water through the skin. But tomatoes sometimes crack in dry weather and while still immature, which must be ascribed to another cause. Sometimes this appears to result from an unequal ripening of the fruit. In this case a circle of cracks forms about the stem, and the portion of the skin within this circle often remains green after that of the remainder has assumed the color of maturity. The growth of the ripening part proceeding faster than that of the remainder, a rupture takes place between the two portions.

The cracking of melons often seems due to a similar cause. The blossom end of the fruit ripens faster than the stem end, and the expansion of this part causes a bursting of the apex. This difficulty appears to be characteristic of certain varieties. In a large number of seedlings of crossed parentage grown the past season some of the fruits burst from the blossom end almost to the stem, and in some cases the parts curved backward as if the fruit were being turned inside out.

The tendency to cracking of the fruit is apparently due in some cases to a pathologic condition of the plant. In an experiment in breeding the Tomato, a strain of the Cook's Favorite variety grown several generations from unripe seed formed the past season seventy-four per cent. of cracked fruits

Fig. 10.—A Vase of Chrysanthemums.—See page 38.

while the same variety grown in the meantime from perfectly ripened seed formed only 25.3 per cent. of cracked fruits. Both strains were grown under equal conditions except in the selection of the seed. In nearly all cases certain varieties are more subject to cracking than others. A difference in the elasticity or permeability of the epidermis, a difference in the absorptive power of the flesh for water, or of the liability to fungous attack, or of the tendency to ripen unequally, causes certain varieties to resist much better than others the influences that tend to cracking.

University of Wisconsin, Madison. *E. S. Goff.*

Lapagerias.

THE several varieties of *Lapageria rosea* now in cultivation may be counted among the most beautiful of greenhouse climbers, and deserving of the widest recognition. And not only in the greenhouse does their naturally graceful habit appear to advantage, but also in cut flower arrangements they deserve a prominent place, for the flowers are not only of good size but also of great substance and lasting qualities. The original species, *Lapageria rosea*, was of Chilian origin, and was first introduced to commerce by Messrs. Veitch, of London, they having received it with several other noteworthy plants about the year 1847 from that indefatigable collector, William Lobb.

Lapageria rosea may be described as an evergreen twining plant, with dark green, cordate leaves, and pendulous, bell-shaped flowers, the latter being produced from the axils of the leaves along the upper portion of the shoots, and in the type are of a dark rose color, the inner surface of the petals being more or less mottled with a deeper color. Among the variations from the type that known as *L. rosea superba* is a very good one, and is of somewhat stronger growth than the original, and also has brighter flowers. Still another is that known as the Nash Court variety, so called in honor of the establishment in which it originated, and is somewhat similar to the preceding, but claimed to be far superior in point of color and also in floriferousness.

But perhaps the most notable of all the varieties is the white one, *L. rosea alba*, the flowers of which are fully as large as the type, but are pure white in color. This does not appear to grow as rapidly or as strongly as some of the other varieties, at least when young, though after the plant becomes well established there is but little difference. As before stated, the Lapagerias are greenhouse (or cool-house) plants, and it is therefore worse than useless to attempt to force them into rapid growth by means of extra heat, as this will only result in a fine crop of insects of various kinds and in ultimate failure. It is therefore recommended that they be grown in a night temperature of forty-five degrees, and be given abundant ventilation whenever the weather will permit, and as the roots do not like to be confined too closely, the most successful method of growing Lapagerias is to plant them out in a bed prepared for the purpose in the end of the house, the end least exposed to direct sunlight being the best adapted to them. In the preparation of the bed much care should be given to the drainage, this being a very essential point, for while these plants enjoy copious waterings during the growing season, yet proper provision should be made to allow all surplus water to escape. The soil most suitable is largely composed of rough fibrous peat, to which may be added not more than one-fourth the quantity of coarse loam, and a moderate quantity of sand. Some broken charcoal may be added to the mixture, and tends to keep it fresh and sweet. The plant or plants may then be planted out and trained up wires to and along the roof of the house, a very pretty effect being gained by planting the white and rose-colored varieties in the same bed, and allowing their shoots to mingle on the roof of the house, each variety thus used heightening the effect of the other.

The propagation of Lapagerias is chiefly effected by layering and from seeds, the first being preferable where the increase of a particular form is desired, as seedlings are liable to vary. But either method requires some time for its completion, as the seedlings usually take from three to four years (and sometimes more) before they flower. Much stronger plants are secured in the same period of time by layering, and therefore this is naturally the more popular plan. Cuttings may be rooted occasionally, but this is always a long process, and frequently a doubtful one, and as such is not to be recommended.

The Lapagerias are not specially subject to the attacks of insects if they are grown in a proper temperature and thoroughly syringed every bright day (except when in flower), the most common pests to attack them being thrips and green fly, but, fortunately, both of these may be eradicated by fumigating, or by syringing with tobacco-water. Slugs are also extremely partial to the succulent young shoots as they appear above the ground, and must be trapped or otherwise guarded against.

It should also be remembered that during the summer the Lapagerias will thrive under moderately heavy shading—full exposure to our July sun being quite injurious to them.

PHILESIA BUXIFOLIA.—This is also a hard-wooded plant from South America, and is quite closely allied to the Lapagerias, so closely, in fact, that a hybrid plant has been raised between these two genera, to which has also been applied the hybrid name, Philageria. *Philesia buxifolia* is an erect growing evergreen shrub with small leaves, the character of the latter being well denoted by the specific name. It has bright rose colored waxy flowers of moderately large size, bearing some general resemblance to those of the Lapagerias, but having only three petals instead of the six found in the Lapageria.

This Philesia is, I think, the only species of the genus, and is a pretty little compact growing cool-house plant that will flourish under very similar conditions to those noted for the Lapagerias. It may be increased by cuttings, though these root rather slowly.

Holmesburg, Pa. *W. H. Taplin.*

Notes on Some Hardy Wild Roses.—IV.

IN 1887 Professor Crépin described,* under the name of *Rosa Wichuraiana*, an interesting Rose from Japan and China, which gives promise of becoming a very valuable addition to our list of desirable hardy species. Siebold and Zuccarini appear to have previously referred it to *Rosa sempervirens*, a very different species, which is a native of southern Europe and northern Africa. Later it was included by Franchet and Rochebrune with their *Rosa Luciæ*, also indigenous to Japan and China. Although it does not appear that this Rose has ever been put on the market under the name so recently given to it by Professor Crépin, yet as *Rosa bracteata* it is found in the catalogues of some German nurseries, and plants have been received so labeled at the Arboretum.

But in this again we have a very misleading name, because the true *Rosa bracteata* is a very different plant, a native of the more southern portions of China, and so far not known to be hardy here, although it has become naturalized in the far southern states. The name has also been applied to a climbing hybrid with double flowers.

R. Wichuraiana is a low trailing species, and it differs from any other Rose of similar habit in this latitude by the unusually prostrate character of its stems. Other species of trailing or climbing Roses usually grow upward for a foot or two at least before they bend over and trail on the ground, but *R. Wichuraiana* rests on the earth almost as closely as an Ivy, and it has a habit of throwing out little rootlets at various points along its creeping stems if the soil is sufficiently moist. It makes a rampant growth, and will produce stems ten or fifteen feet or more in length in a season. The leaves are composed of one, three, five, seven or nine thick, smooth, shining, stiff, small green leaflets. These are serrate, and generally short, obovate, or almost round and blunt at the apex. Generally more or less scattered along the stems are short, stout, recurved spines, which are easily removed from the young shoots. On the flowering branches the spines are small, few or absent. There are no prickles. The flowers are borne in much profusion in short, broad, somewhat pyramidal clusters on the ends of short branches and branchlets. They expand from one and a half to fully two inches across, and the petals are of a pure white color, the stamens being yellow. They possess a strong fragrance, resembling that of the Banksian Rose more than any other familiar species. The period of general flowering here appears to be from about the end of the first week in July until the end of the month. A few blossoms, however, are occasionally produced throughout the rest of the season. The ovate, deep dull red fruit does not mature until quite late in the autumn, but the seeds are generally ripened without injury from severe frosts.

Rosa Wichuraiana is quite hardy here, and probably its low trailing habit is of advantage to it in withstanding our winters. The terminal portions of the long new shoots frequently do not ripen sufficiently to withstand the cold, and they are consequently destroyed; but, in any case, enough of the stems remain to blossom freely the following summer. On account of its handsome evergreen looking foliage, its beautiful white

* *Bulletin de la Société royale de botanique de Belgique*, tome xxv., 2, pp. 189-192.

flowers, which appear after most other single Roses have done blooming, and for its peculiar habit of growth, this species is likely to prove valuable for planting on rockeries, covering slopes or embankments and the ground among open shrubbery. A little further south it will probably prove to be quite distinctly evergreen, as under some circumstances it retains its leaves throughout the winter here. The plant is one of those which may be propagated by cuttings with the greatest ease.

Through some mistake of German nurserymen this species was sent (under the name of *R. bracteata*) to the Park Department of Boston instead of another kind of Rose which was ordered. In this case, however, the mistake proved not entirely at the expense of the purchaser, for the plants are considered to be quite an acquisition. The experienced superintendent of the planting of parks says of it: "I have planted it on very exposed situations in the Franklin Park; for instance, on the top of the Overlook; and also on the slopes of the Back Bay. It stood the last winter exceedingly well; only some of the softest, latest shoots suffered a little on the tops. The six original plants in the nursery made shoots from ten to fifteen feet long the first season. I covered part of them with leaves the first winter, but there was no difference noticed in the condition of the covered and the uncovered plants in the following spring. This is the third winter I have had them." *R. Wichuraiana* is reported as found in nearly all parts of Japan, where it is said to grow on sandy or gravelly soils, often being met with on the sands near the sea-shore, and having stems which attain a length of thirty or forty feet.

The closely allied *R. Luciæ* has not yet been grown here.

In the European Field Rose (*R. arvensis*) we have the nearest approach to *R. Wichuraiana*, in habit of growth, among the hardy white-flowered species. But the Field Rose is not always fully hardy here, its hardiness apparently varying according to the climate of the region from which it was sent. Plants of it, received under the name of *R. repens*, from one of the gardens of central Germany, have proved nearly as hardy as could be wished. It is a desirable plant for rockeries, banks, and for training on walls and similar situations. As is well known, it is a form of this which is cultivated as the Ayrshire Rose.

Although possessing an interest and charm of blossom peculiar to itself, the Field Rose has a formidable competitor for popular favor in the true *R. multiflora* from Japan, which was so recently described and figured in GARDEN AND FOREST (vol. iii., pp. 404-405). This may be trained to a post or pillar, where it will attain a height of fifteen or twenty feet, making a beautiful show when its panicles of small white flowers are in their fullest bloom. It has been used in hybridizing with other species, and some interesting and valuable variations have resulted from these mixtures.

To the professional Rose-grower, however, *R. multiflora* (or *R. polyantha*, as many insist upon calling it) promises to be a great acquisition as a stock upon which to bud our choice cultivated Hybrid and Tea Roses. At the Arboretum it has been found quite equal or superior to the Dog Rose as a stock, and it has been extensively tried by some French propagators, apparently with much success. Among the advantages claimed for it is the fact that stocks are more easily propagated either by cuttings or seeds, the latter germinating within a few weeks from the time of sowing. The roots are not as inclined to be tap-rooted as the Dog Rose, and they are finer and more fibrous, which especially adapts it for forcing in small pots. Plants budded on *R. multiflora* are more easily forced and come into bloom sooner, the earliness not being at the expense of quality. The record of an experiment, on a large scale, with stocks of *R. multiflora* and the Dog Rose (*R. canina*), given exactly the same treatment and budded with one variety of Rose (Etoile de Lyon), showed that the average was twice as many blooms on the *R. multiflora* stocks, and the flowers were fifteen days earlier.

The only known hardy climbing Rose of our own country, the Michigan or Prairie Rose (*R. setigera*), is not surpassed by any other in showy character of blossom. It has also an added value in the fact that it blooms so late, the flowers being contemporary with those of *R. Wichuraiana*, or at a time when the flowers of nearly all other species have faded. It is unfortunate that, although so handsome, the flowers of the Prairie Rose are not fragrant, a fact which is against its value and popularity. Hybrids have been produced with this Rose, but none of them appear to have much perfume. It seems singular that no fruit ever appears to be formed or matured on the Prairie Rose in cultivation in this part of the country.

Arnold Arboretum. *J. G. Jack.*

Protecting Evergreen Plants.—We have been very fortunate so far this winter with our evergreens, and hardly any plants have suffered from the cold. True, it has not been severely cold; but our evergreen Magnolia plants and Gordonias look quite fresh; much more so than they will later on if they are not covered. From this time to the end of March is the trying period for broad-leaved and some other evergreens. In fact, now is the time to shield them from sunshine and fierce winds. Let a few cold days come now, with snow on the ground and a bright sun shining, and very quickly Yews, Cunninghamias, Euonymuses will show signs of distress. It is not protection against cold, but against wind and sun, that must be given. Provide straw, sheeting, mats—anything of this kind for large plants, and headless barrels for smaller ones. Branches of Pine or Arbor-Vitæ will prove a help. And now is the time to guard small herbaceous plants from being thrown out by frost and destroyed in spring. The slightest covering of leaves will prevent this. The protective value of a mulch for this purpose can hardly be overestimated.

Germantown, Pa. *Joseph Meehan.*

Iris Bakeriana.—It is about two years since Max Leichtlin, of Baden Baden, enriched the Harvard Botanic Garden with this little gem. Herr Leichtlin introduced the plant from Kurdistan some three years ago. The specimen at this place flowered last spring, and is now again in bloom. It belongs to the spring-flowering, bulbous-rooted section of Irises, of which *I. reticulata* is a familiar example. The cylindrical, or semi-cylindrical leaves (some of them are flattened on one side), barely exceeding six inches in height, are of a pale green color and minutely ribbed. The spathed flower-stalks proceed from clusters of these leaves, each one bearing a single flower of the characteristic Iris form and about two and a half inches across. The fall segments are white, spotted and tipped with rich purple, and feather-veined at the base with lilac; the interior segments of a beautiful soft lilac.

In England this plant grows and blooms satisfactorily in the open air, but its hardiness has not as yet been tested here. The only specimen in the garden is considered too valuable at present for the risks of experiment, and, therefore, it has been grown in a pot under the protection of a frame heated to exclude frost. It is a charming subject for pot culture. The roots should be potted in fall and allowed complete rest during the summer months. I have not been able to detect the Violet-like odor attributed to the flowers. The amount of forcing, however, to which the plant is necessarily subjected under pot cultivation, though in this case reduced to a minimum, may perhaps suppress the fragrance.

Correspondence.

Orchids at North Easton.

To the Editor of GARDEN AND FOREST:

Sir.—There is now a magnificent display of bloom in the Orchid houses of Mr. F. L. Ames, at North Easton, Massachusetts. Cattleyas and Cypripediums contribute most extensively to this, but many other genera are represented by a bewildering array of species and varieties. An enthusiast would perhaps consider the new Cypripediums, *C. Niobe* × and *C. Calypso* ×, the most interesting plants of the entire collection. They are very beautiful, and the former has often been alluded to in your columns. *C. Calypso* is a hybrid of *C. villosum Boxalli* and *C. Spicerianum*, the latter being the male parent. Some idea of the amount of bloom which this princely collection affords may be obtained from the statement that about 500 racemes are now showing on the Odontoglossums, besides a considerable number already fully developed. There are a considerable number of seedling Cypripediums, Dendrobiums and Masdevallias, from which the gardener, Mr. William Robinson, expects some good things.

One of the best of the small collections of Orchids in the vicinity of Boston is that of Mr. E. W. Gilmore, at North Easton. The greenhouses are situated but a few minutes' walk from those of Mr. Ames, and visitors to one of the places should not miss the opportunity of inspecting the other. Cattleyas, Cypripediums, Odontoglossums and Phalænopses form the largest part of Mr. Gilmore's collection, and his gardener, Mr. Thomas Greaves, evinces a degree of skill in their culture which is rarely excelled. "We attempt only a little here," said Mr. Greaves, "but that little is done as well as we know how to do it." A good example of the utility of this motto is found here in a lot of *Cattleya citrina*, which, after being six years in cultivation, is probably the finest in existence. There are

peculiar difficulties in keeping this pretty species in healthy condition for more than three years after its importation, as every grower of experience knows. The manner in which Mr. Greaves treats his plants is somewhat exceptional. The plants are fastened to little rafts, and arranged so as to leave a vacant space of about one-fourth of an inch between the pieces. This arrangement is decidedly superior to the block or pot system usually practised, for, as Mr. Greaves points out, it reduces to the smallest margin the possibility of water being retained about the plants. In a half-span house with aspect due north these rafts are hung against the back wall as near as possible to the glass. This brick wall is of ordinary thickness, and close behind it, on a level with the plants, there is a series of hot-water pipes, which convey the heat to other parts of the structure, and are, therefore, always warm in cold weather. When the weather is not extremely severe air is given day and night throughout the year, and in winter the requisite tempera- is uniformly maintained by means of artificial heat. Mr. Greaves believes there is a virtue in keeping the foliage dry during winter, and he considers the lodgment of water about the base of the leaves positively injurious at that season. Hence the plants are then watered by being dipped so as to avoid wetting the foliage. In the warm season, however, roots, pseudo-bulbs and leaves are all freely syringed. Under these conditions the masses of extraordinary large pseudo-bulbs develop a most healthful appearance, and almost every growth now gives promise of flowers in abundance.

Cambridge, Mass. *M. Barker.*

The Proposed Monument to General Grant.

To the Editor of Garden and Forest:

Sir.—I agree with your correspondent, Mrs. Van Rensselaer, that credit is due to Mr. Duncan for including the treatment of the ground in his general design. It will be held, however, by some critics that the monument should be adapted to the park instead of seriously modifying the park to suit the monument. Whether the park shall be cut in two and partially obliterated, while the views up and down the river are obstructed by a stone structure for the sake of a flight of steps which few persons will ever feel disposed to climb, is another question. As a matter of practical moment, I should like to be informed whether the Monument Committee has authority to make such changes in the plans of the park as may seem to them desirable.

New York. *A. W. C.*

[Of course, the Park Board is the final authority in such matters. In the regular course of proceeding for such cases provided, permission is asked for the erection of a given structure, and its plans are offered for inspection. These are referred to the Landscape Architect of the Board, as are all matters affecting the design of the parks. Upon the report of this officer the Board will take action. We believe that a design for this portion of Riverside Park has already been adopted by the Board, which contemplates the erection of a mounument and fixes its location.—Ed.]

The Gardens of Wellesley College.

To the Editor of Garden and Forest:

Sir.—There is always something of interest in the greenhouses here, and for the small area of glass very much is accomplished. Mr. Butler, who came here as gardener to Mr. Durant many years before the college was founded, which commemorates his public spirit, has been gardener to the college ever since it was established. No one without experience would imagine how ceaseless are the requirements of such an institution for plants which are of botanical interest only. Mr. Butler is about to begin the germination of seeds, to show the development of the embryos, which are required, in some cases, in two stages, and for two sets of classes meeting on dates furnished him beforehand. It can be easily seen that to have the embryos in the proper stage at certain dates requires very nice calculation. Mr. Butler has therefore prepared a list or diagram, which is a work of art, giving days or hours, as the case may be, which are required to bring the germinating seeds to the proper state of advancement.

Apart from his botanical work, Mr. Butler finds time and space to grow a few plants well, some to be used for decorating the college halls on special occasions, and some for Mrs. Durant's private conservatory. During the summer one will always find some good Fuchsias, Coleus, Caladiums, Gloxinias, Begonias, Achimenes, and a few choice Orchids in bloom. In fall and winter we find Chrysanthemums, small plants, but extremely well grown, Cyclamens, Cinerarias, Primulas, Camellias and Azaleas, which two latter classes of plants have always been his pride.

Ophiopogon Jaburan, var. *variegatum*, is a comparatively rare and interesting Japanese plant, which I saw here on a recent visit. It has stiff, Iris-like leaves and of slow growth, and is nearly hardy. I have known it many years, but never before had the pleasure of seeing its beautiful indigo-blue, drupe-like seed-vessels. The variegation is in stripes, and is really pretty when the new growth is made, but disappears considerably as the leaves age. For botanical purposes it is useful in representing the *Hæmodoraceæ*.

Among Orchids in bloom now are *Cypripedium* (*Selenipedium*) *Stonei*, very finely colored; *Angræcum Lowi*, a very neat little species with pure white flowers, and *Angræcum eburneum*, sent here for *A. superbum*, which Mr. Butler does not believe it is. I had not observed, until my attention was drawn to it, the peculiar double twisting of the fruiting pedicels, which brings the normally superior, but ordinarily inferior, segment of the perianth back to its normal position, giving the flowers a different aspect altogether from Angræcums generally. All the segments of the perianth, including the spur, are green, with the exception of the (in this case) superior one, which is the purest white. It is a very striking species and a robust grower.

Wellesley, Mass. *H. G.*

Lilium Hansoni.

To the Editor of Garden and Forest:

Sir.—Your usually correct correspondent, E. O. Orpet, is slightly in error, I think, in regard to the first flowering of *Lilium Hansoni*. This Lily was first sent from Japan to Max Leichtlin, Germany, with quite a considerable collection, and flowered with him for the first time outside of its native country. Herr Leichtlin sent some bulbs to the late P. Hanson, an enthusiastic amateur of Brooklyn, and named it Hansoni as a compliment to the friend who had sent him all our American species. At least this is the statement, if my memory serves, which Mr. Hanson made to me.

Floral Park, N. Y. *C. L. Allen.*

Recent Publications.

Three Years in Western China.—A Narrative of Three Journeys in Ssu-ch'uan, Kuei-chow and Yun-nan, by Alexander Hosie. Dodd, Mead & Company, New York.

Mr. Hosie undertook the journeys described in this volume as a member of the British Consular Service, and it is the expansion of reports published in the interests of trade. But incidentally it contains a good deal of information which interests students of botany and horticulture, as well as many graphic descriptions of little known tracts of country. The large map upon which his wanderings are marked shows a course where many a botanist would delight to tread in his footsteps; and though his experiences included almost as many hardships in-doors as out, these were naturally less severe than enthusiasts in the cause of science must meet in totally uncivilized countries. The desire of the British Government to open up these provinces to foreigners, was the inspiration of Mr. Hosie's mission; and undoubtedly the cause of science as well as commerce will soon profit by his efforts, while in the mean time his book will show where the botanist is likely to reap rich harvests and how these places may eventually best be reached.

In the valley of the Yang-tsze near Ch'ung-k'ing, he says, "I first made acquaintance with the Poppy in full bloom. Fields of white and purple equaled in number the patches of wheat, barley and rape. Where the flowers had fallen the peasants, principally women and children, were busy harvesting the juice. The tools used in the operation are simple but effective. Towards evening the peasants may be seen moving in the Poppy-fields, each armed with a short wooden handle, from one of the ends of which protrude three and sometimes four points of brass or copper blades, firmly inserted in the wood. Seizing a capsule with the left hand, the operator, with his right hand, inserts the points of the blades near the top of the capsule, and draws them downward to the stem of the plant. From the incisions thus made a creamy juice exudes which gradually becomes of a dark brown color. This is scraped off in the early morning by means of a short curved knife, and deposited in an earthenware bowl, the contents of which are afterward fired or left in the sun to dry. In this way the weight is reduced about one-half, and the opium is

then ready for boiling. The whole process is simple, and may be accomplished by the women and children of the family, thereby permitting the more able-bodied to attend to the other farm duties, thus reducing the price of labor and consequently the cost of the drug. The bleeding of the capsule is continued until the flow of juice is exhausted." At other points Mr. Hosie found still wider fields of Poppy, and describes whole valleys and hillsides as "one mass of Poppies in full bloom—white, mauve and white tipped with pink being the chief colors."

The way in which, in the highly cultivated districts, every acre of ground is utilized is well explained where Mr. Hosie writes of the same valley where he first saw the Poppy: "The remainder of the valley was occupied by Rice-fields, submerged in preparation for the summer sowing. Sometimes they are allowed to soak for months, their surfaces being frequently covered with floating water-plants, which are afterward utilized as manure. They are likewise stocked with fish. In the early spring reeds and rank grass are cut from the hillsides and made up into small bundles, which are then strung on bamboos, laid down in shallow water in the Yang-tsze and weighted with stones. Here the fish spawn, and the ova adhere to the grass and reeds, which are then taken up and sold. The grass is afterward scattered in the higher fields, between which and the lower water-communication is kept up by digging small outlets, which can easily be filled up at a moment's notice. Here the ova are hatched and good fishing may be had after a few months."

Here Mr. Hosie found the Wood-oil-tree (*Aleurites cordata*), "scattered among the fields, seeming to prefer thin-soiled, rocky ground. It grows to a height of about fifteen feet, and has large, beautiful shady green leaves, which were lighted up as we passed with bunches of small pink-white flowers. It produces a large green fruit like an apple, the large pips or seeds of which contain the oil for which the tree is famous." This oil is used for lighting and in various manufactures, but "the seeds, if eaten, cause nausea and vomiting."

In the province of Ssu-ch'uan sericulture is an important industry, and "every homestead where Mulberry leaves are procurable is engaged in it," the work again being carried on by women and children, and markets for cocoons and opium being held in each little village at intervals of five days. Not only the Mulberry, but the Oak, and, likewise, *Cudrania triloba*, furnish leaves for the worms, and the last is believed to be "particularly suited to the infant palate, the silk produced from such a diet being thought superior in quantity and quality." The hemp of this region is furnished by *Abutilon Avicennæ*, and very heavy crops of wheat are produced by planting at intervals of from nine to twelve inches instead of sowing broadcast.

In Kuei-chow and Yun-nan the writer describes the population as scant and lazy, partly because of the mountainous character of the land and the consequent difficulty of transportation. But wars and insurrections in former days have also played their part, and we read of ruined cities, built of substantial stone, where the inhabitants now live in wattled huts, using the floors of the superfluous houses for vegetable gardens.

When approaching the Yun-nan frontier the author met two new crops, Buckwheat and Oats. "I saw, too, a new method of manuring the fields. For some days I had been puzzled to account for the peculiar growth of certain trees whose branches were very short, and for which I could obtain no satisfactory explanation; but all at once I came upon a peasant hacking off the branches and another plowing them into the Rice-fields." When he reached the city of Ning-yuan, in the plain of Chien-ch'ang, he found that but two foreigners had preceded him. This plain is immensely rich, and, in addition to Mulberry-trees, produces "Rice, Poppy, Cotton Safflower, a variety of fruits, medicine and dyes, Cassia, Beans, Wheat and Maize. . . . Pine boards are also a special export from this region. Immense trees are found embedded in the soil on the hills, their positions being discovered from lines of Pine-sprouts. They are dug up, sawn and sent north in large quantities." Here also is the centre of the famous but hitherto little understood "white-wax industry."

Mr. Hosie's third journey was undertaken with the special view of providing the authorities at Kew with information upon this subject. From its results the so-called "Insect-tree" of the Chinese has been identified as *Ligustrum lucidum*, or Large-leaved Privet. The bark of the branches and twigs of this tree are covered with scales containing infant insects—the White-wax insects. In the end of April these scales are collected and carried by porters across the mountains to Chia-ting, made up into paper packets, which must be transported with the greatest care and speed. West of Chia-ting stretches a great plain of Rice-fields, and here "almost every plot of ground . . . as well as the bases of the mountains are thickly edged with stumps, varying from three or four to a dozen feet in height, with numerous sprouts rising from their gnarled heads. These stumps resemble at a distance our own pollard Willows. The leaves spring in pairs from the branches; they are light green, ovate, pointed, serrate and deciduous. In June, 1884, when I visited this part of the country, some of the trees were bearing bunches apparently of fruit in small pods; but as no flowering specimens were then procurable there still exists a little uncertainty as to this tree. I am informed, however, that it is, in all probability, the *Fraxinus Chinensis*, a species of Ash. This tree is known to the Chinese as the *Pai-la-shu*, or 'White-wax tree.'" When they reach the valley the wax-insect scales "are made up into small packets of from twenty to thirty scales, which are enclosed in a leaf of the Wood-oil-tree. The edges of the leaf are tied together with a Rice-straw, by which the packet is also suspended close under the branches of the Wax-trees. A few rough holes are drilled in the leaf with a blunt needle, so that the insects may find their way through them to the branches. On emerging from the scales the insects creep rapidly up the branches to the leaves, among which they nestle for a period of thirteen days. They then descend to the branches and twigs, on which they take up their positions, the females, doubtless, to provide for a continuation of the race by developing scales in which to deposit their eggs, and the males to excrete the substance known as white wax. Whether or not the wax is intended as a protection to the scales I am not prepared to say. . . . The wax first appears as a white coating on the under sides of boughs and twigs, . . . gradually spreads over the whole branch, and attains, after three months, a thickness of about a quarter of an inch." When the depositing is finished the branches are lopped off, as much of the wax as possible is removed by hand, melted in boiling water and skimmed off, when it is ready for sale. Then the twigs and branches are thrown in the pot to secure the remaining wax, and even the insects themselves are squeezed in a bag. It is this method of boiling, of course, which necessitates each year the importation of a fresh supply of scales with eggs or insects. Each wax-tree receives its burden of scales only at intervals of three years. The wax is used in a variety of important ways, and, mixed with tallow, gives much greater consistency to candles, or, used as a coating, prevents their guttering.

We have but culled a few of the most interesting passages from Mr. Hosie's book without attempting to follow him systematically through his wanderings or to describe coherently the character of the many and very diverse districts he visited. To do this thoroughly would have been almost to quote his book entire, so we may conclude by referring our readers to it as a valuable addition to the literature of travel, and a straightforward, interesting account of some of those few regions of the world which, while rich in interest, are still almost unknown to us.

Notes.

The *Revue Horticole* states that Vilmorin & Co. have produced a double hybrid Cineraria, which will soon be put upon the market.

The school children of California are to make a collection of the wild flowers of the state, which will be exhibited at the World's Fair in Chicago.

Mr. C. B. Waldron has been appointed Professor of Forestry and Horticulture in the North Dakota Agricultural College, and Mr. H. L. Bolley, Professor of Botany.

It is said that the Berlin authorities have issued a caution against the use of dried mushrooms, many cases of illness having been attributed to the presence among them of poisonous species.

M. Délaux, well known as an introducer of Chrysanthemums, announces, among the novelties of the year, a collection of early flowering varieties which were highly commended at the exhibitions last year.

According to a report published in *Popular Gardening*, the total shipments of apples from this country to England during the past season and up to date of November 17th amounted to 192,000 barrels, as against 305,000 barrels shipped up to the same time in 1888.

Tom Thumb Dahlias is the name given to a dwarf strain of these plants which have been produced by Mr. Girdlestone, Secretary of the National (England) Dahlia Society. The plants

are only from nine to twelve inches high, and will probably prove valuable additions to the list of bedding-plants.

In a paper on the cultivation of Roses, read at the last weekly meeting of the Massachusetts Horticultural Society, Mr. John N. May, of Summit, New Jersey, said: "Twenty years ago possibly five thousand Roses a day was the limit of supply for New York City; now as many as fifty thousand a day can often be found there, and in the spring of the year the number may reach a hundred thousand a day."

It is reported in the *Popular Science Monthly* that Professor Geddes, of Edinburgh, in consequence of recent investigations, has been led to reject "the commonly accepted views of the origin of thorns. He has found that there is a more or less developed general contrast in vegetative habit between thornless and thorny varieties. The thorny varieties or species show a more diminishing vegetativeness than their thornless congeners; in fact, they frequently develop their thorns by the actual death of their germ points."

In an account of Japanese Pear-orchards, recently published in the *American Garden*, Professor C. C. Georgeson said: "The heaviest item of expense is for the destruction of insects. Using no poisons, and having no spraying-pumps, the work is done by hand. A moth lays its eggs in the flower at the base of the pistil, and the larva is removed as soon as it hatches, before it has buried itself in the young fruit. This is delicate work, and, as I was told, could not be trusted to women and children, who could be had cheaper than men; but the work richly repays the outlay."

French journals state that the great Grape country of Champagne, which as yet has been free from the phylloxera, is now threatened by the dreaded pest. In the commune of Tréloup in the Department of Aisne, and close to the borders of the Department of the Marne, several colonies of the phylloxera have recently been discovered, and although, of course, the most energetic measures of isolation and extermination were at once begun, there is great alarm lest the Marne districts—the great champagne-producing lands—may be infected, as a brisk trade has been carried on by them in the importation of Vines from the now infected village of Tréloup.

In his recently published article on southern California, Mr. Charles Dudley Warner says that the new City of Riverside occupies an area some five miles by three, and that "one avenue through which we drove is 125 feet wide and 12 miles long, planted in three rows with Palms, Magnolias, the *Grevillea robusta*, the Pepper and the Eucalyptus, and lined all the way by splendid Orange-groves, in the midst of which are houses and grounds with semi-tropical attractions. Nothing could be lovelier than such a scene of fruits and flowers, with the background of purple hills and snowy peaks." Yet in 1872 there was only a "poor sheep ranch" where this city of some 6,000 inhabitants now stands.

A "Flower-girls' Guild" was established not long ago in London by certain charitable ladies with a view to improving and cheering the lives of the many girls who sell flowers in the streets at all times of the year. The first step was to provide the often half-clothed girls with warm dresses and bonnets, which are of a special cut and color—gray, trimmed with scarlet—as the idea of a "uniform" is, in England at least, attractive to all members of the poorer classes. Water-proof cloaks for stormy weather were also provided, and in a building set apart for their use they find dressing and washing rooms, and a cool, well-ventilated place in which to store their flowers at night. In the future a sick-relief fund will be established as well as evening classes and entertainments.

At a recent meeting of the Massachusetts Horticultural Society the Harvard Botanical Garden sent a flowering specimen of *Hippeastrum aulicum*. This species was introduced to cultivation from Brazil in 1810, and is interesting chiefly as being one of the plants employed to produce by hybridizing and crossing the splendid varieties of this genus now in cultivation. The flowers of *H. aulicum* are red, green and purplish, between six and seven inches across, with the edges of the segments more or less incurved. When compared with those of some recent varieties they show clearly the improvement which has been made in these plants. The flowers of the variety John Ruskin, for instance, measure from eight to nine inches in width, with broad, flat, imbricate segments. The shades of color have been increased in recent forms to a wonderful extent, and in most cases these shades lack that coarseness which is found in many of the original types.

Over 1,000 persons met in the hall of the Museum of Natural History on Saturday at the call of the New York State Forest Association. Morris K. Jesup, the President of the Association, was in the chair, and effective addresses were made by Honorable Warren Higley, Assistant United States Treasurer Ellis H. Roberts, A. W. Gleason and Rev. Dr. Lundy, President of the Pennsylvania Forestry Association. William Potts, Chairman of the Executive Committee of the Association, offered resolutions to the effect that it is essential for the state to have absolute control over enough of the wilderness to preserve the sources of the streams which rise therein, and that until this control is established the Legislature should take measures to minimize the destruction of the timber in this region. To this end it was urged that laws be enacted to prohibit the building of railroads over state lands and the building of dams which should cause the overflow of these lands, and for increasing the efficiency of the state control in preventing forest-fires, in punishing trespassers, in rewooding denuded lands and introducing practical forest-administration. The resolutions were seconded by Ex-President Cleveland, who counseled moderation in asking for appropriations, and suggested the expediency of gaining the co-operation of clubs and other property-owners in the Adirondacks. The meeting was altogether the largest and most enthusiastic one ever held in this state in the interest of forest-preservation.

"Never throw away a morsel of an Orchid-plant capable of growing until it has flowered, even if you are obliged to wait for years for this event." Such is the advice which Monsieur G. Miteau gives in a recent issue of *Le Journal des Orchidées*, basing it on his own experience, which he tells as follows: "Four years ago, when I began to cultivate Orchids, one of my friends gave me a lot of small bits of a large number of species. Among them were some so miserably small and unpromising that my friends advised me to throw them away, declaring that I should be forced to wait ten years without seeing a flower, even if they ever flowered at all. Among these scraps of plants was a little bit of *Lælia purpurata*, whose life appeared to hang by a thread. I do not know why I did not follow my friends' advice and throw these miserable specimens away. I did not do it, however, and the first year my *Lælia purpurata*, which had been condemned by the Faculty, produced a little shoot and a minute bulb. The second year it produced two bulbs stronger than that of the preceding year. At last, the third year (it was not to flower for ten years at least), it produced four flowers from a comparatively strong bulb, and produced a second shoot strong enough to lead me to hope for two flower-shoots the following year, and now it turns out that the variety is a remarkable, new and beautiful one. I exhibited it at one of the meetings of L'Orchidéenne, and it obtained a certificate of merit of the first class, receiving the name of *Lælia purpurata*, var. *Nolisi*. Some of the other bits flowered before the Lælia, some at the end of the year, others not until a year later. All the others are in good condition, and will doubtless flower next year."

Catalogues Received.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, FEBRUARY 4, 1891.

TABLE OF CONTENTS.

The Adirondack Reservation.

THE meeting held in the Museum of Natural History ten days ago at the call of the State Forestry Association surpassed in numbers and earnestness any similar gathering heretofore held in this city or state. This evidence of a strong and growing popular sentiment is gratifying, because it is the only power which can compel appropriate forest-legislation or enforce forest-laws after they are enacted. The people are slowly learning that they have in their forests a possession of inestimable value, and they are awakening to the truth that their preservation is essential to the national well-being. They are beginning to realize, too, what all experience has proved, that forests in private hands are certain to deteriorate even in countries where their value is recognized, where the proper methods of managing them are understood and where men schooled and skilled in the practice of forestry can be secured to take charge of them. If the remnant of the North Woods which still stands is to continue to do the beneficent work of preserving the streams that flow out of them, and ministering to the health, comfort and prosperity of our citizens, the state must ultimately take charge of them. The state, with its continuous life, its comprehensive concern for the good of all, its ample capital, its purpose which can be held steady from generation to generation, can alone be trusted to administer this property to the highest advantage of the community.

But how and when, and within what limits, the state shall acquire the fee of these forests, are questions of expediency which need ample discussion. The State Commission have prepared one or more bills for the establishment of a park, which we have not seen at this writing. The State Forestry Association are preparing other bills. Certain clubs are advocating still further legislation. It is not intended here to examine these proposed measures or to pass judgment on any of their provisions, but simply to say that in many particulars these provisions clash, and they cannot all be right. Whether the state is to buy the entire tract at once and outright, or to invite clubs and individual owners to retain their proprietorship under such conditions of management as it provides for its own forests; whether it is to buy land and leave the privilege of cutting timber to lumbermen or to work the woods itself and make the profit on its forest-products offset the interest on the bonds issued for the purchase of the park; whether railroads are to be stringently prohibited from entering the reservation or admitted under restrictions; all these and a hundred more questions must be faced. Meanwhile, as the demand for the park grows stronger, the owners are raising prices, and a million dollars of purchase-money will buy only a tithe of the land it would have bought twenty years ago.

Some manifestations at Albany are not such as to encourage the hope that an immediate or satisfactory adjustment of these important matters is probable. The State Commission has been charged with inefficiency and with subordinating public interests to personal ends. On the other hand, the Governor, who appointed the Commission, is said to be plotting to undermine its influence for political purposes. Let us hope that both charges will be proved baseless. But, while there is investigation and recrimination, confidence languishes. Before great sums of money are appropriated there should be absolute faith in the integrity, the public spirit and the business capacity of the agents who are to use it. It is a good time now for the people of the state to let their representatives know that they are expected to give their best thought to these problems and make some genuine progress, even if it is slow. If but few steps are taken, let them be made in the right direction—steps which will not need to be retraced.

One thing, at least, our legislators should bear in mind. The state should show itself competent to take care of the lands it already possesses while it is preparing to acquire more. Not another week should be allowed to pass without the enactment of a measure to prohibit the construction of any railroad across the state lands. The building of any dam which may cause the overflowing of state land should be forbidden with equal promptness. When these laws are passed and more stringent measures are taken against fires and trespasses upon its own lands, the state can ask with greater assurance for the enlargement of its property.

OF the extravagant methods which prevail in the United States none certainly exceeds in extravagance that under which the turpentine industry of the south is conducted; and there is no business connected with the products of the soil which yields so little return in proportion to the destruction of material involved. Mr. W. G. Cooper, in discussing in a recent issue of the *Southern Lumberman* the forest-wealth of the state of Georgia, calls attention again in a forcible manner to the lamentable results which have always followed the manufacture of turpentine in this country. The Pine-forests of Georgia once represented fabulous wealth; they were not surpassed by those of any other region, and could they have been wisely husbanded would have made Georgia one of the richest states in the Union. Mr. Cooper estimates that of the $400,000,000 worth of pine now standing in them, forty per cent., or $160,000,000 worth, have been killed by the turpentine-farmers, as the men are called who tap the Pine-trees. There are, it is said, stills enough in operation in the state to use up the remainder of the timber in seven years; and yet all that is paid for the privilege of destroying the value of the trees is seventy-five cents to a dollar an acre, or $5,000,000 for the destruction of forests which in fifteen years of good management might, it is safe to say, produce $150,000,000 worth of lumber and naval stores without seriously diminishing their productiveness. The men who carry on the turpentine industry do more damage than the lumbermen. The latter leave small trees, generally all those which do not measure ten inches across on the stump. The turpentine-farmers, however, take every-

thing they see, big and little, and once the resinous surface of the tree is exposed, fire is almost certain to finish the damage the axe of the turpentine-farmer has commenced.

It appears from a recent investigation made of the area and condition of the Georgia Pine-forests that 266 turpentine stills are in operation in the state. The farms necessary to supply one still will use up 15,000 acres of timber in three years, and it is believed, at the present rate of operation, that the Georgia Pine-forests would be ruined in twelve years even if a single acre had not already been boxed. But as four-tenths of the trees have been boxed, seven years, at the present rate the destruction is going on, will steal away, Mr. Cooper believes, the life of every Pine-tree in Georgia. It is only necessary to examine the condition of the Pine-forests in eastern North Carolina, where the turpentine industry was first established and has thus been longest practiced, to realize the effect it has on our forests, and the soundness of Mr. Cooper's views. Wilmington, which was once the most important shipping-point in the world for naval stores and the principal shipping-point for southern hard pine, has now lost entirely its commercial importance as a point of distribution for forest-products, the North Carolina Pine-forests being no longer a considerable or even an important factor in the country's supply.

The erection of the Battle Monument to be placed at West Point near the verge of the beautiful bluff whence one looks northward upon the river, has been entrusted to Messrs. McKim, Mead & White, of this city, after a competition, in which the judges were Mr. R. M. Hunt, of New York, and Mr. Arthur Rotch, of Boston, architects, and Mr. St. Gaudens, sculptor. Messrs. McKim, Mead & White, in the memorandum presented with their drawing, said:

"In preparing the design, we have most carefully considered the object of the monument and the site which it is to occupy.

"We believe the monument should be first and foremost a martial one, distinctive in its character and impressive in its design. The beauty of its site and the surroundings seem to us to preclude any bulky or massive treatment, and to suggest rather a treatment where the impression should be produced by height supported by a base which should not interfere with graceful and artistic treatment. For this reason, we have adopted as the feature of our design a single monolithic shaft treated in the shape of a memorial column or column of victory. This form seems to us to be more distinctively martial than any other, and in this form we believe it is possible to obtain impressiveness and dignity without a sacrifice of grace, at the same time preserving a distinctively architectural and monumental character. We lay great stress upon these two points—namely, the necessity of giving the monument a martial character and the relation of the monument to its site. In our design we have had these two points continually in mind with results which you must judge. The shaft is a monolith of polished granite forty-six feet high and five feet six inches in diameter. To the best of our belief it would be the largest polished shaft in the world. It is proposed to surmount it with a figure of Victory and surround it by eagles—a distinct mark of its national character. The shaft rests upon a circular base surrounded by flights of steps, giving the greatest dignity possible to the base. The materials are the most enduring—granite and bronze.

"The estimate for the cost of the monument assumes an expenditure of $50,000 in addition to the value—$5,000—of certain bronze cannon donated for the purpose by the Goverment. It is hoped that the monument will be completed during the course of the coming summer."

The other competitors were Messrs. Babb, Cook & Willard, of New York, whose design showed a Doric column of polished granite, surmounted by a bronze figure, and set upon a raised platform with exedras on two opposite sides; Mr. W. R. Emerson, of Boston, who proposed a triumphal arch of white marble, flanked by a colonnade, and resting on a platform; and Messrs. Carrère & Hastings, of New York, who again proposed a columnar shaft. Their memorandum said (and the point they raise is worth noting in view of the very lofty proportions of the column designed by Messrs. McKim, Mead & White): "In our opinion, on the site chosen, with no background other than the sky and distant scenery, whatever the character of the monument may be, its seeming proportions will so change—apparently lessening in diameter without lowering in height—that it will need some kind of decorative background between it and the landscape. Moreover, while the height of a classic column of such an order as we have studied, if introduced into a building, should be equal to nine diameters, we are persuaded that, standing by itself, it should have seven and a half diameters, and this fact is illustrated in many examples, conspicuously in the Column of Trajan, in Rome, and in the Columns Vendome and La Bastille, in Paris. To illustrate further the principle of having something between the monument and the landscape: a monument in a public square, amid buildings or other surroundings, reveals its true proportions and looks better than it would in a large park. We have, therefore, suggested a decorative colonnade as shown on plans. The shafts of the columns and piers, as also the friezes of this colonnade, would give the space asked for in the programme, to receive the names of the officers and non-commissioned officers who fell in the war."

Dahlias in Mexico.

Heeding the suggestion of an English botanist, I gave, on my latest journey in Mexico, the home of the Dahlia, special attention to this genus, and for the effort was well rewarded as usual. Two new species were brought to light to be added to the half-dozen already known and in the hands of cultivators. These are *Dahlia pubescens* and *D. dissecta* of Watson.

D. pubescens was found on calcareous bluffs of prairies bordering the valleys of small streams in the state of Mexico and to the north of Toluca. The plant struck me at first sight as very distinct in habit from the species I had frequently encountered, the parents of most of our garden varieties; for it is smaller, only one and a half to two feet high, and more strict, the leaves, pinnately parted with narrower and more numerous divisions, being, like the fewer branches, more erect. This strict appearance is further increased by the flowers being held vertically by erect peduncles. The flowers are two or three inches broad, with a yellow disc surrounded by about eight rays, which are purple, with lines of deeper color, but change with age to light purple or dull rose. The tubers are comparatively small, only one or two inches in length, and vary from round to oblong in shape.

D. dissecta was discovered growing on limestone ledges of mountains fifty miles east from San Luis Potosi. It is a very unique species, being scarcely more than two feet high and of bushy habit from an almost woody base. Its leaves are bipinnate, sometimes tripinnate, with numerous divisions only one or two lines wide, smooth, dark green and somewhat fleshy. The flowers are raised above the foliage on peduncles a foot long; they are two or three inches broad with about eight mauve-colored rays. All my breaking up of the rocks, in whose seams the roots of this plant were hidden, failed to bring to view any tubers; doubtless, it is only to be propagated by seed and by division of the perennial branching base, from which arise the very leafy annual flowering branches. Owing to its peculiar habitat this must be a very local species.

Working southward from the boundary slowly and somewhat carefully, I have as yet only reached the latitude of the capital at various points within the states of Mexico, Michoacan and Jalisco; hence I have so far met with only two of the old species of Dahlia, *D. coccinea* and *D. variabilis*, those earliest known and most varied and combined under cultivation.

Of these *D. coccinea* has the more northerly and by far the most extensive distribution. From the Cordilleras of Chihuahua, within 200 miles of the United States Boundary — probably much nearer, and possibly within the limits of the United States on the Chiricahua Mountains of Arizona—it ranges southward through the mountains to Jalisco in a purple flowered variety, and was seen again in the adjoining state of Michoacan in a yellow variety. On the eastern side of the country, also, it was found from the mountains of Coahuila to those surrounding the Valley of Mexico. On this line the colors shown were scarlet varying through orange to lemon yellow. The size of its flowers in the wild state varies from two to three or four inches in breadth, and the stature of the plant from three to six feet or more. Its habitat has been given as "sandy meadows" (probably the alluviums of streams was meant), but I have rarely seen it growing except in the thin, dry soil of ledges—even in the crevices of bare ledges—or (quite commonly) among the broken rocks which form, with a little soil, the talus of cliffs, either mountain walls or cañon walls. A sight of its bright flowers is cheering to the

collector when he is struggling with the difficulties of such situations as these.

D. variabilis was not met with until I had reached the state of Mexico. On the sides of ravines among the foot-hills of the mountains that rim the Valley of Mexico it was seen in abundance and perfection, a royal plant, coloring the slopes with its profuse purple blooms. Many of the flowers measured five inches in breadth. The height of the plants varied from three to six or eight feet. Near by, but far less abundant, *D. coccinea* was growing on the bluffs of streams, the plants here showing the largest development. It added interest to these two plants, as I admired them, to reflect that it was from this vicinity, quite likely, that seed was obtained a little before 1789 to send to the Botanic Garden of Madrid, and again in 1804 by Humboldt. Amidst the enterprise of the present century it seems incomprehensible that the Spaniard, who admires all things that are beautiful, should have been in Mexico 270 years before sending home plants so striking as these.

Walking among these wild Dahlias day by day, admiring the symmetry of their single flowers and the rich contrasts of scarlet and gold displayed by the disc and rays of the one, and of purple and gold shown by the other, the aversion which the botanist feels for the monstrous forms of flowers produced in gardens was intensified in me; and it was with much satisfaction that I learned afterward that single Dahlias are now receiving far more attention among cultivators than double ones. As yet, however, it is only the older double sorts that are seen in Mexican gardens.

After improving this large opportunity to study these two species in their wild state—and probably these are the two most closely related of all which botanists have recognized—I marveled at the audacity shown by the late Mr. Shirley Hibberd when he declared at the Dahlia Show held at Chiswick last autumn that, in his opinion, there was no good ground for admitting more than one original species. If he should be able to refer *D. coccinea* to *D. variabilis*, could he so dispose of such extreme species as *D. imperialis* or *D. scapigera*, not to mention this new *D. dissecta?*

Charlotte, Vt. *C. G. Pringle.*

Plant Notes.

Prunus ilicifolia, var. occidentalis.

THE relegation of the plant to its proper place seems to have been attended with some difficulty, and as regards the authority for the name under which it first appears there has also been more or less question by botanists who have lately noticed the species. So far as I know, Mr. W. S. Lyon published the first account of the plant in the *Botanical Gazette* (xi., 202, 333) in 1886, referring it to *Prunus occidentalis* of Nuttall, a name which cannot be found, and very probably was never used by Nuttall, and if at all, as Professor Greene has fitly remarked, Nuttall would more likely have used it under Cerasus, holding, as he did, the sections of Prunus, as now understood, to be separate genera.

Professor Greene gives the next account of this plant in his "Notes on the Botany of Santa Cruz Island" (*Bull. Cal. Acad. Sc.*, ii., 7,395, 1887) under *Prunus occidentalis*, and failing, as others have, to find that the name was of Nuttall, properly cites Lyon as the authority.

The next mention is by Mr. T. S. Brandegee in his "Flora of the Santa Barbara Islands" (*Proc. Cal. Acad. Sc.*, ser. 2, i., 2,209, 1889), where it appears as *Prunus ilicifolia*, Walp., var. *occidentalis* (Lyon) (=*P. occidentalis*, Lyon). Professor Sargent (Garden and Forest, ii., 400) approves the disposition of the plant in relating it to *Prunus ilicifolia*, and advises that Mr. Brandegee's name be taken up, although very properly adding that *occidentalis* is nevertheless unfortunate, in view of the West Indian species, which bears the same name.

It appears now, however, that the term *occidentalis* is no longer tenable in its application to this plant, either in the rank of species or variety, as, in 1800, Swartz applied it to a West Indian species of this genus ("Fl. Ind. Occ.," ii., 925), a fact which should preclude its further use in the case of our California insular variety, and hence leaves this plant without a name.

I have thought best, therefore, to designate this variety as *Prunus ilicifolia*, var. *integrifolia*.

The following characterization of this variety is drawn chiefly from Professor Greene's remarks (*l. c.*) under *Prunus occidentalis*, Lyon:

Leaves evergreen, glossy, three to four inches long, two to two and a half inches broad; mostly ovate-acuminate, rarely lanceolate-acuminate, and three inches long by three-fourths of an inch broad, sometimes broadly ovate and abruptly acute, with spinose-serrate margins, usually entire or remotely denticulate. Inflorescence racemose, flowers white. Fruit dark red-purple, orbicular, three-fourths of an inch in broadest diameter, slightly compressed laterally and with a well-marked suture on one side; pulp thin, sweet, with bitter almond flavor. Fifteen to twenty-five feet high, bark rough and dark colored, crown compact and well rounded.

As occurring on Santa Cruz Island it is described as resembling a large bush with several trunks from the same root; while on Santa Rosa a single trunk sometimes reaches a height of fifteen feet before branching. Mr. Brandegee mentions a large tree near San Francisco with a diameter of more than two feet, and that in the Santa Inez Mountains it reaches six inches in diameter.

Professor Greene adds that the narrow-leaved form is only occasional, and that the spinose-serrate foliage belongs chiefly to young trees.

Mr. Lyon (*l. c.*) states that in parts of Santa Catalina Island this tree is characteristic and conspicuous in its beauty, occurring on the interior mountain ridges at 3,000 feet elevation, as well as in the rich valleys and cañons to the water's edge. Professor Greene reports it from Santa Cruz Island, where Mr. Brandegee examined it, as well also as on Santa Rosa, where it is confined to the bottoms of cañons.

Washington, D. C. *George B. Sudworth.*

New or Little Known Plants.

Viola ocellata.

THIS pretty Violet (Fig. 13, p. 55) is closely related to our common eastern Canada Violet (*V. Canadensis*). It is a native of California, where it is found growing under the shade of the forests of the coast ranges from the northern borders of the state to Monterey. It has the leafy stems of its eastern relative, and very much the same habit of growth, and the same cordate, pointed, serrate leaves. The petals, however, instead of being white faintly tinged with violet, as in that species, are more gaily colored. The two upper are white on the inner surface and deep purple-brown on the outer, while the others are yellow veined with purple, the two lateral with a purple spot near the base and slightly bearded on the claw.

*Viola ocellata** has been known to botanists for a long time. It has not probably, however, been often cultivated, although well worth a place in those gardens in which plants with pretty and delicate flowers are valued.

Juglans Vilmoriniana.

THE tree whose portrait appears in the illustration on page 53 was planted as a young seedling by my grandfather in his garden at Verriers, near Paris, as a memorial of the birth of his oldest son. Nothing is known of its origin. It is supposed, however, to be a hybrid between the European Walnut and the American Black Walnut. Such, at least, was the opinion of the late Dr. Engelmann, and his conclusion seems fully sustained by an examination of the characters of the tree. The branches are more upright than those of the European Walnut. The bark of the trunk is grayish, with regular vertical rather remote furrows; that of the two to four-year-old branchlets is dark brown and smooth, the young shoots being slightly pubescent near the buds, and the color of Florentine bronze. The buds are enclosed in brown, somewhat fleshy, hairy scales. These characters are almost intermediate between those of the European and of the Black Walnut. The leaves and the fruit are intermediate in character, too, between the supposed parents. The leaves of *Juglans Vilmoriniana* are usually composed of five pairs and a terminal leaflet, the last being somewhat larger than the others. They are ovate, slightly coriaceous, smooth, dark green, and remain on the branches until killed by frost. On the whole, the leaves resemble those of the English Walnut, but with one or two additional pairs of leaflets and

**Viola ocellata*, Torrey & Gray "Fl. N. Am." i., 142.—Hooker & Arnott, "Bot. Beech," 325.—Brewer & Watson, "Bot. Cal.," i., 56.—Gray, *Bot. Gazette*, xi., 291.

with a slight difference in their shape. The fruit, which is not produced every year, and never in large quantities, is smooth. The shell of the nut (figured below) is thicker and more deeply furrowed than that of the European species. The fruit germinates well and produces plants resembling the parent. The original tree has grown very

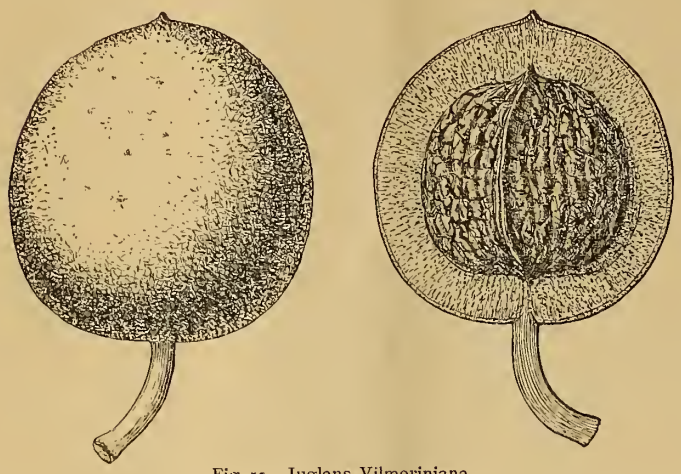

Fig. 11.—Juglans Vilmoriniana.

fast, and, although not more than seventy-three or seventy-five years old, is now seventy-five to eighty feet high, with a trunk-diameter of forty inches three feet from the ground.

Of the few seedlings which have been raised from this tree one is growing beautifully at Segrez, in the Arboretum of Monsieur Lavallée, and produces fertile nuts. All the seedlings have grown thriftily when planted in deep sandy soil mixed with clay.

Is it to be supposed that the fine tree at Verriers is the first-born of its race? So it would appear from the fact that no older specimen is known. Is it probable, however, that the planter would have selected a tree to commemorate an important event in the family history, and to occupy a specially favorable location, unless he had some idea of what it would become in time? Were its peculiarities and value known to him? To this there is no clue. It is not, however, customary in France to plant the European Walnut as an ornamental tree in parks and gardens, and it is more probable that this particular tree was planted for a Black Walnut and selected from a lot of seedlings as being larger and stouter than the rest, a chance cross having caused these conditions. This, perhaps, is the least improbable hypothesis of the origin of *J. Vilmoriniana.*

Paris. *M. L. de Vilmorin.*

Foreign Correspondence.

London Letter.

Hollyhocks.—These noble border plants are attracting considerable attention amongst English cultivators. Mr. Douglas' interesting paper upon them, read before the Royal Horticultural Society in August last, and noticed in Garden and Forest in September (p. 454), drew public attention to them, and a paper on the best varieties by Mr. George Steel in this week's *Journal of Horticulture* is certain to do much toward creating a reaction in England in favor of the Hollyhock as a garden plant.

Twenty years ago the Hollyhock was as popular as the Dahlia is now, and it was not until the appearance of the destructive Fungus (*Puccinia malvacearum*), which destroyed many collections, and appeared to make the cultivation of the Hollyhock almost hopeless, that the plants lost favor. A prospect of overcoming the attacks of this pest by means of various simple remedies, such as soot, lime, Condy's Fluid and weak solutions of sulphate of potash, makes it less formidable to growers than it was a few years ago, and next year will probably see the Hollyhock reinstated among the most popular of summer-flowering plants.

Mr. Steel has been to considerable pains in obtaining, by means of a sort of census among Hollyhock fanciers, a return of the best kinds now in cultivation. Altogether he has no less than 400 named varieties recorded. Of this number, however, only fifty-two are included in his select list, from which I take the first dozen, placed in their order of merit as shown by the returns:

Grace Darling (rosy salmon), Robert Ryle (carmine-red), Maggie Bain (rosy peach), F. G. Dougall (rosy purple), Le Grand (salmon-flesh), John Findlay (vivid crimson), Lord Decies (dark crimson), Mrs. G. Steel (peach, shaded rosy salmon), Agnes Ryle (yellow, stained carmine), Perfection (silvery flesh), Queen of Yellows (bright yellow), Alba superba (pure white).

While many of the florists' ideal varieties of Hollyhock are such as would be admired by the less-exacting horticulturists, I may say a word in praise of common seedling single-flowered kinds. In a garden attached to my house there has been for the last three years a large clump of a single-flowered, rose-colored kind which pushes up annually at least a dozen stems, each about seven feet high, and for at least half their length clothed with flowers. This clump gets no special treatment, yet it grows vigorously and knows nothing of the fatal Puccinia. No doubt the highly bred kinds are exceedingly delicate. They are all the progeny of one species, namely, *Althæa rosea*, a native of Asia Minor.

Phrynium variegatum.—Writing to the *Gardeners' Chronicle*, Mr. Ridley, Director of the Botanic Gardens, Singapore, states that this plant, which M. Linden distributed a few years ago under the above name, has long been in cultivation in Singapore, where it is known as *Maranta arundinacea variegata*, or the variegated Arrowroot. It was obtained by M. Linden's collector from the Singapore Botanic Gardens.

Crossing Chrysanthemums.—I have repeatedly read of the production of so-called hybrids from garden Chrysanthemums, but I have never yet seen one that could not have originated as a seedling sport, uninfluenced by any foreign pollen whatever. I see you have in America also growers who profess to be able to cross one variety with another with certainty. I wonder how it is done? Can any one take, say, Queen of England and Edwin Molyneux, and produce from them a true cross, or would not seeds from either produce all kinds of variations or sports? Mr. A. Forsyth, who was a great raiser and distributer of Chrysanthemums, said, eighteen years ago: "Permit me, in all sincerity and politeness, to say that hybridizing the Chrysanthemum is fudge. Take your seed as you get it, and with it take your chance of the crossing Nature has accomplished for your benefit, but do not suppose that any one less gifted than a magician can manipulate the flowers of the Chrysanthemum with the certainty that we operate on the flowers of the Geranium and Fuchsia." There is much talk here of "intelligent crossing," "judicious selection of the varieties to be operated upon," etc., but much of it means no more than the assurance of the raiser of hybrid Ferns that he "effected a cross by carrying the two kinds of spores mixed in his pocket."

London. *W. Watson.*

[There is much truth in this criticism, and in many cases there is no foundation for the claim that the parentage of a new Chrysanthemum is absolutely known. But this is equally true of many other hybrid and cross-bred garden plants. And yet it is not safe to assert that there can be no assurance of pedigree in given instances, even of cross-bred Chrysanthemums. A few American experts make use of devices and appliances which seem to reduce the uncertainty to a minimum. We hope to give an account of the most approved practice in this direction in an early number.—Ed.]

Cultural Department.

Experiments in Treatment of the Diseases of Plants.

The reports of experiments made in 1890 in the treatment of diseases of plants at the several stations which are directed by Professor B. T. Galloway, Chief of Division of Vegetable Pathology, United States Department of Agriculture, may not be published until late in the spring of 1891. Meanwhile a synopsis of the results of work at the Vineland, New Jersey, station may be of immediate interest.

The experiments made at Vineland were chiefly directed to comparing the values of various solutions of copper in their use as preventives of fungous disease. If it is learned which is the best of these solutions, this one can be recommended for general adoption. It is probable, however, that there is no universal remedy, and yet it is important to know

Fig. 12.—The Original Specimen of Juglans Vilmoriniana.—See page 51.

definitely the various specifics for the various plant-maladies which need to be prevented or cured. Copper is one of these specifics. It is more generally antidotal to the Fungi which cause injury to plants than any element hitherto tried. In France some years ago the discovery was accidentally made that sulphate of copper is preventive of many Fungi injurious to the Grape. This is verified by repeated experiments in the United States, and it is further learned that other preparations of copper are also fungicides. For prevention of the mildews of the Grapevine I have in 1890 tried with satisfactory results the carbonate of copper and the acetate of copper.

What is known as the Bordeaux Mixture still proves to be the most reliable preventive of the Black Rot of the Grape.

The formula of this mixture has been widely published, and should be generally known, yet I have so many letters of inquiry concerning it that it may be well to print the recipe again: Take six pounds of copper sulphate, pulverized, and dissolve it in sufficient boiling water, and six pounds of unslaked lime, dissolved in cold water. Four gallons of hot water is enough to dissolve the sulphate, and six gallons of cold water is enough to slake the lime. When the two solutions have cooled mix them, and dilute this mixture with cold water enough to make twenty-five gallons of the liquid in all. Mix well, then let the mixture rest for a few minutes, so that the coarser particles of lime may settle. Then draw off the superincumbent liquid (which will resemble milk of lime) for use in the spraying machine. When used in spray this liquid should carry with it its chemical contents—that is, the mixture must be kept stirred. The treated plant after it is sprayed with the mixture should appear as if thinly whitewashed. This whitewash after it has dried or "set" will remain on the plant quite persistently; more so on the fuzzy surface of leaves than on the smoother skin of the grape. I have seen the Bordeaux Mixture applied in June yet visible on Grape-leaves in November. The health of these leaves was thus preserved through the season. For protection of the grapes from the Black Rot the spraying should be repeated about every two weeks, according to the weather. If a heavy rain falls soon after a spraying this should be repeated as soon as possible.

The cost of spraying a vineyard is small in comparison to the value of a full crop of protected grapes. I can point to a vineyard in southern New Jersey of some thousands of Concord-vines which, sprayed every ten days, carried a sound crop of fruit full twenty pounds to the vine, while adjacent vineyards were ruined by the Black Rot. These protected grapes were worth to the owner, a wine-maker, fully six cents a pound. The cost of protecting them was about four cents a vine.

The quantity of lime for the Bordeaux Mixture was formerly put at four pounds; I suggest six pounds, to be surely on the safe side. A surplus of lime can do no harm. If there is not enough lime to decompose the copper sulphate the mixture will injure the plant. I had last June an instructive experience as to this. In the hurry of preparation of sundry casks of copper solutions, we carelessly used in making the Bordeaux Mixture only four pounds of water-slaked lime. This quantity is equivalent to scarcely two pounds of fresh lime—hardly half sufficient to neutralize the acid of the copper sulphate. With this faulty mixture I sprayed some 400 vines when they were in bloom. The next day I saw that on these vines my spraying had destroyed all the blossoms and all the foliage! This costly lesson disposes me to suggest the prudence of testing all mixtures, which may contain matters hurtful to vegetation, on a few plants before making a general application. Prepare fungicides and insecticides some days previous to the time when they are to be used and try them on a small scale until sure that they are right.

There is no danger attending the use of the ammoniacal solution of carbonate of copper. The formula for this is: Three ounces of the carbonate, two quarts of aqua ammonia (twenty-six degrees) and fifty gallons of water. The copper carbonate will soon dissolve in the ammonia, after which the solution is mixed with the water.

As a fungicide I used, in 1890, with very encouraging results, a solution of two and a half pounds of acetate of copper in twenty-five gallons of water. In prevention of potato blight and rot this is as good as the Bordeaux Mixture. I cannot judge of its efficiency against grape-rot, because that section of the vineyard subjected to the copper acetate was stripped of grapes by the Rose-beetles.

All of the solutions of copper mentioned seem sufficiently preventive of Grape-leaf mildews. Here the efficacy of the copper is complete. All of the treated vines held their foliage green and healthy until frost. The leaves of the vines not treated were destroyed by mildew by the last of August.

A solution of copper highly recommended by the Delaware Experiment Station is, to thoroughly mix in half a pail of water one pound of carbonate of copper, to which is added three ounces of common glue dissolved in hot water. Then dilute to twenty-five gallons. It is reported that this mixture had no action on the foliage, was easily prepared, and gave remarkable results at a time when the rot was making rapid progress in the vineyard where it was used.

The Delaware Station recommends also the following preparation: Mix together three ounces of carbonate of copper and one pound of pulverized carbonate of ammonia. This mixture will entirely and quickly dissolve in a couple of quarts of hot water, when it can be diluted to fifty gallons. The cost of materials for fifty gallons of this mixture is twelve cents.

As the infection of Black Rot must be prevented, but cannot be cured, it is needful that treatment of the vine must begin early in the season. In spring, before the buds swell, spray the vine thoroughly with a solution of one pound of copper sulphate in twenty gallons of water. Then, not later than the middle of May, just before the vine blooms, spray with the Bordeaux Mixture; again in ten days, and then at intervals of two weeks until about the last of July. The last two or three sprayings may be with the carbonate of ammonia and copper mixture, in order to avoid the whitewashing of the fruit consequent on late use of Bordeaux Mixture.

Contrary to the experience of others, I have not succeeded in controlling Anthracnose on a variety of Grape-vine peculiarly afflicted by it with any of the copper solutions. I fail also to find any fungicidal value in solutions of sulphate of iron.

The Pear-leaf blight (Entomosporium) and that of the Quince are fully prevented by timely sprayings with Bordeaux Mixture.

Of the copper solutions used in the summer of 1890 for prevention of Potato blight and rot, the Bordeaux Mixture and the acetate of copper give decidedly the best results. By spraying the Potato-plant every two weeks with either of these solutions it will be effectually defended against the Fungus which causes the rot. In very rainy seasons and in very wet locations it may be difficult to keep the Fungus from blighting the Potato-tops. Such was the case with me this last fall. Nevertheless, although the tops blighted before maturity, the tubers were saved from rot in those sections of the field treated with the Bordeaux Mixture and with the acetate. The rest all blighted and rotted badly.

Vineland, N.J. *A. W. Pearson.*

Plant-houses for Amateurs.—I.

EVERY one who is interested in flowers is almost certain, as winter approaches, to wish for some proper shelter for his plants. If much interested he dreads the long season of cold weather, when the plants housed in makeshift quarters will require much attention, and make little, and that unsatisfactory, growth. Window gardening, even with carefully selected plants, entails a vast amount of labor, and there are always many plants to which the atmosphere of an ordinary house heated with a furnace and lighted with gas or oil is fatal. Not every household is willing to adapt its doings to a windowful of plants. Usually, where means are at command, a greenhouse or a conservatory is soon added to the grounds of the village or country dweller who cares for flowers, and many times added simply as a fashionable luxury. But the ordinary grower of limited means hesitates at the mention of a greenhouse as involving great expense in construction and maintenance. This is an erroneous idea; for a plant-house can be erected at a very small expense, quite within ordinary means. As with most things, the necessary parts are inexpensive, and it is only by the addition of ornaments and fanciful work—luxuries—that the cost is made formidable. The horticultural papers have published article after article on small greenhouses, year after year, and yet such houses are far from common, while it would seem that a large proportion of the owners of gardens would erect such houses and enjoy them were the facts clearly understood.

My notes probably will add little to the general information, but may interest some one else who finds recreation among growing things. My small house, which faces north and south in one corner of the garden, is not without its faults—like all first attempts at building—but proves a good working house for my requirements, which are sufficient space, light and heat to winter over tender stock, to grow and flower plants and bulbs, with a space for propagation and seed pans. It also provides "the den," necessary to most men, where confusion may reign without the danger of a revolt in the household.

The house is a span roof with seven-foot ridge eighteen feet by eight feet (a width of nine or ten feet would be better, and would cost only a trifle more). It is covered with sash for fifteen feet and boarded for three feet over the furnace. The lumber cost within a few cents of twenty-five dollars, the sash twenty dollars, the paint, etc., perhaps five dollars; in all fifty dollars for materials. The labor bill will depend somewhat on one's own handiness, or the activity of the builder, who will do the erecting in two or three days. The side-walls are of hemlock boards, covered with building paper, and faced with patent sheathing boards, which answer capitally to keep out cold. The heater, pipes, etc., suitable for such a house, ready for screwing together, may be had for fifty dollars cash, so that an expenditure of $100 to $110 will furnish one with a small plain house, quite large enough for an amateur gardener who is engaged during the day in other occupation. If larger,

Fig. 13.—Viola ocellata.—See page 51.

the care is apt to become a burden sometimes, and it is much better to start with a small house and long for more space, than to have so much to water, etc., that pleasure changes to disgust. The heater is the article which gives the pause to many people desiring a greenhouse; and various arrangements are constantly recommended and said to work perfectly. The hot-water apparatus, with furnace, pipes and expansion-tank, is in general use by florists, and as it is a commercial matter with them it may be concluded that what they use is the most desirable for the purpose. The first cost is rather more than other fixtures, but a base burner gives out heat quite uniformly, will burn with slow combustion a long time without attention, and by the pipes a uniform heat is distributed through the house. Their fault seems to be that they are wasteful in radiating heat from the outer surface, as this is lost in the furnace-room. However, the stove can be jacketed and water in pipes thus kept hotter. In my case the surplus heat tempers an adjacent frame. My house has a single two-inch flow and return, and, though not at all air-tight, is rather overheated.

Elizabeth, N. J. *J. N. Gerard.*

Cypripedium venustum.

ALTHOUGH by no means a large-flowered species, *Cypripedium venustum* is an object of much attraction during the winter months. From December until February, and even later, this pretty Lady's Slipper will be met with in flower, occupying a prominent place in the Orchid-house as much on account of its beautifully marbled foliage as for its flowers. The latter appear generally singly on an erect scape, six to nine inches high, but it is not unusual to see two flowers on one scape. The white upper sepal is broadly cordate-acute and conspicuously striped with bright green, while the much smaller lower sepal is pale green, with darker green veins. The bearded petals are dark green at the base, with some blackish purple spots near the edges, and the apical portion is dullish purple, the entire length being traversed with dark green veins. The lip reminds one very much of an inverted helmet; it is small, yellowish green, but nicely netted with dark green veins, and sometimes washed with purple, while the basal incurved lobes are of a shining tawny yellow, with numerous small spots or warts. Great variation exists among the flowers as regards coloring, some forms being much more highly colored than others, owing no doubt either to geographical or cultural differences. The two varieties known in gardens as Pardinum and Spectabile are, however, the most distinct, and may always be recognized by deep coloring and beautiful markings on the lip.

The discovery of *C. venustum* is due to the well-known Indian botanist, Dr. Wallich, who met with it in north-eastern India, and had plants sent to be cultivated in the botanic gardens at Calcutta. About 1819 plants were obtained from the botanic garden and introduced to England, where it met with a favorable reception. Since this time it has been imported in quantity on several occasions by enterprising nurserymen, whose chief desire, however, is not so much for the typical plant as for its more attractive varieties.

The cultivation of this species is very easy. An intermediate house, with a temperature varying from fifty-five to sixty degrees Fahrenheit in winter to sixty to seventy degrees in summer, will suit it admirably, with plenty of light. The compost should consist of rough peat and sphagnum moss, and during the period of growth water may be given in liberal quantities, but at other times must be given sparingly.

Isleworth, London. *John Weathers.*

Color in Conifers.

IT is noticeable that the public interest in the multiplied varieties of conifers has greatly increased within a few years past. Especially has this been true in the case of the Silver Firs and Spruces. At the present time there is a large demand for the light colors of *Abies concolor* and *Picea pungens* to contrast with the darker shades of *Abies Nordmanniana* and similar kinds. Nor is this in any way surprising when we consider the striking effects which are produced by grouping trees of differing shades of color, which retain their beauty throughout the year. To one unfamiliar with these conifers it will be a revelation to witness how completely a winter landscape, even in our northern latitude, may be transformed into a garden of color.

But it is objected that in the case of some of the kinds most desirable on account of color, this characteristic is lost as the tree attains age. At a recent discussion before the Massachusetts Horticultural Society the opinion was expressed that *Picea pungens* would soon lose its popularity, because of the unreliability of its color even with the best selected trees. The fact was stated that in its home on the mountains the forests of this Spruce have lost the silvery sheen of young trees. This is not the case with *Abies concolor*, which retains its glistening gray foliage even to old age. But we must not be hasty in our judgment of *Picea pungens*. In the first place, it is to be considered that to a great degree the beauty in color and form of many conifers is confined to their youth and middle age. Stately specimens of mature age are, indeed, magnificent. But we may well be satisfied if we can secure results which will continue for twenty-five or perhaps for fifty years.

And again, I think there are numerous indications that this quality of color is to a considerable extent within our control. An observer who has visited the forests of northern New England, especially on the coast of Maine, will have noticed the fine color of our native White Spruce. It delights in a cool, moist climate. The Balsam Fir is also at its best in such localities. In a hot and full exposure these trees lose this distinctive coloring. I have had young seedlings of *P. pungens* planted in a warm, sunny place, which became almost without exception of a uniform green. It was very apparent that the position was too hot and too sunny and the soil too sandy for them to develop the glaucous color. A marked improvement has been noticed upon transplanting them to a cooler western slope and into a good loamy soil. So many instances have been observed that I think we may lay down the rule that rich color depends largely upon culture. It is well known that Rivers' Purple Beech, when it is a large tree, requires feeding. Left to an impoverished soil its foliage becomes a dull bronzy green. But a generous feeding will restore it to its early color. The same principle applies to conifers. It is a fact that where well-rotted manures have been applied the colors have been restored. The secret of the remarkably distinct color of some notable trees near Boston is from the fact that they have an abundant supply of compost or cow-manure. Specimens of *P. pungens* twenty-five or thirty feet high are of the richest shining silver and show no signs of change. Give the tree good treatment and it will retain its beauty for years.

And it may be added that the luxuriant effect of conifers is surprisingly enhanced by a judicious application of fertilizers. It is an exploded idea that evergreens will not bear feeding.

Some Useful Acanthads.

ERANTHEMUM PULCHELLUM.—Those who grow a mixed collection of plants would find this free-flowering species very serviceable in winter. It is not common in cultivation, though known since 1796, when it was introduced from the East Indies. It branches freely, but is, nevertheless, of compact habit. The opposite leaves of deep green are elliptical, pointed at the extremity, and narrowed at the base to a short petiole. The flowers are borne in short terminal and axillary spikes. The tube is narrow and an inch in length; the limb an inch in diameter, spreading abruptly, and divided into five oval segments of bright blue color. The calyx divisions are white, insignificant, and covered by the conspicuous bracts, variegated green and white. Blue flowers are nearly always scarce in greenhouses, and it is, therefore, desirable that a plant which produces them abundantly in winter should be known to every one.

PERISTROPHE SPECIOSA.—In a warm greenhouse this plant is extremely prolific of its pretty flowers during the winter and early spring months. It is a native of the East Indies, and was introduced to the notice of gardeners in 1826. The plant is of an erect, free-branching character, with opposite, ovate-acuminate, pale green leaves. The flowers proceed singly or in pairs from the axils of the leaves which clothe the little branches at the top. The narrow twisted tube is about an inch in length, and the limb consists of two broad but slightly shorter segments, one of which is thrown backward, while the other opposite protrudes or droops slightly. A reddish purple color prevails, and the upper segment of the limb is spotted with dark purple at the base. It is a very attractive plant. *Justicia speciosa*, though now considered generically erroneous, is a much commoner name for this species.

STROBILANTHES ISOPHYLLUS.—Although deficient of the showiness which characterizes the subjects generally grown by florists, this plant deserves notice as one worthy of a prominent place in those private gardens where easy contrasts of color give more satisfaction than glaring effects. It was introduced from Sylhet in 1845. But the nurserymen have never given it much attention, and thus the plant is seldom met with

in any but botanical gardens. Those who visit such institutions during its flowering season agree in praising it, and they usually note the name with the intention of securing a specimen. But the venders of plants seldom keep it, and the search for it ends with the first disappointment. It is a plant of neat, bushy growth, with dark green lanceolate leaves. The bell-shaped flowers are over an inch in length and three-fourths of an inch in width at the mouth. They are of a pleasing lavender shade, and appear very freely in winter. This plant was formerly known as *Goldfussia isophylla*, and it is also occasionally referred to under the generic name, Ruellia, an allied genus.

These three plants can be grown to full perfection very readily—a quality which renders them fit subjects for amateurs—and the directions for the propagation and culture of one will suffice for all. It is advisable to propagate annually in order to obtain the most decorative specimens. The tips of the young branches, in the form of cuttings, root quickly in heat at any season of the year. But it is best to propagate in spring, so that the plants may have a proper season of growth previous to the flowering period. Transfer the plants to pots singly when thoroughly rooted; grow them on in pots until the weather becomes sufficiently warm to permit of their being hardened off, and plant them in the open garden early in June. With a free supply of water during prolonged terms of drought they will thrive luxuriantly in ordinary garden soil. They must, however, be taken up not later than the latter part of August and potted, using a compost of rich loam and leaf-mould, with a small percentage of sand. They may remain outside, taking care to give them a shady position and plenty of water for a few days after potting, until about the middle of September, when they should be placed in a cool greenhouse. Increase the temperature of the house gradually as the weather grows colder, until it reaches the intermediate limit, and maintain a tolerably dry atmosphere when the plants are in bloom.

Cambridge, Mass. *M. Barker.*

New Hardy Herbaceous Plants.—Of late some splendid novelties in this class of plants of Asiatic origin have been added to my collection. *Arnebia macrothyrsa* much resembles *A. echioides*, but the individual flowers as well as the cluster (thyrsus) are much larger, the latter having often a diameter of nearly a foot and consisting of some forty golden yellow flowers. *Onosma albo-roseum*, a low herb with numerous gray, hairy, lanceolate leaves and hundreds of bell-shaped flowers, is a very striking plant. The flowers resemble those of a Corea or a *Brodiæa coccinea*, and when opening are white, changing through every shade of rose and red to become finally blood-red. *Papaver glaucum* is also a splendid novelty, bearing numerous large flowers of a dazzling crimson, the sepals forming a regular pouch, which only opens in bright sunshine. Another Poppy not yet named has numerous comparatively small minium-red flowers, which are remarkable because some twenty-five of them are united in an umbel. *Tchihatchefia isatidea* is a plant whose flower-spike rises from a rosette of hairy, dark green leaves, and shows a compact spike thickly set with numerous purple flowers. Some showy species among hardy bulbous plants are growing here, but of these I must report when more ample material is before me.

Baden-Baden. *Max Leichtlin.*

Chrysanthemums.—Success with these flowers depends upon care given to the stock-plants during winter as much as upon after-treatment. It is essential that cuttings should have a good constitution to start with. Last year I kept my stock-plants in the Violet pit, and was convinced that a light, airy, dry and cool place just suited them. This year I am growing Carnations in the Violet pit, which requires to be kept at a temperature too high for Chrysanthemums. I had perforce to prepare fresh quarters, and this I did by partitioning off a part of a deep pit and putting a false bottom in it, which I barely kept frost-proof. The plants made no growth until I took them into the greenhouse about a fortnight ago. I can now get good, strong, healthy cuttings, the rest apparently having imparted vigor to them. The plants are rooted with a little bottom heat, although this is not essential; but cool air overhead is important, so that a drawn or unnatural growth is prevented.

Wellesley, Mass. *T. D. H.*

Nematodes Attacking Bouvardias.—Spots of a dead brown are developing on the leaves of Bouvardias in the greenhouses near New York, and these are followed by a wilting and drooping of the whole plant. Microscopic examination of these lifeless spots reveals no Fungus, but multitudes of minute worms. In one greenhouse examined I observed that the white sorts of Bouvardias had escaped entirely, while the pink varieties growing with them were badly affected. This may be only accidental, that is, not a peculiarity of the varieties, but due possibly to the fact that the white sorts came from one soil and the pink ones from another. Coleus plants were usually associated with the Bouvardias examined. The leaves of these were also blotched, and in the browned spots nematodes were abundant. The fact that the Coleus is subject to attacks from these eel-worms was stated in GARDEN AND FOREST some months ago, but I have not seen the Bouvardia mentioned among the list of plants infested by them.

Rutgers College. *Byron D. Halsted.*

Correspondence.

Notes from Brookline.

To the Editor of GARDEN AND FOREST:

Sir.—In going through greenhouses attached to old places around Boston, it is interesting to note the large number of tender and half-hardy specimens of evergreen plants stored away for use in the summer on lawns and in flower-gardens and other appropriate places. During a recent visit to the greenhouses of J. L. Gardiner, Esq., among plants kept for such purposes I noted fine examples of *Myrtus Ugni*, the variegated *Eurya Japonica latifolia* and *Coprosma Baueriana*, *Ficus acuminata*, together with Grevilleas, and some of the hardier Palms, like *Phœnix reclinata*, *Livistona humilis* and *Chamærops excelsa*. Stored away in pits, or what might be termed sunken greenhouses, were found plants which are hardy in England and the south of Europe, such as Hollies, Japanese Evonymus, Caucasus Laurels, Portugal Laurels and Yews. These pits are also used for storing Indian Azaleas, Cytisus, Boronias, and many other hard-wooded plants. As the conditions of temperature are nearly uniform, there is very little to excite the plants into growth before spring, and for this reason they are much better adapted to this purpose than structures above ground. It was gratifying to note some uncommon hard-wooded plants for the culture of which Mr. Atkinson has a well-deserved reputation. Although it is generally conceded that Heaths will not endure our dry and torrid summers, yet here we find excellent home-propagated and home-grown plants of *Erica hyemalis*, *E. Wilmoriana*, *E. melanthera*, and the easier grown, yet elegant, *E. gracilis* and *E. codonoides*.

Special attention has lately been paid to *Boronia megastigma*, which forms an elegant little bush, although it is chiefly valued on account of the agreeable perfume of the flowers. Last season Mr. Atkinson planted them out, and for this purpose a number were cut back rather severely. They made strong, clean growths, far healthier than those kept in pots, and now are blooming equally well. *B. heterophylla* is probably a little more attractive than the preceding, but as it possesses scarcely any perfume, it is not so desirable.

Eriostemons are Australian plants which have been grown here many years and deserve more general culture. There are several species in gardens, all making neat bushes, and flowering freely with ordinary attention in a cool-house during winter. The flowers are borne solitary, as in *E. buxifolium*, or in twos or threes in the axils of the leaves, as in *E. myroporoides*, which is the species here grown. They are pink or white in color, with a profusion of stamens and unanthered filaments, giving the flowers a tassel-like appearance. These plants are grown in a composition of peat and loam in pots, well drained. During summer they are placed in a somewhat shady place until autumn, when they are removed to one more sunny in order to get the growth ripe and buds well set.

The advent of the beautiful hybrid Hippeastrums several years ago has not altogether displaced the humbler, yet lovely, Vallotas and Nerines. I noted in a cool-house another and uncommon South African bulbous plant, *Veltheimia viridiflora*, having dense spikes, about one foot high, of small, tubular, red, yellow and green flowers.

The roof of the Water Lily house is covered with some interesting and beautiful climbers, two of which are American plants. The Cherokee Rose is not yet in flower, although the buds were visible all over the roof. The roots are outside, the plant being trained through the wall. In bloom now, also, is *Gelsimium sempervirens*. This is a lovely, sweet-scented climber—the Yellow Jasmine of the South—and one which ought to be grown wherever a suitable position can be found for it. The flowers are sulphur yellow, funnel-shaped, about one inch long and half an inch in diameter, borne on short pedicels, two to three in the axils of the leaves,

and when trained as it should be, it is really beautiful with its festoons of flowers. In the tropical plant house was a plant of the exceedingly bright and showy *Ipomœa Horsfalliæ*, evidently grafted on the tubers of some other species, probably the Sweet Potato, *I. Batatas*. *I. Jalapa* was a species of great interest to the late Dr. Thurber, of Passaic, New Jersey, chiefly, I believe, on account of associations. This is a lovely plant when grown where it can mature sufficiently early in the season to bloom before frost. We planted every spring and stored the tubers in the fall, but it seldom bloomed until frost came to blight it. *Toxicophlœa spectabilis* I found, and large specimens well bloomed are really beautiful. The flowers are borne in umbellate corymbs, clear white in color and powerfully scented. Here, also, I saw some admirable Poinsettias. They were very vigorous, some having made growths of between five and six feet during the last season, with a spread of bracts measuring twelve to nineteen inches in diameter. The secret of taking vigorous shoots in July and August and rooting them without losing any foliage to speak of does not seem to have been discovered here. I have seen it done, however, and nothing is more striking than a group of Poinsettias, the foremost plants of which are not more than eighteen inches high, with leaves right down to the pots, which are often not more than five inches in diameter, with heads of bracts six to eight inches across.

Among Orchids particularly noteworthy were large specimens of *Phajus grandifolius*, always well done here. This is a magnificent plant, the spikes of bloom measuring three feet high, and as many as twelve to fifteen in a twelve-inch pot. Of the handsome *Cattleya Percivaliana* there were some fine varieties. The deep color of the flowers is conspicuous, and especially the orange-yellow of the interior of the labellum. There was also a deeply colored form of *Lælia autumnalis*, with good specimens of *Cypripedium insigne*, *Odontoglossum Rossii majus* and many more Orchids.

Wellesley, Mass. *H. G.*

Meetings of Societies.

The Western New York Horticultural Society.—I.

THE thirty-sixth annual convention of this body, which took place at Rochester last week, was one of the largest and most successful ever held, notwithstanding the fact that last year was one of very general failure in the fruit crop. Mr. S. D. Willard, the first Vice-President of the Society, in his annual address alluded to the general disaster which befel orchards and vineyards, and yet he spoke hopefully, and called attention to the fact that fruit-growers were more thoroughly equipped to-day than ever to meet with the trials which come from bad seasons and the attacks of insects and diseases, and he predicted that the era of low prices was about to give place to more prosperous times. Mr. Willard spoke with feeling of the late President, Mr. Patrick Barry, and noticed the death of two or three other prominent members of the Society which had occurred during the year. Two hundred and eighty subscriptions for membership were made, and, although there were no prizes offered, an admirable display of fruit, especially pears, apples and grapes, was made. The officers appointed for the following year were: President, W. C. Barry; Vice-Presidents, S. D. Willard, W. Brown Smith, J. S. Woodward and George A. Sweet; Secretary and Treasurer, John Hall.

As usual, the addresses and discussions were practical and pointed, and the reports of the various county committees were full of instruction. Abstracts of some of the more important papers are given below:

DO VARIETIES RUN OUT?

This was the subject of a paper by Professor Bailey, which we reproduce entire:

"Few questions have occasioned more discussion than this, and few have been so imperfectly answered. At the present time there are the most diverse opinions concerning it, but with a strong trend toward the negative side; and yet the affirmative of the question admits of almost mathematical demonstration.

"If we define our propositions we shall see immediately that two or three separate questions have been mixed up in this discussion. By "running out" is meant the disappearance of the characteristics of any variety. It does not mean that the line of succession, the series of generations, actually becomes extinct, but that the sum of attributes by which we are able to identify the group of individuals has become so modified that we no longer recognize it. Running out, therefore, is not necessarily deterioration, although the two are commonly confounded; it is simply change, modification. If we say that the Peachblow potato, for instance, has run out, we simply mean that it has disappeared. It has broken up into many forms, perhaps. We cannot say that it has degenerated, for degeneracy is a relative term, and a variety or an individual which is inferior for one purpose may still be superior for some other; and it is probable that there are many different grades or kinds of variations in the remnants of the variety, some poor, some good.

"Again, running out does not mean that the life of the variety is necessarily limited in duration. As a matter of philosophy, we are safe in assuming that the duration of any particular form of life is prelimited, for there is evidence that species have become extinct. Yet, as a matter of practice, the limits of the genetic duration of species and varieties in nature concern us little; and, at any rate, there is no reason to suppose that varieties possess necessarily a different limitation from species. The presumption is, however, as Dr. Gray long ago pointed out,* that the older the variety, that is, the greater the number of its generations, the greater must be its chances of permanence, because it has become pronounced in its character and has proved its capability to persist. But I propose to limit the present discussion to the mere disappearance of varietal characteristics by which we lose sight of the variety, rather than to extend it to the philosophical question as to whether varieties, like individuals, become old and die or wear out.

"My proposition and the proof of it are simply these: Running out is the disappearance of varietal characteristics through change; all plants vary or change, therefore varieties must tend to run out. While there can be no doubt of this general fact or law, there are still degrees of running out, because no two plants vary in the same way or at the same rate—that is, as there are diverse kinds of variation so there must be diverse kinds of running out. The causes of running out are therefore as numerous as the causes of plant variation, and they include all such considerations as the influences of soils, climates, methods of culture, attacks of fungi and insects. It is necessary, however, to distinguish from this the disappearance of varieties through mere fashion, which often banishes varieties which are in every way well marked.

"We can divide variation into two general groups, seed variation and bud variation. Seed variation may be called a progressive tendency, because the new forms or variations are generally different from their ancestors, and possess a greater or less tendency to perpetuate themselves. The seed grower is obliged to exercise constant vigilance to keep his stock "true." He knows that, as a rule, stock is more likely to remain true on poor soils than on very rich ones, because on the latter it tends to sport or "break" more. Dwarf peas soon become half dwarfs upon strong soils, and they possess a tendency to perpetuate their characteristics. These are instances in which soils cause running out. Climate exerts wonderful effect upon vegetation. Transfer northwards dwarfs plants and induces co-ordinate changes. Dent Corn, taken far north, after a time becomes flint, as has been shown by the experiments of Beal and others. And Beal observes† that in southern Michigan Dent "ears grow shorter, kernels become shorter and rounder at the ends." Some plants possess a strong tendency toward variation which appears to be in a measure independent of surroundings. The tomato is a good example; varieties do not long retain their original characters. It is probably impossible to find in the market to-day the Tilden tomato as it was known when the variety first appeared. And the Trophy has changed considerably from its original self. In short, the very fact that we can improve varieties by good culture and that we are enabled to obtain new varieties at all, is indubitable proof that varieties run out. Upon this fact depends all possibility of advance in the origination of varieties, and upon this general law, also, hangs the whole framework of evolution.

"Bud variation comprises all change which comes through the agency of grafts, cuttings and tubers. By grafting or cutting we simply multiply the original plant—we do not take offspring from it—and we have every reason to expect, what all observation shows, that propagation by buds should give a

* *New York Tribune*, Dec. 8th, 1874. Reprinted in the *American Journal of Science and Arts*, and Sargent's "Scientific Papers of Asa Gray."

† Rep. Mich. Bd. Agr., 1876, 113.

less variable result than propagation by seeds. And yet there are instances in which plants do not come true from cuttings or grafts. As a philosophical question, the presumption is that varieties propagated by buds wear out sooner than those propagated by seeds, for the experiments of Darwin and others have shown that the special office of seed propagation is to increase the vitality of the species through cross fertilization. It must follow, therefore, that in the absence of cross fertilization vitality must be less.*

"But as a matter of practice we do not need to consider this phase of the question, for we are concerned with variation rather than with ultimate longevity. And it is also probable that any tendency toward weakness through lack of fertilization is fully counterbalanced by protection which such varieties receive under cultivation.

"The question comes simply to this: If buds are taken from parts which possess stable characteristics they will give stable products under similar conditions. But if the buds are taken from parts which have been developed into abnormal conditions, and which tend to vary, they must tend strongly to depart from the parent, especially when the means by which the high development was produced and is maintained are removed. Bud variation may therefore be said to be indeterminate. The best example of running out in plants propagated by buds is the potato. It is a matter of general observation that varieties of potatoes disappear. And Beal† has performed experiments which show that in eight years varieties which gave good crops so far ran out as to produce nothing. These varieties were grown in the same garden throughout the experiment, but they were constantly shifted over an area of from five to eight acres, so that potatoes were not grown two seasons upon exactly the same ground. And during the time when these potatoes were decreasing in yield the garden was each year producing better crops of other kinds, and the newer varieties of potatoes did well. In this case it may be argued that the plants showed signs of wearing out rather than running out by variation, but there is no evidence to show that the plants were in any way weaker or less able to perpetuate themselves after they had run out than before, for it is probable that seed production increased as tuber production decreased. At all events, we cannot determine if the varieties wore out, so long as we have no record of their seed production. It seems, rather, that the plants returned to a comparatively tuberless condition. Large Potato-tubers are abnormal to begin with, and it is not strange if their characters are transitory.

"At present I see no reason for supposing that fruits propagated by buds run out so long as equal conditions of culture and soil fertility exist; but if the buds were to be taken from parts which are abnormally or unusually developed, as they are in the potato, I should expect that we could not long hold the offspring to their assumed character.

"The conclusion of the whole matter is simply this: Varieties grown from seeds tend to vary or run out. Varieties grown from buds tend to remain permanent, or nearly so, unless the parts which are propagated possess abnormal, or what we might call fictitious or unstable, characters, in which case further variation or running out may be expected."

BACTERIA AND GREEN MANURING.

Professor Caldwell delivered an unusually instructive address on this subject. About four-fifths of any crop plowed under is water; one-fiftieth of it, or what would remain after burning, is called ash, and the rest is organic matter which mostly comes from the air. There are twelve pounds of this in every hundred of the crop turned under, and this addition to the soil improves it in many ways. In the first place, it adds humus, which makes the soil more porous and warmer, and is a constant source of carbonic acid, which does good work in making soluble the food already in the soil. Besides this, it has been clearly demonstrated by recent research that organic matter in some kinds of plants contains much nitrogen, the costliest of plant foods, which it has gathered from the air. The crops which are known to have this faculty are Clover, Peas and other leguminous plants. On the roots of these plants are nodules formed by bacteria, and somehow, in the formation of these swellings, the free nitrogen of the air in the pores of the soil is taken up by the plant. It has been proved that Peas or Lupins will grow in sand which is entirely free from nitrogenous food of any kind if there is only added to the sand a sufficient quantity of the other constituents of plant food with some of the bacteria to secure the nitrogen. Professor Caldwell concludes as follows:

"But the bacteria have still another part to play in the preparation of green manure in order to convert it into assimilable food for the following crop. Green vegetable matter is not food for plants. It must first undergo decay, or, to use a less elegant phrase, it must rot. Now another set of bacteria come in here and carry on this work of decay. They live and multiply in the green vegetable matter, and in connection with their life and growth this matter is converted into humus. There is still another valuable piece of work done by the bacteria besides making the humus, which is the conversion of the nitrogen into nitric acid, or the very important process of nitrification.

"For the best results, then, in green manuring, take for your crop some leguminous plant, such as Pea, Bean, Vetch, Clover, Lupin, Alsike, or others, and select the one that will give you the largest quantity of green matter before the middle of August at the latest. Have your soil well drained and fertilize it well with phosphate and potash, buying no fertilizer that is claimed to contain any nitrogen. For if such a claim is made you have to pay more for manure on that account, and one of the objects of your green manuring is to get your nitrogen for nothing. Plow the crop in even by the 1st of August if you have the ground well covered with a luxuriant growth by that time. Avoid plowing it in deep, and, if practicable, loosen up the ground before the cool weather sets in. This is just the sort of treatment required for putting in a grain crop. Soon after this crop is turned in the bacteria will begin their arduous labors of humufication and nitrification.

"Finally, let me give an account from one of the German journals of the successful use of green manuring in a vineyard. On a German experimental vineyard thirty-five pounds of clover-seed (*Trifolium incarnatum*) were sown per acre, with Thomas' phosphate added for mineral fertilizer. The roots of the plants from a small plat were carefully taken up, and found to be well covered with tubercles. The gain in nitrogen was estimated to be about 118 pounds to the acre. This would have required 20,000 to 25,000 pounds of stable manure for the same quantity of nitrogen. The whole cost of this crop was about 126 marks, while the cost of the stable manure to accomplish an equal result would have been 200 to 300 marks."

DISEASES OF THE GRAPE IN WESTERN NEW YORK.

A carefully prepared paper on this subject was made by David G. Fairchild, of the Department of Vegetable Pathology at Washington. What he said in reference to the various mildews, rots and anthracnose, with their remedies, it is not necessary here to repeat. These matters have been already treated in this journal. We present, however, some facts in reference to a new disease of the grape, which may prove a serious matter in our vineyards:

"About the 1st of September, 1890, complaints reached the Department from numerous localities through western New York of a disease which was threatening the grape in that region. Specimens were received from various parties, and, although carefully examined, revealed no parasites upon them. Accordingly, although so late in the season that many of the vineyards had been touched by the frost, an examination was made of numerous vines in different localities through the infected region, and notes taken of the varying conditions under which the disease appeared. From a study of the trouble in October the following diagnosis may be made: The leaves first show the disease manifesting at the outset irregular, somewhat star-like red blotches between the veins, which gradually enlarge and run together, at the same time becoming browner until they fill up the spaces between the main veins with a deep red-brown tissue, giving to the leaf a pronouncedly striped appearance. This striped look is quite characteristic and may often be seen from a distance of several rods. Upon those vines diseased the berries are of an insipid flavor, often intensely sour, and drop from their stems in the later stages on the slightest touch. Badly diseased veins may often be distinguished by the layer of shriveled berries covering the earth beneath them.

"The trouble is not entirely confined to cold, heavy soils, although apparently worse upon such land, nor is it connected, so far as can be ascertained, with the use or absence of any fertilizers. The shade which is afforded by the foliage of trees and by houses, although in one or two cases seeming to afford protection, cannot be surely connected with it. Examinations of the roots of many diseased and healthy plants, while revealing the fact that the young fibrils had almost entirely rotted away in the diseased ones and were only partially decayed upon the healthy ones, have shown no parasite of a nature adequate to cause the injury. In some respects the disease resembles that which lately appeared in California and threatened the grape interest of that state, and until one or both are more fully worked out must stand in the same general category.

† Rep. Mich. Bd. Agr., 1876, 111.

"Comparing it with the descriptions of the French malady known as Rougeot, it is found to possess many points of resemblance, and the eminent French viticulturist Viala, who noticed this disease in his recent journey in the United States, thought that it was probably the same. In the judgment of this authority, Rougeot follows as a concomitant a sudden lowering of the temperature in mid-summer when the vines, loaded with fruit, are in full growth, and is much more likely to occur upon heavy, ill-drained soils than upon light, well-drained land. Both Viala and Foix recommend as the surest prevention against its attacks thorough underdraining. If the wood has failed to mature, and enough bearing wood cannot be secured to furnish good healthy canes, the wisest plan will be to prune close to the ground and raise an entirely new growth.

"Although considerable time and attention has been paid to the class of diseases to which this new malady probably belongs, the prime cause is not positively known, and until a longer time for experimental research is afforded the trouble must remain only partially explained."

Notes.

The fifth annual Orchid show of Messrs. Siebrecht & Wadley will open on the 4th of March at Madison Square Garden.

An exhibition of Orchids will be held at the nurseries of Messrs. Pitcher & Manda, Short Hills, New Jersey, from the 9th to the 14th of February.

A German journal reports that a horticultural establishment in Brussels has already received "much more than $20,000 from the sale of plants of the recently introduced *Cattleya Warocqueana*."

Gartenflora reports that *Pachystima Canbyi*, a rare shrub of the southern Alleghany Mountains, is in cultivation in the public gardens at Münden, in Germany, and endures the winter weather well, although it makes growth very slowly.

The first greenhouse in Chicago was, says the *Prairie Farmer*, erected by one Samuel Brooks in 1840. It was a lean-to structure about fifty feet long by twelve feet wide. Part of the house is yet standing in that city. Perhaps the Chicagoans will place it on exhibition at the World's Fair.

Statistics prove that the horses of England haul on an average twice as much as American horses. This is not due to the superiority of English horses, but of English roads. We cannot afford to build good roads, it is said, but we are compelled by this failure to keep two horses to do the work which should be done by one.

Mr. Frank Hinckley, who recently died at his home in Old San Bernardino, first went to California as an engineer, but of recent years had been one of the most successful horticulturists in the southern part of the state. It is said that his father, in the year 1846, brought to California the first fruit-trees ever imported from the east.

The favorite flower of Mohammed was the Narcissus, probably the yellow Daffodil, which grows abundantly all through western Asia, and he gave his followers the following counsel: "Whoever has two loaves of bread, let him trade one for a blossom of Narcissus; for bread is nourishment for the body, but the Narcissus is food for the soul."

It is estimated that by careful cultivation almost one-fourth of all the cultivated land in China is made to bear two crops a year, while many portions produce three crops. The utmost ingenuity and economy are displayed in the use of manures, even the burnt fire-crackers which are left from the frequent festivals being strewn on the fields for the sake of their nitrogenous elements.

A western paper recently described a curious example of the natural "in-arching" of trees in Lawrence County, Illinois. The trunks of two Elm-trees, standing about twenty feet apart, have met at about the same distance above the ground, where they blend into a perfectly symmetrical trunk of large dimensions. The tree is nearly a hundred feet in height and very well developed, and wagons can, of course, easily be driven through the great triangle which forms its base.

Experiments reported by Professor Maynard, of the Massachusetts Agricultural College, give renewed testimony of the effectiveness of the Bordeaux Mixture as a preventive of mildew and black rot of the grape. Paris green added to the Bordeaux Mixture, even to the amount of one pound to 200 gallons, did no injury to either leaves or branches of Plum-trees, and, in the opinion of Professor Maynard, when used in the form of spray it will hold in check the curculio and the destructive black wart.

The Ministry of Imperial Property in Russia recently issued the following edicts: "1. Forests shall not be cut throughout, but in small portions at a time. 2. When a part of a forest is cut the ground shall immediately be cleared of the rubbish and fenced in so that no cattle can graze there. 3. Shepherds are forbidden, under a heavy penalty, to build fires either in the woods or within the limits of a forest in spots that have been cleared of trees."

At a recent meeting of the Society for Horticulture and Botany at Cologne one of the members highly recommended cellulose paper as a covering for plants which are left outdoors in winter, and especially for Roses. "This paper," says a report of his words in *Gartenflora*, "has been tried in the Public Garden of Cologne, and perfectly resisted the action of cold, snow and rain. Plants covered with it have remained uninjured in the very coldest winters."

In a recently published paper Professor S. Coulter says that the forest-area of Indiana has been reduced to 2,000,000 acres, about one-tenth of the total extent of the state, although it is still the fifth state in the Union as a producer of lumber. In Professor Coulter's belief, the distribution of forest-trees within the limited area of Indiana is but little influenced by geological differences, the main influences being elevation, the location of swamps and the course of rivers and streams. The most generally distributed tree of the 106 species that are indigenous to the state is Sugar Maple, which is found in every county.

In an article on plant legends, recently published in the *Deutsche Rundschau*, Dr. Von Langegg says that there is as much uncertainty with regard to the true meaning of the Biblical "Lily-of-the-Field" as with regard to that of "Rose of Sharon." Many persons have believed it to be *Tulipa Gesneriana*, which grows abundantly to the westward of the Sea of Genneserath, while others have found it in the yellow Daffodil, so common in many parts of Palestine. Later travelers say that it is *Lilium Chalcedonicum* or the red *L. Martagon*, which was formerly called the Byzantine Lily, and is especially abundant about Galilee, while still others speak for the purple flower of *Cynara Scolymus*, the wild Artichoke. The monks of the middle ages believed the Chalcedony Lily to be the true "Lily-of-the-Field," and hence introduced it into Europe and cultivated it largely, as the typical flower of the Virgin, in their convent gardens.

A correspondent of *Gartenflora* writes of a recent Chrysanthemum exhibition at Leipsic: "A well-developed specimen of Mrs. Alpheus Hardy was shown and must have pleased every expert. The downy covering was, indeed, not so prominent as to justify a comparison with a 'head of curls,' nevertheless it was downy. For myself, I am not enthusiastic with regard either to this or to the newer Louis Boehmer with reddish hairs, which comes from Peter Henderson in New York. It is not probable that either will reach commercial importance, for Mrs. Hardy is a lazy bloomer and so delicate that it is of little use for transport." To this the editors of the journal add: "We saw Mrs. Hardy at the end of November in Charlottenburg, but little of its lauded beauty was descernible; the flowers were not well developed." From this it appears that we have succeeded better with these famous varieties than have German horticulturists.

There is much truth in the following words which we quote from an article recently published in the New York *Tribune*: "Conservatories are much more frequently seen in England than in this country. Over here they are seldom met with even in houses of decided pretensions, and never, or hardly ever, in an ordinary dwelling. In London, however, almost every suburban house has its little greenhouse full of lovely bloom, opening invariably into the dining-room or drawing-room, . . . and it is really a pretty sight, that of a liveable English drawing-room, with its air of indescribable comfort and its glimpse through the half-opened door of the conservatory. . . . Whether it is the climate or the greater care taken, or because they are more genuinely loved than in this country, flowers certainly seem to thrive better in England, under amateur management, than in America. We suspect it is the latter reason. Americans do more for effect than the English; their flowers are decorations instead of dearly loved companions. These little conservatories, in ordinary well-to-do-families, are generally the charge of one of the daughters of the house, who daily cares for the delicate plants with undeviating regularity."

GARDEN AND FOREST.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, FEBRUARY 11, 1891.

TABLE OF CONTENTS.

Congress and the National Forests.

PERSONS who appreciate the important influence which our forests exert upon the well-being of the nation are often impatient at the apathy and dilatoriness of Congress in taking measures for their protection. It is true that our law-makers seem strangely inactive in this matter when we consider the energy they display in affairs of much smaller moment. Certain it is that no subject is likely to be brought before Congress which approaches this in the gravity of its ulterior consequences. A few years ago Mr. Carl Schurz, who not only has a comprehensive knowledge of European forests, but has been in a position while Secretary of the Interior to obtain special information as to the waste of the timber on our public domain, stated in a public address that he considered this question one of paramount importance; that discussions of tariff and currency and other economic problems might be postponed to some future day, for mistakes in this direction might be rectified by a change of system, and the losses incurred might be retrieved; but he added that "if the destruction of our forests goes on at the present rate it may bring on a train of disasters from which the country may never recover." This is a simple, unexaggerated statement of a truth which neither Congress nor the people of the country seem to realize. The untold millions of dollars which vanish into smoke every year by forest-fires; the additional millions which are stolen from the public domain and wasted; the millions more which are destroyed by flocks and herds, not to speak of the destruction of the very capacity of the soil to produce timber in the future; the more remote but equally certain disasters which come to soil and climate and public health from disturbing the balance of natural forces—all these things are either unknown or unheeded by the members of the national legislature, and the destruction is allowed to proceed from year to year without any honest attempt to check it.

It should be remembered, however, that members of Congress fairly represent their constituents in this matter. If the people of the country were adequately instructed they would stand appalled by the magnitude of the loss and danger which threatens, and they would speedily compel their representatives to take efficient action for maintaining the forest-property of the nation. The business interests which are benefited by protection take pains to make themselves felt in Washington; so do those industries which will be benefited by free trade. The men who imagine that the free coinage of silver will bring prosperity to them, and the other class who are equally convinced that such coinage will interfere with their prosperity, have agents at the Capitol at every session to force upon the attention of the members their demands in one direction or the other. The forests, however, have comparatively few friends. The people read of the devastation by fire, and feel a temporary flush of indignation at the waste of the present resources of the nation and of their children's inheritance, but they say little and do less. A few public-spirited men and women hold meetings now and then and pass resolutions, but their words lack the direct vigor of those which come from men whose personal interests are at stake. Proper legislation for our forests will never be accomplished until the people themselves are burdened with a personal sense of the need of such legislation. When public sentiment is once thoroughly aroused throughout the country the laws will come. Every attempt, therefore, to arrest attention and direct public thought to the necessity of a careful husbandry of our forest-resources should be gratefully welcomed; and we have been pleased to read that at a late meeting of the Nantucket Improvement Association the following resolutions were passed:

Whereas, the illegal and wanton encroachments upon the forest-lands of our nation are rapidly reducing the area of forest throughout the country, and leaving bare the tops and slopes of mountains, thus rendering difficult their reclothing with a growth of wood, and increasing the danger and damage from flood due to the destruction of the leafy mould; and

Whereas, selfish interests of individuals, land and railroad corporations are seeking to encroach upon tracts of land in the Rocky Mountain range, California and other sections of the country set apart for public use; or are seeking to prevent their enlargement as the best interests of the nation and the proper protection of said national reservations demand;

Therefore Resolved, That we respectfully request and urge the Congressional delegation of our commonwealth in the national Senate and House of Representatives to promote and press all measures that tend to protect our forests, and to suitably extend and improve our national parks, having especially in mind the Yellowstone Park Reservation, the Yosemite Park and the Sequoia Groves of California.

And, whereas, the Commissioner of the General Land Office recommends the repeal of laws forbidding the entry of rugged, stony or other timber lands unfit for cultivation and allowing settlers to use the timber on such lands which they may actually need to develop the country; and whereas, we believe that the repeal of these laws is a menace to the best interests of the country, that the time has fully come when the timber lands of the nation should be jealously guarded from destruction, and that a little forethought in the present may prevent serious injury and agricultural ruin to great sections of our country in the future, or may obviate the necessity of expending vast sums of money to recover from such injury and ruin; therefore

Resolved, That we urge upon the members of Congress to resist the repeal of any law that protects forest-land and to advocate all laws that may render forest-protection and extension more effective.

The national forests belong to the people of Massachusetts as truly as they do to the people of the states and territories in which they are situated; and it is their right to make protest against the failure to protect their property. It would be a hopeful indication if other organizations throughout the country would take similar action. If every rural improvement association, farmers' institute, grange convention, horticultural or agricultural society would discuss the propriety of making such petition it

would develop interest in the subject, stimulate inquiry and promote popular knowledge. It would organize and unify the thought and effort which are now lost because so desultory and disunited. It would impress Congress with the paramount importance of our forest-interests and serve notice upon our law-makers that here is one subject concerning which the people expect them to make laws.

A friend communicates the following from a letter recently received from Professor Goodale, who is now in Australia on his way to New Zealand:

It may interest you to know what species are grown as garden-plants in the cooler parts of Ceylon and in extra-tropical south Australia. In Ceylon, for instance, around the railroad station at Matale, in a well-kept enclosure, were the ordinary perennials and annuals of our own gardens. Phloxes, Pelargoniums, Portulacas, Zinnias, Tagetes and Roses were growing side by side with truly tropical plants. The juxtapositions were, in some cases, positively startling.

In Adelaide and vicinity, where oranges ripen in perfection and where the Date-palm is of vigorous growth (although practically unfruitful), one finds Chrysanthemums, Amaranths and the ordinary bedding plants in good condition. Some of the parterres in the Botanic Garden at Adelaide are extremely beautiful.

The Orchid houses contain about 400 species and varieties, mostly in good condition. The Fern houses contain almost 500 species and varieties, but there are many specimens distributed through the other houses. Overcrowding, that most natural and pardonable fault, is very marked, and would seem to demand imperatively that Dr. Schomburgk's request for additional houses should be granted by the colony.

I regret to say that Dr. Schomburgk, the Director of the Garden, the veteran explorer, the discoverer of the *Victoria regia*, is now very seriously ill. He has been indefatigable in his strenuous efforts to develop certain resources in the colony and to place its Botanic Garden among the attractions of Australia. In some cities one is asked at the clubs: Have you seen such and such a street or such and such buildings? In Adelaide the stranger is accosted by his host with the inquiry: Have you seen our Botanic Garden? And I can assure you that it is well worth seeing.

It is now a week before Christmas. The journal, *Garden and Field* (Adelaide, December), contains advertisements as follows: "For present sowing, new seeds of Primula, Calceolaria, Cineraria, Mimulus, Coleus, Pansy, etc." On our tables at luncheon we have strawberries, cherries, figs and apricots, but the latter are hardly yet ripe. They will be ripe, it is said, a week or fortnight after Christmas.

Insect Enemies of the Pitch Pine.

In Garden and Forest for January 7th I gave some account of the Tortrix-moth and the White Pine-saw-fly, which are injuring the Pines in southern New Jersey. But I find that these two pernicious insects are not the worst enemies that are attacking these trees, but that several species of beetles are making still greater havoc.

One of the most destructive is the Fine-writing Bark-beetle (*Tomicus calligraphus*). The female beetle of this species is small, not more than a quarter of an inch in length, but she is strong enough to bore through the rough bark of the Pitch Pine until she reaches the sap-wood and there makes a mine from ten to twelve inches long, running lengthwise of the tree. Along either side of this mine she makes little pockets quite close together, into which she drops her eggs. These hatch into tiny white grubs, and, as the little mother has prepared the foraging ground for this numerous offspring, all they have to do is to strike out for themselves, eating as they go, making little zigzag galleries extending at right angles from the mother's central mine.

The entomologist who named this beetle must have had considerable imagination to have called it the Fine-writing Bark-beetle, as the writing is not specially fine. Although it is so small, they come in large numbers and will soon kill a young tree. They loosen the bark, and the tree puts on a sickly look which seems to invite other beetles of larger size to help on the work of destruction. I have noticed several species of Buprestis on the leaves and trunks of the trees in May, June and July, and we know that the mission of these beetles is to perpetuate their race. Their main business here is to find good places for the next generation, whose food while in the larva state will consist of the pine wood.

These beetles are from half an inch to an inch in length, and most of them have a metallic reflection, which in some of the species is quite brilliant. It is wonderful how quickly they will find a disabled tree. Last summer about the middle of July a high wind struck our town, leveling a good many trees. Among those that were destroyed on my place was a Pitch Pine, which was broken off about twelve feet from the ground. The top was dense and heavy, and the trunk broke just below the branches, where it was about a foot in diameter. In less than a week from the time it was broken I noticed two or three species of Buprestis beetles on the trunk. *Chalcophora Virginiensis* and *C. liberta* were the most abundant, and they soon began to work their way through the bark until they reached the sap-wood.

Before the summer was over the result of their work could be seen by the sawdust all around the base of the tree, and their sawing could be heard at a distance of several feet.

I shall now have an opportunity of learning how long these beetles live in the larva state, and shall be able to tell whether any will come out next summer, or whether they will pass the second winter in the pupa state. I think, however, it will take two years or nearly that time for them to mature. I base my conclusion on the fact that two years ago some of these Pines were cut down, and I have just examined the wood and find the creatures in the pupa state still. I removed the bark from a portion of the wood and had a piece split off about fifteen inches long by three in width. In this small piece I liberated twenty-one pupæ, all alive.

These beetles ought to be called wood-engravers, for the mother's work in the soft sap-wood is really beautiful. It consists of moderately broad, wavy, irregular depressions, with narrow borders of raised work, which reaches up to the bark, making separate compartments. Their work is left very clean and white. In each of the compartments, placed on one side, is a little hollow or cradle, which the mother made for the safe-keeping of her eggs. She puts one in each hollow. On this piece of wood which lies before me most of the eggs hatched, and the larvæ have spoiled their little cradles by eating their way down into the wood. Some of them went nearly straight down two or three inches. Others went not more than half an inch, and then turned and went lengthwise of the grain.

The larva pupates in the bottom of its mine, where it makes a cell rather larger than the rest of the tunnel. The holes at the mouths of their tunnels, from which the beetles will escape next spring, are about one-fourth of an inch in breadth.

Dr. Packard says in his "Insects Injurious to Forest and Shade Trees": "After several years' attempts we have not been able to clear up the habits of either species of Chalcophora, or to detect the larvæ." I think he would have no difficulty in finding the culprits here in all of their stages.

I occasionally meet with the common Long-horned Pine-borer, *Monohammus confusor*, but it is not common here. The most that I have seen have come from White Pine lumber which has been brought from other localities. This beetle is remarkable for its longevity. I have a white pine bureau which I know to be thirty years old, and I do not know how much longer it is since it was made. In the summer of 1889 I heard a grating, creaking noise in this bureau for the first time, and as I had read accounts of this beetle living so long in pine furniture, I was much interested to see what would make its appearance. The saw-dust work of the creature was sprinkled quite liberally over the contents of one of the drawers. Finally a male Long-horned beetle nearly an inch in length, with antennæ about three times the length of the body, made its appearance. The creaking noise still continued and the dust was still thrown down, but I saw no more beetles that summer. Again last spring the noise commenced, and two more beetles of this species came out. These were females with antennæ not much longer than the length of the body.

Had these beetles been imprisoned there all these years, or had some mother beetle gained access to the bureau and left her eggs there?

Some twenty years ago I occupied a house with an unfinished attic. The timber in the attic was all of white pine. During the ten years that I remained there every summer more or less of these beetles came out of the wood. I never became satisfied whether they continued to reproduce their kind here, or whether they were all in the lumber at the time of building and remained dormant all these years. When a beetle came out from its imprisonment its first move was toward the light. There were several windows in the attic, but the blinds were usually all closed; still light came in between the slats, and the beetles always started for the nearest window, as if they had no purpose in view except to make their escape. The windows were generally closed, and so

not many left the attic alive, but died on and around the windows.

This bureau of which I speak stood in this house on the second floor just beneath the attic. It is veneered on all sides except the back, where possibly a mother beetle might have gained access. It is eleven years since it was removed, and if we conclude that the eggs were left then by one of these attic beetles, it must have taken them nine or ten years at least to come to maturity.

Vineland, N. J. *Mary Treat.*

Lenoir's "Elysée."

SOON after the National Assembly took control of affairs in France it charged its "Committee of Alienation" to see that all works of art contained in buildings which had been declared national property should be preserved and properly cared for. In consequence a "Monument Commission" was formed of artists and savants; the Maison des Petits Augustins, in a street of the same name in Paris, was set apart for the reception of works of sculpture and painting, and other confiscated monastic houses were appropriated for books, manuscripts and minor works of art. In the year 1791 Alexandre Lenoir, a young man of good education who had studied to be a painter, was appointed curator of the museum. The work of filling it was begun and completed by him, but when he died, in 1839, it had long been a thing of the past. After the Restoration, in 1817, his "Museum of French Historical Monuments" was suppressed, and its contents were either returned to their original homes or, in most cases, transferred to the Louvre, the Ecole des Beaux Arts or Père-la-Chaise. But, in the beautifully illustrated book which Lenoir fortunately wrote, the history of his museum and the description of its contents are preserved for us.*

If we judge by the light of our own happier day, the idea of dragging noble monuments from all parts of France to be set up coldly in a Parisian museum, shorn of their historic associations and of their old artistic environment, seems close upon a crime. Yet it is proved by almost every page of his book that Lenoir was a man of artistic feeling, and especially by passages like the one in which he says: "In spite of the multiplied protests of various artists, I have constantly solicited the transport of monuments of the Middle Ages, which they regarded as useless to the arts, and have succeeded in obtaining them." This is not merely to say that he was a more wide-minded vandal than most of his contemporaries. The Revolution had just spent its first fury, not only upon aristocrats and priests, but upon countless works of art which, in the minds of the populace, were dishonored by their connection with aristocracy or priestcraft. Monasteries had been confiscated and destroyed and their contents reduced to powder. Churches were faring hardly better. Less damage was done to the cathedrals of France, it is true, than had been done, by a more gradual process, to the cathedrals of England during the Reformation and the long years of indifferentism which followed it; yet they were greatly injured, while scores of other churches, sometimes of equal size and beauty, had been secularized or torn stone from stone. For years after Lenoir began to form his museum the work of destruction went on, though in a more legalized way. When Napoleon came with his strong hand to enforce respect for art as well as for law, there was less excuse for enlarging, or even keeping up, the museum. But Napoleon's intense desire to enrich his capital may well have encouraged the despoiling of his own provinces while he was ravishing foreign lands. Lenoir tells us of the state in which he found, for example, the famous Church at St. Denis, "which the fire seemed to have devoured from the crown of the vaults to the bases of the tombs," and of how he rescued from these tombs "such *débris* as could be restored." It is unquestionable that with all the harm he must have wrought in transporting his monuments, and especially in restoring them according to the skill of his unsympathetic time, he did more good than evil, preserving, if in a mutilated state, many things which would otherwise have perished, and, by the mere formation of his museum, insisting upon the value of the art of other days.

Just now, however, I wish to speak not of the museum itself, but of the so-called "Elysée" which Lenoir connected with it. The Maison des Petits Augustins, and even the street to which it gave the name, are now blotted from the map of Paris; but a hundred years ago it still had its old walled-in conventual garden, and in this Lenoir established a sort of factitious cemetery, naming it, in the classicizing spirit of the day, after the "Elysian Fields" of the Greeks. Such an Elysium, he says, seemed to suit the historical character which he had endeavored to give his museum, although one hardly sees the connection between a series of rooms filled with French monuments chronologically arranged, and a cemetery in which he strove to realize what he fancied to have been the idea of the Greeks with regard to a future world! However, his description is as charming as his cemetery must have been. "In this calm and peaceful garden," he says, "one may see more than forty statues; tombs, placed here and there on the green turf, lift themselves with dignity in the midst of silence and tranquillity. Pines, Cypresses and Poplars accompany them; small columns and cinerary urns, set on the walls, concur in giving to this happy spot the sweet melancholy that speaks to a sensitive soul. Here one finds the tomb of Abélard and Héloise, upon which I have had engraved the names of this unfortunate couple; the cenotaphs and recumbent statues of the Good Constable and of Sancerre, his friend; in sarcophagi executed after my plans and drawings rest the illustrious remains of Descartes, Molière and La Fontaine, and those of Turenne, Boileau, Mabillon and Montfaucon. Further off a column supports, in a vase, the heart of Jacques Rohault, worthy rival of Descartes. Near this philanthropic heart one discovers the modest and touching epitaph of Baptiste Brizard, that favorite of Melpomene, who once made the stage of France beloved."

Thus Lenoir writes in the general introduction to his book, and in the concluding volume a whole chapter is devoted to the Elysée. Much of it is taken up with sentimental explanations and reflections, but it also includes descriptions of some of the monuments and tells whence a number of the relics they enshrined had been brought—as the remains of Descartes from Sweden, and the heart of Jacques Rohault from the church of St. Geneviève, in Paris. This last fact certainly proves that something of vandalism had crept into Lenoir's original wish merely to preserve threatened treasures from destruction.

But our chief interest is with Lenoir's cemetery as a whole and the manner of its arrangement. As he says nothing to the contrary, he probably did not alter the disposition of the monastic garden, but simply arranged his looted and newly manufactured tombs among the Cypresses, Myrtles, Poplars, Pansies, Violets and Rose-bushes, to which he constantly refers as harmoniously surrounding them. His pictures show us many of these, and, if the delineators were faithful, the grouping of tall shafts with slender trees, and of lower tombs with masses of shrubbery, must have been both tasteful and effective. The most interesting, because most extended, view is the one which, on a slightly smaller scale, is reproduced on page 67. The monument in the foreground is that of Descartes, and was a creation of Lenoir's own. But in the middle of the picture we are delighted to recognize the famous statue of "Diane chasseresse," which Jean Goujon modeled, it is said, from Diane de Poitiers herself, and which formed the chief ornament of the *cour d'honneur* in her château at Anet. But for Lenoir this statue would have perished, as likewise Goujon's splendid gates which now stand in the court-yard of the Ecole des Beaux Arts; and on the fountain pedestal where he placed the statue it stood somewhat as it had at Anet (where its still loftier pedestal rose from the centre of a large ornamental basin), and must have looked far better than it does to-day near the eye in a small salon in the Louvre.

Another glance at the picture will show the chief reason why an account of Lenoir's Elysée is here in place. It is an almost ideal picture of that natural aspect which we strive to give our own cemeteries and which is generally thought a distinctively American conception. Of course one dares not speak too decidedly; but it seems as though this Elysée may well have been the first realization of such a conception—as though Lenoir had been the inventor of a scheme which, probably in all ignorance of his ephemeral creation, has since been so widely and variously elaborated in the New World. And where have we improved upon his execution of the scheme? Certainly not in our monuments themselves, even if we judge by the most *banale* of those which he himself designed, and certainly not in their arrangement as regards one another and the natural features associated with them—a fact which would be still clearer could we show more of the pictures in his book. Is not such an unsymmetrical yet harmonious grouping as his far better than our usual attempts, where we vibrate between a formality at variance with natu-

* *Musée des Monumens français, ou Description historique et chronologique des Statues en marbre et en bronze, Bas-reliefs et Tombeaux des Hommes et des Femmes célèbres pour servir à l'Histoire de France et à celle de l'Art. Par Alexandre Lenoir, Fondateur et Administrateur du Musée.* A Paris. [The first volume bears the date 1800, while the others were published from time to time down almost to the date of Napoleon's banishment.]

ralistic surroundings and a heterogeneousness without harmony or coherent effect? Would his Elysium have been improved by railings to show just how much property each dead man might claim? Or by mounds to explain beneath just what square of turf his body lay? Have we not here at once harmony and variety, dignity, grace and true repose? And while each monument helps the effect of the others, is not each sufficiently conspicuous and individualized? Of course we cannot often have Grecian colonnades or statues of the importance of the "Diane"—nor should we want one just like the "Diane," which was evidently out of place in a so-called cemetery. But simple square tombs, columnar shafts, and small monuments like the one we see to the right of the "Diane" are well within our reach, and there is no possible reason why our planting should not be as artistically done as the old monks had done it, in unwitting anticipation of Lenoir's needs.

One longs to know whether Lenoir really altered the garden, or, if not, just when and by whom it had been arranged. For, at the end of the last century, "natural" gardening arrangements had only just begun to be liked in France, Marie Antoinette's famous "English Garden" at Versailles having been the first of its kind. A small urban garden is the last to which we should have looked for an innovation upon the long-prevailing formality in design.

New York. *M. G. Van Rensselaer.*

Plant Notes.

Some Recent Portraits.

A LARGE part of the first number of the new volume of the *Botanical Magazine* is devoted to the wonderful Aroid of Sumatra, *Amorphophallus Titanum*, which flowered last year at Kew, two double and a single plate (*t.* 7153, 7154, 7155) being necessary to display its habit and floral structure. This plant is certainly one of the wonders of the vegetable world, and the fact that it has been grown and flowered at Kew is pretty good testimony, if such testimony were needed, of the enterprise and skill of the Director of that great establishment and of his assistants. "The single flower," to quote from Dr. Beccari's account of its discovery, reproduced by the editor of the *Botanical Magazine*, "with the tuber from which it springs almost directly, form together so ponderous a mass that for the purpose of transporting it it had to be lashed to a long pole, the ends of which were placed on the shoulders of two men. To give an idea of the size of this gigantic flower it is enough to say that a man standing upright can barely reach with his hand the top of the spadix which occupies the centre of the flower, and that with open arms he can scarcely reach halfway round the circumference of the funnel-shaped spathe from the bottom of which the spadix arises." Forbes, in his "Naturalist's Wanderings in the Eastern Archipelago," encountered the plant, and describing it says, on page 175, that he found it in the Barisan range growing in sandy soil, the largest specimen measuring seventeen feet in height, and again that on the Kling River he met with the largest tubers which have yet been noticed. They were six feet six inches in circumference, the stem at the base girthing two feet seven inches, the whole forming a load for twelve men. But perhaps even a better idea of the size of this plant appears from the fact that a full-size drawing of it, made under the direction of its discoverer, Dr. Beccari himself, and presented to Kew, occupies a canvas, without margin, which is eighteen feet long by fifteen feet six inches broad. It represents a leaf of the full size growing out of the ground, and underneath it two Sumatrans carrying a flowering specimen lashed to a pole.

The other plant figured in this issue of the *Botanical Magazine* is *Dipladenia illustris*, var. *glabra* (*t.* 7156), a native of Brazil, where it has a wide range from the Province of Bahia, in the north, to that of St. Paul, in the south. It is a pretty stove-house climber, with rosy red flowers and thick, coriaceous, dark green leaves.

The colored plate of the issue of January 1st of the *Revue Horticole* is devoted to the beautiful new hybrid dark red Rose, La France de 1889, obtained by Monsieur Moreau-Robert, of Angers, by crossing the Rose Marie Henriette with pollen from La France. The seed obtained from this cross was sown in the spring of 1883. It produced two plants only. Of these one produced a single flower, and the other, which grew vigorously, is the one to which this rather unfortunate name has been bestowed. Monsieur Carrière believes that La France de 1889 is one of the best seedling Roses ever obtained in France.

The colored plate of the issue of *The Garden* (London) for January 10th represents a flowering branch of one of the varieties of *Clematis Viticella*, a native of southern Europe and western Asia, and an inhabitant of gardens for three centuries at least. *Clematis Viticella* is one of the most graceful and charming of all hardy climbing plants, with long-stemmed drooping flowers, which appear in succession from June until September. Many varieties have been developed in cultivation, that figured in *The Garden* being one of the most attractive.

New or Little Known Plants.

Clethra alnifolia, var. tomentosa.

THIS handsome plant, which botanists consider a variety of the Clethra or Pepper-bush, which is so common along the borders of swamps near the sea-coast of the northern states, is quite distinct from the garden point of view and a desirable plant to cultivate, because it does not bloom until the northern Clethra is out of flower, and because it continues to produce its flowers late into the autumn.

This variety, as it appears in the Arnold Arboretum, forms a spreading bush three or four feet high with ample, ovate leaves, entire toward the base, sharply serrate above, two and a half to three inches long, one and a half inches broad, pointed or rounded at the apex, and covered even at maturity on the lower surface, as are the shoots of the year, the branches of the panicles, the pedicels and the outer surface of the calyx, with dense hoary tomentum, which is the characteristic feature of this plant. The flowers are produced in panicled racemes, which exceed in length those of the northern plant, and are sometimes six or eight inches long. The individual flowers, too, are considerably larger, but otherwise not different from those of the common Clethra.

Clethra alnifolia, var. *tomentosa*,* is probably a rare plant in its native swamps, and I have never found it in any part of the southern states I have visited. It was discovered by the elder Michaux growing in swamps in South Carolina, and there is a specimen in the Gray Herbarium collected by Chapman in Florida, without any particular locality being indicated, and one from Alabama, also without locality. It is, however, an old inhabitant of European gardens, where it appeared during the last century, and various portraits of it have been published, although none of them do much justice to the beauty of the plant.

The specimen from which our figure (Fig. 14, p. 65) has been made has been growing for a number of years in the Arboretum, where it flowers regularly during nearly two months every autumn with the aid of a slight winter protection of evergreen branches, but it has not produced fruit. It was derived from the Royal Gardens at Kew.

Foreign Correspondence.

New Plants of 1890.

THE new and noteworthy plants introduced into English gardens last year were noticed by me almost weekly in my letter to Garden and Forest, while in his lists of new Orchids Mr. Rolfe has kept your readers well informed of these plants. It may, however, be worth while passing in review the most noteworthy of all these new introductions, judging them on their merits as plants for the garden. For a plant may interest, and even appear pretty, in a botanical sense, and yet have little or no claim to the notice of horticulturists.

The whole catalogue of the new plants of last year contains scarcely anything of exceptional merit. Not even among Orchids, usually so rich in new prizes for the cultivator, is there any one plant of extraordinary interest or beauty equal to those we already possessed, though there are not a few which might be classed as first-rate acquisitions did they not resemble so closely others already in cultivation.

* *Clethra alnifolia*, var. *tomentosa*, Michaux, "Fl.," i., 260.—Chapman, "Fl. S. States," 264.—Gray, "Syn. Fl.," ii., i., 45.
C. tomentosa, Lamarck, "Dict.," ii., 46.—Hooker, *Bot. Mag.*, t. 3743.—Watson, "Dend. Brit.," i., 39, t. 39.—Loudon, "Arb. Brit.," ii., 1128, Figs. 928, 929.
C. incana, Persoon, "Syn.," i., 482.
C. pubescens, Willdenow, "Enum.," 455.

Fig. 14.—Clethra alnifolia, var. tomentosa.—See page 64.

The question naturally arises, How is it that so few good plants are introduced now, compared with the rich harvest each year brought, say, in Dr. Lindley's time or even later? Have nurserymen and others interested discovered that more can be made out of the material already at hand by cross-breeding, selection, etc., than out of new introductions? It cannot be that the ground is exhausted; that everything worth having has been secured. There are scores, one may safely say hundreds, of beautiful plants known to botanists which have never yet been seen in the garden. China, upper Burma, New Guinea, Madagascar, Africa and South America teem with good garden-plants of all kinds. Even ground already beaten over by collectors contains many beautiful plants unknown in horticulture, while among early introductions, which have since disappeared from gardens, there are a great number of first-rate things.

Of course we have an enormous number of beautiful plants in every department of the garden, and, as many would say, more than sufficient for our needs. Yet a new introduction of sterling merit is certain to find general favor, and while we all love old favorites we are all of us always ready to welcome new friends.

Orchids.—Perhaps the most interesting new Orchid of 1890 is *Moorea irrorata*, a new genus, which flowered at Glasnevin, and is named in compliment to the Curator, Mr. Moore. It is allied to Houlletia, has a spike eighteen inches long, bearing a dozen fleshy flowers, two inches across, and colored rich reddish brown. Unfortunately, Mr. Moore's plant is unique, and we do not even know of what country it is a native. *Dendrobium Macfarlanei*, introduced and flowered by Messrs. J. Veitch & Sons, is beautiful in flower, but it comes from New Guinea, and, like almost all the Dendrobiums from that region, it is, unfortunately, too difficult to manage to ever find general favor. Among Cattleyas the only new introductions of note are *C. Warocqueana*, *C. Lindeni* and *C. Rex*, of the Messrs. Linden. The first-named is an improved *C. Gaskelliana*, the second a good *C. labiata*, and the third not unlike the white *C. aurea*, known as *C. Imschootiana*. *Cymbidium Traceyanum* is a big-flowered *C. Hookerianum*, the older name for which is *C. grandiflorum*. Three new Sobralias, named *S. Lowii*, *S. Sanderæ* and *S. Wilsoni*, differ only slightly in color from species already known in gardens. There are only two newly introduced Cypripediums—*C. Schomburgkii* and *C. Siamensis*—and these are scarcely more than botanical curiosities. The same may be said of the seven new species of Masdevallia. This genus is attracting an unusual amount of attention just now, as is shown by the fact that more new species have been introduced lately than of any other genus of Orchids. The pick of the lot is *M. Lowii*, which has the habit of *M. Chimæra*, tailed flowers, three inches across, and white with purple spots.

Varieties of species already established in gardens continue to appear among the numerous plants annually imported, and some of these are valuable. Cattleyas have produced *C. Lawrenciana*, var. *Vinckii*, with flowers of a decided bluish or magenta hue; *C. aurea*, var. *Imschootiana*, with white sepals and petals and a richly colored lip; *C. granulosa*, var. *Buyssoniana*, with white sepals and petals. Lælia have revealed several excellent varieties, particularly in *L. præstans alba* and *L. elegans Broomeana*.

Hybrid Orchids eclipse in beauty and interest the new introductions. Best of all is *Phajus Cooksoni*, a hybrid between *P. tuberculosus* and *P. Wallichii*, raised by Mr. Norman Cookson. It has the constitution of the latter parent and the elegance of the former, plus a rich rosy color. This Orchid ought to prove a useful garden plant. Equaling the Phajus in interest is the hybrid *Odontoglossum Leroyanum*, raised by M. Leroy, gardener to Baron E. de Rothschild at Gretz, its parents being *O. crispum* and *O. luteoparpureum*. It is the first hybrid Odontoglossum originated in the garden. Equally interesting are the two bigeneric hybrids produced and flowered last year by Messrs. J. Veitch & Sons—namely, *Epiphronitis Veitchii* and *Sophrocattleya Calypso*. *Masdevallia Stella* is an additional hybrid in this genus. Dendrobiums have produced several beautiful hybrids, those exhibited by Sir T. Laurence at the beginning of the year being at least as beautiful and interesting as the best of those previously raised; they are named Juno, Luna, Chrysodiscus and Melanodiscus. Something like thirty hybrids have been added to Cypripedium, and, whilst a few of them are good, most of them are of no account. The cream of them are Aylingii, H. Ballantine, Pollettianum, Vipani and Osbornei. Cattleyas and Lælias have added nothing particularly noteworthy.

Stove and Greenhouse Plants.—The most interesting new plants in this department are the following: *Heliamphora nutans*, which has been successfully introduced from Roraima by Messrs. Veitch and which flowered in their nursery last year. It is a near ally of Sarracenia, having erect, pitcher-like leaves and regular white flowers not at all like those of Sarracenia and Darlingtonia. Hitherto, however, the Heliamphora has not shown a disposition to grow freely under cultivation.

Messrs. Veitch have also distributed three new Nepenthes of good quality—namely, *N. stenophylla*, a narrow pitchered species not unlike *N. Curtisii*, and two varieties of the excellent *N. Burkei*, named *prolifica* and *excellens*.

Clematis Stanleyi must be numbered among the prizes of last year, but it needs no more than mention in these pages. *Hæmanthus Lindeni* is a handsome species in the way of *H. Kalbreyeri* and *H. puniceus*. Mr. Bull's *Sonerila orientalis* and varieties are pretty additions to this class of stove plants; they have prettily marked foliage, a free branching habit, and produce bunches of bright-rose, attractive flowers in profusion. A new Fern, in the way of *Pteris cretica*, but far more elegant, has been introduced by Mr. Bull and distributed under the name of *Pteris ensiformis*, var. *Victoræ*. This will become popular as a table-plant, as its fronds are semi-erect, very graceful and prettily mottled with silvery gray on a bright-green ground.

Calla Elliottiana is a plant which ought not to be lost sight of, as it has all the charm of the common *C. Æthiopica*, differing only in the clear sulphur-yellow of the spathe. *C. Æthiopica*, var. Little Gem, is remarkable in having small flowers and leaves scarcely a foot high.

Cineraria lanata, a tall, handsome-flowered, greenhouse plant, and *Dipladenia atropurpurea*, with rich purplish-maroon flowers, were reintroduced into gardens last year after an absence of long enough to make them practically new.

Hardy Plants.—*Lilium Henryi* is the most interesting and promising of these. It has already been noted in Garden and Forest, but I may supplement the information already given by recording the fact of the bulbs having stood uninjured the severe weather here of the past two months. *L. Bolanderi* is another new Lily, small-flowered, almost black in color and likely to please those who cultivate this beautiful but somewhat refractory genus. Three new species of Gladiolus, namely, *G. decoratus*, *G. primulinus* and *G. Kirkii*, flowered at Kew last year, and were so distinct in color and size as to have attracted the attention of breeders of these plants. These three will no doubt eventually be heard of again. *Thalictrum Delavayi*, a pretty hardy Fumitory from south-western China, completes the list of new, good, hardy, herbaceous plants.

Trees and Shrubs.—*Cytisus scoparius*, var. *Andreanus*, is the only beautiful new plant in this department. It is a seedling variety of the common broom, the flowers large, rich yellow, with the wings colored velvety maroon. Grafted on short stocks of the type it makes a presentable pot-plant and flowers freely when small, so that it should prove valuable in spring as a greenhouse plant.

London. *W. Watson.*

So select the material of planting, or the native material to be left growing, that, within reasonable limits, the principle upon which Nature, unassisted, proceeds in her selections shall be emphasized, idealized or made apparent in landscape quality. *F. L. Olmsted.*

Cultural Department.

Notes on Some Hardy Wild Roses.—V.

We have, indigenous to America, a little group of several species of hardy wild Roses which are not surpassed for beauty and general effectiveness by any introduced species which possess similar characteristics in habit and in color of flowers. So far it appears that few variations from the natural types have been derived from them. One of the most common and familiar wild Roses, which is found on the rocky soils in many places along the sea-coast of New England, is *Rosa lucida*, the so-called Dwarf Wild Rose of Gray's "Manual." This popular name, however, is not to be relied upon as indicating its habit or stature, because, although it is generally rather a dwarf plant in exposed situations, under more favorable conditions it commonly attains a height of from four to five feet.

This species may generally be distinguished from its congeners, by persons who are not botanists, by its rather thick, dark-green leaflets, which are smooth and shining above.

The foliage often assumes brilliant reddish or orange colors in the autumn, and for this reason it is often effective when growing in masses in shrubberies and similar places. The plants have more or less of a tendency to spread over the ground by underground shoots. This characteristic, however, is not nearly so highly developed in this species as it is in *R. nitida*, which spreads very freely and thickly over the surface of the ground by means of surculose stems from the parent plant. *R. nitida* may generally be readily distinguished from the last species by its smaller, narrower leaves, and especially by having its stems densely covered with straight slender prickles, which are of a reddish color. The plant is much more slender than *R. lucida*, and rarely grows more than two or three feet high in cultivation.

The flowers of both species are in best condition in the latter part of June and they are of a bright rose color. Although equally beautiful, those of *R. nitida* often seem slightly more attractive, an effect which may be due to its smaller bright green leaves and slender stems. This species generally grows best in moist situations, and the bright color of its foliage in autumn is often quite striking. The fruit of this and of *R. lucida* often remains bright and fresh-looking throughout the winter; but in this region, owing to the attacks of the beetle, *Rhynchites bicolor*, the hips are generally imperfect.

The surculose habit of *R. nitida* is imitated by the little Prairie Rose, *Rosa foliolosa*, which was figured on page 101 of the last volume of Garden and Forest. *R. foliolosa*, however, is a very much more slender and more dwarf plant, with very few branches; and, moreover, it differs in having its stems, which are of a light green color, entirely free from prickles, and only possessing straight, geminate, infrastipular spines, which are often weak and slender. On the flowering branches, indeed, the spines are either absent or so little noticeable when handled that the species might almost be called a thornless Rose. The stems of this Rose are peculiar from the fact that they do not live more than two or three years. The new shoots branch and flower the second season, after which they wholly or partially die and are replaced by new stems arising from or from near the ground. In this habit it is like some of our Raspberries.

Although naturally only native to regions so far south as Arkansas, New Mexico and Texas, *R. foliolosa* seems perfectly hardy at the Arboretum, where it grows from eight or ten inches to a foot and a half in height, and spreads freely by underground stems or suckers, by which it may be very easily propagated. The sweetly fragrant flowers are two inches in diameter, and usually solitary on the ends of the shoots. The earliest of them do not open in this latitude until the first or second week of July. There is no profusion of bloom at any time, but a few flowers continue to be produced throughout the rest of the summer, so that the species appears to have more or less of the character of the ever-blooming Roses.

It is a curious fact that, although it has been collected by many botanists, there do not appear to be any definite observations or statements on record regarding the color of the flowers of this Rose. In the original description of Nuttall's specimens in Torrey & Gray's "Flora of North America," p. 460, the flowers are described as "apparently rose-colored," and the description accompanying the illustration in Garden and Forest states that they are "bright pink." Berlandier, who collected it in Texas, notes that the color of the flowers is "pallide rosei"—pale rose color; and in the only nurseryman's catalogue where I have seen it advertised it is described as from Texas and producing "pinkish-white, very fragrant

flowers all the season." The plants in the Arboretum, however, originally grown from seed collected by Dr. George Engelmann in New Mexico, have flowers of a very pale lemon-yellow or creamy-white color, and there is not the slightest appearance which would give the suspicion that the blossoms were ever rose-colored or pink, unless it is that a slightly rosy tinge may be detected on the outer edge of the petals when they are about to fall. It may be that the color in these plants is abnormal, but it hardly seems probable.

The fruit ripens in late autumn, it is light red in color and is rather sparingly produced here. On account of its white flowers and continuous blooming habit this Rose may prove to be of much interest and value to hybridizers as soon as it becomes well known and disseminated.

Of the hardy wild Roses indigenous to the eastern part of North America the species known as the Swamp Rose (*R. Carolina*) is one of the most familiar.

It is the tallest-growing of our local species, as well as the latest to flower, the rather small blossoms not appearing until the first or second week of July, or after the beauty of most other wild Roses is past. In the shrubbery the flowers usually appear in large corymbose clusters, and they are followed by a profusion of bright red fruit, which retains its color throughout the winter.

Arnold Arboretum. *J. G. Jack.*

Fig. 15.—Cemetery of the Musée des Monuments français.—See page 63.

Plant-Houses for Amateurs.—II.

THE amount of coal consumed in any stove will vary somewhat according to the judgment of the fireman, but firing twice a day a stove for the house described in an earlier article will consume half a ton of coal a month, during ordinary winter weather, in maintaining a sixty-degree Fahrenheit night temperature. Where more frequent supervision is given and the cinders utilized a saving on this amount of fuel can be made. The small stove has a capacity for the consumption of a much larger amount of fuel than this, so that in extreme weather its heating capacity is quite up to the house of the size described. My preference is for a larger stove which has a larger fire-pot, and which, while burning slightly more coal, has a larger body of fire and requires the minimum of attention. Such a stove will burn steadily with closed drafts on a consumption of 1,200 pounds of coal a month. Probably in most cases the small stove would prove entirely satisfactory, my preference for the larger being not only because it requires less attention, but because it is also useful in the fall, when I screw on 200 feet of pipe to warm a Chrysanthemum shelter, at which time, of course, the consumption of coal is largely above the winter average.

Among other methods of heating, the old tile flue seems to be the best, and is no doubt good as long as the flue is tight. There are numerous suggestions for heating with coal oil and sketches of arrangements to make it efficient. Perhaps, for a cold house, where an occasional fire is desired, coal oil may answer as a makeshift, but in my experience coal oil is expensive for a steady heat, and I have never found odorless oil or smokeless stoves, and these latter require at all times great care, and are unpleasant things to handle. A flue is necessary to carry off products of combustion, and the slightest downdraft will throw smoke into the house.

Such a small plant-house has, of course, its limitations, and will not hold many specimen plants, but will shelter more plants than would seem credible. With a judicious selection one may have a fair number of flowers at all seasons, especially if a supply of bulbs is potted up and held in reserve to be brought on as required. As our piscatorial friends do not measure the success of their expeditions by the weight of the fish caught, so the amateur grower of flowers has other pleasure in the cultivation of plants than in the mere magnitude of the crop of flowers. A place in the warmest corner should always be reserved for seed-pans, for until one grows seedlings, and notes from day to day their development, he misses one of the most interesting features of gardening. There is a never-ending interest attached to the germination of seeds. In the same corner, also, should be made a bed of sharp sand, to be changed as required, where propagation of all kinds may be carried on. If a frame be made over this, on which a plant may be temporarily placed, it will often be useful in grafting or in other cases where a close atmosphere is required. Of course, this bed should have a bottom of slate or zinc, and it is well to box in the space under the bench at this point to confine the heat. A sash house is considered a rather crude structure, but I find it has one advantage, which is that where a house is left without attention all day, it gives a certain amount of desirable shading when, as often happens, the sun becomes unexpectedly powerful, and the ventilators

are not open as freely as they should be for the rapid change of air. It seems to me that modest houses of this character would often be satisfactory to those who have a fancy for flowers and do not care to maintain a show-house or employ a professional gardener.

Elizabeth, N. J. *J. N. Gerard.*

Tomatoes Under Glass.

IN the rapidly extending practice of winter-gardening at the north the variety as well as the quantity of crops grown has largely increased. Among these crops the Tomato has assumed considerable importance, and has been the subject of various experimentation at the Cornell Station for the two seasons since the erection of forcing houses here.

The first crop of this season, which began to ripen the last of December, has been very thrifty throughout its growth. The seed was sown in the usual manner in August, and about a month later the plants were placed in their permanent quarters in boxes upon the benches of the forcing house. The boxes used are of two sizes, the smaller being ten inches each dimension (for a single plant), and the larger eighteen inches square by twelve deep, being used for four plants, which are placed near each corner. The bottoms of the boxes are nailed on somewhat openly, and an inch of cinders or other broken material is placed over them to ensure abundant drainage. Upon this was placed a layer of decaying sods, followed by garden soil, filling the boxes a little more than half full. As the plants grow several inches more of soil are added, thus inducing the development of the secondary roots upon the stem. All lateral shoots are removed as fast as they appear, and the terminal shoot also when the plant reaches a height of about four feet. As soon as the main stem begins to lop over the plants are trained to upright cords stretched to the rafters, being loosely tied to them with a loop of raffia placed just below a leaf.

As would be inferred from its behavior out-of-doors, the Tomato requires a high temperature in the house, not less than sixty degrees at night, ventilating at seventy degrees on cloudy days, while on sunny days the mercury may safely run much higher. When the plants are in flower some aid should be given in pollinating. As the flower of the Tomato is self-fertilized, this is easily accomplished by jarring the plants on bright sunny days by gently striking the stem with a padded stick. As the fruit sets the larger clusters should be tied up to the stem to prevent them from breaking down. Throughout the fruiting period it is profitable to apply liquid manure once a week; or, as was done with this crop, place a layer of stable manure over the soil, the leachings from which will be carried into the earth from day to day as the plants are watered. It is absolutely indispensable to the success of this crop that the houses should be so located as to receive all the light possible throughout the day. This necessity has been forcibly illustrated in the present instance by a few plants which stood in the end of the house and received the direct sunlight only until noon because of an adjacent building. Although they were by no means in the dark through the remainder of the day, yet the lack of light was plainly indicated by the greatly decreased fruitfulness, sufficient, as was remarked by an observer, to make all the difference between a liberal profit and absolute loss.

We have had to fight a number of insect pests, including the ever-present aphis and a black mite which is a near relative of the red spider and which has appeared with it. This mite appears not to yield readily to the commoner remedies which prove more or less effectual with the red spider, although it is destroyed by a solution prepared from one part of pyrethrum to four parts of alcohol (by weight), and applied with an atomizer. This is a tedious process, however, with plants as large as Tomatoes, and it is hoped that a better method will be discovered. On the plants mentioned it has been quite successfully held in check by burning the leaves which were most infested.

Four varieties have been grown this winter—the Lorillard, Ignotum, Dwarf Champion, and a yellow variety, the Golden Queen.

Of these, the Lorillard appears best adapted to forcing, although the Ignotum seems to approach it. The Dwarf Champion, while fairly productive, would be objectionable in most markets on account of its color, which is tinged with purple. The same objection would hold with the Golden Queen, although it is a beautiful fruit, and, if grown to a limited extent with the red varieties, would certainly add to their attractive appearance if tastefully arranged with them in the markets.

Although the cultivation of the Tomato is attended with somewhat more difficulty than many other forced crops, it brings generous profits when once its management is understood. In the crop referred to each plant occupies two square feet of space, and is producing, upon a very conservative estimate, at least an average of one pound of fruit a plant.

While this is very far short of the claim of an average crop of twenty-five pounds a plant for 300 plants, which was made and published last season, it is still large enough to allow of very satisfactory returns, as the wholesale price in our large cities ranges from fifty to seventy-five cents per pound through the winter months, so that one can readily estimate the returns of the crop from a house of a given size.

Cornell University. *C. W. Mathews.*

Some Useful Palms.

Astrocaryum Mexicanum.—This handsome species deserves a place in any collection of Palms, for, although it ultimately attains considerable size, it may be kept within reasonable bounds for several years. It has large pinnate leaves, the pinnæ being somewhat irregular in width in a young plant, dark green on the upper side, while the under surface is clothed with a silvery tomentum. The leaf-stalks, well armed with long dark spines, give this plant quite a formidable appearance, but also add to its beauty, and, as the foliage is of stout texture and lasts a long time, it usually remains well furnished. This Astrocaryum may be grown in a temperature that falls to fifty degrees at night, but will make more rapid progress in a warmer house, and it enjoys copious watering in bright weather. It is propagated by seeds and by suckers, when these are obtainable.

Ceroxylon Andicola.—The Wax Palm of New Grenada, as this magnificent plant has sometimes been called, is also a useful Palm when small, the leaves being quite tough and capable of enduring out-door exposure in the summer if they are not placed in the full sun, while for conservatory ornamentation it has few equals. It has pinnate leaves that sometimes attain a length of fifteen to twenty feet, this extreme size only being reached by fully grown specimens. The petioles are nearly erect and well clothed with narrow pinnæ, which are dark green and glossy on the upper side, and covered underneath with silvery scales, so as to make an effective contrast. In the young plants the leaves are frequently entire, as is the case with many other Palms. But this condition is gradually outgrown. The name of Wax Palm has been applied to this species from the singular fact that the trunk, when fully grown, is more or less covered with a coating of highly inflammable wax. This characteristic is not seen, however, in the ordinary conservatory specimen. In the matter of temperature this Ceroxylon is not very exacting. Though usually grown in stove heat, the fact of its having been found almost up to the snow line in New Grenada seems to indicate that cool treatment would be the most reasonable.

Acanthophœnix crinita.—This graceful Palm, originally introduced from the Seychelles, has the general character of an Areca, but differs from it in being profusely armed with long, needle-like black spines, which are abundant both on the stem of the plant and also on the leaf-stalks. The leaves of *A. crinita* are pinnate and from five to twelve feet in length, the pinnæ being pendent, and light green on the upper surface and silvery beneath. This Palm enjoys a rather high temperature, and in the winter should be watered with judgment, or the roots may suffer. It can only be propagated by seeds, as it makes no suckers, and, as the seeds sometimes take two or three years to germinate, patience must be exercised, or the seeds may be discarded as worthless before they have a chance to germinate. *A. crinita* is, however, a valuable plant when well grown, and quite repays any special effort that may be required in order to obtain a good specimen.

Nephrosperma Van Houtteana.—This elegant Palm is probably better known under one of its previous names—that is, either as *Areca nobilis* or as *Oncosperma Van Houtteana*—and is the only representative of the genus as it now stands. It is also a native of that favored locality for tropical Palms, the Seychelles, and has most gracefully arched pinnate fronds, with long dark green pinnæ. The stems of this species are also well protected by long dark spines, and, like all other spiny Palms, it is difficult to clean if brown scale secures a foothold, and therefore this pest should be closely watched for. *N. Van Houtteana* grows best in a warm moist house, and may be potted in such soil as would be suitable for Arecas, one of the requisites to success being good drainage. This Palm is by no means common, though its notable beauty entitles it to more extended recognition.

The Martinezias comprise another handsome genus of stove Palms. *M. caryotæfolia*, *M. erosa* and *M. Lindeni* are good examples of these moderately dwarf South American plants. *M. caryotæfolia* has dark green pinnate leaves, with pinnæ arranged along the petiole in groups of several pairs, wedge-shaped, and quite broad at the apex. This is a decidedly handsome species, and also a very thorny one, as the spines are not only arranged on the stems, but also to a greater or less extent on the under side of the pinnæ. *M. erosa* has also pinnate leaves, and, as its name indicates, the tips of the leaflets look as though they had been bitten. This species is extremely spiny, not only on the stems and under side of the leaves, but also on the upper surface. *M. Lindeniana* is somewhat similar in general characteristics to *M. caryotæfolia*, but has larger terminal pinnæ, which are lighter-colored beneath. *M. Lindeniana* makes very handsome specimens, and should be seen more generally.

Holmesburg, Pa. *W. H. Taplin.*

Notes from a Pennsylvania Garden.

Clematis graveolens.—This plant is not new, but it ought to be more widely known. It is hardy, of such vigorous growth that it rapidly covers a trellis or arbor, and yet it is exceedingly delicate and graceful in appearance. The flowers, it is true, are not as large as they are in some other varieties, and are not a perfectly clear yellow, but they are abundant, and are followed by pompon-like heads of fruit, which are far finer than those of any other species of Clematis. They are very symmetrical, of exquisite delicacy of detail, and last in good condition for several weeks. This species, moreover, is practically free from the mildew which attacks so many of our climbers. *Clematis Virginiana* ought never to be placed in even partial shade on that account, for it will be ruined by mildew before midsummer. It would be hard to say which is the best Clematis, but *C. graveolens* claims attention for its vigorous, graceful habit, striking fruit and freedom from fungus attacks.

Akebia quinata.—This woody climber is well known for its vigorous growth, which starts early in the spring, and its close-twining habit. It will soon cover a large surface almost as closely as an Ampelopsis. The quinate leaves are of a type not common with us, and they keep their shape and color so far into the winter that they barely escape being fully evergreen. The flowers, although not conspicuous, are deliciously fragrant, and become more abundant as the vine gets older. In order to reach good development it should have considerable direct sunlight. The most difficult problem to deal with in planting about buildings is to find plants that will thrive in the shade.

Saururus cernuus.—Experience here with the Lizard's Tail has been curious and interesting. It is not native to this region. About ten years ago a few root-stocks were planted in a small artificial bog along with several other species of marsh plants. The Saururus flowered that season, from buds previously developed, but has never flowered since. The yearly growth is exceedingly strong, and it has crowded out everything else, covering the whole surface of the bog. The water sometimes dries away entirely in the fall, but if this has any effect it would seem to be to diminish rather than increase the vigor of the plants, and therefore to induce, rather than prevent, their flowering. *Pontederia cordata* has not been affected unfavorably by this drying, nor has *Nymphæa odorata*.

State College, Pa. *W. A. Buckhout.*

Seed-Sowing.

WORK among hardy plants is now entirely suspended in the colder sections, but when the season reopens there will be many other things that will need attention at the same time, and, therefore, there is no better time than the present to arrange for the coming year's display. There is also no better time than the present to sow seeds of hardy perennials if one has the convenience of a heated house or a cold frame. We have found that many seeds of this class of plants are greatly benefited by a steady but thorough freezing. It seems to matter little whether the freezing period be long or short, provided it is steadily maintained for the time being. Seeds of the new *Aquilegia Stuarti* were sown last October in separate pots, the one being kept in the greenhouse and the other placed in a cold frame and frozen. The seeds in the former have germinated but sparingly, while apparently every one in the latter has germinated. The plant in question claims close relationship with *A. glandulosa*, and this is what suggested the experiment, it being well known that freezing is necessary to obtain the best results with that species. *Aquilegia Stuarti* is, however, said to be the finest Columbine in cultivation by the most competent authority. Many of the Columbines are benefited by the above treatment, while others will germinate readily if placed in heat at once. The more one has to do with this most fascinating part of gardening, seed-sowing, the more there seems to be to learn; and I repeat that if it is intended to raise perennials the coming season sow the seed at once, and place all in a cold frame for a week or two, and, if desired, they can later on be placed in heat, and time may thus be gained, or they may be left to germinate with the spring sunshine in the frame.

It is a good plan to sow the seeds, if obtainable, in the fall, and this gives the opportunity to handle the young seedlings during the dull winter months, for when these seedlings are to be cared for later in the season, the pressure of other work often leaves them neglected, and a season's flower is sometimes missed in this way.

The value of frost as an agent in helping seed to germinate is well known, but is capable of much wider application than is generally supposed. In the fall of 1889 we had a quantity of seeds of *Rosa rugosa*, which were sown in flats as soon as ripe and these were placed in a cold frame. That winter being remarkable for its mildness the seeds showed signs of activity early in March, and on being placed in heat they came up so evenly as to raise the covering of soil with them, and thousands of fine young plants were obtained in this way, which, with two years' good growth, would be very valuable young stock, as this Rose is largely used by planters, and quantities are imported annually to meet the demand. Seed of *Rosa rugosa* is somewhat difficult to clean, and to separate the seeds they must be freed from their outer covering; the best way to do this is to cover the hips with water in an open vessel and allow the mass to ferment until the seeds can be easily rubbed out with the hands. The seeds will then float and the refuse will sink. If it is intended to sow them this should be done as soon as the seed is dry enough to handle and treated as above. Cleaning by fermentation is perfectly safe as long as the seed has a hard outer covering.

South Lancaster, Mass. *E. O. Orpet.*

Begonia Scharffiana.—This new Begonia is now in bloom in Mr. B. P. Cheney's greenhouses at Dover, Massachusetts, and the flowers are rather disappointing. The flowering stems are produced sparingly and at uncertain intervals, so that never at one time can it be expected to be an effective and decorative plant, although its handsome foliage will always make it a desirable species and a fit companion for the Rex varieties. The flowering stems are coarse, extending about a foot above the foliage and covered thickly with reddish hairs. The flowers are white, but do not fully open, the larger sepals incurving, so as to give them a globular appearance, and their covering of reddish hairs somewhat mars their beauty.

Wellesley, Mass. *T. D. H.*

Streptocarpus Kewensis is still flowering abundantly, with no sign of ceasing, and it seems worthy of the praise given to it except for its color, which is a light purple and not satisfying. As some of the later hybrids are said to bear flowers of white and varying shades of red, perhaps these may prove more satisfactory in that respect. The crimped leaves are very attractive, and, unlike those of most Gesneraceous plants, do not seem liable to damp off under careless treatment, a point which will commend it to many. The introducers of the new varieties, apparently, do not intend that they shall be common, as their packets contain surprisingly few seed. They are about as small as Begonia seed, and germinate readily under same conditions.

Correspondence.

Intelligence in Plants.

To the Editor of Garden and Forest:

Sir.—Ever since reading Darwin's "Climbing Plants," I have wondered why he did not suggest that plants possess something akin to animal intelligence. I beg to narrate an instance which corroborates Mr. Ingersoll's observation in Garden and Forest (vol. iii., p. 318). I once planted a root of the *Ampelopsis quinquefolia* close to a dead Cedar-tree, which stood about five feet from the corner of my house. The vine climbed to the top of the tree, which had been trimmed of its branches, and here its upward growth was arrested. At first it threw out branches about equally in all directions, which bent over symmetrically. Then, as if conscious that in one direction only was anything it could reach, the branches on the side nearest to the corner of the house grew longest.

One branch, larger than the rest, was apparently selected to make the attempt to bridge the distance, and, to aid it, other branches on that side entwined around it, making a kind of rope. The leading branch continued to extend, reaching out its tendrils until it touched the corner of the house, when it fastened its sucker-like disks to the board. Then its supporters, one after the other, applied their tendrils to the house, and all together climbed in various directions until they reached the roof. Meanwhile the branches on the other side of the plant discontinued their growth and remained drooping.

Who that has watched the flower-stalk of the Cyclamen bend over until it buries its seed in the ground, has not been astonished at this intelligent effort? Many instances could be enumerated which are equally surprising, and in view of such cases it seems pertinent to ask why we credit animals with intelligence and do not credit plants with similar faculties?

Chicago. *E. M. Hale.*

The Name of Rhode Island.

To the Editor of Garden and Forest:

Sir.—Permit me to suggest as a more probable derivation of the name Rhode Island than the one given in your issue of December 24th, 1890, that *Rhode* in the old German idioms signifies to throw down, exterminate, clear up a forest, and corresponds to the English words "root out." Is it not possible then that Rhode Island signifies an island which has been cleared of wood? Geographical names with this meaning are common in Germany, Switzerland, England and other countries once covered with forests.

Bale, Switzerland. *H. Christ.*

Any argument that the name of the island of Rhode Island, afterwards transferred to the State, was derived from its being bare of wood seems to rest on mere assumption. According to local tradition, the island was well wooded till stripped of its trees for fuel by the British during their long occupation in the Revolutionary War. The records of the colony there in 1642 also indicate the existence of no small amount of woods, as wolves and deer were then so abundant that Roger Williams was specially appointed to agree with Mi-an-tun-no-my, Chief Sachem of the Narragansetts, as to the killing off of these animals by the Indians.*

The name of the island was not changed by the colonists from Ac-quid-neck to "Rhode Island" till 1644.†

It is also of record that in May, 1650, the General Court at Newport ordered, "That Pes-si-cus (successor of Mi-an-tun-no-my) shall have libertie to gett so many chestnut ryens [rinds or bark] upon the common of the island as may cover him a wigwam—provided he take John Greene with him, that no wrong may bee done to any particular person upon the island."‡

This suggests that not only Chestnut-trees of considerable size were then on the commons of the island, but that there were many others on the portions of the lands already allotted to individual proprietors. It must be borne in mind, too, that the lodge, or wigwam, of the Chief Sachem of the powerful Narragansetts was doubtless the council-house of the nation and no small affair.

The existence of wood on the island at its earliest settlement is further established by the fact that, "At a publiche meetinge held at Portsmouth (1640) there is libertie for men to get a shipp load of . . . . and pipe-staves and clap-board, under directions of the toune of Portsmouth. . . . ." "They . . . . to see to gett plankes and . . ."§

Further, in relating the settlement of this island, Arnold says: "The earliest export trade of Rhode Island was in lumber. The home prices were regulated by law. In the earliest enactment (January, 1639) these are fixed at eight shillings the hundred for sawed boards, seven shillings for half-inch boards delivered at the mill, and one shilling a foot for clapboards and fencing, to be sound, merchantable stuff." Timber was not to be cut "or exported without a license."‖

This was at Newport, the south end of the island, while the ship-load of lumber, "pipe-staves and clapboards," referred to above, was taken from Portsmouth, at the north end, about the same time.

It was also ordered at Newport in 1641, "That no fiers shall be kindled by any whatsoever, tu runn at randome, eyther in Medows or Woods."*

Arnold says: "The derivation of the name has given rise to much discussion, and that it is difficult to imagine by what strange fancy it was ever supposed to resemble the Island of Rhodes on the coast of Asia Minor, and that it is equally strange such a tradition should be believed, except that it is easier to adopt a geographical absurdity than investigate an historical fact."

Verrazano, in the service of Francis I., explored the coast and spent more than two weeks, in the spring of 1624, in the spacious harbor of Newport. His narrative of an island resembling the island of Rhodes refers distinctly to Block Island, which may be thought to resemble the Mediterranean island. But to this island Adrian Block, the Dutch navigator, gave his own name. Afterwards, like his Italian predecessor, he sailed into Narragansett Bay, and commemorated the ruddy aspect of the place, caused by the red clay in some portions of its shores, by giving it the name of '*Roodt Eylandt*' (Red Island) and by easy transition Rhode Island."†

Meetings of Societies.

The Western New York Horticultural Society.—II.

IN addition to our report of last week we give abstracts of a few more of the addresses delivered. No prizes were offered for fruit, but there was a remarkable display of apples, pears and grapes, notwithstanding the unfavorableness of the season. The advantages which fine exhibitions of fruit bring to fruit-growers, and the educating influence of such exhibitions upon the public, were discussed, and a committee was appointed to confer with the State Agricultural Society in order to secure the offer of such premiums for excellence in various fruits as would ensure a creditable display at the state fairs.

FRUIT-GROWING IN CANADA.

Professor William Saunders, director of the Experiment Stations in the Dominion of Canada, made an informal address on Fruit-Growing in Canada, from which we quote the following paragraphs:

"A few years ago it was decided to establish five experiment farms in various parts of the Dominion. These included a central farm at Ottawa and four others, making altogether 2,200 acres, under a common management. On Prince Edward Island are some of the best farms of Canada, and the system of rotation of crops—a seven-year system—is superior to any other system in America. The climate is very favorable to the production of apples. Nova Scotia likewise has a large area which is one of the best Apple-growing districts in eastern America. There is an unlimited demand for the fruit grown here, and the orchards are very profitable. The climate is very favorable for the production of cherries. During the late war some emigrants from western New York took cherries with them, and a great variety of promising seedlings has resulted from this introduction. The Bear River district has become noted for its cherries, producing them in great abundance. Peaches, also, contrary to what would naturally be expected, ripen nine out of ten years. The fruit interests are capable of being developed a hundred-fold without overdoing the business. One of the government experiment farms is located near the centre of Nova Scotia, which has a climate much milder than that of Ontario. Our Nova Scotia farm-experiments are devoted largely to apples and small fruits. A thousand miles west of this farm is the central farm at Ottawa. In addition to the usual experimentation in dairying and stock-raising at this farm, the entire work of a botanical, chemical and entomological nature is done for all the other farms, all questions of this character being referred by them to the

central farm at Ottawa. Notwithstanding the short period since the establishment of this farm, we have succeeded in getting a large number of varieties of fruits for testing. In addition to many varieties of standard American apples there are over 200 Russian varieties being tested and 3,000 seedlings, the seeds of which were collected from the best fruit obtainable near the northern limit of apple-production in Russia. In addition to the apples, we are testing many varieties of pears, plums and small fruits. Sixteen hundred miles west from Ottawa in Manitoba, near the town of Brandon, is the next experiment farm, part of which lies in the valley of the Assiniboin River. Here many experiments in forestry are taking place. The next farm is 200 miles farther west, lying in a dry belt of country, swept by hot winds from the south, thus giving very different climatic conditions from the farm next east of it. The most western farm is 1,500 miles farther on, near the Pacific coast. The climatic conditions in this territory of British Columbia are difficult to understand.

"Within twenty-five miles there is a change from a rainy climate similar to that of England to a rainless district just as there is in Washington upon the other side of the line. Here fruit-growing can be carried on with the greatest promise, most of the plant diseases of the Atlantic states being unknown here. The climate is especially good for apples and pears, which possess a peculiarly fine flavor. In Manitoba and Assiniboin, fruit-growing is difficult. The soil is so rich that the trees grow vigorously throughout the summer and fail to ripen their wood sufficiently to endure the rigorous winter. For this reason it is difficult to make even the hardy Russian trees succeed, and eastern trees are of no use whatever. We have yet to determine what fruits can be adapted to this region. A few Russian Cherries and Apples have grown fairly well. An important condition of fruit culture here is that of shelter, and with this aid trees develop an unexpected degree of hardiness, so that we feel that there is much to hope for from this source. The wild Raspberry grows well here, and Currants and Gooseberries also are quite successful.

"One of the most valuable lines of experiment work for these various farms seems to be the testing of all attainable varieties, as sometimes trees, from which it would not be expected, prove successful in our climate. In Manitoba, for example, very good specimens of the Wealthy apple have been grown.

"These farms are visited by hundreds of farmers who seem anxious to learn the results of these various experiments. Having observed that the forest-trees were very fruitful this year, a large collection of tree-seeds was made at the various farms, and these have been distributed in small packages through the mails to farmers throughout the Dominion."

HISTORY AND CURRENT PROGRESS OF ECONOMIC STUDY OF PLANT DISEASES.

In an instructive paper on this subject Professor A. N. Prentiss stated that while early writers on agriculture noticed the occurrence of diseases of plants, several chapters of Pliny's Natural History being devoted to the diseases of trees, the remedies suggested were all in the line of superstitious beliefs and practices. No real progress was made in the knowledge of this subject for centuries. Without referring to the history of the economic study of plant diseases in the Old World, Professor Prentiss went on to say:

"The first meritorious work of this kind in the United States appears to have been a paper on the diseases of the Grape, by Dr. Engelmann, in 1861. It was not until 1876 that Dr. W. G. Farlow's exhaustive study of the Black Knot was published.* This must be regarded as the first paper which, while possessing the highest merit as a biological study, was also of much value in its practical bearings. For as a rule the first step to be taken in gaining a knowledge of the proper method of combatting a plant disease is to acquire a thorough knowledge of the parasitic Fungus which is its cause. This paper of Dr. Farlow's was speedily followed by other important contributions by the same author. In our own state the work of the State Botanist, Mr. C. H. Peck, begun in 1868 and continued to the present time, has been of great importance. The work of Dr. J. C. Arthur on plant diseases at the Geneva Station in 1884–1887, largely of a practical and experimental nature, is well known. Nor should we forget to mention the researches of Dr. Burrill, especially on the Pear Blight, which established beyond doubt the cause of that destructive malady.

"No organized work of any importance was undertaken by the General Government until 1885. In that year was established the efficient section of Vegetable Pathology of the National Department of Agriculture. The work of this division, carried on by Professor Scribner from 1885 to 1887, has since been under the direction of Mr. Galloway. The division has now grown into large proportions, with a number of assistants and agents. Valuable information has already been widely disseminated, which, while touching all branches of agriculture, is of principal value to the fruit-grower.

"The most recent advance in the way of special work in the field of our present inquiry, is that of the experiment stations organized in every state under the Hatch Bill. In the published report of these stations no less than eighteen of them mention the Fungus diseases of plants as one of the most important subjects of investigation. Of course, provision for this work is no where completely adequate. Indeed, if the energies and funds of a station were wholly devoted to this subject, the ground could not be completely covered. The vastness of the field may be indicated by noting the number of Fungi which live upon almost any one of our cultivated plants. Thus, no less than fifty species are recorded as living upon a single species of Grape (*Vitis Labrusca*); on the Peach, twenty-eight; and on the common apple more than eighty.* Not all of these are parasites preying upon the living plant, and of these only a comparatively few are known to be to any important degree injurious; but no one can say when any one of them may not spring into prominence as causing plant disease, owing to changed climatic conditions or other obscure or unknown causes. The contributions that have thus far been made to our subject by the experiment stations could not in the very nature of things been very great; but a beginning has been made, and we must not be too impatient for results. An examination of the bulletins of the several stations for 1889 shows that some twenty papers were published. These vary greatly in extent and value, those of the Cornell Station, so far as fruit-growing interests are concerned, occupying the first place in point of merit and importance.

"As a further indication of the hold which the subject has on the public mind, it may be stated that laws intended to prevent the spread of plant disease, or looking to its suppression, have been enacted by some of the states, and the subject has been more or less agitated in others. How efficient these laws are, or may become, can only be ascertained by experience. Besides this, the subject is now receiving attention in all of the more prominent agricultural, horticultural and even botanical journals. During the past year many valuable contributions have been made, and in at least one of our horticultural journals a special department, fully abreast of the times, in which the articles are well written and admirably illustrated, is maintained.

"In the line of remedies for Fungus diseases only a single general method, varying more or less as to the details of its application, appears to be of unquestioned benefit. The underlying purpose in all cases is to destroy the germ or spore from which the injurious Fungus springs. The method consists of treating the affected plant with some preparation which, while not injuring the plant to any material degree, destroys the parasite. A very considerable literature is now available which discusses the best substances to be used and the best methods of application. While the operations called for are not especially difficult, the work can best be accomplished by those who have acquired skill in the matter by study and experience. It may therefore transpire that in time every community will have some one person, well equipped with suitable apparatus and material, who will make it a business to perform the work for the fruit growers of his region to the profit of all concerned."

The Committee on Ornamental Plants advised a more general planting of native trees and shrubs, and they recommended among promising novelties the following: A golden form of Hop-tree (*Ptelia trifoliata*), which is easy to transplant and is said to retain its color better than any other shrub or small tree, its foliage remaining a pure yellow until November; a pendulous form of the American Elm found in Cayuga County by Mr. Henry A. Morgan, and which is represented as growing with an upright trunk and long, drooping branches which have abundant foliage; the form of Black Locust which has foliage resembling the Mimosa, and which, with a large number of other varieties of this American tree, originated in Europe; a purple form of the Weeping Beech, and a sport of Nordmann Fir, which has yellow shadings on its dark-green foliage.

Mr. C. A. Green, in speaking of the value of improved varieties of fruits, gave some figures to show that the Concord

*The Black Knot. W. G. Farlow. *Bulletin of the Bussey Institution*, 1876.

*A Provisional Host Index of the Fungi of the United States. W. G. Farlow and A. B. Seymour. 1888–1890.

Grape has been worth at least $50,000,000 to the country. He added that the improvement in Strawberries had been most marked, and at an exhibition of seedlings at the Geneva Experiment Station last summer there were hundreds of varieties of such a high average excellence that a grower might safely have taken plants at random and secured a good collection. Our wild fruits offer a tempting field for experiments. It is only a few years since the Black Raspberry was domesticated; the Juneberry and High-bush Cranberry are already on trial. Dried elderberries are now sold at the groceries, and the fresh fruit was sold in the streets at paying prices last year.

Last year Mr. George Ellwanger gave the Society $1,000, with the provision that its annual income be devoted to prizes open to members of the Society. The committee to whom the matter was entrusted reported the establishment of the Ellwanger prize, which is to be awarded to the owner of the best maintained private place, special reference being had to the planting and general treatment of the grounds. The Barry medal, costing $50, will be awarded to the originator of the new fruit, ornamental tree, shrub or herbaceous plant or vegetable which, in the opinion of the committee, shall have the highest value.

In the report of the Grape Committee, Mr. W. C. Barry named as the six varieties which possessed the most decided value for western New York: Lady, Niagara, Barry, Concord, Worden and Gaertner.

Notes.

Professor S. T. Maynard states, on the authority of the Entomological Division of the Department of Agriculture, that the loss to the farming interests, including all its branches, for the past year from insects and fungi amounts to four hundred millions of dollars.

A comparison made at the Ohio Experiment Station for two years between male Asparagus-plants and female plants show that the former are earlier and more productive, and have a higher market value on account of the larger size and finer appearance of the shoots.

The fact that Grape-vines suffer from disease in so many parts of the world seems less surprising than the fact that they ever are in health when we read, on the authority of Von Thüman, a German expert, that 323 species of Fungus parasites have been recognized on *Vitis vinifera*.

The death is announced at Lyons, in his eighty-seventh year, of Jean Sisley, one of the most famous French horticulturists of the century, and known wherever plants are cultivated for his success in the production of new varieties of Roses, Tree Carnations, and especially of Cannas. More than any one else he made Lyons one of the centres of horticulture in Europe.

Elwes' Snowdrops have been in bloom in open borders for a fortnight, and their appearance is most grateful in this wild February weather. They were three weeks earlier in the exceptionally mild winter a year ago. Plants of *Galanthus nivalis Imperati* we have also seen flowering in a cold exposure. In a warmer border they would have been nearly as forward as *Galanthus Elwesii*.

A recent issue of *Le Jardin* contains a portrait of Victor Lemoine, the famous horticulturist of Nancy, with a list of the principal plants which he has originated in his long and successful career as a hybridizer. The list includes the double-flowered Portulaca which he raised in 1851, and many Clematis, Begonias, Lilacs, especially the double-flowered varieties, and Gladioli. M. Lemoine, who was born in 1823, is still active, and is as enthusiastic and eager in his favorite pursuit as at any time in his long career.

Governor Tuttle, of New Hampshire, recently called attention to the work of the Commissioner of Immigration, in consequence of which "more than 350 abandoned farms have been repopulated, mainly by Americans, and the business of summer entertainment has largely increased." The Legislature of the state has been asked by the Commissioner for an appropriation to pay for the preparation and circulation of a pamphlet describing and illustrating the attractions of New Hampshire as a summer resort, saying that "from the best statistics at our command there have been left in the state by summer tourists during the year more than $5,000,000," and that "a large portion of this has been left with the farmers."

It may now be considered as a well-established fact, says the *Botanical Gazette*, that vegetation exerts a definite and easily demonstrable drainage action on the soil. Ebermayer's earlier researches have shown that more water penetrates the soil of shaded regions than into that of naked fields. By some recent researches he shows that, while the surface portions of the soil in a forest is moister than open fields, this is not true of the deeper parts within the range of the roots of the trees, for this is distinctly drier. For example, at a depth from eighteen to twenty inches in a Fir forest of sixty-year-old trees the percentage of water is 15.12, as against 19.89 in naked soil. He has also determined that in soil covered with young trees (six years old) the loss of water by transpiration is intermediate between that from soil covered by mosses and that covered by grass.

The Brooklyn Society for Parks and Playgrounds has issued a circular calling attention to the law of this state under which it is incorporated and which makes it possible for the citizens of any town to associate for the purpose of providing recreation grounds for children and others. An association has been formed in this city, and it is desirable that similar ones should organize in other parts of the state. Ample and well-planted school-grounds, which will not only afford space for play but will insure abundant air and light in the school-building, are of vital importance to the health of the young, and liberal space should be provided in anticipation of the rapid growth of our towns and the increasing school population. We have already given the provisions of this law, but all persons who desire fuller information will receive a copy by addressing the Secretary of the Society, Mr. E. O. Ball, 43 Lee Avenue, Brooklyn, New York.

Mr. John Thorpe delivered a practical and interesting address on Chrysanthemums before the Massachusetts Horticultural Society last Saturday. He said that if the production of fine blooms was the chief object aimed at, the plants should be grown under glass continuously; they should be started in May, grown on in pots until they are planted on benches in late June or July. Recognizing the greatly increased number of varieties offered yearly, he urged the necessity of much greater restrictions in the matter of awarding prizes and certificates for seedlings. Out of the 120 American seedlings to be distributed this spring he thought it probable that only twenty-four of them would take rank with the best when the flowering season comes round again. Early-flowering varieties were considered very desirable, but the lecturer expressed the belief that, with very few exceptions, the early sorts which afford so much satisfaction in Europe would not succeed here. It was his opinion that if early varieties suitable to the American climate are to be had they must be raised in this country. He does not consider a blue-flowered Chrysanthemum outside the range of possibility, and argued that a sport may produce it. One of his hearers having attributed the decline of the outdoor cultivation of Chrysanthemums to the ravages of insects which render good growth impossible, Mr. Thorpe stated that the pests can be held in check by syringing the plants, while growing outside, twice a week with a solution of one ounce of bitter aloes in four gallons of water.

Catalogues Received.

Joseph Breck & Sons, 51, 52 and 53 North Market Street, Boston, Mass.; Vegetable and Flower Seeds, Agricultural Implements.—William Bull, 536 King's Road, Chelsea, London, S. W., England; Select Flower and Vegetable Seeds, Bulbs, etc.—A. D. Cowan & Co., 114 Chambers Street, New York; Garden, Farm and Flower Seeds.—De Lamater Iron Works, 21 Cortlandt Street, New York; Ericsson Hot Air Pumping Engine, The Improved Rider Compression Pumping Engine.—Ellwanger & Barry, Mount Hope Nurseries, Rochester, N. Y.; Wholesale Catalogue of Small Fruits, Fruit and Shade Trees.—V. H. Hallock & Son, Queens, N. Y.; Flower and Vegetable Seeds.—Herm. A. Hesse, Weener, Hannover, Germany; Nursery Novelties.—George S. Josselyn, Fredonia, N. Y.; American Grapevines and Small Fruit Plants.—John R. & A. Murdoch, Pittsburgh, Pa.; Flower and Vegetable Seeds, Fruit and Ornamental Trees, etc.—William Parry, Parry, N. J.; Small Fruits, Fruit and Ornamental Trees.—Phœnix Nursery Co., Bloomington, Ill.; Wholesale Catalogue of Trees, Shrubs, Roses, Bulbs, etc.—Pitcher & Manda, United States Nurseries, Short Hills, N. J.; Souvenir and Descriptive Catalogue of the Great Flower Show held at Madison Square Garden, New York, Descriptive Catalogue of Chrysanthemums and Single Dahlias.—Dr. H. Shroeder, Bloomington, Ill.; Grapevines, Fruit Trees, Small Fruits.—William Stahl, Quincy, Ill.; Fruit Trees, Plants and Vines, Excelsior Sprayer and Spraying Pump.—W. Thompson, 34 and 36 Tavern Street, Ipswich, England; Choice and Rare Flower Seeds.—Thomas S. Ware, Hale Farm Nurseries, Tottenham, London, England; Novelties in Dahlias, New Chrysanthemums, Vegetable and Flower Seeds.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, FEBRUARY 18, 1891.

TABLE OF CONTENTS.

An Experiment in Forestry.

THE Adirondack League Club, of which we have before spoken, owns a hundred square miles of timber in a compact body on the south-western outskirts of the mountain region of the wilderness. Some Beech and Black Spruce are mixed with the prevailing Birch and Maple, which here attain magnificent proportions, and scattered among them are small quantities of White Pine, Fir, Tamarack and Hemlock, besides single trees of Black Cherry and Elm, with Black Ash on the swampy land. The quality of the timber is said to be excellent; Birch-trees, which are three or four feet in diameter, as well as the tall, straight Spruces, are still vigorous and healthy. This region is within easy reach of the greatest lumber markets of the east, with waters capable of floating soft wood and a topography which admits of easy grades for roads, so that it offers good advantages for carrying on lumber operations and for intelligent forest-management. The lands of the Club have recently been inspected by Mr. B. E. Fernow, of the Forestry Department at Washington, and, if the recommendations in his report are adopted, the people of the United States will have for the first time a practical object-lesson in the management of their woodlands, according to the established principles of forestry. The tract offers a favorable field for such an experiment, for it is sufficiently large, and it contains a large amount of available and valuable material uninjured by fire, and within an accessible distance of good markets.

Bearing these facts in mind, Mr. Fernow's report is one of exceptional interest and value, in that it brings out clearly what the true function of forestry is, and it sweeps away some of the misconceptions that are almost universally prevalent, and which must be corrected before any successful forest-management can be established in the United States. Systematic forestry is a business carried on for profit in the production of wood-crops, just as agriculture is practiced for the profitable production of food-crops. Attention to this primary object does not exclude other considerations, such as the preservation of our water-supply and of certain climatic and soil conditions. Indeed, forest-management for profit and forest-preservation for other reasons may be in certain localities harmonious, but economic forestry in a wooded country means primarily the utilization of a wood-crop in such a way that the original growth, or a forest of trees superior to those of the original growth, will be reproduced with the least expense. The operations of the lumberman and of the forester differ in that the forester cuts his trees with the view to secure a desirable reproduction, while a lumberman cuts them without such forethought. The efficient management of a forest like the virgin tracts of the North Woods requires no planting unless it is desired to introduce new species, or unless clearing out and replanting appears profitable, and the most successful way of perpetuating the forest. In order to secure continued wood-crops, the forester takes advantage of the constant struggle for supremacy that is going on among the different trees of a wood. One species will gain a foothold by prolific seed-production, another by its dense shade, which will kill out its rivals, a third by a vigorous root-system, which enables it to endure the shade and bide its time until light is let in to give it aid. Different kinds of trees and the same species at different periods of its life have different needs in regard to light and other influences, and it is the practice of the trained forest-manager to assist the desirable kinds in their struggle for existence, to check the undesirable kinds and to create such conditions of soil and light as will improve the composition of the forest as it is reproduced, and secure for it the most profitable growth.

Hitherto prudent forest-management, looking toward continued reproduction, has not existed in this country, and therefore forest-property has had only a temporary value. The lumberman's practice has been to secure the valuable timber as quickly as possible, and leave the rest to rot, or burn, or deteriorate. So long as there are virgin forests to attack, the lumberman finds the greatest immediate profit in stripping one tract of its most salable timber, and then abandoning it to invade another. The owner of a large office-building will expend in repairs a part of his income from its rent in order to improve its future productive value, but the owner of a forest will not sacrifice a part of his present profit in the interest of a permanent investment. He operates his timber-tract so as to insure the quickest returns, and when it is exhausted he buys more land. Of course there must be a limit to such short-sightedness and extravagance. When that limit is reached the lumberman as we know him will give place to the forester, of whom we have heard. The man who plans for the future will supersede the man who works for the present.

This day may be nearer at hand than many of us imagine. At all events it is none too early to begin preparation for it. We have acquired great skill in the methods of forest-destruction; we know practically nothing of the best means of forest-reproduction. The ability to direct and modify and control the growth of a great forest can only be acquired by study and practice. This technical knowledge must be adjusted to the ever-changing commercial aspects of the forest as new uses are found for wood products and new markets opened. The managers of our future forests, plainly, must be men of sound judgment born of wide experience. It is to be hoped, therefore, that the Adirondack League Club will not be diverted from its purpose to carry on its proposed experiment. Let us have one example of a forest managed as a permanent investment. In other countries such ventures have proved profitable. The state forests there are not public burdens, but they help to pay the taxes, and it is not improbable that if the state of New York could buy the land in the proposed Adirondack Reservation at a reasonable price it could be made to pay as a business investment if placed under proper administration. The experiment to which we have called attention ought to furnish data which will help in

solving questions of this sort. At all events it ought to give Americans the unique opportunity of seeing a forest which is not in danger of being devastated and then abandoned, but which is looked upon as a property of ever-increasing productiveness and value—a forest in which the lumber camp and shanty and the temporary road give place to houses for constant occupancy, well-laid roads and permanent constructions for a scheme of operations which looks to the distant future. Not to speak of the educational value of such an establishment, its moral effect would not be inconsiderable. When the function of a forest as a source of production which is never to fail comes to be generally understood the public indignation at forest-destruction will be quickened. It will not seem a trifling or venial misdemeanor to fire a property which is growing in value under the expenditure of much thought and labor and money. Our forests will be guarded from destruction when the people understand how much they are worth, and an object-lesson in successful forest-management will be of signal assistance in spreading a popular appreciation of their value.

The Forsythia as a Pillar Plant.

THE illustration on page 79 represents the front of the entrance lodge of Mr. Hunnewell's estate at Wellesley, Massachusetts, draped with plants of *Forsythia suspensa*. It is published for the purpose of showing the value of this beautiful and well-known Japanese shrub for covering porches and arbors, and for training to pillars, for which purposes its long, flexible, pendulous branches admirably adapt it. There are, indeed, few plants capable of supporting the rigors of our northern winters which are so well suited to ornament the garden in this manner; and there is not in all the long list of our hardy shrubs a single one which produces year after year a greater wealth of brilliantly colored flowers and of dark-green, lustrous, handsome leaves, or which grows more freely and vigorously, or is less liable to the ravages of disease and of noxious insects. This plant is easily propagated by seed, which in some seasons is produced in large quantities, or by cuttings, which root very freely. Every branch when it touches the ground produces roots, and broad thickets are soon formed from which young rooted plants can be obtained. These planted in rich soil will grow, in the course of two or three years, into broad masses six or eight feet high.

Recent Botanical Discoveries in China and Eastern Burma.—I.

IT is now nearly eighteen months since I finished a series of articles in GARDEN AND FOREST on recent botanical discoveries in China. Since the last of that series was written Kew has received further consignments from D. A. Henry, partly from central and western China and partly from the little-explored island of Hainan, an island of considerable size in the extreme south-east of China, situated within the tropics. The collection from central and western China, mainly from the provinces of Hupeh and Szechuen, consisted of about 2,700 members, and probably not less than 1,500 species, including many new ones, to say nothing of new generic types. The collection from Hainan consisted of about 750 members, but was less interesting horticulturally. Since then, too, Forbes & Hemsley's "Index Floræ Sinensis" has been published down to the end of the gamopetalous orders, and some progress has been made with the apetalous orders. Further, the writer has assisted General H. Collett in working out an interesting collection of dried plants made by the latter in the southern Shan Hills, Upper Burma. Mr. A. Franchet has published three parts of the "Plantæ Delavayanæ," a marvelously rich collection from the province of Yunnan; and Mr. Maximowicz has made some important contributions to the flora of central Asia, north-western China and the contiguous territories from the collections of various Russian explorers, notably of Przewalski and Potanin. Although highly interesting botanically, these plants, generally speaking, are not of an ornamental character. In addition to these partly described collections, Kew has lately acquired a valuable collection made by Mr. A. E. Pratt in western Szechuen on the Thibetan frontier, at elevations of 9,000 to 13,500 feet. From a cursory examination this last collection promises to be equally as rich in novelties as any of the preceding.

When the late Dr. Asa Gray wrote on "Forest Geography and Archæology" about twelve years ago he drew some comparisons between the composition of the forests of the Atlantic and Pacific states of North America, and contrasted the American forests with the European and with those of the extreme east of Asia, eastern Mandshuria and Japan. The principal results of Gray's investigations were the relative great poverty of the forests of the Pacific side in deciduous trees as compared with the forests of the Atlantic side; the general poverty of the European forests having regard to the number of different genera and species represented in their composition, and the surpassing richness in genera and species of the extreme east of Asia, especially when taking into consideration the smallness of the geographical area. Dr. Gray computed the arborcous element in the flora of Japan and eastern Mandshuria and the adjacent borders of China to consist of sixty-six genera (nineteen coniferous and forty-seven non-coniferous) and 168 species, of which forty-five were coniferous. His estimate of the arboreous element in the European flora was just about half these numbers; but it was probably a little too low. Be that as it may, the estimate for eastern Asia was not too high; and Gray was of opinion then that the figures given were not exaggerated, and were much more likely to be sensibly increased by further knowledge than were those of any of the other regions. Subsequent botanical explorations in China have emphasized the wealth of the forests of temperate Asia. In central and western China what may be termed Japanese and Himalayan types overlap, the latter predominating. By types I do not mean identical species, for the majority are local, but species of the same genera, facies and character.

Not the least interesting among these recent collections is that alluded to above from the Shan Hills, in Upper Burma, the results of General Collett's spare moments. One of the most remarkable features in the Shan Hills flora is the predominance of plants belonging to genera characteristic of temperate regions, and this at elevations of about 4,000 feet above the level of the sea and within the tropics!

Before proceeding to an enumeration of the more noteworthy plants of the Shan Hills it may be well to say a few words respecting the climate, physical features and general character of the vegetation, extracted from General Collett's observations recorded in our joint report, which lately appeared in the *Journal of the Linnean Society of London*.

The area in which the bulk of the collection was made lies between the nineteenth and twenty-second parallels of north latitude, and is bounded on the east by the Palween River and on the west by the plains of Upper Burma, and consists of several distinct ranges of hills running north and south and rising in occasional peaks to a height of 6,000 or 7,000 feet, and enclosing table-lands of 3,000 to 4,000 feet above the sea-level. Along the western border of this mountainous region is a belt of jungle or forest of tropical composition. Up to about 2,000 or 2,500 feet of elevation the forest is dry, the soil poor, the trees stunted, and fires are of frequent occurrence. At an elevation of about 2,500 feet, and up to 3,500 to 4,000 feet, there is a great change in the character of the vegetation, owing partly to greater humidity, partly to a lower temperature. The trees are larger; Mosses, Lichens and Ferns abound; the hill-sides are covered with undergrowth, and numerous trees and herbaceous plants appear that are not found at lower levels: such are Quercus, *Schima Wallichii* and two or three of the arboreous compositæ of the genera Vernonia and Leucomeris. From the gloomy depths of this forest the traveler passes, by one step, as it were, on to the open breezy table-land intervening between the skirt of the forest and the next range of mountains; and the sensation is a pleasant one, after days of toilsome marching along narrow pathways cut through the dense jungle, where the atmosphere is stagnant and the view restricted to objects immediately at hand. Rolling grassy hills open before one, studded here and there with clumps and solitary trees of Oaks and Pines, and carpeted with low flowering shrubs and charming herbaceous plants. The presence at elevations of only about 4,000 feet of such genera as Thalictrum, Anemone, Ranunculus, Delphinium, Viola, Silene, Stellaria, Hypericum, Polygala, Impatiens, Agrimonia, Poterium, Epilobium, Œnanthe Galuim, Echinops, Primula, Swertia, Fraxinus, Pedicularis, Mentha and Ajuga will give an idea of the temperate character of the flora. Of course it does not follow that the species there found of the genera just enumerated would prove hardy in the climate of either New York or London. Indeed, the probabilities are that they would not; but General Collett collected a good many novelties that would well deserve the shelter of a greenhouse. His whole collection contained up-

ward of 800 species of flowering plants, belonging to very nearly 500 different genera and 110 natural orders—proportions only paralleled in some insular floras. It is not supposed, however, that these figures represent the true proportions of species, genera and orders in the whole flora of the Shan Hills, though the only kind of selection exercised in forming the collection was the exclusion of common and familiar weeds.

Kew. *W. Botting Hemsley.*

Notes on North American Trees.—XXIII.

45, *Rhamnus Caroliniana.*—This name of the arborescent Rhamnus of the eastern states was published in 1787. Miller, in the eighth edition of his "Gardeners' Dictionary," published in 1768, describes a *Frangula Americana*, which is perhaps this plant. Miller's description, however, can as well be applied to *Rhamnus alnifolia*, to which De Candolle ("Prod." ii., 25) doubtfully referred it. Unless, therefore, the identity of *Frangula Americana* with *Rhamnus Caroliniana* can be satisfactorily established, Walter's name should be retained.

47, *Rhamnus Purshiana.*—The black-fruited Buckthorns of the Pacific coast have lately been critically studied by Professor H. H. Rusby, of the College of Pharmacy, New York, who has contributed an important paper on the subject to the *Druggist Bulletin* for October, 1890; and by Mrs. M. K. Brandegee, the curator of the botanical department of the California Academy of Science, who has had excellent opportunities to study these plants in the field, and who has most obligingly communicated to me a large number of specimens collected in different parts of California and Oregon. The two working independently arrive at quite different conclusions with regard to the specific rank of the two plants known as *Rhamnus Purshiana* and *R. Californica.* Professor Rusby finds sufficient ground for keeping these two plants specifically distinct, and later investigations lead him to consider not only these two distinct, but incline him to give specific rank also to the pubescent form of the Mexican boundary region to the mountain form characterized by Mr. Greene as *Rhamnus rubra*, and to what seems a small-leaved form of the northern *Rhamnus Purshiana* distributed several years ago as *R. occidentalis* by Mr. Thomas Howell, of Oregon. The principal differences Professor Rusby finds in these plants are: the ordinarily greater size of *R. Purshiana*; the length of the petioles, which "are commonly two or three times as long in *R. Purshiana*," and in the leaves, in which he finds the chief distinguishing characters. "Those of *R. Purshiana*" he describes as "from two to six inches long, broadly elliptical, the base occasionally slightly cordate, but generally rounded or very slightly produced, and the apex rounded or very shortly pointed. The margin varies from nearly entire to slightly crenate and finally serrate. They are deciduous, thin and veiny; green on both sides, but somewhat paler below. The lower surface is densely and softly hairy, the veins hirsute. The upper surface is softly hairy when young, but becomes smooth, or nearly so, except within the strong channel along the midrib, which remains reddish or whitish-hirsute," while the leaves of *Rhamnus Caroliniana* "are only half the length of the last, elliptical-oblong or obovate, rounded or slightly heart-shaped at the base and occasionally short-pointed. They are often rounded at the apex, the margins varying from densely serrate to almost entire. They are thick and persistent, and generally evergreen. The under surface is strongly reticulate, reddish-veined, and the primary veins not nearly as numerous, straight or fine as those of *Rhamnus Purshiana.* Above the channel of the midrib is shallow and inconspicuous and smooth within, or there may be none. In this channel of the midrib I seem to have found an excellent characteristic." But it is in the structure of the bark of the two plants revealed by the microscope that Professor Rusby finds the unfailing guide by which they may be distinguished. "The characters and arrangement of the bast bundles, resin areas and medullary rays form quite as good evidence as do the leaf characters above detailed, and guide us to the recognition of the barks alone, which the leaf characters cannot do. The general structure of both exhibits medullary rays supported on either side with small bast bundles, circumferentially elongated, of an elliptical form. Of these there are sometimes two side by side between two medullary rays, while at other times a single large one reaches from one medullary ray to the other. In *Rhamnus Californica* they are more likely to occur in pairs. At the region where the medullary rays terminate, and extending from there to the corky layer, begins a zone of very large resin spaces of variable size and form, but many times larger than the bast bundles, which in appearance resemble them very closely indeed."

Mrs. Brandegee (*Zoe.*, i., 240), who passes over the characters based on the nature and the arrangement of the bast bundles, resin areas and medullary rays of the bark, with the remark "that their value in classification is yet to be tested, even if they hold good through large series of specimens, as in those of the writer, at least, they fail to do, and that there is no reason why these characters should not vary with age, exposure, climate and luxuriance in the same manner as the leaves do," finds that the only differences in different individuals from different parts of California consist in the form, texture and coating of the leaves, and that connecting the extreme forms are many intermediate ones, that the number of the nutlets (three in *R. Purshiana* and two in *R. Caroliniana*) which has always been depended on to separate these plants is of little value. These species, certainly, like all others of the genus, have sometimes two and sometimes three-seeded fruit. Mrs. Brandegee points out also that the red color of the bark of the branches, a character partly relied on by Professor Greene to distinguish his *R. rubra* (*Pittonia*, i., 68), is by no means unusual, plants not otherwise distinguishable being found in the same neighborhood, some with red and some with green-barked twigs. Of the southern tomentose form (*R. tomentella*), which Professor Rusby considers specifically distinct, Mrs. Brandegee says it "furnishes one of the strongest arguments for the specific identity of *Rhamnus Caroliniana* and *Rhamnus Purshiana.* It runs in the northern part of Lake and Collusa Counties into broad-leaved forms, which apparently bear the same relation to *Rhamnus Purshiana* that the southern *R. tomentella* does to *R. Californica.* It can hardly be supposed that if the species are distinct each can have a variety *tomentella* varying in the same manner as the species."

I have examined a large number of specimens gathered in all the great region where these plants are found, from the shores of Flat Head Lake, in Montana, through all the Pacific coast region to Mexico, and I confess, although it is several years since I have seen the plants growing, except in cultivation, I can find no characters which can be depended on to distinguish the described species. In all the essential characters upon which botanists depend to separate one species from another, *Rhamnus Purshiana* and *Rhamnus Californica* are the same—in external appearance of bark and in wood, in flowers and fruit, and in the color of the branches. This last is a character of little value, as in Oregon as well as in California it is sometimes red and sometimes green.

The only variation recorded in the structure of the flower is that noticed by Mr. Greene, in his *Rhamnus rubra*, the petals of which he describes as "externally setulose-hairy below the middle," a peculiarity which we cannot detect in the dried flowers he has sent to me; while the filaments described by him as deltoid are not apparently thickened at the base more than those of other flowers from California and from Oregon. Professor Rusby's character, based on the structure of the bark, would seem to require confirmation by the examination of a very large number of specimens gathered in all parts of the region occupied by this plant and from individuals growing under different conditions of soil and exposure. Until this has been done it hardly seems safe to depend upon it to separate species

otherwise not readily distinguishable. While there is no difficulty in distinguishing the extreme forms, these are connected by so many intermediate forms that it does not seem practical to characterize them specifically or even to find satisfactory varietal characters except in the case of the plant of the Mexican boundary region, which is distinct in the character of the tomentum which covers the branches and lower surface of the leaves.

In the humid atmosphere of the north-west coast-region and of the northern Rocky Mountains, where *Rhamnus Purshiana* grows in the dense shade of coniferous forests, it becomes a tree with slightly pubescent bright red or green branchlets and large, thin, broadly elliptical, obtuse or abruptly pointed deciduous leaves, sometimes hairy on the upper surface and on the principal veins below, with short pubescent petioles and prominent veins. In the less humid climate of central California the leaves are semi-persistent, usually thicker and smaller, sometimes lanceolate and acuminate. The pubescence increases as humidity decreases, the principal veins appear less prominent and their reticulation is more apparent; but in central California individuals occur in favored localities with the large thin leaves with the prominent straight veins of the northern plant, while near them are found others with the narrow coriaceous leaves of the more common California form. The California-mountain plant, with slender virgate branchlets and narrow, rather thin leaves, appears to pass, on the one hand, into the broad-leaved form of the north, and on the other into that of the California coast-region. With so many and so closely connected forms to be disposed of, the only way seems to be to consider them climatic varieties of the same species.

The species considered in this way serves to illustrate the influence of climate upon the gradual development of different closely connected forms. Abundant humidity produces arborescent habit and large thin deciduous, nearly glabrous, leaves which, as the climate becomes drier, are thicker, more persistent on the branches, smaller and more generally protected with a pubescent covering which increases in density as the amount of humidity decreases, the size of the plant decreasing also in proportion as humidity is withdrawn from it, the essential organs of reproduction being left unchanged. Very few of our trees, with the exception of certain western conifers, which seek high elevations as their range extends southward, and therefore are not subjected to very great diversity of climate, grow over as wide a range of territory of varied climate as *Rhamnus Purshiana*. Exceptions are the Negundo and the Celtis, both of these varying in different parts of the continent as remarkably as the Pacific coast Rhamnus in foliage and in pubescence.

Rhamnus Purshiana was discovered in 1805 or 1806 in what is now Montana by the members of the Transcontinental Expedition under command of Lewis & Clark. It was first described as *Rhamnus alnifolia* by Pursh. De Candolle first noticed that it was distinct from the eastern plant and described it in the second volume of the "Prodromus," published in 1825. The California plant was detected by Eschscholtz on the shores of the Bay of San Francisco in 1816, and was described by him in the tenth volume of the Memoirs of the Academy of St. Petersburg, published in 1826, so that the two plants being considered specifically the same, De Candolle's name of *Rhamnus Purshiana*, being the older by one year, would have to be adopted for the species thus enlarged.

In 1838 Rafinesque describes in the "Sylva Telluriana" his *Persoon laurifolium*, his description being drawn from a plant which he found in Bartram's Botanic Garden, in Philadelphia. It is a tree, he says, from the Oregon Mountains, with elliptical acute subentire shining, glabrous leaves; pubescent on the lower surface when young, reniform petals, and a slightly emarginate stigma. The plant in Bartram's Garden was twenty feet high, and the "berries form fine clusters and assume three colors, being by turns green, red and black when fully ripe." This is the earliest record of the cultivation of *Rhamnus Purshiana*, for there does not seem to be much doubt that it was this plant Rafinesque had in mind. Certainly there is no other tree from the mountains of Oregon which could be made to answer to the description. If Lewis & Clark, as is possible in the case of a plant of whose medicinal value they must have learned from the Indians, had brought home seed, these might very well have produced by 1838 plants twenty feet in height.

C. S. Sargent.

New or Little Known Plants.

Viola hastata.

THERE are several species among our American Violets which are rarely seen in gardens, although they possess much charm and beauty as garden-plants. Our common northern *Viola cucullata*, *Viola pedata*, the Birds-foot Violet, the charming little yellow-flowered *Viola pubescens*, and the white-flowered *Viola Canadensis*, one of the best plants which can be grown in a rock-garden sheltered by overhanging trees, are all excellent subjects to naturalize in the garden. Equally attractive, although much less well known, is the Halbert-leaf Violet (*V. hastata*, Fig. 16), which grows very locally in northern Ohio, and is found in the forests of the Alleghany Mountains from Pennsylvania to the northern borders of Florida. It is a yellow-flowered, slender, nearly glabrous species, distinguished by its halbert-shaped stem-leaves, which in one remarkable southern form are three-lobed, or even trifoliate (var. *tripartita*). This pretty plant will doubtless thrive in cultivation under the conditions which are favorable to the growth of *Viola pubescens*, to which, botanically, it is very closely related.

Plant Notes.

Barbacenias and Vellozias.

FROM the number of enquiries recently made with reference to the cultivated species of these two genera, it would appear that they are attracting the notice of horticulturists, and as many of them, particularly the uncultivated species, are of quite exceptional interest and beauty, some notes upon them may be acceptable.

They form a section or suborder of *Amaryllidaceæ*, but in general characters they differ widely from the common garden representatives of that order. Their most characteristic features are thus described by Lindley in his "Vegetable Kingdom":

"In Brazil, southern Guiana, and also in the Mascarene Islands, there occurs a race of plants which may be compared to Conestyles, of New Holland, on a gigantic scale. Martius, who calls them Vellozias, describes them as perennial Lilies, with their trunks closely covered by the withered remains of leaves, branching by forks, and bearing at their points tufts of leaves in the manner of a Yucca or Dracœna; some of them are from two to ten feet high, with a trunk sometimes as thick as a man's body. I find the structure of their trunks most curious. It consists of a central slender subcylindrical column, which never increases in diameter after its first formation, and which has the ordinary monocotyledonous structure. Outside of the column are arranged great quantities of slender fibrous roots, which cohere firmly by their own cellular surface, and form a spurious kind of wood, which is extremely like that of some kinds of Palm-wood, only it is developed by constant additions to the very outside of the stem."

Living plants of several species at Kew exhibit this remarkable stem growth, and in the Museum there are fine specimens of large stems.

The flowers of the cultivated species are large, elegant and richly colored, but they are small and unattractive when compared with some of the Brazilian species of Vellozia, which are described by collectors as forming beautiful plants with elegant foliage and Lily-like flowers from four to six inches across, their color purple, yellow, blue or white. Gardner collected specimens of some of the finest of them in Minas Geraes, and both he and other collectors state that they are common on the mountains of Brazil.

Seeds of these plants are freely ripened when in cultivation, and they may be kept at least six months without losing their

power to germinate. This has been proved this year at Kew, where seeds of *Barbacenia squamata* have been ripened. Indeed, we have proof that seeds offer an easy means of introducing these plants, in the fact that some of what may be *V. compacta* were sent to Kew by the ex-Emperor of Brazil in 1888, and that plants have been raised from them which are now eighteen inches high.

The mountains of south Brazil being the happy hunting-grounds of the Orchid-collector, it ought not to be difficult to obtain through him seeds of the most striking of these plants. Even the stems may be sent a long voyage with safety, for at Kew and also in the Jardin des Plantes at Paris may now be seen beautiful examples of a most striking species as yet undetermined, the stems many times branched, triquetrous, and clothed at the tops with bright green plicate leaves. These have been sent from Brazil within the last three years. Mr. Sander also introduced two years ago a fine specimen, four feet high, of *Barbacenia squamata* which is now at Kew, where it flowered freely all last summer.

Fig. 16.—Viola hastata.—See page 76.

According to Bentham and Hooker there are eighteen species of Barbacenia, all of them Brazilian, and fifty species of Villozia, natives of Brazil, Africa and Madagascar. Some very fine species have lately been found in this last country.

The cultivated plants of these two genera are as follow :

BARBACENIA PURPUREA. — This was introduced accidentally, seeds of it having been concealed in a small quantity of soil adhering to some epiphytes sent to Dean Herbert from Rio Janeiro. Some of the seedlings were sent to Lord Milton, whose garden at Wentworth House was at that time famous, and they flowered in August, 1827. This species is the only one that is generally known in horticulture, and even it is rare. It has a short stem, elegant grassy-green leaves, with spiny margins and tall, single-flowered scapes. The flowers have a trigonous tube, a flat, spreading limb of six lanceolate segments, colored a rich maroon-purple. What is probably merely a large-flowered variety of this is figured in Moore's *Magazine of Botany* under the name of *B. Rogieri*, which is said to have been produced by crossing *B. purpurea* with *B. squamata*. This plant is cultivated now in continental gardens as *B. hybrida*.

B. SQUAMATA was introduced from the Organ Mountains by Veitch of Exeter in 1841. It has the foliage of *B. purpurea*, but the stem attains a length of several feet and branches. The flowers are produced singly upon thin, wiry scapes, each flower being one and a half inches across and colored bright scarlet. This is almost certain to prove a most useful garden plant. It appears to have been lost from gardens until introduced to Kew last year.

B. SCHIDIGERA was introduced from Minas Geraes into Belgium by the collector, De Jonghe, in 1849, and was figured in Lemaire's *Jardin Fleuriste*, *t.* 198. It has a short stem, leaves six inches long, clothed with silky hairs, twisted and brown when old. The scapes are erect, one-flowered, and the flower is two inches long, the limb spreading and colored rich vermilion.

B. MACRANTHA was also described and figured by Lemaire from plants obtained through De Jonghe in 1853. It resembles the last-named in foliage and habit, but differs in having scarcely any flower-scape, and in the flowers being nearly twice as large. Neither this nor the last is in cultivation in England so far as I know.

The cultural requirements of Barbacenias are simple. They prefer an airy, sunny position in a warm greenhouse, an open soil such as suits *Odontoglossum crispum*, and a moderate amount of water. They seed freely, and their seeds vegetate readily if sown on peat in a warm house.

VELLOZIA ELEGANS is the only cultivated African specimen. It was introduced from the Cape or Madagascar in 1866, since when it has been in cultivation at Kew. It forms a

tuft of short wiry stems, branching freely at the base; the leaves are bright green, lanceolate, keeled, and about six inches long, and the flowers, which are borne singly on thin scapes as long as the leaves, are not unlike those of *Milla biflora* in form and size; they are at first lilac-colored, changing to white before finally turning green; they remain upon the plant several months before withering. This is a pretty little plant for the stove or warm greenhouse. It delights in sandy soil and plenty of sunlight.

V. candida flowered at Glasnevin in 1865, seeds of it having been sent to Dr. Moore from Brazil by Gardner. It has narrow-channeled, semi-erect leaves, with fine marginal teeth, and white star-shaped flowers three inches across, borne on erect scabrous peduncles.

There are young plants at Kew which may probably turn out to be *V. compacta*, which is one of the large-stemmed kinds described by Lindley, and which has flowers about six inches across, colored rich purple. There are also young plants of a Cape species, raised from seeds, but they have not yet flowered. Evidently these plants grow very slowly, and the tree-like specimens seen in Brazil and Africa are probably of great age. Of these stems might be introduced, but, failing them, seeds ought certainly be obtained for cultivation.

Kew. *W. Watson.*

Cultural Department.

Planting and Pruning in the Orchard.

ONE sees a good deal of advice offered in regard to orchard work, which, while it may be good under the conditions given, is only of value under those conditions. When we have to buy our trees from a nursery, often at a considerable distance, we must take the trees as we get them; and it is not strange, therefore, when we have to use many precautions, not in themselves essential under better circumstances. For example, take young trees grown in a highly manured soil, dig them carelessly, perhaps with a mechanical digger, leaving the roots short, with their ends so bruised that still more needs to be cut away, and the advice given to shorten in the young wood in a corresponding degree is good. Even then, it is too often the case that no growth can be expected from such trees the first season. On the other hand, if the farmer grows his own trees, or has them from a neighboring nursery, where he can have them taken up under his own inspection, he may get them with their whole root system practically intact, and can set them into the ground again within a short space of time. If this work is properly done, and the ground about the trees liberally mulched, the growth in an ordinary year will be but little checked, and cutting back wholly uncalled for.

There is a good deal being said just now about the formation of a "Nursery Trust," and perhaps this of itself will cause many who contemplate engaging in orchard work as their main business, to think seriously of growing their own stock. If this should be so, the organization of such a trust would not be without advantage. When one considers how simple a business, comparatively, the propagation of fruit-trees is, it is remarkable to note how few fruit-growers attempt to grow their trees from the start. Possibly the chief objection is found in the time supposed to be lost. This may be a good reason for buying a few trees to start with, in order to get an early supply for family use; but if home propagation is started at the same time, the orchardist will soon discover that but little time need be lost. If he is in a great hurry, he may get his stocks, or even his root-grafts (or stocks in bud), from a nurseryman; but if he at the same time begins with the seeds, growing his own stocks and grafting or budding them, experience will demonstrate to him that the loss of time is mainly imaginary.

From the necessity of the case, being without the means to buy many trees, I began in this way in my fortieth year, and expect next spring to complete the planting of a new orchard of 1,000 Apple-trees, begun two years ago, and I am now in my sixty-fourth year. Although laboring under the disadvantage of planting in a part of the country where no really iron-clad varieties were then known, and consequently having to replace nearly all of my earlier plantings during the first ten years, my oldest orchard has long been abundantly productive, even during the past unfavorable year.

The advantage of a well-managed home nursery is, first, in the knowledge acquired in regard to the character of each variety from its youth up, and second, in acquiring skill in forming the heads of the trees, so that but little subsequent pruning, other than that of a pocket-knife, will be needed. An orchard so grown from the beginning is worth many times more than one which has required and received heavy pruning in order to form a practicable top to each tree. A third advantage is in the opportunity to select the very best trees for planting. Seedling roots, even the best, differ among themselves. The union formed between stock and cion is not equally good in all cases; and there are other reasons why there is a great choice between individual trees in the best nursery, and such a choice the grower of his own trees alone has.

But greater still is his opportunity, not only to plant properly, but to take up the trees with all their roots practically uninjured and to set them out at once, with his own hands, in holes ready dug for them. Instead of being obliged to cut back all, or nearly all, of the previous year's growth, it may be left with the assurance, if the work is all well done, that a good growth will be made the same season. The cutting back at planting, so strongly insisted upon by commercial nurserymen and by most writers on the subject, is substantially a confession of the bad condition, comparatively, in which nursery trees are apt to reach the planter. "No growth the first year" has to be accepted as almost an axiomatic statement; but it will be found to have no reality when the practice I advise is carefully followed.

In the "cold north," except with the most perfectly iron-clad sorts, even the penknife cutting back of last year's growth is followed by serious and permanent injury to the young tree. The cut surface blackens, in part, perhaps, in consequence of the aphids collecting upon it, and, I have sometimes thought, poisoning the wood by thin saccharine excretion, which affords a nidus for Fungi that subsequently attack the wood. Certain it is that on dissection these cut limbs show death, and even decay, the second and third seasons; and though a thrifty growth may follow, yet, when full-bearing age is reached, an overladen limb, breaking down, will reveal advanced decay. I find this even in such a hardy variety as the Wealthy; and rigid investigation with saw and knife traces it back directly to the shortening of the young growth at planting, so generally taught by supposed experts in the business.

Newport, Vt. *T. H. Hoskins.*

Aquatics in the Flower Garden.

DURING the past few years a great change has been effected in our parks and private gardens in the style of "bedding out" toward something more natural than the ribbon border or set patterns and pictures. It has also been found that bold masses of foliage, combined with flowering plants, have a much more pleasing effect than when flowers alone are used. The Public Garden in Boston was much admired last summer, with beds of foliage plants representing the badges of the different army corps that visited that city, but there were no beds so effective or graceful as those by the side of the centre walk over the bridge, which were filled with sub-tropical foliage plants. These beds doubtless cost less labor and required less attention than the smallest of the badge beds.

Very effective groups can be made by the liberal use of aquatics, Palms, Cannas and other large-leaved and strong-growing plants. Musas are very effective in sheltered spots, where the leaves are not torn by the winds. Among aquatics the *Nelumbium speciosum*, or, as it is more generally known, Egyptian Lotus, takes the front rank. This is the largest of Water Lilies, with the exception of *Victoria regia*, but it has the advantage over the latter in being hardy, and can be grown in almost any garden. It is a strong grower and a rambler, and requires to be kept under control in the flower-garden or in the Lily-pond with other aquatics, as the roots spread so fast that it would soon crowd out all others. Almost any kind of tank will answer to grow it in, provided there is a depth of about three feet of water and brick walls or divisions to keep the plants within limit. About a foot of soil, composed of old sods and rotten cow manure, will be needed, and the planting should be done about the 1st of May or as soon as growth commences. The tank should be filled gradually with water as the plants grow, and on the approach of winter, if the water is deep enough to save the roots from freezing, it may be left in the tank; if not, the water should be drawn off, and the plants covered with leaves, salt hay, or litter to protect them. This makes a grand background in a tank where hardy and tropical Nymphæas are grown, or a stately object by itself, or in large tanks and lakes in parks. The native and hardy kinds of Nymphæa are all worthy of a place in the aquatic garden. The pink Cape Cod Lily is especially fine, and the white European Water Lily (*N. alba candidissima*) is the largest hardy white variety, a most profuse bloomer and a chaste and exquisite flower. Too much cannot be said for the new yellow variety, *N. Marliacea*, which is perfectly hardy and of easy culture. The habit of the plant is like *N. alba candidissima*.

It is a robust grower, flowering freely the entire season, with a beautiful flower, with broad petals of a light yellow color, and bright orange stamens. It is a great acquisition. These require no protection in winter, but to save the masonry-work of a tank leaves or evergreen branches or other litter may be used to cover the edges. All tropical

Fig. 17 —Forsythia suspensa trained on a Porch at Wellesley.—See page 74.

Nymphæas can be grown in the same tanks, either planted out or grown in tubs, plunged in the tank, but these cannot be safely planted till June, and must be taken out in the fall and protected in a greenhouse.

The Egyptian Papyrus is another very interesting plant, either to grow in water or to plant in a border grouped in a mass. In either case it requires a good rich soil and moisture. It forms a beautiful contrast to the deep green and metallic shades of Cannas. This plant and the Egyptian Lotus have a very remote antiquity, and figure constantly as sacred plants in early Egyptian art. Both were very useful aside from their ceremonial and religious uses, the Papyrus furnishing the material for paper and ropes, of which samples are found in the Egyptian tombs. The Lotus-seeds were eaten and the roots cooked as we cook potatoes. The Japanese and Chinese to-day plant the Lotus in the fields after the rice has been harvested and use the roots as food. There is a tradition that the American Indians used both the seeds and

roots of the American Yellow Lotus, *Nelumbium luteum*, for food.

Associated with Aquatics and in the rear of the tank, specimen Palms, Rubber-plants, Cannas, Ricinus, Caladiums, Phormiums, with Arundos, Bamboos, Eulalias and other hardy ornamental grasses, in single plants or clumps, are most picturesque. Many other plants will suggest themselves to lovers of flowers for use near the water edge and in suitable places. Spiræas, Iris, Acorus, Sagittarias, Cyperus and others may be planted beside Aquatics that require shallow water, such as Limnocharis, Pontederia, Pestia, etc. In half-shady places some of the fine foliaged Begonias and Caladiums planted along with hardy Ferns are very beautiful. If water can be combined with rock work it will give a much more pleasing effect in sub-tropical gardening. Foliage plants can be used in a variety of ways, and some of the commonest plants can be made most effective and to harmonize with plants of greater rarity if judiciously introduced.

Dongan Hills, S. I. *W. Tricker.*

Perennial Gaillardias.

WITHIN the past few years Gaillardias as hardy plants have become well known among those who cultivate such plants extensively, but the decorative value of the perennial Gaillardias is not so generally appreciated as it should be. The ease with which they may be raised, and the short time required to secure an abundance of flowers, are strong points in their favor, and the various uses to which the flowers are adapted when cut, owing to their durability, is another reason why they should be widely grown. The perennial Gaillardias are the offspring of *G. aristata*, a North American species which is found over a wide area in the western states, and although in cultivation for a number of years, it is only recently that it has been taken in hand for development, and the results are so far most satisfactory. It is not the best way, in commencing to grow Gaillardias, to get expensive named kinds. Our first attempt at their culture was to import a dozen named varieties; the greater portion arrived dead, and those which survived were not to be compared with others obtained later from seed. To those who have not hitherto grown these plants we would say procure at once, if heat is at disposal, a packet of *Gaillardia grandiflora* and sow thinly in boxes, and, as soon as the young plants are large enough to handle, pot them off singly in small pots, and, when weather permits, plant them out where they are to stay, and they will flower the same season. There is a great advantage in potting the young seedlings, as their roots are very delicate and do not bear the disturbance which is unavoidable in transplanting when the young seedlings are placed in flats. Should any variety of special merit in the opinion of the cultivator occur, the particular one may easily be perpetuated by means of root-cuttings. To do this the plant must be carefully lifted, the roots preserved and placed in sand in the propagating bench, and, if not covered too deep and kept moist, they will speedily commence to grow and make plants that may be treated as young seedlings. We have always found all the perennial kinds of Gaillardia, including the variety known as *G. Templeana*, to come readily from seed, though the reverse has been asserted. It is just possible that seed of perennial varieties may be offered under other names than *G. grandiflora*. This need not cause any hesitation, for the hardy kinds, under whatever name, are all derived from *G. aristata*, which is, so far as I know, the only hardy perennial species in cultivation, though several others are enumerated by Gray, in the "Synoptical Flora."

South Lancaster, Mass. *E. O. Orpet.*

Notes from the Harvard Botanic Garden.

ÆSCHYNANTHUS SPLENDIDUS.—The Æschynanthuses are tropical epiphytes which require stove treatment. The stems usually trail or hang down, and they are furnished with opposite leaves. Their trailing stems render them very appropriate plants for cultivation in hanging baskets. The plant here mentioned, however, has cylindrical stems of somewhat erect, scandent growth, and elliptic-lanceolate, pale green leaves, about three inches in length, occasionally arranged in whorls of three. It is a hybrid of garden origin. The flowers are borne in dense terminal clusters. The corolla consists of a curved tube three inches long, widening toward the five-lobed mouth, which is three-fourths of an inch across, the color orange-yellow at the base and scarlet at the top, with brownish marks on the three lower lobes. The creamy white pistil, with large circular stigma, protrudes an inch beyond the corolla and adds to the pleasing character of the flower. This plant usually blooms twice a year, once early in spring and again late in summer. Every young branch will produce a cluster of the showy flowers, which retain their full-blown beauty for several weeks. The plant should be grown in a pot and trained to a rafter or trellis; it is most effective in this way. Fibrous peat, with the addition of a little rough charcoal, is the most satisfactory material for potting. Cuttings planted in sandy soil, and kept moist in a close propagating box, will take root quickly.

JASMINUM SAMBAC.—The Arabian Jasmine, as this species is commonly called, is an old occupant of greenhouses. It is a stove plant of free climbing habit, the opposite, ovate-acuminate, cordate, rich green leaves, with very short petioles, measuring between two and three inches in length. The leaves are so closely arranged upon the stem that they often overlap. The pure white, salver-formed flowers are deliciously fragrant, and they are borne in clusters of about five on the little branches, which proceed from the axil of almost every leaf on vigorous young growth. The tube is an inch in length; the limb an inch and three-quarters across, divided into about eight oblong, reflexed segments. The flowers are most abundant during the latter part of summer, but old-established plants are almost continuously in bloom. This plant is seen at its best when trained somewhat loosely to a pillar or rafter, and, although more at home in a prepared border, it succeeds very well under pot-culture. It is propagated by inserting cuttings, prepared from the half-ripened growth, in sandy soil. There are two other quite distinct varieties of this Jasmine. One of these has semi-double or double flowers; it is of decidedly bushy habit, and therefore better adapted for pot-culture than the species. The name of the remaining variety, *J. Sambac trifoliatum*, affords all necessary description of the plant.

JATROPHA PANDURÆFOLIA.—A miscellaneous collection of stove plants is much enlivened during autumn and winter by the scarlet flowers of this free-growing shrub. The stem is woody, and, unless the tip is pinched out occasionally during active growth, of a somewhat rambling character; indeed, there is a tendency toward lankiness where this course is not pursued. The alternate leaves are green above and much paler on the under side. The specific name, meaning fiddle-leaved, indicates an outline which is common to them, but far from constant. The blade of the leaf is from three to four inches in length and toothed at the base, where it sometimes deviates from the regular form in being lobed or angular. The bright flowers, with five obovate petals, are rather more than an inch across, and freely borne in terminal cymes on a peduncle four inches long. The plant was introduced from Cuba, about 1800, by Mr. J. Fraser, at whose nursery in the vicinity of London it flowered shortly afterward for the first time in England. Cuttings of the young branches root freely in sandy soil with the aid of moderate bottom heat. When rooted the plants should be potted in a mixture of loam, peat, old cow manure and sand, in equal parts, and placed in a sunny part of a house in which a stove temperature is maintained, after having been started into growth in a more shady position. *J. acuminata* is a synonym frequently met with.

Cambridge, Mass. *M. Barker.*

Freesia xanthospila.—A plant of this favorite flower now in bloom does not differ in habit from others of the family. The scapes are furnished with five or six flowers produced in succession. The individual flowers are pure white, with a small blotch of yellow on one of the segments. The segments are narrower than in *F. refracta*, spike-shaped, narrowing abruptly into a long and rather slender tube. The flowers are rather more graceful and elegant than those of the more common species. *F. refracta alba* is now a very popular flower and widely cultivated, as it is so easily managed, but it seems to be inconstant in its markings; some forms are entirely white, and others vary from a slight blotch of orange at the base of tube to a considerable marking on the segments. *F. Leichtlini*, which also varies from this variety in its form, is usually suffused with orange-yellow in all its parts. *F. Fosteri* seems nearly, if not quite, identical with this variety, but is said to bloom later.

Elizabeth, N. J. *G.*

Begonia Winter Gem is one of several useful winter-flowering hybrids raised by Messrs. Veitch by crossing *B. Socotrana* with others. It was exhibited in beautiful condition by the raisers at a recent meeting of the Royal Horticultural Society, and proved its superiority over almost all other Begonias by the way it has weathered the fogs and darkness of this winter. The plant is scarcely a foot high, and it has rich, glossy green leaves and graceful, almost erect, scapes of regular bright crimson flowers. A peculiar character of *B. Socotrana* and all hybrids from it is that of retaining their flow-

ers until they wither. I have seen Begonia Winter Gem and its brother hybrid, Begonia John Heal, bear their flowers fully six weeks before they fade.

London. *A. S.*

Correspondence.

Winter Notes from North Carolina.

To the Editor of Garden and Forest:

Sir.—The Yellow Jasmine (*Jasminum fruticans*), a low shrub from southern Europe, has been constantly in flower for two weeks or more, notwithstanding the coldest night of the winter came within this time. *Spiræa prunifolia* also showed a few flowers in January. Shepherd's Purse (*Capsella Bursa-Pastoris*) and the little Dead Nettle (*Lamium amplexicaule*), so common in some gardens of southern Massachusetts, are also in bloom. I observed one plant of the Trailing Arbutus (*Epigæa repens*) and one of *Asarum Virginicum* in full flower; but the former was well budded, and our New England plants would have bloomed with half as much mild weather. Both of the Hepaticas grow here (*Anemone acutiloba* and *A. Hepatica*), but with handsomer mottled and colored leaves than those farther north, owing, no doubt, to their being so much exposed to the sun in winter. They do not bloom here, however, in the first warm sunny days, as plants in New England do, but seem to wait for the proper time, whatever the weather may be. And this seems to be the habit of most native plants here. The same number of warm days in New England, with no frost in the ground, would bring out almost all of our first spring flowers.

Both of the species of Ginger Root common to this locality (*Asarum Virginicum* and *A. arifolium*) are scattered through the woods of the lower elevations. Nowhere abundant as *A. Canadense* often is in New England, but almost everywhere, in moist, well drained, shaded soil, a sprinkling of them will be found, with their shiny, mottled green leaves as handsome as at any season. Several troublesome weeds here are sometimes cultivated north. On dry, cultivated soil, in places, the Passion Flower (*Passiflora incarnata*) is as common as the Canada Thistle is in parts of northern New England. The Cypress Vine (*Quamoclit coccinea*), Small Morning Glory (*Ipomea Nil*) and *I. lacunosa* are troublesome weeds in many cultivated fields. On the mountain-sides the Wild Potato Vine, or Man-of-the-Earth (*I. pandurata*), is abundant.

One species of the Greenbrier (*Smilax glauca*) is very abundant here, its leaves and fruit often persistent through the winter. The leaf is ovate, and sometimes cordate in outline, and turns to a reddish purple. These, with its black grape-like fruit, which it sometimes bears in great abundance, make the plant an interesting one as seen growing along the margins of thickets, but one who tries to penetrate these thickets, and finds himself arrested by its stout prickles, soon loses his admiration for its beauty. There are places, no doubt, where it might be used to good advantage, but the possibility of its spreading beyond its intended bounds might overbalance its merits.

The American Holly (*Ilex opaca*) shows the handsomest foliage of any native tree I have seen here. It is not abundant, but scattered specimens are found along the bottoms of ravines in which brooks flow, and also occasionally in the open country along the margins of streams. I have seen only two or three specimens in fruit. The severe frost of last March seems to have prevented its fruiting.

Lynn, N. C. *F. H. Horsford.*

Winter Flowers in California.

To the Editor of Garden and Forest:

Sir.—The earliest herald of the new year here is the Chinese Narcissus. Mongolian washermen are quite liberal with their national flower, and many specimens, after having blossomed once in water, have been turned out-of-doors, and blossom annually in the open border. They have been in flower now for several weeks. To-day one of my Trumpet Major Narcissus is in bloom. The Violets commenced to blossom when the cool weather set in. They have kept flowering ever since, and now are quite full. The Pansies, too, and a bed of Verbenas, in a warm situation, have bloomed in a desultory sort of a way all winter, and now present quite a bright appearance. A plant which seems strangely out of season is a Polyanthus, which threw out stray flowers late in the fall and is still in blossom. The Roses, too, feel the influence of the warm spell, and their buds are swelling. There was a Rose carnival at Pasadena, in the southern part of the state, about the New Year, but we wait till May for our Roses.

Ukiah, Cal. *Carl Purdy.*

Recent Publications.

Die Krankheiten und Beschädigungen unserer landwirtschaftlichen Kulturpflanzen. Von Dr. Oskar Kirchner. Stuttgart, 1890. 8vo, pp. 637.

The number of treatises on plant diseases which have appeared in Germany in recent years is so large that one could hardly expect any novelty in the method of treating the subject. In this well-printed and neatly bound volume the author has, however, arranged his material on a plan which differs considerably from that of previous works. In the first part, under the heading of Grains, Fodder-plants, Fruit-trees, etc., are arranged the principal plants known in the agriculture and horticulture of Germany, and under each species is given a popular account of the more frequent morbid appearances, as spots, distortions, tumors, etc., with the name of the fungus or insect which causes them. The plan might be called a dichotomous key to morbid appearances, and, except in its more detailed character, resembles the synoptical keys common in botanical manuals. A key to morbid appearances is, as far as we know, quite novel, certainly on such a large scale as the present. The second part of the book is a condensed account of the principal genera of injurious fungi, with a few genera of parasitic phænogams, and the genera of injurious worms, insects and snails. Under each genus is a description of the species mentioned in the first part of the book, cross references being made by bracketed numbers.

The plan is certainly simple, and, if practicable, the work must be of good service to those who have little previous knowledge of fungi and insects. Whether really practicable or not experience alone can decide. But fungi are so numerous and complicated that it may perhaps be doubted whether the unlearned reader could be supposed to follow the key with any great degree of confidence. If it should happen, as might easily be the case, that he had before him something not in the key, he would go hopelessly astray. For those who know something of fungi, the present key is cumbersome and less accurate than other methods found in previous works. Since there are no figures to aid the beginner, and he must depend on the text alone, we shall look with interest to know whether in practice the plan works well, for, if it proves to be a good one, it is likely to be adopted by future writers.

Exhibitions.

Orchids at Short Hills, New Jersey.

All last week the United States Nurseries were receiving visitors at the invitation of the proprietors, Messrs. Pitcher & Manda. Many persons from distant cities were there, and every one was repaid for the journey by the abundant display of Orchids in flower. In the chain of houses, 425 feet long, the Cypripediums were most numerous, the plants in flower numbering a scant dozen less than 700, while the Cattleyas flowering in brighter groups mustered 567 strong. These numbers give some idea of the extent of the exhibition, while the neatness of the whole, with the skillful arrangement and perfect health of the plants, made it unusually attractive in quality throughout.

In so extensive a collection, it is, of course, impossible to name all the plants of special merit. The 126 varieties of Cypripedium in flower, for instance, would naturally include most of the standard sorts which flower at this time. Perhaps the searcher for novelties would be most interested in the varieties Electra, Pitcherianum and Galatea, all good in their different types, and all flowering now for the first time in this country. Some hybrids between *C. venustum* and *C. Boxallii* were interesting. They were raised in this establishment, and the extent to which the production of new seedlings is carried on is appreciated by the visitor when he is introduced into a house where 1,700 seedlings are growing. Some of the Cypripediums are coming into bloom now about two years after the seed was sown. One of the hybrid Dendrobiums raised here is now in flower. It is from *D. Rukeri*, fertilized by *D. nobile*.

Other noteworthy Dendrobiums in bloom were the rare white form of *D. densiflorum*, large specimens of *D. thyrsiflorum* and *D. Wardianum grandiflorum*. There were fine varieties of *D. Ainsworthii*, and the variety *Wallichianum* of *D. nobile*.

The pick of the Angræcums was a large specimen of *A. sesquipedale*, with seven of its great white star-like flowers open at once. A good plant of the white variety of *Cælogyne cristata*, and some fine varieties of *C. flaccida* were the attrac-

tions offered by this genus; and among Cymbidiums there were good specimens of *C. giganteum*, *C. Lowianum* and its dark purple variety. The choice Cattleyas were varieties of *C. Percivalliana*, one specimen showing twenty-seven flowers, and some exquisite forms of *C. speciosissima*.

About the best of the Masdevallias in bloom was the large-flowered variety of *M. Veitchiana*, and the best of the Lycastes were some plants of *L. plana* and the ever-pleasing white variety of *L. Skinneri*. There were some fifty fine Odontoglossums in flower, one of them a grand specimen of *O. Pescatorei*, and some specially elegant varieties of *O. crispum*. The best Oncidium was a really splendid plant of *O. splendidum*, and of the Phalænopses a specimen of *P. Schillerianum*, with a spike thirty inches long and bearing thirty-four flowers, took the lead, followed by good specimens of *P. Stuartiana* and *P. amabilis Dayana*. There were many other things besides Orchids to see, but these plants should not be left without mention, of a magnificent specimen of *Vanda gigantea*, some fine examples of *V. tricolor* and Rollins' variety of this species.

Outside of the Orchid houses the visitors found the greatest delight in the long structure, where they walked under an almost interminable line of arching fronds of Tree-Ferns and the spreading leaves of great Palms, with Musas, Dracænas, Encephalartos and other plants grown for graceful effects of foliage. The houses branching off from this were each devoted to some special plants—one to Anthuriums, another to *Pandanus Veitchii* and Dracænas, a third to Camellias and Azaleas, a fourth to Cocos and Kentias, and so on. Perhaps the most interesting of these contained a broad central bench, devoted throughout its entire length of a hundred feet to Araucarias. The middle row of these was of a uniform height of some four feet, the outer rows growing shorter toward either side. The perfect evenness of the plants, with the delicate texture and color of their foliage, made a long, regular mound of soft green which was strangely beautiful.

New York. *S.*

Meetings of Societies.

Iowa State Horticultural Society.

THE twenty-fifth annual meeting of this Society, at its rooms in the state capitol at Des Moines, was largely attended, and although a series of severe winters has given a check to fruit-growing in the state, and many orchards have been killed, yet two mild winters have once more given good fruits and renewed hope. The apple industry in parts of southern Iowa is now fairly prosperous, and there are many large commercial orchards there. In northern Iowa, aside from some of the new Russian varieties, only the Oldenburg, Tetofsky, Wealthy and Whitney Number 20 can be recommended for general planting. The sum of $2,000 was appropriated by the Society for horticultural experimentation next year, and it was decided to continue on an enlarged scale the work of last year in crossing and hybridizing, with the hope of producing varieties of fruits which are better adapted to the various climates of the state. The following officers were elected: President, Eugene Secor; Secretary and Director of Experiment Stations, G. B. Brackett; and Treasurer, Henry Strohm.

PLUMS AND CHERRIES FOR THE FARMER'S ORCHARD.

Mr. H. A. Terry, of Crescent City, Iowa, delivered an address on this subject, from which we make the following extract:

"It is a well-known fact that the Sweet Cherry and the European Plum have not been grown successfully on the fine loam soils of the west, but on the clay soils on the eastern side of the state they are grown quite successfully. I have been experimenting for several years with many varieties of Plums, but my main successes have been with the American varieties. I have much faith in some of the Russian and Japan varieties, however, as they seem much hardier in tree and fruit-bud than any of the older European varieties. The following list of American Plums I can recommend for general planting in the farmer's orchard, and the names are arranged in the order of their ripening: Milton, a new variety, and the earliest of the Chickasaw class, has large, bright red fruit. The tree is a fine upright grower, very hardy and productive. Wild Goose is the well-known variety next in earliness, and very good for culinary use. Forest Garden follows close after Wild Goose, and is a fine dessert or cooking fruit. The tree is a strong grower, perfectly hardy and wonderfully productive. The fruit is a light mottled red, with a very thin skin, and is superior for canning. De Soto is a native of Wisconsin, with large yellow fruit, which becomes red when over-ripe. It is excellent in quality and unexcelled for canning. Rollingstone originated in Minnesota. The tree is hardy and productive of medium-sized free-stone fruit of excellent quality. The Wolf is a strong, rather upright grower, very hardy and productive of large, rather dark red, firm, free-stone fruit of good quality. Hawkeye, another new variety, has done well wherever it has been tried. The tree is a vigorous grower, upright while young, but becoming more spreading with age, very hardy and productive. The fruit is of largest size and finest quality; it is light red, mottled with darker red; the whole fruit becomes dark red when fully ripe. The firmness and large size of the fruit make it very desirable for canning. Forest Rose is a late variety, with fruit of good size and good quality. The color is dark red, like that of the old Miner, of which it is a seedling. It bears abundantly, and the fruit keeps well. Maquoketa is another seedling of Miner, with fruit a trifle larger than its parent, and is one of the best for culinary purposes. If the farmer wishes to prolong the plum season he should plant a few trees of the Moseman, probably the latest variety in cultivation. The fruit is only medium in size, of a bright shining scarlet, and it ripens in early October, but will keep fresh until November. The tree is vigorous and most productive. The fruit is not of the first quality. Its chief value consists in the lateness of its season and its great productiveness.

"The list of really valuable Cherries is not a long one, but two or three of the old sorts would pay to plant, even if one has to replant, say every ten years. Early Richmond, Dyehouse and English Morello are all good varieties, but are not long-lived trees, and will require to be renewed every ten or twelve years. The Russian varieties that have been sent from the State Agricultural College seem to be hardier and more enduring for our severe climate. Among the most promising varieties so far in our state is the Wragg, introduced by Mr. John Wragg, of Dallas County. The fruit is a little larger than English Morello and of fine quality. Another Russian variety is a hardy and handsome tree, with fruit of finest quality, which ripens eight to fifteen days earlier than Early Richmond. The cherries are large, light red, and they hang on stems two to three inches long in a convenient way for picking. If it has a name I do not know it."

CROSSING AND HYBRIDIZING FOR FRUIT.

An address on this subject was delivered by Mr. N. E. Hanson, who did much practical work in this direction under the direction of the Society last year. He said:

"Much excellent work has been done in improving flowers, garden vegetables, grapes and some of the small fruits by hybridizing and cross-breeding, but comparatively little work has been done with the orchard fruits, because results are not so quickly reached, and we have been satisfied with chance seedlings and allowed insects and the wind to do most of the work for us. But the peculiar climate of the north-west requires especial care in originating new varieties better adapted to this vast region. The indiscriminate sowing of seeds is an expensive lottery. Breeders of animals select the parents, why should not breeders of plants do the same? Crossing and hybridizing plants is a method of abridging the process of evolution by introducing new elements of variation. The primitive types peculiar to each region should be used, if possible, for one side of the cross to impart hardiness, because they have become fully adapted to the environment by centuries of selection. The cultivated types should be used to impart size, beauty and quality of fruit.

"In conducting a series of experiments in crossing fruits for this Society last year I adopted the following general method: About twenty-four hours before the flower opened the stamens were removed with a pair of small forceps or pincers, such as are used in botanical laboratory work. In practice, only the anthers are removed, leaving most of the filaments. Generally, only two flowers in each cluster of Apple-blossoms were operated upon; the others were removed. Blossoms growing on a strong spur were preferred to those near or at the end of a limb. Most, or all, of the petals were removed to give easier access to the stamens. A one-pound thin manilla paper sack, with bottom squared so it could stand on a level surface, was then used to cover the blossoms and protect them from insects and foreign pollen. The next day the sack was removed, pollen applied to the stigmas with a camel's-hair brush, and the sack replaced. This time it

should be fastened with fine wire, such as is used for nursery-tree labels, because pins fail to hold the sacks satisfactorily in heavy storms. In about two or three weeks the paper sack should be removed and a sack of mosquito netting substituted. The paper sacks will withstand the ordinary wind and rain storms of an entire summer and fall, but the fruit does not hold on as well as when mosquito-netting sacks are used, soon after the fruit has set, to give access to sunshine and air.

"In crossing Grapes, from fifteen to thirty flowers were left in each cluster. I found that pollenizing could be performed to good advantage by taking clusters of bloom just opened and fastening them with string and fine wire in close proximity to the emasculated clusters. This was much easier than gathering the pollen and applying it with a camel's-hair brush. Paper sacks were used until the grapes were well set, then mosquito netting.

"The principal work was with the native Crab (*Pyrus coronaria*). The two representatives of this species used were a large-fruited variety growing on the grounds of Mr. B. A. Mathews, at Knoxville, Iowa, and the Soulard Crab. Pollen was applied of the following fourteen varieties: William's Favorite, Jonathan, Ben Davis, Pound Sweet, White Pippin, Willow Twig, Roman Stem, Summer Pearmain, Grimes' Golden, Red Stripe, Haas, Mother, Munson's Sweet, American Beauty or Sheriff. Sixty-eight fruits were obtained, containing 235 seeds. The hope is that we can combine the hardiness of the wild Crab with the size, quality and color of the cultivated Apple. If this be not accomplished by the first crosses the work is to be continued, using these as a foundation.

"The work with the Soulard was done near Des Moines, and its pollen was applied to the Red Stripe, Summer Pearmain, Ben Davis, Jonathan, Early Joe, Haas, Plum's Cider, Lowell. One hundred and forty-one fruits, containing 590 seeds, were obtained.

"The general theory followed in this work is that hardiness is imparted by the seed-bearing parent; quality and size by the pollen-bearing parent. But, to test the theory, Rawles' Janet was pollenized with Mr. Mathews' Crab, and twenty-nine apples, containing 111 seeds, were obtained. With the Raspberries the chief aim was to combine the earliness of Tyler and Marlboro with the size and quality of Shaffer's Colossal and Antwerp, and to improve the color and shipping qualities of Shaffer's. With the Blackberries the aim was to increase the hardiness and improve the fruit and habit of growth. The wild Blackberry was crossed with Snyder and Stone's Hardy, and the cultivated Blackberry with Lucretia and Windom Dewberries. The purpose is to obtain a variety with fruit as large as the Lucretia Dewberry or Erie Blackberry, and with a half-reclining habit, so as to keep the berries out of the dirt, and yet make winter protection easy where that is necessary; also to combine the hardiness of Snyder with the quality of Taylor's Prolific.

"The Blackberry and Raspberry were hybridized, and berries of both were obtained. These two species have been united before this by Saunders, Carman and others, but, so far as I know, no valuable variety has been obtained. The union appears to be too violent. But the plants produced have not all fruited, and, perhaps, success may yet be attained. Probably the best results will be from seedlings of these hybrid fruits; that is, by partial reversion the plant will be largely of one species, but retaining some desirable characteristic of the other species, thus giving it a special value.

"With Grapes the plan was to combine the earliness of Worden, Cottage, Champion and Moore's Early with the fine quality of Empire State, Salem, Agawam and Vergennes. Worden was the chief variety used as the pistillate parent, because it combines, in a pre-eminent degree, hardiness, earliness and productiveness."

STONE FRUITS AND THEIR PROPAGATION.

Professor J. L. Budd, in speaking on this subject, said that none of the varieties of Cherries first introduced into Iowa from south-west Europe have proved really satisfactory except in a few favorable locations. Some of the varieties introduced by the Iowa Agricultural College from north-east Germany and Russia promise well in parts of Iowa and the north-west, where the older varieties have failed to live. As for propagation of the Cherry, root-grafting on Mazzard is better here than budding on Mahaleb. Promising hardy stocks are *Prunus Pennsylvanica*, *Prunus pumila* and east European forms of the Morello. European experience favors growing all the stone fruits on their own roots, especially from root-cuttings. Successful experiments in growing stone fruits from short root-cuttings have recently been carried on at the Iowa Agricultural College. The Myrobalan, Black Damson and St. Julien have proved failures as budding stocks for the Plum in the west, because they are not hardy and are liable to root-kill in the nursery. Native Plum stocks of the type of De Soto, Wolf, Wyant, Hawkeye, etc., are the best stocks obtainable for western use for the native and foreign varieties.

Sun-scald and gumming of the stem can be avoided in a large measure by growing the trees in bush form with very low stems, those not more than a foot high being preferable. Trees on tender stocks should be set from four to six inches deeper than they stood in the nursery, to protect the roots and to encourage the emission of roots from the scion. One-year trees of the stone fruits are best for planting in orchard. Regular bearing is promoted by mixed planting of several varieties to insure better pollenization of blossoms.

FORESTRY FOR THE NORTH-WEST.

The following extracts are from the address of Mr. C. F. Gardner, of Osage, Iowa:

"In a prairie region like ours it is useless to plant trees until the sod has been turned and completely rotted and the soil mellowed. On an open prairie the first requisite is protection against winds. The ground for shelter-belts should be prepared first, and rapid-growing evergreens planted. My plan is to plow a strip not less than a rod wide, enclosing the area to be planted in forest. I go over this strip with a pulverizer until the soil is in fit condition to plant Onion seeds, and then plow a deep furrow, perfectly straight, on the line of the proposed hedge-row. In this furrow I set the trees, digging deeper with a spade when necessary, so that the trees will stand a little deeper than they grew in the nursery. Trees about eighteen inches high that have been transplanted should be chosen.

"I would recommend the following selection of shelter-trees in the order of their merit: White Pine, Norway Spruce, White Spruce, Scotch Pine, Red Cedar and Arbor Vitæ. Plant White Pine or Scotch Pine not more than two feet apart in the row, the other varieties not more than eighteen inches. This gives a chance, in thinning, to leave the Pine at eight feet apart and the others six feet. The thinning must be done before the plants begin to crowd; either transplant them or cut them out.

"After planting the ground should be kept absolutely free from grass and weeds; but it should be cultivated very shallow, never more than two inches deep, and less than that if possible. Go over this belt with a hoe as many times as necessary during the season.

"After the wind-break is started prepare the enclosed area for the planting of forest-trees. Free the surface from all clods, corn-stalks and rubbish. Mark off, in rows four feet apart, rows running east and west. Plant no tree within twenty-four feet of the wind-break already planted. This space should be planted with Corn, Potatoes or Beans. By planting in this way the wind-break or the forest-trees will never be broken down by drifting snow. In winters where the fall of snow is heavy, accompanied with high winds, it is not unusual for the snow to pile up from twelve to fifteen feet deep on the side of the wind-break opposite the direction from which the wind comes. Such volumes of snow are extremely liable to crush everything beneath them, as we have found to our cost.

"The Black Walnut, Butternut and Ash should be interspersed with the other varieties, as their foliage is not dense enough to properly shade the ground during the earlier stages of their growth. Always plant two or three times as many seeds as the number of seedlings you desire, for there is always a loss from mice, birds, accidents, etc. The trees should stand, at the end of the first year, not more than six or twelve inches apart. The end to be attained at first is to have the ground completely shaded as soon as possible. When this is secured, at all stages of growth thereafter, the thinning process should be so conducted as to keep it covered. At the end of the second year the plants ought to be thinned to two feet in the row."

Upon the same subject Mr. M. E. Hinckley said that there was little waste land in north-western Iowa, and while each acre in grass or grain yields immediate income people will not plant timber extensively, and yet, except in the newer sections, it is rare to see a farm without some trees. One to five, and sometimes ten, and rarely twenty, acres are found in groves. These groves are composed almost entirely of native trees, with some White Willow and Catalpa. Trees on low land are noticeably most vigorous. The Black Walnut bears when ten years old, and the White Ash at fifteen years gives a stick fit for a wagon tongue. Two acres of Maple and Willow furnish a family with fuel for a year, renewing itself as needed. The Catalpa comes short of expectation, and its introduction in this

region was probably a calamity, for if the money and labor expended upon this tree had been directed to other species we should have had something more valuable.

The errors of the past have been a neglect of proper cultivation and thinning, either of which is ruinous. The obstacles to interest in forestry are: (1) Remote profits; few people are making investments for their children when there is no certainty that real estate will remain in the family. Indeed, when the proverbial restlessness of the American citizen is considered, the probabilities are the other way. (2) The tenant system of land cultivation, which is on the increase. (3) Recent losses by drought have discouraged planters. Thorough cultivation, or if this is not possible, a heavy mulch of straw as a substitute, will alone secure success.

Mr. John Wragg said that for Iowa farmers a shelter belt could be most rapidly and cheaply grown by planting one row of Norway Spruce and one of Scotch Pine. One of these makes a rapid upright growth, while density is secured by the other. A more beautiful belt is made by planting two rows of White Pine and one row of White Spruce, the latter on the leeward side. Care should be taken, however, that the Black Spruce, an altogether inferior tree, is not substituted for the White Spruce. Red Cedar yields the quickest returns for posts, and the Larch is the best for the many uses which farmers have for small straight timber.

The most valuable Grapes for the west, according to Hon. Silas Wilson, are seedlings of Concord, and, named in the order of their value, these are Worden, Moore's Early, Lady, Pocklington, Cottage, Martha, Hayes, Woodruff's Rud, Moore's Diamond, with Esther, Colrain, Rockwood and Eaton as promising seedlings. Among the promising seedlings recommended by Mr. T. V. Munson, of Texas, are Brilliant, George W. Campbell, Romel and Hermann Jaeger. Of sixty varieties fruited last year, Mr. Wilson names for his region the following as the best six: White, Moore's Diamond, Pocklington and Lady; black, Worden, Moore's Early and Cottage.

Notes.

Of the varieties of Beans tried for forcing at the Experiment Station at Ithaca, New York, Sion House was found superior to any of the other varieties tried in compact and rapid growth, earliness, productiveness, and long, straight, symmetrical pods.

Two years ago some tests were made at the Cornell Experiment Station to ascertain whether deep-set Cabbage-plants were superior in any way to those set at their natural depth. No appreciable difference was observed. This year two hundred plants of the Early Wakefield Cabbage were set in six parallel rows, every other row containing plants set at the same depth as they stood in the seed-bed, while the alternate ones contained plants set with the first leaves even with the surface. In a heavy clay soil without fertilizers the shallow-set plants gave an average of eighty-five plants to the hundred which produced solid heads, while the deep-set plants gave only seventy-seven solid heads to the hundred. The heads of the former also weighed twelve per cent. more on an average than the others.

The disease known as the yellows is decreasing in Michigan, and the planting of Peach orchards is increasing. In Maryland the disease is said to be rapidly on the increase. This indicates that the Michigan law, which seems to have been vigorously enforced, is having a good effect, and tends toward the eradication of a malady which so far has proved incurable. It has been held by many people of southern New Jersey, as well as of the Chesapeake peninsula, that the yellows could be cured or, at least, held in check by the use of proper fertilizers, but the experiments of Dr. E. F. Smith, the special agent of the Government, who has made more than a hundred tests and tried all the remedies recommended, seem to make it clear that no treatment of this kind can be trusted either to cure or prevent the disease. It appears, therefore, that it is only by a rigid law, which is enforced by a strong public sentiment, that the Peach industry can be saved from ruin.

One of the best collections of greenhouse and other plants in the neighborhood of New York is in the garden of Mr. William Brown, of Flatbush, Long Island. It is always accessible to visitors, but on special occasions it is thrown open to the public, and an admission fee is charged, the proceeds being devoted to some charitable object. No expense is spared at such times to give a gala appearance to the place, and preparations for an exhibition in April are now being made. The beneficiary in this case is to be the Home for Destitute Children, which will undoubtedly receive a handsome sum. At the grand Chrysanthemum exhibition, held last autumn at the same place, nearly $1,500 were received for charity. The main feature of the April show, besides a great display of Orchids, will be an immense collection of Ixias, Sparaxis, Calceolarias and bulbous plants in bloom. We mention this as an example which is not unworthy of imitation by other gentlemen who have extensive greenhouses and grounds.

The work done at the New Haven Agricultural Experiment Station has long been favorably known, especially in the line of chemistry. Since the appointment of Professor Roland Thaxter as Mycologist excellent work has also been done on the subject of plant diseases. The report for 1889, issued in 1890, contains an interesting account of Fungi which attack Onions, an important crop in Connecticut. Professor Thaxter gives a detailed notice of the smut (*Urocystis cepulæ*), describing the germination of the spores, which he was the first to observe, the relation of this species to other species of Urocystis. He then considers the means of checking the disease, and shows by photographic reproductions the favorable effect of different chemical substances. He also discusses other Fungi injurious to Onions, and gives notes on Fungi injurious to other crops in Connecticut, the mildew of Lima Beans, caused by *Phytophthora Phaseoli*, Thaxter, a species related to the potato-rot, being especially interesting. A recent bulletin, issued last December, has a preliminary account of the potato-scab as it occurs in Connecticut. Professor Thaxter finds that in his region the scab is not due to the attack of a specific bacterium, as is supposed to be the case in the scab found in some other regions, but by a minute fungus which, except for its apparently true branching and aërial fructification, resembles in some respects certain of the polymorphic bacteria, but cannot as yet be referred to any described form and answers to no generic description.

The *North-western Lumberman* says: "For several years certain Germans have been experimenting with a view to using sawdust as a material for mechanical purposes. It was discovered years ago that vegetable fibre, after subjection to certain chemical action, and afterward to a pressure sufficient to expel all liquids from it, could be made into a substance almost indestructible by the elements, and of great utility in the mechanical and ornamental arts. The only trouble has been from the fact that but a few kinds of fibre were capable of the transformation under any existing formula. It might almost be said that there was only one fibre that, so employed, produced results satisfactory in respect of economy of manufacture and beauty and usefulness of the resulting product; and that one fibre is cotton, its delicate structure, strength and ready submission to the action of the necessary chemicals keeping it almost alone in its adaptability for the purpose. Thus far, almost the only result has been the manufacture of celluloid, which is unsuitable for anything but the finer mechanical uses. Scientists claim, however, that all vegetable fibre is, to a certain extent, identical—that is, having its essential constituents in common, there must be some means by which the coarser kinds can be transformed into similar substances. The experimental processes have included nearly the entire list of common vegetables, but within the last few years attention has been specially directed to the waste products of the saw-mill, especially the dust. The first results were the production of paper-pulp. But as only certain species of timber could be used satisfactorily for that, the experiments have been continued further with a view to not only using any kind of sawdust, but to broaden the field, so as to produce a substance that can be used for more general purposes than paper or celluloid, and which should, if possible, combine the best characteristics of both substances. A German scientific journal professes to give the results of the experiments in that country thus far. It claims the production of a substance made from common sawdust, by means of an acid process, that promises to be of great value. It is described as being exceedingly firm of texture and of great hardness, incapable of being bored by a common gimlet or of being penetrated by a nail, more impervious to the action of the elements than the ordinary metals or the common building stones, and practically indestructible by fire, a Bunsen burner simply charring the exterior surface. It is claimed to be stronger than timber for joists and girders and several times lighter than iron or steel, and, above all, the cost of manufacture is claimed to be so low as to bring it into competition with both wood and iron. It is said that experiments will be made to still further decrease the cost and increase its field of influence, and that its manufacture is to be pushed."

TABLE OF CONTENTS.

The "Tree of the Janissaries."

THE famous tree, of which a picture is given on page 91, is an ancient Plane that stands in the so-called Court of the Janissaries in the Old Seraglio at Constantinople.

From the time of Mahomet II., in the fifteenth century, until the middle of our own century, the Old Seraglio was the residence of the sultans, and at once, says De Amicis,* "a royal palace, a fortress and a sanctuary. Here were the brain and the heart of Islamism. It was a city within a city, inhabited by a people and guarded by an army, embracing within its walls an infinite variety of edifices, places of pleasure and of horror." It stands, he continues, "upon the most eastern of the hills of Stamboul, which descend gently toward the Sea of Marmora, the mouth of the Bosporus and the Golden Horn, on the spot anciently occupied by the acropolis of Byzantium, by a portion of the city and a wing of the palace of the emperors. The whole hill is encircled at its base by a battlemented wall with towers, and along the sea this wall is also the city wall. This is the external boundary of the Seraglio. The Seraglio proper stands on the summit, surrounded in its turn by high walls, forming a sort of central redoubt in the great hill fortress." Formerly, when one looked down upon the hill from its upper battlements or from a minaret of St. Sophia, it looked like "a green forest composed of enormous trees, encircled by walls and towers and crowned with cannon and sentinels. Upon the highest point extended the vast rectangle of the Seraglio buildings, divided into three great courts, or rather into three small cities built around three unequal squares, from which arose a multitude of variously colored roofs, gilded domes and white minarets half-concealed in groves and gardens—a little metropolis, brilliant and irregular—at one point full of life and movement, at another mute and solitary; here all gilded and open to the sun; there inaccessible to every eye and plunged in perpetual shade; gay with infinite fountains, embellished with a thousand colors and silvery reflections in the marbles of the colonnades and in the waters of the little lakes."

The Old Seraglio was abandoned almost forty years ago by the son of Mahmoud II., with whom the history of our Plane-tree is most strikingly connected, when he built himself a new palace further westward on the Bosporus; and to-day its aspect is very different from that of old. It has been ravaged by fire and neglect, a railway bisects it, and bald new buildings for military use have been erected in its desolate courts. But certain parts are fairly well preserved, and among them the first enclosure of all, the Court of the Janissaries. This lies near one end of the ancient Hippodrome, and forms a long space, flanked on one side by the Church of St. Irene, which was founded by Constantine and converted by the Turks into an armory; and it is shaded by groups of large Plane-trees, among which the most conspicuous is the "Tree of the Janissaries." The court is entered by the Bab-Umaium, or August Gate, on either side of which is a niche where, hanging from nails, were exposed each morning for the edification of the people the heads of such notabilities as, in the twenty-four hours gone by, might have excited the animosity of the Sultan. And under the great Plane-tree still stand two small columns on which decapitations took place, while, according to local story, the janissaries were fond of hanging their victims from its branches. But the court and the Plane-tree get their modern names from the awful day—June 15th, 1826—which saw the annihilation of these terrible guards.

In the year 1808 Mahmoud II. became Sultan after his predecessor had been slain by the janissaries, and, to lessen the chances of another revolt, promptly assassinated his own brother. The reign thus begun in blood continued in disaster. A war with Russia cost Mahmoud some of his fairest European provinces, the Greek Revolution further contracted his territories, and he is chiefly remembered for the most extensive massacre that modern history records.

The whole corps of the guards had risen in insurrection and threatened to fire the four quarters of Constantinople. Gathering around him the troops that still were faithful, Mahmoud displayed from the Mosque of Achmet the "Standard of the Prophet," which is never unrolled save when the empire is in danger, and solemnly decreed the annihilation of the janissaries. His followers were then engaged in a "sacred war," in which the most murderous would be held the surest of heaven. The first cannon-shot tore a bloody furrow through the closely crowded guards, and from the beginning it was less a conflict than a slaughter. Fire was set to the barracks where many of the janissaries took refuge, and those who survived flame and sword were murdered singly at closer quarters until not one of the whole corps remained, while Mahmoud himself stood behind the railing of the Mosque of Achmed, in the Hippodrome, and from this safe distance directed the massacre, until some 20,000, or, as some say, even more had been slain.

The great Plane-tree which, in its fresh garment of June leafage, witnessed this horrible scene, is believed to be about 400 years old, and, despite its hollow trunk, is still a fine and vigorous specimen of the characteristic shade-tree of the East. Measurements taken last summer, when the photograph from which our illustration has been made was procured, give its girth as thirty-nine feet at three feet above the ground, so we must allow for a little exaggeration in the statement of De Amicis that "it takes ten men to embrace its trunk." These dimensions are not remarkable when compared with those given of some of the famous Plane-trees of antiquity. But, perhaps, we may also allow for a little exaggeration where the tape-line was not used to verify the descriptions of the giants associated with the names of Godfrey, Xerxes and Menelaus. The Tree of the Janissaries is nearly as large as the great American Plane on an island of the Ohio River, the measurements of which were put on record by Washington and Michaux.

*"Constantinople." By Edmondo De Amicis. Translated from the Seventh Italian Edition by Caroline Tilton.

The inhabitants of cold climates have little idea of the fierceness of the conflict which has been carried on from time immemorial between man and the ant tribe, and can hardly appreciate the extraordinary capacity shown by these tireless insects in their depredations upon the human race. In the tropics no satisfactory remedy has yet been devised by which the balance of advantage, always largely in favor of the ant as against man, can be overcome, and the insignificant-looking insect, by force of numbers, industry and perseverance, is master of the situation. Even in more temperate regions like some parts of our southern states ants are troublesome enemies, and the suggestion made in the November issue of the *Tropical Agriculturist*, published at Colombo, in Ceylon, may be worth trying in some parts of this country. The suggestion is, that ants may be frozen out of existence by means of a cask of the freezing mixture used by engineers in excavating in quicksands fixed over the entrance of the nest, the other entrances being closed with clay, with a tube placed in the hole also well packed with clay. The pressure from the head of liquid would, it is claimed, be sufficient to drive the freezing mixture down into the furthest recesses of the ants' galleries, which would almost instantly become lined with solid ice, or, at all events, would be made so cold that no ant, however tenacious of life it might be, could long survive the exposure. These freezing mixtures are not very expensive, and, as our contemporary suggests, it is possible that the progress of science has here achieved a victory in the interest of man for which so many generations have contended in vain.

Plants which Grow about Lynn, North Carolina.

Lynn is the name of a popular southern resort in Polk County, near the mountains of western North Carolina. It is situated in or near what is called the "Thermal Belt," at the foot of the Tryon and Warrior range, a mile and a half from Tryon Station on the Ashville and Spartenburg Railroad. The very mild climate, milder than that of many places farther south, and its fine scenery, its variety of fruits, and its rich native flora, etc., are to me its chief attractions. To come from New England, when it was covered with snow two feet deep, into a climate where the thermometer rises to ninety-five degrees in the sun at noon, and is not rarely fifty-five and sixty degrees at eight o'clock in the morning, is a change that cannot fail to gratify those who like mild weather. It is, however, something of an aggravation to a botanist to visit this country in winter, because he sees so many strange plants which he would like to know and cannot then determine.

Three species of evergreen Rhododendrons, *R. maximum* (the Great Laurel), *R. Catawbiense* and *R. punctatum*, are common to this region, but the last-named, I believe, is found only on the mountains. The Great Laurel (*R. maximum*) here attains its largest size, and it is not rare to find it over twenty feet high by five or six inches in diameter. With it and *R. Catawbiense*, but much more abundant than either, is found the Laurel (*Kalmia latifolia*), growing even taller and larger than the Great Laurel. Another handsome shrub often with these last mentioned, but more common along the banks of streams, is *Leucothœ Catesbœi*, a shrub one to three or four feet high, with evergreen, lanceolate-oblong, acuminate leaves, often six or eight inches long by a little more than an inch wide, shiny above, and dark or purplish green in color. At this season it has the handsomest foliage of any shrub I have seen here. It is quite hardy in southern New England, and ought to become a popular plant for certain places. Its flowers are small and not very showy, but its foliage is always handsome. Two or three Azaleas (now classed with Rhododendrons) also grow here. The most common is the Pinxter Flower, *Rhododendron nudiflorum*, which is almost everywhere, on the mountain-tops as well as the lower foot-hills. Another, the Flame-colored Azalea, *R. calendulaceum*, though not so generally distributed, is abundant in certain localities. It is a taller shrub than the Pinxter Flower, bearing its orange or flame-colored flowers in great profusion. It is a more southern plant than the former, yet quite hardy in southern Massachusetts.

Quite common on shaded banks and slopes of the lower foot-hills, its handsome evergreen foliage more conspicuous than at any other season, may be found *Galax aphylla*. Its round, heart-shaped, crenate-toothed leaves are more exposed to the sun in winter, when the deciduous trees have shed their leaves, and they have a darker and richer color in spring than in autumn. It is, I think, destined to become a popular plant when it is more generally known. It spreads from underground stems, and, though not so rapidly as to become a pest, it soon establishes itself in thick patches.

Another interesting shrub, everywhere common in the woods, is *Hydrangea radiata*. Its foliage is its chief attraction. The large ovate, heart-shaped leaves, white and downy underneath, light green above, are very handsome. It is not quite hardy in New England, and is killed down to the ground by severe weather; but it grows rapidly, and the new stems give an abundance of firm foliage each year, so that one gets about all the beauty of it even as far north as Springfield, Massachusetts.

Tecoma radicans (the Trumpet Creeper) is a great pest here. Everywhere—in the alluvial river-bottoms, in pastures, by the road-side, in Corn-fields or along the river-banks—it is abundant. Its roots penetrate deeply, and below the reach of cultivation. It is cut off each year by the plow, but it springs up again, so that at the next season it is about as large as it was the year before. These small plants in such fields never get large enough to bear seed, but are constantly replenished from the few large plants which are left along the fences and water-courses and which bear fruit. The seed is carried long distances by the wind, and most of the best farming land is constantly seeded from the large plants along the streams.

Tipularia discolor, the little Orchid which in some ways resembles our more northern Puttyroot (*Aplectrum hyemale*), and which is mentioned as "very scarce" in Gray's Manual, is scattered through the woods on the lower foot-hills and is much more common here than I ever saw Aplectrum at home. Its single green leaf is now quite conspicuous, and it is not rare to find ten or twenty-five plants within a radius of two feet.

There is not as large a number of Ferns in this section as I expected to see. *Aspidium acrosticoides* is the most common, and *Asplenium ebenium* next. *Aspidium marginale* is occasionally seen; also the Maiden Hair (*Adiantum pedatum*). On and under rocky cliffs and terraces in the mountains *Cheilanthes vestita* is very abundant, forming large patches which, even at this season, look beautifully fresh. This plant is one of the best Ferns for in-door cultivation in winter. It requires perfect drainage, however. Near it, in more sheltered nooks, but quite abundant where the right situations occur, grows what I take to be *Asplenium Trichomanes*, var. *incisum*, a more slender and shorter plant than its type is with us. On mossy rocks and the trunks of trees *Polypodium incanum* is found, sometimes quite abundant. It is the richest-looking Fern here at this season. *Cheilanthes tomentosa* grows with *C. vestita*, but I have never seen it so abundant. *Woodsia obtusa* and *Cystopteris fragiles* are also here. *Asplenium parvulum* is abundant in places, but not so common as the *A. Trichomanes*, var. *incisum*.

Southwick, Mass. *F. H. Horsford.*

The Perfume Industry in the United States.

During the recent development of horticulture in Florida and California many experiments have been made in the production of perfumes from flowers, and many of these have resulted successfully. There is little wonder, therefore, that inquiries are often made as to the possibility of growing flowers at a profit for manufacturing purposes in the genial climate of these and other states. Many of these inquiries are evidently from persons who have not even a vague idea of the result to be arrived at, not to speak of the details to be pursued, so that perhaps a few hints from one familiar with the products may be useful. Despite all the triumphs of modern chemical science which has produced synthetically many odors which are more or less useful, it still remains the fact that all high-class floral extracts, by whatever name known, are composed, to a greater or less extent, of one or more of the following odors: Violet, Rose, Jasmine, Acacia, Orange, Tuberose and Jonquil. With one or more of these in combination with some resins, oils and animal secretions, the skillful perfumer is able to imitate the odor of any other flower and produce pleasing bouquets. These odors are bought by the perfumer in the form of pomades, experience having taught that this is the only feasible means of securing them properly. Practically, then, our citizens have this problem before them very clearly, namely, to produce a highly charged pomade at a price which will enable them to compete with the flower-farm-

ers of southern France, who at present supply the world's markets. This pomade is marketed in eleven and twenty-two-pound tins, varying in price according to quality. It pays fifty per cent. duty, and the present wholesale price is about $2.50 per pound for violet, and $1.50 to $1.65 for the others.

Like all manufactures, the making of pomade cannot be taught by books, but a few hints may help the experimenter. The process of extracting odors is known as *enfleurage*, and it is carried on either with or without heat. Jasmine and Tuberose flowers are exposed to lard spread thinly on sheets of glass in suitable frames; this soon absorbs the odor, and by renewing the flowers the grease becomes saturated. The perfume of the other flowers is extracted by hot *enfleurage*. In this case an addition of beef fat is made to the lard (ensuring a higher melting point); this mixture is heated to the melting point, when the flowers are thrown in and rapidly stirred through the grease; the semi-liquid mass is put under a strong press with suitable filtering material until the flowers are separated. The process is continued till the grease is practically saturated with odor. These processes are simple, and with a supply of flowers there is no reason why a good pomade cannot be produced in this country.

Judging from some inquiries, however, it does not seem to be generally understood that the process depends primarily on securing perfectly pure and inodorless lard, which is by no means the same as the lard of commerce. No amount of perfume will make impure grease fragrant, and the perfumer will not buy an article of the kind at any price. In his laboratory the perfumer is one of the most practical of men, and buys his materials on their merits. It is just as important to have his pomades free from false odors as that his spirits should have no trace of fusel oil.

The process of securing lard free from albumen, membrane and blood, is as follows: Cut up the fat in small portions, separating the membranes as far as possible by hand, and wash till the water runs clear. Melt with a gentle heat in an iron or copper vessel over a water bath and continue till it becomes anhydrous, or free from water, which may be known by its becoming perfectly clear. Finish by filtering through a clean cloth. This lard will retain an odor which may be removed by remelting and adding a small portion of alum or common salt, and keeping it over the fire till a scum rises, which should be skimmed off. The salt must then be washed out and the lard again rendered anhydrous. Such lard is kept in a moderate temperature in tin, sealed from the air, and it will remain sweet as long as is usually necessary.

It will be well for one who intends to try the perfume industry to secure a sample of the French pomade from some perfumer, so that an idea may be had of the strength of odor desired in the market. The prospect of success offered by this industry can only be learned by experiment, but it is certain that no careless methods will answer. As in other things, there is room at the top, and high-class products are certain of a market.

New York. *J. N.*

Our Trees in Ice-storms.

IN the changing aspects of landscape which Nature, even in our northern winters, constantly lays before us, there are few which furnish more enchanting pictures than some of the so-called ice-storms which occasionally, but fortunately rarely, occur. When, owing to peculiar conditions of humidity and temperature, every limb and branchlet of tree and shrub is covered with a heavy coating of clear ice, the ground white with snow and the sunlight is bright on the whole scene, we are treated to an exhibition such as the most careless and unobservant cannot fail to appreciate in some degree. Such a storm prevailed over a large portion of New England during the last week of January. While the storm, which results in the formation of clear, transparent, solid ice on every exposed object, produces perhaps the most beautiful effect, it is also the most likely to be destructive to arborescent vegetation because of its greater weight and the tenacity with which it clings during wind-storms and until dissolved by melting temperatures. In the late storm the weight of the ice was often twelve or fifteen times as great as that of the supporting branchlet it enclosed.

When the limbs become covered with soft snow there is usually not so much danger to trees because the weight is less in proportion to the bulk and the masses are more easily shaken off in a wind-storm. Such snow-storms, however, are sometimes hurtful to many kinds of evergreens. The beautiful glistening spiculæ, often produced on every object in foggy weather, are rarely sufficiently abundant and heavy to do much damage. In Europe, however, somewhat similar ice formations have been recorded as doing much damage to trees; and in English journals, under the name of "rime," there are frequent notices of injuries caused by this hoar-frost. In this case the greatest accumulation of icy particles usually takes place on the under side of the branches or on the side opposite to the direction of any slight wind which may prevail at the time of formation. It takes the form of delicate spiculæ or of flat sheets of ice as thin as paper, and sometimes two inches wide. The accumulation of this has been so great at times that large limbs of such sturdy trees as Oaks and Elms have been broken down by the weight. In some parts of Europe, where the peasants are allowed the use of all fallen wood, the poor people are very apt to look upon such occurrences as providential dispensations.

The beauty of ice-coated trees depends largely on the manner in which the different species branch or form spray, and the injury these storms inflict is very different upon different trees. Fortunately these storms are rare, for if they were of frequent occurrence it would be almost impossible to grow some of our most valued shade-trees, or at least to preserve their symmetry and normal appearance. The frequent loss of branches and leading shoots would give most kinds of trees a ragged and misshapen aspect, which would make them unsightly. But, besides the direct injury to the trees resulting from the loss of limbs, there is the increased liability to attacks by insects and destructive fungi which may gain their first entrance into the wood of the tree through the exposed stump of some broken limb or stem. The danger of further injury from these causes is not so generally understood as could be desired. Wherever lacerated wounds occur on choice or valued specimens of trees they should be cut or pared smooth and carefully covered with a protecting coat of coal tar or some similar substance calculated to prevent the entrance of boring insects or of wood-destroying fungi.

Of all our trees few are liable to suffer so severely in the ice-storm as the native White Pine. The wood of its branches is more brittle than in the majority of trees, and as every one of the long leaves or cluster of leaves becomes incased in a heavy icy covering, or supports its proportion of snow, the weight on the limbs becomes out of proportion to that which most other trees have to bear, and the slightest movement by wind or the suddenly added weight of a bird is often sufficient to cause the branches to snap off. As the weighted branches usually rest upon and partially support each other, the breaking of an upper limb often causes much greater destruction in its fall. Such species as the Scotch and Pitch Pines, which possess shorter, stouter branches, are apparently not nearly so liable to suffer injury. The Spruces may become covered with heavy sheets of ice or snow, but, as the branches are tough and elastic as well as comparatively short, they rarely break; and the terminal shoot, being stout, and bearing few branches or leaves, hardly ever bends or is moved from its erect position. The common Savin, or Red Cedar (*J. Virginiana*), usually assumes a slender and pyramidal form in our northern latitudes, and in these ice-storms the narrow spire-like tops undergo an astonishing amount of bending before they will break. But if the leading shaft does break under the strain, the beauty of the form of the tree is forever ruined.

While the evergreens appear most beautiful in a snow-storm, they lack the charm of deciduous trees when ice-laden and ice-bound. In all the variety of leafless limbs and branches the beauty of our native American Elms is seldom equaled under these trying circumstances. The long slender branches present an unusually pendulous appearance when ice-bound. As the branchlets are numerous and each bears its proportion of ice, the branches become more heavily burdened than most of the coarser-branched trees of other genera. Breaking of the limbs may occur at any point, but it is noticeably more apt to take place where a smaller branch diverges at a sharp angle from a larger one; and limbs, which from any cause have become defective or weakened, are very likely to be exposed by ruptures or breaks. Twistings and partial splittings of sound branches sometimes occur which are not readily detected at the time.

Among deciduous trees, the much-planted White or Silver Maple is one of the most subject to serious injury under similar conditions. The wood does not bear a great strain, and the break is usually rough and jagged. The loss of buds or small tips of branches in these storms is usually unimportant, and if what is sometimes carelessly called "nature's pruning" was never more serious, little harm would be done.

Some of the larger shrubs are liable to be much broken, while others bend until the strain is relieved by their ice-covered tips resting upon the ground. The elasticity and supple-

ness of our slender White Birches (*B. populifolia*) is sometimes shown by the fact that trees as much as thirty-five feet high will bend until their tops touch the ground, and will remain in this position until released by a thaw, when they once more assume their natural attitude.

Those deciduous trees which have not a very branching habit, or whose lateral branches are few, are rarely or never affected by the average ice-storm. Such are the Horse-chestnuts, Walnuts, Catalpas and even the Magnolias. It is not easily conceived that the thick naked branches of the Kentucky Coffee-tree (Gymnocladus) would ever be affected, as their burden of ice must be much smaller than that of diffusely branched trees; but, of course, it is possible for such accumulations of ice to take place under which no tree could remain uninjured.

Jamaica Plain. *J. G. Jack.*

Recent Botanical Discoveries in China and Eastern Burma.—II.

Beginning with the trees, we find, as in Mexico, at somewhat higher levels, that Pines and Oaks predominate. Two species of the former and nine of the latter were collected. The common Pine is *Pinus Kasya*, a species abounding in Assam, Chittagong and Burma; and the other, *P. Merkusii*, inhabits Martaban, Tenasserim, Sumatra and Borneo. Some of the Oaks are very fine, both in foliage and in fruit. Associated with these Oaks and Pines are a Willow, a Birch, replaced in the Mexican uplands by an Alder, two species of Engelhardtia, a species of Pyrus, and several other members of the *Pomaceæ*, an Ash, one or more Figs, a Mulberry and a Holoptelea, a genus of trees next to the Elms. Intermixed with the foregoing trees are members of genera chiefly tropical or sub-tropical, such as Dalbergia, Bauhinia, Acacia, Albizzia, Melastoma, Marlea, Vernonia, Wightia (a remarkable tree of the *Scrophularinaceæ*), Helicia (*Proteaceæ*), Lindera and several *Euphorbiaceæ*.

Among shrubs are Brambles and Roses, Honeysuckles, Privets, Jasmines, Barberries and Viburnums, associated with genera of a less decided temperate type, such as Lagerstræmia, Capparis, Pittosporum, Actinidia, Evonymus, Millettia, Woodfordia, and many others.

Especially noteworthy among the new shrubs are *Rosa gigantea* and *Lonicera Hildebrandiana*, each in its genus surpassing all previously described species in the size of its flowers. The Rose is an exceedingly robust kind, very closely allied in botanical characters to *Rosa Indica*. It forms thick, woody stems, and climbs to the tops of lofty trees, clothes them with long hanging branches, bedecked with beautiful white flowers, sometimes exceeding five inches in diameter. General Collett describes it as one of the most striking ornaments of the forest, reminding one, when seen in the distance, of a large-flowered Clematis rather than of a Rose. Fortunately, General Collett secured abundance of good seeds, and vigorous plants are now growing at Kew and other places in the United Kingdom, though nobody has yet succeeded in flowering it. Talking of its seed reminds me that it is the largest in the genus, being about half an inch long. When I say seeds, botanists will understand that I mean "carpels." The pome-like fruit is an inch and a half in diameter. In justice to the original discoverer of this fine Rose, it should be put on record that, although General Collett rediscovered it in a new and distant locality, gave it a name, and sent seeds of it to England, which have germinated, and is entitled to all the honor appertaining thereto, to Dr. G. Watt, of the Indian Educational Department, belongs the credit of having first discovered it. Dr. Watt was attached as Botanist to a Government demarcation survey expedition to Muneypore in 1881–82, and made extensive botanical collections, including the Rose in question, which he regarded as a new species, and to which he gave a manuscript name, but it was never published.

The Honeysuckles of the Shan Hills, so far as known, belong to three species, one of which, *Lonicera Hildebrandiana*, is an exceedingly showy, apparently evergreen, shrub with dark, thick, glossy leaves and handsome crimson flowers, seven inches long, and borne in pairs in the axils of the upper leaves and at the tips of the branches. General Collett found this fine Honeysuckle in only one locality, and only one plant was seen; but it is probably abundant in other localities, as he was informed that the flowers were much used in decorating the temples at Pindiah. When collected it was almost past flowering, but the fruit was not yet ripe, so there was no chance of introducing it into our gardens. Now that the country is open, however, we should not have long to wait for this and many other ornamental plants growing in the same region.

A tall, bushy Lespedeza (*L. Prainii*) is a highly ornamental shrub some ten feet high, bearing large panicles of fine purple-blue flowers, and would be well worth cultivating; and there are several other pretty species of the same genus.

Prominent among the numerous *Leguminosæ* of the region are several arboreous and shrubby species of the large Asiatic genus Millettia, a genus closely allied in botanical character to Wistaria, and probably hardly inferior to it in the beauty of the flowers of many of the species. About twenty-five species are known to inhabit Burma, most of them being endemic, and three fine new species are described from the Shan Hills. *Millettia macrostachya* is a shrub or small tree with pinnate leaves a foot to eighteen inches long and clustered flower-spikes, or racemes, as long as or even longer than the leaves, bearing a profusion of pretty pink or rose-colored flowers about an inch long. *Millettia multiflora* and *M. Dorwardi* are hardly less beautiful. *Osteomeles anthyllidifolia*, a species of a genus otherwise confined to the Andes of South America, deserves notice, not alone as an ornamental shrub, but also on account of its singular distribution. It was first described by Lindley, in 1822, from specimens collected by Alexander Menzies in the Sandwich Islands, and it has since been collected in Pitcairn Island, Maingaia, the Bonin group, the Luchu group, Japan, central China and now from the Shan Hills. It is a dense bush, growing gregariously and presenting a pretty sight when covered with its white Hawthorn-like flowers, contrasting well with the dark-green, finely pinnate leaves. The somewhat fleshy fruit is probably a favorite food of some birds; hence, perhaps, the wide distribution of this shrub.

Before leaving the shrubby element in the flora of the Shan Hills a word should be said respecting the shrubby parasites that live on the Oak-trees. The Oak-forests here support a considerable variety of both parasites and epiphytes; but the latter are by no means so numerous and varied as those found in the Oak-forests of Mexico, consisting of a few species belonging to the genera Dendrobium, Bulbophyllum and Cirrhopetalum, and two or three other genera, to some of which I shall have occasion to refer again. On the other hand, the trees in the upper forest-region, from about 4,000 to 5,000 feet, are much infested by parasitic plants of the genera Loranthus and Viscum. Altogether seven species were collected, five of the former genus and two of the latter. The Loranthi are very conspicuous when in flower, two, previously undescribed, especially so, having very large flowers of a brilliant dark crimson. A remarkable biological phenomenon in connection with these parasites merits mention here. Structurally the *Loranthaceæ* and *Santalaceæ* are closely allied; but, whereas the former are mostly parasitic on the branches and trunks of trees and shrubs, the latter are mostly parasitic on the roots of other plants, at least in an early stage of their existence. A curious exception is offered by the genus Phacellaria (*Santalaceæ*), of which four species are now known from eastern India and Burma. These are small, leafless, shrubby plants, with slender clustered branches, and, so far as our present knowledge goes, they always grow on other parasites. General Collett collected two species, one of which was previously undescribed; and one of these was parasitic on a Loranthus, the other on a Viscum! Similar instances are not absolutely unknown in other plants. Thus, *Tupeia antarctica*, a member of the *Loranthaceæ* inhabiting New Zealand, has been found growing on *Loranthus microphyllus*, though it also grows on a variety of other shrubs and rees.

Kew. *W. Botting Hemsley.*

New or Little Known Plants.

Aster macrophyllus.

THIS handsome plant is one of the most common of the Asters which inhabit, in such vast quantities, the northern and eastern states. It often almost covers the ground along borders of the forest, where it finds the rich, moist soil in which this species delights. The large, heart-shaped, radical leaves, which grow to a large size early in the season, are very conspicuous in these situations and draw attention to this plant long before the flowers make their appearance. These radical leaves are sometimes eight or ten inches long and four or five inches wide; they are broadly ovate, reniform-cordate, and are coarsely and sharply serrate. The flower-stems are angled, three or four feet tall, and bear ovate-oblong, winged-petioled

Fig. 18.—Aster macrophyllus.—See page 88.

leaves, the uppermost becoming sessile by a broad base. The flowers are produced in corymbose cymes, and have white or bluish purple rays.

Aster macrophyllus, which is one of the most variable of our Asters (see figure above), is distributed from Canada and Manitoba to the mountains of Carolina and Georgia. There are several species with showier and more beautiful flowers, perhaps, and, therefore, better worth a place in the garden. None of the American Asters, however, are more useful than this species to naturalize in the wild garden under the shade of trees or by the borders of woodland-walks or in forest-glades.

Foreign Correspondence.

London Letter.

Hybrid Calanthes.—It is thirty-five years now since Mr. Dominy, at that time manager to Messrs. J. Veitch & Sons at their Exeter nursery, raised the invaluable *Calanthe Veitchii* by crossing *C. vestita* with *C. rosea*. At that time the latter was known as a species of Lematodes, and the fact that this was the first supposed bigeneric cross naturally caused some excitement among botanists. Mr. Bentham, however, deprived the hybrid of some of its interest when, in 1881, he wrote: "The facility with which *Lematodes rosea* can be made to hybridize with *Calanthe vestita* has been given as an instance of ready hybridization between two distinct genera; but the fact appears to be that *L. rosea* itself has all the characters of Calanthe, and is, indeed, a species very nearly allied in every respect to *C. vestita*." As a garden Orchid, however, *C. Veitchii* remains among the very finest hybrids ever raised, superior as a decorative plant to both its parents, and at least the equal of any other seedling Calanthe of garden origin. Well grown, it produces many flowered scapes a yard long, perfect as regards elegance and the arrangement of the flowers, which in their turn are pretty in form and colored a bright rose. Then there are the varieties: Alba, with pure white flowers, and Versicolor, which is peculiar in having white, rose and variegated flowers on the same spike. A remarkable feature in this hybrid is its being at least as dark in color as *C. rosea*, although its other parent is almost wholly white.

Twenty years elapsed between the birth of *C. Veitchii* and the next hybrid Calanthe, also a Veitchian production, namely, *C. Sedeni*, the progeny of *C. Veitchii* crossed with the red-eyed variety of *C. vestita*. This is a beautiful plant, the flowers being rose-carmine, almost crimson, and of good size and substance. The unexpected often happens in hybridizing experiments, as is shown by the form and color of the hybrid figured in Garden and Forest (p. 17) under the name of *C. Eyermanii*. By simply reversing the parentage Mr. Gardner obtained a cross with flowers half as large again as *C. Veitchii* and "whiter even that *C. vestita*"—if that is possible. Hybrids, crosses, seedlings of Calanthes, have been produced in abundance in English collections recently, Sir Trevor Lawrence and Mr. Norman Cookson having raised some exceedingly pretty-flowered ones. Many of these have not been named. They have an interest for horticulturists, as they reveal a disposition in *C. vestita* and its near allies to cross and sport to almost any extent; and Calanthes of this section are so exceptionally useful that we cannot well have too many of them.

According to Messrs. Veitch, the raising of hybrid Calanthes is comparatively quick work. The capsule usually ripens in three or four months, and the seed takes from two to three months more to germinate; the seedlings, under favorable circumstances, will flower in the third or fourth year. The multiplication of Calanthes is equally rapid by means of dividing the pseudo-bulbs. In short, Calanthes have proved themselves in every way adapted for the every-day greenhouse, and as deserving of general cultivation as the most popular of winter-flowering plants. They have been grown at Kew some years for the decoration of the conservatory.

The section of this genus represented by *C. veratrifolia* differs widely from the *C. vestita* group, so widely, indeed, as to appear to have nothing in common with it. But among them there are some beautiful-flowered species which have the commendable quality of thriving in a greenhouse temperature all the year round. They enjoy copious watering, they are evergreen, and their tall spikes of flowers are a durable attraction at various times of the year. *C. Masuca* is in flower now. It has a spike two feet long, and flowers one and a half inches across, colored soft lavender-purple. *C. veratrifolia* will shortly produce its tall scapes of pure white flowers; *C. Natalensis*, of similar habit to the last and colored lilac, with a reddish lip, also flowers in spring. The only hybrid in this section is *C. Dominyi*, raised from *C. Masuca* and *C. furcata* about the same time as *C. Veitchii*, and by the same operator.

The genus Phajus has proved so near an ally to Calanthe as to hybridize with it. *P. irrovatus* is the offspring of *P. grandifolius* and *C. vestita*, while in *P. Sedeni* we have a hybrid between *P. grandifolius* and *C. Veitchii*.

Two new Grapes have lately been brought into notice, and are likely to become valuable acquisitions as high-class varieties for indoor cultivation. They were raised by Mr. Myles, gardener to Lady Hutt, Appley Towers, Ryde, Isle of Wight, who obtained them by fertilizing six flowers of Gros Colmar with pollen from Meredith's Alicante. One is named Lady Hutt, and may be called a white skinned Gros Colmar, but better in flavor than that popular variety. The second is called Appley Towers, and has large round berries, black, thin-skinned, perfect in flesh and flavor, and an excellent keeper. It is somewhat remarkable that two first-class varieties should be the outcome of so small an experiment, and that they should differ considerably, not only in color, but in form and flavor, from each other.

Fruit-trees in Ornamental Gardening.—A suggestion that many fruit-trees deserve to be planted for decorative effect in shrubberies and on lawns appears in this week's number of the *Gardeners' Magazine*. Although not new, the idea is one that deserves attention. We are apt to overlook the ornamental character in things otherwise useful. Double Cherries, Almonds, Flowering Currants and the species of Prunus are not uncommon features of good shrubberies or as lawn specimens. But why stick at the flowers? There are few more beautiful pictures than a tree well-laden with richly colored apples, or cherries, or peaches, or plums, or pears. Nor have we anything among berried bushes so effective as the Red, Black and White Currants, while many varieties of Gooseberries are not without considerable claims as decorative objects. It is a fact that if all these trees produced inedible fruit they would be universal favorites for planting for effect. In an old garden where I worked when a boy the old kitchen-garden was included with the lawn and shrubberies, but some favorite old Apple-trees were left as lawn specimens. They were beautiful when in flower, equally beautiful when laden with rosy fruit, and last, but not least, they contributed considerably to the requirements of the kitchen.

Amorphophallus campanulatus.—Some people appear to have confused this plant with *A. Titanum*, if one may be guided by an advertisement which has lately been circulated in England and America. The first-named is a well-known Indian Aroid with tubers from six inches to a foot in diameter; leaves four feet high, and vasiform flowers a foot in diameter, green and vinous purple in color, with a large chocolate-colored spadix, and emitting when fresh a disgusting odor. The plant is strictly tropical, will not thrive in cultivation except when grown in a hot, moist stove, and is not easily flowered. When in flower it is a curiosity, which finds little admiration, its odor as well as its dull colors being all against it. Of course it is widely different in stature, form of flower and interest from the Sumatran *A. Titanum*, of which the only plant known in cultivation is that which flowered at Kew in 1889. There is an Amorphophallus which comes from northern China, and is almost hardy in England—namely, *A. Rivieri*, which is sometimes used here as a bedding plant on account of its ornamental leaves—but it rarely flowers, and when it does it differs considerably from *A. Titanum* and *A. campanulatus*. No true Amorphophallus is found in Africa.

London. *W. Watson.*

Cultural Department.

Notes from the Harvard Botanic Garden.

Phyllanthus nivosus.—There are but few members of the genus Phyllanthus worthy of cultivation for decorative purposes. *P. nivosus*, however, is one of the most notable exceptions. It is a native of the South Sea Islands, and was introduced in 1873. The plant is a deciduous shrub of free-branching habit, with the alternate, ovate leaves two inches long and closely arranged on the branches. The flowers are inconspicuous; but their lack of showiness is made good in the foliage, which, under certain conditions, develops a beautiful variegation of green and white. As the leaves become old they turn to a pale green color, and they then produce a nice effect with the long branches of younger ones, in many of which the green is almost entirely absent. Specimens of this plant should be kept somewhat closely root-bound and freely exposed to the light, in order to secure the most pleasing combinations of color. A stove temperature is essential to their luxuriant growth, and a mixture in equal parts of loam, peat and sand should be used in potting. Propagation is effected by planting cuttings, prepared from firm material, in sandy soil and placing them in bottom heat. The plants grow quickly, and soon form handsome specimens under the treatment generally accorded stove plants.

Senecio Petasites.—This would be found a most valuable plant for those who have large conservatories to be kept attractive during winter. It is a native of Mexico, and has been known in English gardens since 1812, when it was introduced by means of seeds, and first flowered there during the latter part of the same year in the gardens of a Mr. A. B. Lambert. Then, and for many years afterward, it was known only as

Fig. 19.—Ancient Plane-tree in Constantinople.—See page 85.

Cineraria Petasites, and in 1813 it was figured in the *Botanical Magazine* under that name. It is an evergreen shrub of bold habit; the cylindrical stems robust and erect, and from three to four feet high; the leaves alternate, circular, with sinuously lobed margin, cordate at the base, dark green above and pale green beneath, and from six to twelve inches broad, with petioles as long as the blades are wide. These parts of the plant are all more or less downy. The flowers, each a trifle more than an inch across, with the disk-florets brownish, and those of the ray of a bright yellow color, are produced in enor-

mous terminal panicles, beginning to open about the middle of December, remaining attractive until late in February. The handsome foliage renders these plants very serviceable, even when not in bloom, in imparting an artistic effect to arrangements of flowering and other less massive foliage plants. The sombre solidity of this Senecio is much relieved by the elegance and brightness of the flowers, which when cut are of further utility in that they keep fresh in water for a considerable period. The plant is of exceptionally easy culture, and during the flowering season the temperature may fall as low as forty degrees Fahrenheit without injurious results. The young branches which develop on the sides of the main stems after the flowering season make excellent cuttings. They should be taken when from four to five inches long, with a slight heel of the older material, and inserted in sandy soil, taking care to place them where an ordinary amount of bottom heat is combined with shade and a close, moist atmosphere. The shading should be removed when the cuttings are rooted. It will be necessary to advance their growth in pots until they may be trusted with safety out-of-doors in the open garden. Here they must have abundant space, for, under ordinary conditions, they grow vigorously. Early in September they should be taken up and potted and placed under cover. In the greenhouse they thrive best, with plenty of room, air and light, otherwise their requirements are similar to those of the general run of greenhouse plants. Larger but no less ornamental specimens are obtained by cutting down the old plants after the flowering season to within a few inches of the soil. Young shoots soon push from the old stumps, which in the planting-out season are turned out of the pots and transferred to the garden like younger plants, the greater part of the old soil having, meanwhile, been shaken from the roots. Their subsequent treatment does not differ from that prescribed for young plants.

Stereptocarpi in Winter.—Our friends across the Atlantic are ahead of us in appreciation of the good qualities of these plants. The genus, although it comprises many excellent garden plants, is scarcely known here. This is all the more surprising when it is considered that at least one of the species, *S. Rexii*, has been cultivated in Europe since 1824, when it was introduced from south Africa. But it is only within the past few years that these plants have attracted much attention even in Europe. The recent appearance of a number of meritorious hybrids is probably the occasion of their rapidly increasing popularity. *S. Rexii* has been known in cultivation longer than any of the other species, and it has proved to be a most serviceable plant in the hands of hybridizers. It is, with the exception, perhaps, of *S. Gardeni*, the handsomest species of the genus. The plant is stemless ; the prostrate leaves are ovate-oblong, crenate, villous, bright green and much wrinkled on the upper surface, paler with prominent midrib and veins beneath. The erect, slender scapes are from six to nine inches in length, and they rarely bear more than one flower. The trumpet-shaped carolla, of blue-lilac color, is two inches long by an inch and a half wide, five-lobed, the three lower lobes being larger than those above and veined far into the throat with deep purple. *S. Rexii* and *S. polyantha*—a species in which the panicles of small flowers rise from the base of one large leaf that develops to the almost entire suppression of the others—are both in bloom at the present time. These plants usually flower during the summer months, but they may easily be had in bloom at this season by sowing the seeds late in spring or early in summer. A somewhat sandy soil, plenty of light, and an intermediate temperature are primary essentials to the successful cultivation of these greenhouse plants.

Cambridge, Mass. *M. Barker.*

Flowering Plants in the Hot-house.

Bougainvillea glabra.—This remarkably handsome plant has long been known in cultivation, but it deserves to be more largely grown, for few summer-flowering plants surpass it in effectiveness when used for conservatory decoration, and the flowers are also valuable for cutting. It is of scandent or semi-scandent habit, but may be kept by pruning in the condition of a good pot plant, and as it flowers very freely, small plants will be found very useful, while large ones can be called gorgeous without exaggeration. The foliage of this species is entire, bright green and smooth, the latter being a good characteristic to remember, as the other members of the genus are more or less downy or pubescent. The flowers proper are insignificant both in color and size, but the chief beauty of the plant is found in the bracts which surround them. These are deep rose in color and produced on the tips of the branchlets in great quantity.

The Bougainvilleas are readily propagated by cuttings made from firm young wood and placed in a propagating frame or in a snug corner of the conservatory, and the young plants should be potted on as they become root-bound in good, open loam and in well-drained pots. The most satisfactory method in order to secure a good crop of flowers is to dry these plants off during the winter until the wood is well ripened, after which they may be trimmed into shape, and then started into growth by a little additional heat and frequent syringing. When showing flower some liquid manure will be beneficial.

Gloriosa superba.—This also is an old plant, but a very pretty one. It is a bulbous-rooted stove climber, and is essentially a summer-blooming plant. The bulbs require a season of rest, as Gloxinias and other plants of similar habit do. The plant has bright green leaves, rather narrow and sessile, with a midrib lengthened out into a long tendril, by means of which the plant is enabled to climb. The flowers are six-petaled, the petals undulate and standing erect, while the color shades from orange to red. Altogether this is a showy plant, and has the merit of being quite easy to grow in a warm house, if the bulbs are not disturbed after they have started into growth. The most suitable soil for it is an open mixture of loam, peat and sand, with some old dry cow dung for fertilizer, and the bulbs are best shaken out of the old soil before active growth commences, for they are somewhat impatient of any disturbance of the young roots, and therefore should be placed in the pots in which they are to bloom.

Gloriosas are but little subject to the attacks of insects, red spider being the most likely pest unless the plants are regularly syringed until they begin to bloom. It is propagated by seeds, and also by offsets from the bulbs, the first method being probably the most satisfactory. After the blooming season is over water should gradually be withheld until the season's growth is finished, after which the pots may be stored away under the benches or in some other convenient place until required the following season.

Tabernæmontana coronaria.—This is another plant often found among the stove-flowering collections, and it is probably the best-known representative of a large genus, though, strange as it may seem, its native country is not positively known. It is under cultivation in various parts of India, from whence it was most probably introduced into European gardens. *T. coronaria* bears some resemblance in growth to a Gardenia, while the flowers are pure white, tubular, and with wide-spread petals like a Jasmine, to which they also have some similarity in perfume. The peduncles are produced from the forks of the branches, and are furnished with from two to six flowers. There is a variety with double flowers which resemble miniature Gardenias, though their odor is not quite so pronounced.

The Tabernæmontanas are of easy cultivation in a warm house, and possibly might be grown on in the open ground during summer. They would be in danger, however, of losing their foliage, unless very carefully lifted. These plants are increased by cuttings, which should be placed on bottom heat, and, if not allowed to flag, they soon root. Any ordinary well-drained soil will answer if sufficient sand is added when necessary, to make it more open. A moderate shade will be found beneficial.

Holmesburg, Pa. *W. H. Taplin.*

Plants for Shady Places.

In most gardens of any extent there are places in which it is difficult to get grass to grow—shaded spots, for example, like those under the dark shadow of evergreen trees and sometimes under trees that are deciduous. Bare, unsightly patches of this description are an eyesore until taken in hand and covered with some of the many hardy plants suitable for this purpose, and those which may be relied upon to thrive under this adverse condition, and that, too, with but little attention after the first year. One of the most useful, and, at the same time ornamental, of trailing plants we have is the Trailing Myrtle, which, as often happens with common names, is not a Myrtle at all, but a Vinca. It is also known as Periwinkle, which is the most suitable common name, being a corruption of the old Latin name, Pervinca, applied to the genus by Pliny. Of this Periwinkle or *Vinca minor* there are many varieties, all low, trailing, evergreen plants, with flowers that are either single or double, blue or white, as the case may be, and all well-known to every one who takes an interest in hardy plants. In addition to the varieties named there is a variegated form of *Vinca minor* which, to my mind, is the prettiest of all. The young growth in spring is bright yellow and green, and it is covered with starry blue flowers, which stand up above the carpet

made by the previous year's growth, which with age assumes a deep olive green.

When the space to be covered is under the shade of trees very little preparation is necessary; but as the planting is for permanent effect, a good coat of manure should be dug in deeply, for it will be found that Chickweed will be troublesome the first season if the manure is placed near the surface. Weeds, however, will be choked out the second season as the Periwinkle roots descend to the richer soil. After the ground is prepared, small pieces of the Periwinkle with roots attached should be planted in rows, the plants being set a foot apart each way. Little attention besides weeding will be necessary the first year, and a neat covering will be secured, and, as the plant is evergreen, it will always be pleasing, and especially so in the spring months, when it is in flower. If it is desired to give the beds a more showy appearance it is a simple matter to place the plants a little further apart, and place between each a bulb of any of the varieties of Narcissus, such as *N. poeticus*, *N. princeps*, *N. trumpet major* and others that are strong and robust. But if Narcissus are planted they should be set six to eight inches deep, according to the texture of the soil; in light soils Narcissus can be safely planted eight inches deep, or even deeper. In a similar way Lily of the Valley may be interspersed among the Periwinkles if the latter be the blue-flowered variety, as the Lilies will also succeed admirably in a shady position for an indefinite period. The Wood Lilies or Trilliums of the strong-growing kinds, as *T. grandiflorum*, *T. erectum* and its white variety, *T. cernuum*, also, though not so showy as others, with the Pacific coast species, such as *T. ovatum*, *T. petiolatum*, *T. sessile* and others, are all hardy, and, although not so often met with in cultivation, are equally useful for the purpose named. Numerous other spring-flowering bulbs will suggest themselves to the planter to be introduced among the setting of Periwinkle as fancy may suggest, but it is best not to attempt, under trees, any display that would be in season at any other time than the spring or early summer months for obvious reasons. Under trees the soil during the warmer season is much drier than in open cultivated ground. This would not in any way interfere with the ripening of bulbs, quite the reverse, but might seriously interfere with the success of an attempt to use other plants for a later display.

There are other plants of trailing habit which will answer in place of *Vinca minor*. *Lysimachia Nummularia* is sometimes used, but it is such a rampant grower that it often gives serious trouble to keep it within reasonable bounds. Here in Massachusetts it may often be seen as an escape from cottage gardens, monopolizing the road-side to the exclusion of grasses and other native plants. But where a vigorous growing plant is desired it might possibly be used with advantage.

South Lancaster, Mass. *E. O. Orpet.*

Sciadopitys verticellata.—The Umbrella Pine seems as thoroughly hardy here as any of the conifers we have received from Japan, and it holds its green color well through the coldest weather. One specimen here is eight feet six inches high. I do not know its exact age, but it has made fifteen annual growths from a point eighteen inches above the ground, and, as it grows slowly at first, this tree is perhaps nearly twenty years old. Last year it increased in height a foot, and the year before ten inches. We need a wider experience before we can be sure what situation it prefers. It does not seem particular about soils. The specimen here mentioned stands in soil eighteen inches deep, below which is a rock bottom.

Germantown, Pa. *Joseph Meehan.*

The Forest.

Forestry on the Prairies.

WE have in former numbers made allusion to the Farlington forest in Kansas, or, as it is called on the map, the "Tree Farm," belonging to the Kansas City, Fort Scott and Memphis Railroad Company. Something like 500 acres of prairie were broken up about twelve years ago and planted with different kinds of forest-tree seedlings. The experiment was particularly interesting as the most extensive plantation of the kind that had been then made on the prairies in that longitude, and because the planting was contracted for on terms which were novel and worthy of trial. Messrs. Robert Douglas & Sons agreed to prepare the ground, furnish the trees and plant them four feet apart each way, and then take charge of the plantation for a certain number of years, and deliver the forest to the Company, with the guarantee that each acre should contain a certain number of trees which should be of a given size and completely shade the ground. After the trees have reached this condition it was assumed that they could fight their own battles against the weeds and prairie grass. The advantages of the arrangement seemed to be that the critical work of planting as well as the care of the trees in their earliest and feeblest stages would be in the hands of experts, and good care was secured by the fact that the forest was to have attained a certain established growth before it was delivered over to its owners. Below we give some of the chief points in the report of Mr. George E. Kessler, the Superintendent of the work, and we add some figures relating to the size of the trees, which we gather from tables of measurements in Mr. Kessler's report, but which are too long and elaborate for our purpose.

The diameter measurements are taken at a point one foot above the surface of the ground. The Catalpas planted in 1880, standing in good loam in rows, next to the forest-road, average 5.7 inches in diameter, some of them reaching a diameter of seven inches. Their height will average twenty-five feet. Trees in rows some fifty feet from the forest-road average 4.5 inches in diameter. Trees of the same year's planting on higher ground and thinner soil, will average along the road 4.6 inches, and fifty feet from the road 3.07 inches in diameter with a height of twenty-one feet. Black Cherry-trees, planted in 1878 on good land, are now from twenty-five to thirty-five feet high and average 4.35 inches in diameter. Black Walnuts, planted in 1878, standing mixed with Chestnut and Cherry-trees, are twenty-eight feet high and 6.37 inches in diameter. Chestnuts, planted in 1878 among Cherry-trees, average 2.5 inches in diameter and eighteen feet high. Black Walnuts standing alone, and planted four feet apart each way in 1878, are now eighteen feet high and three inches in diameter. Box Elders planted the same year show a weak growth and look starved. Trees of *Catalpa bignonioides* planted in 1878 are 3.8 inches in diameter and eighteen to twenty feet high. This is a good growth, and it seems to have been nearly uniform each season, although the growth of last summer was not equal to that of former years. This is not to be taken as an indication of waning vigor, for it is apparent in the later as well as in the earlier plantations. Catalpa-trees, differing from most others, grow until checked by the frosts of autumn; and the dry season, which last year impeded the growth of Corn, had the same effect on the Catalpa-trees. But while there has been this checking of new growth the ripening has been very thorough, and the wood is in better condition to make a strong growth next year than it was last year, for a close examination showed that the terminal buds then were not so well developed as they are now. This lack of size might have been caused by a frost which suddenly arrested the growth, or by late rains, which excited a growth which did not harden up thoroughly, owing to subsequent cold weather.

In regard to the thinning it is probable that a suggestion made by Mr. Kessler will be tried to some extent. Instead of allowing the trees to fall as they are cut off at the ground, it is proposed that they should be leaned up against another tree with the idea that they will be more out of the way than if dropped on the ground overlapping each other. Perhaps they would be in better position, too, for future removal.

It would probably cost more to cut off the dead branches which remain on the Catalpas than to thin out the wood. Most other trees shed their dead limbs readily, but these Catalpa limbs show no sign of falling off even when they have been dead for five or six years. If the limbs remain sound and the tree makes growth around them, these knots would be no injury to sticks used for fence posts or railroad ties, but if they are to be used for finishing or furniture, the sooner the dead branches are taken off the better. The whole experiment will be watched with great interest, and it

does credit to the men who invested their capital in it. They probably will make a trial of cutting away these dead branches, at least in certain parts of the plantation, in order to arrive at some intelligent idea of the value of such work, and whether or not it is possible to trim the trees with profit. The following is the substance of Mr. Kessler's report :

The Catalpa occupies a larger area in the plantation than any other tree. Of this area *Catalpa speciosa* was the species used wherever the planting was done by Robert Douglas & Sons, and the condition of the trees now proves very conclusively the wisdom of the selection of that species. It seems that the railroad company began the plantation with *Catalpa bignonioides*, and also planted some *Catalpa Kæmpferii*, both of which, as I understand, were bought as *C. speciosa*. Aside from these trees, they planted Black Walnut, Butternut, Pecan, White Ash, Chestnut, Black Cherry, Osage-orange, Ailanthus and Box Elder.

The seedlings of *Catalpa speciosa* (as in fact all the other trees) were planted four by four feet apart, and owing to this close planting they have all made an excellent upright growth. Except on the outside rows along forest-roads or openings the trees are perfectly straight, have few large branches, and all the smaller, and most of the larger, branches that did grow have died out from want of light on the lower part of the trunks to a height of ten feet from the ground. These branches, however, have not fallen off, and few show any indication of decay. Some of the stronger trees are now beginning to overtop the weaker ones, and would, I think, soon thin themselves. However, the difference in growth shown between the trees standing on the forest-roads and those in the interior prove the necessity of hastening the process of thinning out, and this I am having done now.

Catalpa bignonioides does not do as well as *C. speciosa*. It looks rough. Each year's growth shows the struggle between the natural branching habit of the tree and the confining conditions of close planting. The trunks are crooked and often forked. It is quite large in diameter, but only for ten to twelve feet up, and from there seems much reduced in size.

Catalpa Kæmpferi is hardly worth mention as a forest-tree, however valuable it is in park-planting. The trees of this species are about one-half the size of the other Catalpas, very crooked and scrubby.

In the thinning out, some 600 trees are removed from an acre—this means about every fourth tree. This first thinning is entirely a matter of expense, as none of the trees culled are large enough for use in any way, and cannot be disposed of even for fuel, though there is no timber for miles around, because of cheap coal. For this reason the trees are merely cut from the stumps and allowed to fall where cut. At the present rate of work I should say that the thinning will cost not to exceed seventy-five cents per acre.

By way of comparing the results of close and open planting of Catalpa, I noted that some trees on a farm close by, on similar soil and same conditions—trees planted eight feet by eight apart—were one-fifth larger in diameter, from five to eight feet shorter in height, and branched out too much to make straight timber. Whereas the closely planted Catalpas are growing tall and straight enough for some of the future thinnings to furnish excellent telegraph and telephone poles.

The tree covering the next largest area is the Ailanthus. With this the company has had varied success. On rich loam and with a loose or sandy subsoil the trees have grown well, showing good strong trunks and straight, upright growth. Unfortunately, however, these trees do not form sufficiently dense shade to prevent grass and weeds from growing underneath. This means that the sod formed stifles the trees, and they remain stunted. The worst of this, however, is that the weeds and grass furnish food for fires, the only real danger and greatest obstacle to forest-growth on these dry prairies. On the light and thin soil and on places that are taken to have been "buffalo wallows," the Ailanthus makes a growth similar to the Sumach. The best Ailanthus-trees are found where a few were planted isolated among the *Catalpa speciosa*. Here they have kept up with the Catalpa and form fine trunks.

Of the Osage hedge-plants I can only say that they are excellent for hedges. When planted closely, they form bushes instead of trees ; and when the trees do grow, they look small and stunted. None of those on the plantation will exceed three and a half inches in diameter and are about sixteen to eighteen feet high. They will never make trees like those in Texas.

In the mixed planting of Wild Cherry, Black Walnut and White Ash I found a strange condition of growth. The Cherry-trees were planted about sixteen to twenty feet apart in the rows, apparently at haphazard, the space filled with Black Walnut and White Ash, four feet apart. The Cherry stands twenty-five to thirty feet high and six to ten inches in diameter—exceptionally large, fine trees. The Walnut and Ash are only twelve to fifteen high and two to three and a half inches in diameter. Close by, where the Cherries were planted closer together, the trees were much smaller, and the intermediate trees, also Walnut and Ash, have made nearly the same growth as the Cherries. At another point in a mixed planting a few isolated Walnuts seem to have taken the lead, but the Cherries are not far behind, and crowding out the larger number of smaller Walnuts.

Where planted alone the White Ash is making a good, steady growth, and seems to form just enough shade to keep down grass and weeds. In the mixed planting mentioned above the Ash is crowded out to some extent.

The Butternut, Pecan and Walnut do not grow as well here as they usually do when placed in the rich deep loam of creek or river-bottoms. The American Chestnut does no better than the Walnut, and there are only a few left of the small number planted. The Box Elder (Negundo) looks starved, and probably is so, as this tree is usually found only on the bottom-land in moist, shaded places. As its wood is very soft and brittle, it does not appear to me to be of any value as a forest-tree, unless, possibly, as a nurse for other and better kinds.

The best trees of all kinds are naturally found on the deepest loam, but this, strange as it may appear, is nearly always on the high ground.

Correspondence.

The Fruit Interests of California.

To the Editor of Garden and Forest :

Sir.—The State Assessor's report for 1890 makes the total number of fruit-trees in the state 13,180,134. This is a great gain over previous reports. Lassen, Los Angeles, San Francisco and Solano are not represented in this report, and it is unfortunate that the Los Angeles and Solano assessors have failed in their duty, for those two counties are largely devoted to orchard interests. Solano in 1889 reported 669,774 trees, and it is probable that Los Angeles had 1,000,000 trees. This would give a grand total of 14,849,908 for the orchards of California in the summer of 1890. We can safely say that 15,000,000 trees are reported by the township assessors of the fifty-two counties of the state—and not one tree more. Compared with the extravagant estimates and forced statistics of some sensational newspapers, this sober result of the forty years' orchard-work of Californians does not seem large. But every man who knows how great an amount of labor, capital, energy and skill the planting and cultivation of 15,000,000 fruit-trees means, is able to measure the extent of the achievement. Careless writers state with airy grace that 5,000,000 or 10,000,000 trees are planted in a single year in California. The plain statements of the assessors show that considerably less than a million trees are planted in a single year ; but that is a great many.

The total number of acres planted in 1890 to grapes, for table, wine and raisin purposes, was 142,534, according to the assessors' reports from all but twelve counties, only two of which—Los Angeles and Solano—are important in this connection. It is worth while to note relative importance of the several divisions of this industry. The acreage devoted to wine grapes is still greater than that devoted to both raisins and table grapes ; but the area of raisin culture is increasing, and the prospect is that it will soon equal that of the wine grapes. The present order of supremacy in table grapes is, Tulare first, Placer second ; in wine grapes, Sonoma first, Napa second, Santa Clara third ; in raisin grapes, Fresno first, San Diego second.

These brief notes from the latest statistical reports of the state of California help to prove what many of us have learned, through painful experiences, that floating newspaper items about horticultural subjects are not always reliable.

Niles, Cal. *Charles Howard Shinn.*

Flowers and the Perfume Industry.

To the Editor of Garden and Forest :

Sir.—In your issue for January 14th I find the above heading, and I have thought it would interest your readers to know that for over six years efforts have been made by myself and many other southern women to learn how flower pomades are made in southern France, for we believe our climate and soil perfectly suited to this industry. Our lack of success comes, we believe, entirely from not knowing by what process the fat is deodor-

ized and clarified, and this process none of us have yet succeeded in obtaining from the manufacturers. The grease must be so clarified that rancidity is impossible. I have corresponded with Mr. George Keene, Mrs. Antoinette Wakeman, Colgate & Co. and others, but as yet we are still uncertain as to the process. In Piesse's "Art of Perfumery" a recipe is given, but, although followed closely, failure resulted. About three months ago I received a letter from a resident of California, in which it was stated that an experiment with raw or uncooked leaf-lard had resulted in success. If true, it would open up another industry to our southern states, where the Jasmine, Violet, Tuberose and Acacia are all hardy and grow in prodigal profusion. Success in one instance came near crowning the efforts of Miss Ida Nowell, of Georgia, who used the Cape Jasmine (Gardenia) for her experiment. The pomade was submitted to Colgate & Co., who, after it was tested, offered her a contract to make from 100 to 200 pounds of the pomade at $1.50 a pound. This pomade sent to the Messrs. Colgate & Co. as a sample was made into an "Extract of Gardenia," which, after being returned to me, I turned over to Freeman, perfumer, who kindly exhibited it at the Cincinnati Exposition in 1887. It was such a small bottle, not holding over one-eighth of a gill, that it must have been lost, as it was never returned to me.

I am one of the managers of the Columbian Fair for South Carolina, and even to-day I have been busily writing to different persons urging the desirability of a renewed effort to discover the secret of the preparation of the pomade. There was imported into the United States in 1890 $3,000,000 worth of these flower pomades alone. I am now negotiating for the purchase of a copper still in which I hope to distill the oil of Rose Geranium, which is used by unscrupulous dealers to adulterate attar of rose.

Spartanburg, S. C. *J. S. R. Thomson.*

[In an article in another column some of the questions raised by Mrs. Thomson are discussed and the general method of preparing the fat for pomade is indicated. We should be greatly obliged if any reader who is familiar with the processes of preparing marketable perfume would forward specific directions. It should be remembered, however, that, like any other manufacturing business, this must be learned by experience, and it can only be prosecuted with profit with skilled labor and the most approved appliances, so that uniform excellence can be secured by the most economical methods.—Ed.]

Periodical Literature.

One subject treated of in the latest bulletin of the Cornell Experiment Station is the crossing of plants of the Squash-family, and the experiments recorded seem to demonstrate the fallacy of many popular beliefs. It is pretty widely believed that the different species of cucurbitaceous plants intermingle readily and hybridize freely, so that almost any story about the crossing of these plants will find believers. Professor Bailey began experiments in crossing those plants three years ago, and has continued them on a large scale ever since. After having made more than a thousand careful pollinations by hand, Professor Bailey asserts that there is no immediate effect of crossing Pumpkins and Squashes—that is, the effects of the cross are not seen in the fruits of the first year, but only in the offspring of the seed. Of course, ordinary experience would lead to the same conclusion; for if there were any immediate effect we should always look for different kinds of fruits on the same vine, while, as a matter of fact, the squashes or pumpkins on any vine are always alike, with such exceptions as are due to arrested development or some other immediate cause.

There is a prevailing belief that Pumpkins and Squashes cross indiscriminately, but, in studying the question, Professor Bailey divided the fruits called squashes into two groups, one including the summer and fall squashes, like the Scallop, Crook Necks, Bergen and the like, which belong to the same species as the field pumpkin—*Cucurbita Pepo*. These squashes cross with each other and with the field pumpkin, although the mixture is not indiscriminate. The Hubbard, Turbans and so-called Mammoth squashes and pumpkins, like the Mammoth Chili, belong to another species—*Cucurbita maxima*. After many careful pollinations between these two classes of fruits seeds were not produced in any case, and all the experiments show that these different species will not hybridize. In large collections of summer pumpkins and squashes fruits which might be taken for hybrids with the Turban class may be found, but they are nothing more than incidental variations of *Cucurbita Pepo*.

In Pumpkins and Squashes the flowers are either wholly staminate or wholly pistillate, and therefore they cannot be self-fertilized. The two kinds of flowers, however, are borne on the same plant. A great number of trials were made in which the pollen from a staminate flower was used upon a pistillate flower of the same plant, but in every case the seeds were thin and worthless. In cross-pollinations, that is when the pollen from the flowers of one plant were applied to female flowers of another plant, a large part of the trials were successful, which indicates the impotency of pollen to fertilize a flower produced on the same plant. Pollen of Squash-flowers, however, which cannot produce fertile seeds, may still cause the development of the fruit. This influence of pollen is well attested in other instances, and it is not impossible that squashes may sometimes develop without any pollination whatever. It is the common belief that the best way to render new varieties permanent—that is, to fix them so that they will reproduce themselves from seed—is to inbreed them to establish their ancestral qualities; but the above trials seem to prove that close pollination is practically impossible in the case of the Pumpkin and the Squash.

It is generally accepted among gardeners that musk melons are rendered insipid when cucumbers grow near them. Some growers suppose this influence is immediate, but others hold that it appears only in the offspring of supposed crosses between the two species. Last summer ninety-seven Musk Melon flowers of various varieties were pollinated with Cucumber pollen of many kinds, but not a fruit developed. Twenty-five Cucumber flowers were pollinated by Musk Melon pollen; one fruit developed, and that was seedless. These trials indicate that the two species do not cross and that the influence of one upon the other is imaginary.

An examination of the flowers on Musk Melons, Water Melons and Cucumbers show that from six to twenty-four times as many staminate as pistillate flowers are produced. The pistillate flowers appear later in the season, five days in the case of the Cucumber to thirty days in the case of one Musk Melon-plant. The staminate flowers continue to appear later than the fertile ones. This fact justifies the common observation that the Cucumber is more precocious than the Melon, and enforces the necessity of starting Melons early in short seasons.

The most interesting paper to the general reader in the January *Bulletin of Miscellaneous Information* issued from the Royal Gardens at Kew doubtless is the one which relates to the origin of the ginger which comes to us from China in earthenware jars of more or less artistic merit. Professor Wright, of the University of Dublin, several years ago pointed out the fact that the "large, flat, finger-like masses sent from China as preserved ginger" were different from anything that the ordinary Ginger-plant (*Zinziber officinale*) could possibly produce. The question then arose, What was the plant that supplied the preserved ginger of commerce? The common Ginger-plant, as is the case with many cultivated plants, is not known in the wild state. It is believed, however, to be a native of Asia, and was known to the Greeks and Romans, who received it by way of the Red Sea, and believed that it came from southern Arabia.

The Ginger-plant was introduced into the West Indies, from which it was shipped commercially to Europe as early as the sixteenth century, it is said; and the dried ginger of commerce is now almost entirely derived from the West Indies, from Senegambia, from Egypt and India. None apparently is produced in China. The long correspondence which the authorities of Kew have carried on with regard to the origin of Chinese ginger, and their experiments in cultivating various plants sent from China, for the purpose of determining the source of the preserved ginger, leads at last to the conclusion that it is produced by *Alpinia galanga*, and the specimens, curiously enough, which enabled this determination to be made, did not come from China, but from the Botanical Department at Jamaica, where Alpinia has long been grown. Probably one or two species of the same genus also produced edible ginger in Siam and other countries of tropical Asia.

The other papers in this issue are on west *African Bass Fibre* and on the *Production of Seed and Seminal Variation in the Sugar-cane*. The fact lately discovered that the Sugar-cane, which from time immemorial has been propagated by buds, sometimes produces seeds, is a matter of considerable agricultural importance as suggestive of the possibility of producing improved seedling varieties.

Notes.

It is said that in north-western Persia and in eastern Afghanistan the bulbs of a species of Tulip (*Tulipa montana*) are largely used as food. They may also be found in the markets of Bombay, where they are called "Salep."

The patience characteristic of modern students of plant-life is well exemplified by the fact that Herman Mueller, when studying the cross-fertilization of flowers, recorded ten thousand instances, observed by himself, where insects had visited flowers in such a manner as to carry the pollen from one to another.

According to *Gartenflora* the district of Reutlingen, in Germany, had, in the year 1885, an income equal to about $65,000 from the fruit-trees planted along its highways. In the district of Monheim the fruit-trees on the public roads, which had been planted in 1858, yielded in 1868 a revenue of some $1,850, in 1878 $4,250, and in 1885 nearly $7,000.

In a recent issue of the *Official Gazette* of Montenegro, Prince Ferdinand ordered that every military man in active service should, during the year, plant a given number of Grape-vines, the number varying according to his rank. Each guide, furthermore, is to plant two Olive-trees, and each corporal one; and the *Gazette* calculates that by this means 4,000,000 Vines and 20,000 Olive-trees will have been set out by January, 1892.

A monument is to be erected in France to Jean Nicot, who introduced the Tobacco-plant into that country, and whose name it since has borne. In the year 1560, when ambassador at the Court of Portugal, he sent a package of seed to the French queen, Catherine de Medici. Sixty years later the first tobacco tax was imposed by Cardinal Richelieu, and not long afterward the revenue from this source amounted to some $50,000, while in 1718 the tax was "farmed" to a collector for an annual sum of $3,200,000.

Writing of Japan in the *American Garden*, Professor Georgeson says: "The total area of the main islands is 112,000 square miles, but of this total 68,000 square miles are entirely unproductive mountain and desert lands, and 24,000 square miles more are in forests and uncultivated agricultural lands. . . . The remaining 20,000 square miles contain the 40,000,000 inhabitants of the country, which thus gives an average of 2,000 people to the square mile. Kansas contains 81,000 square miles. If her people could live as the Japanese do, she could sustain 40,000,000 souls, and still leave three-quarters of her territory a wilderness!"

The Tea-industry of China is very much demoralized by the increase of Tea-production in other countries, especially in India, and great distress prevails in many of the Tea-districts. We learn from a recent issue of the *Fouchow Echo* that the authorities are advising the owners of Tea-gardens to destroy their Tea-plants and replace them with Rice or Potatoes. This advice is being adopted wherever a supply of water can be obtained for irrigating the Rice-fields. The cultivation of opium is also increasing in some parts of China, in the place of Tea-plant. But thousands of families, it is said, who were formerly supported by cultivating Tea-gardens are now ruined.

The danger from damage to forests by fire where lumbering is carried on, arises largely from the fact that the tops of the trees and large limbs which are left on the ground dry rapidly and give fuel for any running fire to catch in. The burning of these leavings is an expensive matter, and it is suggested by Mr. Fernow, in his Adirondack report, that the branches might be lopped, so that both they and the tops would fall to the ground. In this way the tops, which are ordinarily braced up from the ground by the branches and kept as dry as tinder, would be likely to be kept moist from snow and rain and rot sooner. A trial of this method would be an interesting experiment. To answer the purpose most completely, the lopping should be done as soon after the felling as possible.

A correspondent inquires if the Strawsonizer is a machine for throwing poison spray as an insecticide. It is that, and it is more. It is a machine which may be adapted to many uses, such as the sowing of grains, the distributing of fertilizers and of dry or liquid insecticides by a blast of air produced by a revolving fan, worked by the traveling wheels of the machine. It is said that rapid and even work in broadcasting grain is done with this machine, and that the grain is scattered with great regularity over a track from eighteen to twenty feet wide, and it is equally good as a distributer of fertilizers and poison-powder for insects. There are some machines worked by hand-power, and larger ones by horse-power. The machine is more fully described in the issue of *Insect Life* for January in the article by Profesor Riley in the "Outlook for Applied Entomology."

It seems doubly fortunate now that the prehistoric "Serpent Mound" in Ohio should have been preserved against all the dangers man's agency might work by the establishment of a public park to contain it, for we are told that another famous work of the same kind, "Monk's Mound," is to be destroyed, that its materials may be used to fill in certain low-lying portions of East St. Louis. It was described by Charles Dickens in his "American Notes," and is said to cover an area of thirty acres, its peak rising nearly a hundred feet above the level of the surrounding country. "On the apex," says the New York *Times*, "there was a dwelling at one time, and a few years ago an extensive Peach-orchard flourished on the southern slope. Nearer the base, on the opposite side, field products and garden truck were cultivated—the soil yielding bountiful crops."

In commenting upon the statement that three successive Dukes of Athol had planted altogether 14,000,000 Larch-trees on their estate in Scotland, *Galignani's Messenger* recently remarked that it had been doubted from the apparent belief that it implied that the noble owners had set out the trees with their own hands. Such, of course, was not the fact, "but," adds the *Messenger*, "if it comes to planting trees with one's own hands there is still something to be said" for royal and noble personages. With his own hands "Charles II. planted nearly all the trees in the avenue at Windsor . . . . and some that are now in St. James' Park; and George III. had a mania for planting his own trees as well as innumerable Grape-vines. Her present Majesty has planted over 5,000 trees in various places she has visited, and the Prince of Wales cannot be very far behind her in so doing."

The *Journal of the Society of Arts* (England) recently said: "A memorandum, together with a sample of the plant, lately received from Sir Alfred Moloney, K.C.M.G., the Governor of Lagos, gives an account of the endeavor he is making to encourage the exportation of the fibre known as African Bass, the fibre of the Bamboo Palm or *Raphia vinifera*. The Bamboo Palm or *Raphia vinifera* is perhaps the commonest tree in the swamps and lowlands which line the waterways of the colony. Dense thickets of these Palms, traversed only by the palm-wine gatherer or the bamboo-cutter, push their way into the lagoons, and extend over the flood grounds, and even to a distance of from fifteen to twenty miles up the river valleys into the interior. The area occupied by the Raphia-forests it would be impossible to calculate, but it may be accepted without doubt that they extend throughout the length of the colony, and to a distance of at least fifeen miles from the sea-coast, and that over this area of about 5,000 square miles they form a considerable proportion of the vegetation; next only in numbers to the Oil Palm (*Elæis Guineensis*) and the Mangrove (*Rhizophora mucronata*). The fibre itself is the one in most common employment on the coast, being used by the natives for all sorts of purposes—cloth, cordage, thatch, fishing-lines, etc. The cost is only that of collection and preparation, the latter being a very simple process of soaking and scraping. The price, delivered in England, is said to be £30 to £32 per ton for good fibre. The cost of production is estimated at £14 per ton, shipping and other expenses at £4 10s. The samples are now on view at the Society's house, and can be inspected by anybody desirous of doing so."

Catalogues Received.

Bush & Meissner, Bushberg, Mo.; American Grape Vines.—H. Cannell & Sons, Swanley, Kent, England; Vegetable and Flower Seeds; Illustrated Floral Guide.—Chadborn & Coldwell Mfg. Co., Newburgh, N. Y.; Lawn Mowers.—Cold Spring Seed Farm, Big Horn City, Wyoming; The Buffalo Berry and Native Wild Fruits of Wyoming.—D. M. Ferry & Co., Detroit, Mich.; Vegetable and Flower Seeds.—Peter Henderson & Co., 35 and 37 Cortlandt Street, New York, N. Y.; Ornamental Plants, Flower and Vegetable Seeds; Everything for the Garden.—McMath Bros., Onley, Accomack County, Va.; Vegetable Seeds; Small Fruits and Vegetable Plants.—Rea Brothers, Norwood, Mass.; Hardy Plants.—E. W. Reid, Bridgeport, O.; Vegetable Seeds, Fruits and Small Fruits.—Selover & Atwood, Geneva, N. Y.; Ornamental and Fruit Trees, Bulbs, Shrubs, etc.—J. C. Vaughan, 146 and 148 West Washington Street, Chicago, Ill.; Vegetable and Flower Seeds, Small Fruits.—Vilmorin-Andrieux & Cie., Quai de la Mègesserie No. 4, Paris, France; Flower and Vegetable Seeds.

TABLE OF CONTENTS.

The True Function of City Parks.

THE *Atlantic Monthly* for February contains an article by Mr. Alpheus Hyatt entitled "The Next Stage in the Development of Public Parks." What is interesting and valuable in this paper is a plea for the establishment in cities of more museums and a sketch of the principles on which collections should be made and arranged so as to serve the highest practical purpose. Mr. Hyatt urges that at our present stage of civilization collections of the varied forms of animal and vegetable life are as necessary as are public libraries and universities. We have learned that the highest education in the natural sciences is not acquired from books—that is, by a study of what other people have recorded—but by original investigation of the objects themselves; and public museums and gardens could aid in this direction by supplying natural objects for the use both of teachers and pupils just as libraries furnish books for those who wish to read. A museum, according to this view, is not a place of amusement merely—a collection of natural curiosities or rarities to excite the wonder of the ignorant—but a source of constant and adequate supply of objects for investigation by persons who are engaged in serious study. A zoölogical garden should not be a menagerie for the sole display of animals which are large or strange, but should include creatures of humbler structure, creatures which are small indeed, but whose functions in the economy of nature are of the highest importance to man and his physical surroundings. This means that we should have insectaries, where the various transformations of insect life could be observed; aquaria for the exhibition of marine animals and plants and sea birds, and fresh water aquaria for the fish and other inhabitants of inland lakes and rivers, together with such plants as grow in or near the water.

Of special significance are Mr. Hyatt's ideas with regard to grouping the animals in zoölogical collections according to the laws of geographical distribution as well as to those of specific relationship, and of supplying "a proper representation of the flora of each great area or country in the shape of some characteristic trees and flowers," in order to furnish the animals with appropriate surroundings "and give scientific and artistic completeness to these illustrations of the fauna." But, perhaps, the most novel of his suggestions is that, in addition to objects of study, teachers should be provided, who would do more than a printed guide-book in pointing out and naming and describing the interesting forms in any collection. No catalogue can ever keep pace with living and growing collections, and its pages are never large enough to answer the inquiries which every visitor is eager to make. Mr. Hyatt, therefore, would substitute for the catalogue educated men, who would be present not only to satisfy all reasonable curiosity, but to awaken interest, and, at the same time, give instruction that would be of permanent benefit.

All this is very attractive, and not impracticable. But when Mr. Hyatt declares that a public park does not fulfill its highest mission until it develops into a vast and multiform museum for popular instruction, he plainly ignores the specific purpose for which pleasure-grounds like Central Park, for example, have been created. Indeed, one may read Mr. Hyatt's article attentively and fail to discover whether he has ever cared to inform himself precisely what that purpose is. The fact is that in popular language there is no well-defined group of ideas suggested by the word park, and it is applied to areas of ground which are used for the most varied and incongruous purposes. To one man it may mean a base-ball field; to another a military parade-ground; to a third a place where racehorses are used to facilitate gambling. Indeed, the danger of assaults upon the integrity of city parks is constant because of the lack of clear popular conception of their true functions, and they never will be safe from attacks until their primary purpose is universally understood, and until this purpose is admitted to be of sufficient importance to justify their existence and maintenance.

We have some hesitation about stating elementary principles with which our readers are already familiar, but there seems to be need of repeating pretty frequently that a park, such as is now under consideration, should be primarily and essentially a rural retreat—a place which will enable the people of a city to visit the country without leaving the town—and that its highest purpose is not to furnish instruction nor pure air nor a place for exercise on foot or on horseback, but to furnish that relief and repose of mind which natural scenery brings to those who are wearied by city sights and sounds. We need not inquire why this is so, but the fact is universally known and recognized that rural scenery has an intrinsic value in enabling us to resist successfully the wearing influences of town life and to recover the mental energy thus wasted. Every one is more or less susceptible to the charms of scenery, and a city park has a greater or less value for a city population, according to the degree in which this poetic charm of scenery is preserved and developed. Of course, a park designed and constructed with such a leading motive will not fail to furnish pure air and a field for exercise and opportunity for study, while if it is designed primarily with reference to any of these subordinate uses its highest purpose will not be reached.

It is true that the highest authorities on these subjects have made in some parks provision for boating, for tennis, for skating, for music, for children's playhouses and the like, but wherever such introductions have been successful they have been incidental and subordinate to the controlling motive of the park which has been steadily kept in view. A botanical garden, a zoölogical garden or an aquarium might well be placed in grounds adjoining a park, but separated from it so as to avoid any tendency to combine the ideas of a park and a museum, for the object of a museum and the object of a park are utterly distinct, and it is no more possible for a park to develop into a museum than it is for a library to develop into a cathedral.

Unless we hold fast to these primary truths our parks may be changed into places for miscellaneous out-door sport and recreation; they may afford the advantages of speed-roads for the owners of fast horses or spacious promenades where fashion may display its bravery and equipage, or, in accordance with Mr. Hyatt's idea, they may be "placed in correlation with the educational systems" of our cities by offering a home for thronging colonies of vertebrate and invertebrate animals besides vast collections of stuffed and dried curiosities, with all their vegetation ticketed and labeled, and trained lecturers discoursing on biology at convenient intervals. Public grounds prepared on any of these plans would no doubt be of great value to any city, but they would not be parks, nor serve the use of parks. Neither recreation, in the specific sense of amusement, nor education, even under its most attractive guise, but refreshment, pure and simple, for body and mind is the primary office of the public park. And nowhere should this fact be insisted upon more strenuously than in eager American communities where there is little inclination to give either mind or body their needed quota of peaceful, unambitious hours.

Recent Botanical Discoveries in China and Eastern Burma.—III.

Herbaceous Plants.—The herbaceous element in General Collett's collection of plants from the southern Shan Hills is not less interesting botanically than the shrubs and trees, and there are many novelties sufficiently ornamental to engage the attention of the horticulturist, and a few are exceptionally beautiful or singular plants. Taking them in systematic order, the first demanding notice is a species of Balsam (*Impatiens ecalcarata*), a species so strongly resembling the pretty *Impatiens Chinensis* as to be taken for it at the first glance; but, as the specific name denotes, the flowers are spurless. With this exception, it is so like the species named, in the dried state, at least, as to suggest its being a morphological variation of it. Yet among the very numerous specimens in the Kew Herbarium we detected none in which the spur was wanting or modified. It is a slender, almost unbranched, annual, a foot to two feet high, with narrow, opposite, more or less toothed leaves, whitish beneath, and solitary, axillary flowers on slender stalks. The color is not stated, but they are probably white or rose. *Impatiens Chinensis* itself deserves a word in this place, as it is certainly a most elegant plant, the flowers varying in the wild state from deep purple to a soft rose, and there is also a white variety. Although introduced into English gardens as long ago as 1824 it is now rarely seen. *Impatiens fasciculata* (*Botanical Magazine, t.* 4631) is a pale variety of this species, and *I. setacea* (Hooker's "Exotic Flora," *t.* 137) is another variety, having beautiful rose-purple flowers.

The herbaceous *Leguminosæ* from the Shan Hills offer little that is specially interesting from a purely horticultural standpoint, though there are several remarkable novelties. *Crotalaria perpusilla* is a miniature representative of its genus; *Neocollettia gracilis* is a singular creeping plant with minute flowers, belonging to a small group having one-seeded pods; and *Phylacium majus* is a fine new species of a previously monotypic genus from the Malay archipelago.

The herbaceous *Compositæ*, again, are few of them ornamental. *Inula crassifolia* is one of the most striking, having thick, almost fleshy, leaves, and large yellow flower-heads. This plant was collected in two very different conditions, though all the specimens were in the same stage of development. In one set they are thickly clothed with long, spreading hairs; in another set they are quite glabrous, so that at first sight they would be taken for distinct species, but the plants are probably all hairy at first, and the hairs early deciduous.

Notonia crassissima is a shrubby member of this order which I omitted to mention before. It has thick fleshy branches, resembling some of the Euphorbias, such as *E. neriifolia*, and long-stalked, showy yellow flower-heads, and it grows erect or trails over rocks.

About half a dozen different *Campanulaceæ* were collected, including several very pretty things, notably the elegant little twiner *Codonopsis convolvulacea*, previously only known from the contiguous province of Yun-nan, in China. General Collett describes it as common all over the plateau, creeping among grasses and twining around their culms until it reaches air and sunlight, when it produces its beautiful, dark blue, Convolvulus-like flowers. One species of the highly ornamental, mainly east Asiatic, genus Adenophora was collected. It is also common in the Khasya Mountains, but had not hitherto been referred to this genus.

Primula Forbesii is a pretty species, originally and recently described by Mr. Franchet from Yun-nan specimens. With one or two other Chinese species, it forms a new section of the genus of annual duration, and intermediate in character between Primula and Androsace. It is a very floriferous plant, with an almost flat rosette of thin leaves and very slender, erect scape, bearing from one to three or more tiers of small flowers similar to those of the Himalayan *P. floribunda*. It grows abundantly in almost all damp localities throughout the Shan States, being equally at home in the shady depths of the forest and in the ridges raised to divide irrigated rice-fields; and it was found in flower in some situation or other in every month of the year.

Among Asclepiads, a very dwarf, tuberous-rooted Ceropegia deserves notice. The flower-stems rise only four or five inches above the ground, while the curiously constructed flowers are themselves two inches long. *Brachystelma edulis* is an allied plant of even smaller dimensions with small rotate flowers. It is common on the sandy plains of Upper Burma, and its fleshy tubers are collected and sold in the bazaars as an article of food; but their flavor is not agreeable to a European palate.

There are two new species of the section Ophelia of Swertia, neither more nor less pretty than most of those previously described of this elegant genus.

Specially conspicuous and beautiful among the herbaceous plants on the uplands are various *Convolvulaceæ*, especially the genus Ipomæa, of which sixteen species were collected, including two very ornamental new ones. *Ipomæa nana* is a dwarf species almost concealed by the grasses among which it usually grows. From the woody root-stocks spring erect stems from six inches to a foot high, bearing very hairy, undivided leaves, and large, axillary, solitary flowers of a rich deep purple. *Ipomæa Popahensis*, the other new species, has very similar flowers and foliage, but it has weak stems that twine around grasses and other plants. It inhabits the isolated Mount Popah, which rises to an altitude of 5,000 feet in the plain of Upper Burma.

There is nothing ornamental among the herbaceous *Scrophularineæ*, and the solitary new Gesnerad has inconspicuous flowers. *Acanthaceæ* are more numerous, and some of them very pretty, notably among the new ones *Strobilanthes connatus*, found in great abundance in the dry forest-tract at 2,000 feet. The *Labiatæ* are numerously represented, and many of them are ornamental, but all of them were previously known. Prominent among them are *Orthosiphon staminens*, *Colebrookia oppositifolia*, *Leucoscephum canum*, and various species of Plectranthus, Elsholtzia, Scutellaria and Coleus. But the most ornamental of all is the previously little known *Colquhounia elegans*, which General Collett specially signalizes as worthy of cultivation. It is an erect shrub, eight to ten feet high, with ample foliage and dense axillary clusters of showy flowers in the way of a Leonurus. As a species it is near *C. coccinea*, figured in the *Botanical Magazine* (*t.* 4514). Two varieties were collected, one having dark red and the other salmon-colored flowers. A second and almost equally beautiful species, *C. vestita*, was less common, though it inhabits the mountains of northern India from Assam westward to Kumaon. Orchids were not numerous, only twenty-two species having been collected, though of these five are accounted new, and two of these are exceedingly distinct, curious and beautiful. A word first respecting the old ones, which included *Dendrobium lituiflorum*, *D. infundibulum*, *D. fimbriatum*, *D. capillipes* and *D. heterocarpum*, better known as *D. aureum*. Also among them were *Vanda cærulescens* and *Cypripedium concolor*, var. *Godefroyæ*.

The gem of the whole collection, perhaps, including the big Rose and the big Honeysuckle, is an Orchid, which I have named after its discoverer. It is *Cirrhopetalum Collettii*, the finest species of the genus, and most nearly allied to *C. ornatissimum*, figured in Warner's "Orchid Album," plate 369, but having dark purple flowers, with exceedingly slender lateral sepals about five inches long. These long, tail-like sepals are wafted about by the slightest breath of air. But, what is more curious, the comparatively small upper sepal and the two lateral petals are furnished on their margins with small, extremely delicate, highly mobile appendages resembling tiny banners and streamlets, which "wriggle about in a very odd manner." Amateurs will be glad to know that there is a good healthy plant of this attractive novelty growing at Kew.

The only other new Orchid I have to mention is *Bulbophyllum comosum*, which has a bottle-brush-like inflorescence of

small, pleasantly fragrant flowers borne on a slender scape. It is nearest *B. hirtum*, but neither the pseudo-bulbs nor the leaves are known. The plant was common, and the flowers, which are highly prized by the Shan maidens for ornamenting their hair, were sold in the bazaars, so that General Collett thought it must be known in Europe and was satisfied with bringing away two or three inflorescences.

A new Lily (*Lilium Bakerianum*) may close my remarks on this collection. It is intermediate in character between *L. Dahuricum* and *L. Japonicum*.

Doubtless, a country so rich in ornamental novelties as the Shan States will soon be explored by the collectors of some of our nurserymen.

Kew. *W. Botting Hemsley.*

The Chollas.

ONE of the most characteristic features in the landscape of southern California, especially in the region of the coast, is the extensive, impenetrable thickets of a cylindrical species of Cactus, familiar to all under the Mexican name, *Chollas*. The common Cholla in the vicinity of San Diego is *Opuntia prolifera*, Engelm., which grows abundantly on arid hills or mesas, especially on precipitous cañon-slopes bordering the usually dry water-courses. Chollas Valley, within the limits of the city of San Diego, received its name from the abundance of this plant. It grows from three to eight or ten feet in height, the stems from two to four, rarely six or seven, inches in diameter, and at the base forming a woody stem or trunk a foot or more in diameter.

The plant has never been utilized by stockmen for forage to my knowledge, as has been the case with some species of the genus, and it is quite a formidable task to clear land of this obnoxious plant. The short, stout spines are especially painful and tenacious after they have entered the flesh, and strangers in our land, human and brute, soon learn to give it a wide berth.

The flowers are an inch and a half in diameter, of a pretty wine or pomegranate purple, but are so well guarded by a multitude of formidable spines as to almost repel admiration. The fruit is proliferous, the seed almost invariably abortive.

Professor E. L. Greene records it from the Coronado and Guadalupe Islands, while T. S. Brandegee reports it from the Santa Catalina Island and as far southward as San Ignacio, in Lower California, where, he says, "the plants are sometimes almost spineless." I have not found it south of Todos Santos Bay, Lower California, but to the southward a very similar Cactus appears, identical in appearance, but very distinct in its fruit. I am, therefore, inclined to doubt whether the species which Mr. Brandegee reports or Professor Greene's Guadalupe Island plant, which he says is "smaller than in California," is the same as our San Diego species. The fruit is fleshy, spinous, very rarely containing even a single seed. The perfect seed is much larger than in the above-mentioned Mexican species.

Opuntia serpentina, Engelm., is a slenderer, usually prostrate, species, not gregarious nor so abundant as *O. prolifera*, producing yellowish green, purple-tinged flowers, followed by a dry many-seeded fruit, broadly umblicated and very spiny. The stems of this plant are seldom more than three or four feet long, an inch or two in diameter, and less woody in structure than the last species.

On the Colorado desert and eastward and southward through Arizona and New Mexico into old Mexico, the species and varieties of Chollas seem almost endless in number. The Indians in the mountains of San Diego County and in northern Lower California formerly planted them above the graves of their dead, and often a valley may be found dotted over with little groups of a slender, erect species (probably *O. Bernardina*, Engelm., ined.) planted by their hands.

One species (*O. Bigelovii*, Engelm.) has been sparingly utilized as fodder for cattle, after the spines had been burnt off, but all the species are very generally detested by all who are brought into intimate relations with them.

San Diego, Cal. *C. R. Orcutt.*

An Insect Pest of Cattleyas.

(*Isosoma orchidearum.*)

THIS insect does not appear as yet to have become common or generally known among collections in this country, and it is well that growers should be on their guard against it, because it seems to have become quite common in Europe, and is therefore liable to be introduced with any fresh importation of the plants.

The pest has appeared in more than one locality and in past years has not been unknown even in such carefully guarded collections as those of Mr. Ames, at North Easton, Massachusetts. A notice of its occurrence in another collection appears in *Insect Life*, vol. ii. (1890).

About two years ago, Dr. C. G. Weld, of Brookline, Massachusetts, imported a lot of Cattleyas from England which at first appeared to start into good healthy growth, but soon proved to be badly infested by this so-called "orchid-fly." The young buds or pseudo-bulbs which would eventually produce the flowering-spikes were noticed to become checked in their development, and upon cutting them open numerous little maggots or larvæ were found in cavities which they had eaten. Some pupæ were also found, and these, together with a few of the larvæ, afterward developed into small, black, four-winged flies.

From an investigation of the history of this insect it would appear that it was first publicly referred to by Professor J. O. Westwood at the meeting of the Royal Horticultural Society of February 16th, 1869, and a brief mention of the fact was given on page 196 of the *Gardeners' Chronicle* for the same year. On page 1230 of the same volume (1869) Professor Westwood gave a slight sketch and a brief notice of the insect, for which he proposed the name of *Isosoma orchidearum*. It is more fully figured and is technically described by the same author in the *Transactions of the Entomological Society of London* for 1882, pp. 322–324, pl. xiii.; and occasional brief notices of the pest have appeared in various foreign journals.

The perfect insect or fly is black, and has clear, shining, iridescent wings. The female is about one-seventh of an inch long, while the male is considerably smaller, being only about one-tenth of an inch in length. The head and thorax are rough and unpolished, the microscope showing them to be covered with tiny pits, from each of which little bristles or hairs project. The abdomen is black, smooth, polished and shining, and is without hairs except on the smaller last segments. The abdomen of the female is pointed and somewhat wedge-shaped beneath, while that of the male is small, being not more than half the length of the female abdomen and terminating bluntly or abruptly. Under the microscope the sexes may be readily separated by the antennæ. In the female most of the joints are about of the same size and shape, being symmetrical and connected together by inconspicuous pedicels; while the male antennæ are somewhat longer, the chief joints being longer and abruptly tapering to a slender neck or pedicel at the anterior ends, and lacking symmetry by being much more swollen on one side than on the other. The whorls of hairs or bristles are very much longer than on female antennæ.

It may be also worth noting that, counting the less distinct articulation in the terminal joints, the antennæ of the females are apparently ten-jointed, while in the males only nine divisions are noticeable.

The legs at the joints are red; the femora or thighs black; the tibiæ or middle portion yellowish or reddish, except on the hind pair, where they are blackish, and the feet (tarsi) are pale or dull white and tipped with minute dark claws. From the specimens collected the females appeared to greatly outnumber the males.

The female is provided with a long and extremely slender ovipositor, which it inserts into the tissue of the plant when depositing its eggs. When not in use, this ovipositor lies quite concealed by a groove and protecting sheaths, and only very careful manipulation with a slender-pointed instrument will bring it into view. In the figure the ovipositor and free portion of the sheaths are shown removed from their closely fitting position along the under side of the body.

The little footless grubs or maggots are white, and a sixth of an inch or less in length when fully grown.

Several of them may be found together, and they change to pupæ, and eventually to the winged state, within the cavity they have made in the Orchid, out of which they emerge through a small round hole in the side. Owing to their small size the flies are not easily detected after they escape, but they have been found resting on the under side of the leaves of the plants.

If this insect once gets a foothold in a collection it becomes a difficult one to exterminate. No means of trapping the flies are known, and the only apparent remedy has been the heroic one of cutting off and destroying all portions of the plants suspected of being infested. The young pseudo-bulbs usually become somewhat abnormally swollen if the maggots are at work within, although the indication is not always a certain one. To cut these young shoots off means the loss of flowers for a year.

It has been suggested that the larvæ could be killed in their burrows by prodding the infested shoots with a triangular dis-

secting pin (*Bull.*, p. 23; *Ann. Soc. Ent. de France*, 1888), and it seems that such experiments have been made in Paris, although the final results do not appear to have been published. Instead of making the numerous punctures which would be necessary in order to destroy all the larvæ, it might be worth while to try some experiments with insecticides. A drop of strong tobacco decoction, or of some oil, injected through a perforation, would destroy the insects reached; but the experiment should be carefully watched, both as to its effect on the plants and insects. Fumigating has been practiced in attempts to destroy the flies, but it is questionable whether fumes strong enough to kill these insects would not also injure the plants.

To keep a collection free from the pests every new importation should be thoroughly examined, and, if not known to be from uninfected establishments, they should be quarantined in a separate house for at least a year before placing them with unaffected plants.

The full history of this insect is not yet thoroughly known, and it is not at all certain that it does not live in other parts of the plants besides the new shoots or pseudo-bulbs. Similar-looking, and probably identical pupæ have been found singly in cavities in the fleshy leaves, the spot being indicated by its lighter color and a slight swelling on each side. It has also been reported that the insect makes pea-shaped swellings on the roots, but it has not been proved that this is the work of the same species.

Isosoma orchidearum, figured on page 103 from drawings by Mr. C. E. Faxon, was probably first imported into England with Cattleyas from South America. To the entomologist the insect is interesting, from the fact that it belongs to a group which was long considered to be purely parasitic upon other insects. It seems that a few European entomologists still maintain this theory; but the studies of Harris, Fitch, Walsh, Riley and others on the Isosomas of the wheat and other grasses in this country have clearly shown that insects of this genus, in many cases at least, subsist entirely on vegetable food and that they are capable of doing much injury to cultivated crops.

Arnold Arboretum. *J. G. Jack.*

Notes on North American Trees.—XXIV.

57. *Hypelate trifoliata.*—This small West Indian and Floridian tree has been known for nearly two hundred years, having been discovered in Jamaica by Sir Hans Sloane, who published an account of it in 1696 in his Catalogue of Jamaica Plants; and all subsequent writers on the flora of the Antilles have described it more or less accurately. The best account which has been published is found in Lunan's *Hortus Jamaicensis* (i., 387), where the structure of the seed is hinted at. Hypelate produces male and female flowers in separate panicles on the same plant, the males probably predominating, as fruit is rarely produced; and the seed has never been described in the two centuries this tree has been known to botanists. We have been able at last, however, to find a single perfectly developed fruit, and Mr. Faxon has succeeded in working out its structure for the plate in "The Silva of North America."

The flowers of Hypelate consist of a five-lobed calyx with ovate lobes imbricated in æstivation, slightly puberulous on the outer surface, ciliate along the margins and deciduous. The petals are rather longer than the calyx-lobes, imbricated in æstivation, concave, and rounded at the apex, with ciliate margins; they spread at maturity and are white. There are seven or eight stamens inserted on the margin and between the lobes of the annular fleshy disk; the filaments are filiform, as long as the petals in the sterile flower, and shorter in the fertile flower; the anthers are oblong, attached on the back near the bottom with two cells spreading from above downward and opening longitudinally. The ovary is sessile on the disk, slightly three-lobed and contracted into a short, stout style, terminated by a large, declinate, obscurely three-lobed stigma; in the sterile flower it is reduced to a mere rudiment. There are two ovules in each cell borne on the middle of its inner angle, amphitropous and superposed, the upper ascending with the micropyle inferior, the lower pendulous with the micropyle superior. The pistil ripens into a small, black, one-celled drupe, crowned with the remnants of the persistent style, and supported on the persistent base of the calyx. The outer covering is very thin, although fleshy and rather juicy. The stone has very thick bony walls, and contains a single suspended seed developed from the lower ovule. The seed is destitute of albumen, with a thin, slightly wrinkled testa. The embryo is conduplicate, filling the cavity of the seed, with thin, foliaceous, irregularly folded cotyledons incumbent on a long radicle which points toward the hilum.

It appears from the character of the embryo that Hypelate must occupy an anomalous position among the genera of *Sapindaceæ*, and that it does not readily fall into any of the tribes into which the family has been divided by Bentham and Hooker in the "Genera Plantarum." It may perhaps best be placed at the end of *Sapindeæ*, which it serves to connect with the *Acerineæ*.

Another West Indian tree which occurs also in Florida has often been referred to Hypelate. This is the *Hypelate paniculata* of Cambessides, which was first referred by A. L. de Jussieu to *Melicocca*, and which much later was described independently by Macfadyen in his "Flora of Jamaica" as *Exothea oblongifolia*, his genus Exothea being established for this plant. Radlkofer has already taken up Macfadyen's genus Exothea in Durand's "Index Generum," and the structure of the fruit of Hypelate shows that his view is correct, and that these two Florida trees cannot remain in the same genera. The fruit of Exothea, unlike that of Hypelate, is baccate, with one perfect cell and the rudiments of the second, with thick dark purple flesh surrounding a large, solitary, oblong, suspended seed without albumen, and with a thin shining testa. The embryo fills the cavity of the seed with very thick, fleshy, plano-convex, slightly puberulous cotyledons, and a short, superior, uncinate radicle turned toward the hilum, and enclosed in a lateral cavity of the testa.

Our Florida tree should be known as *Exothea paniculata*, Radlkofer, instead of *Hypelate paniculata*, Cambessides.

Radlkofer (*Sitz. Acad. Münch.*, xx., 276) refers to Exothea as a second species, *E. Copallilo*. This is a plant discovered in southern Mexico many years ago by Schiede and Deppe (No. 1295), and merely noticed under its vernacular name, "Copallilo," in the enumeration of their plants published in 1831 by Schlechtendal in the sixth volume of *Linnæa*. According to Radlkofer, it is the *Retonia* species of Hemsley ("Bot. Biol. Am. Cent.," i., 213). Of this plant I have no knowledge beyond that gathered from the brief account inserted in Radlkofer's paper. *C. S. Sargent.*

New or Little Known Plants.

Lycium Chinense.

ALMOST every one who has lived in the country is familiar with the Matrimony Vine, with its weak, drooping stems, which fall to the ground unless supported, its pale gray-green foliage and purple flowers, which are borne in pairs from the axils of the leaves, and which, from their close contact side by side, give to this plant its familiar name. It is a species of Lycium, and is related to the Potato, the Tomato and the Solanum, as may be seen from the fruit, which is a small, bright red, oval berry, a good deal like that of some Solanums. It is a native of the Mediterranean region, and botanists call it sometimes *L. Europeum* and sometimes *L. vulgare*. Fifty years ago it was the custom in this country to plant a Matrimony Vine on an out-house or a fence whenever any attempt at all was made at gardening, and now, in some parts of the United States, this plant has become fairly naturalized.

Lycium is a genus with many species widely scattered through the temperate and warmer regions of the world, especially in the countries surrounding the Mediterranean basin, in China, and in the south-western parts of the United States and the adjacent territory of Mexico. There is another species which is an old inhabitant of European gardens and which is sometimes cultivated in this country.

Indeed, it is probable that it has been often confounded with the more common species. It is *Lycium Chinense*, a native of China, and in every way a more desirable plant than the first. It produces weak stems ten or twelve feet long which, unless they are attached to a support, lay prostrate on the ground and are never strong enough to support themselves. When trained, however, to a post or pillar or over an arbor, they assume an upright position and soon cover a large space. The branches develop stout lateral spur-like branchlets, and are more or less armed with stout spines. The leaves are bright green and are produced in great profusion; they are ovate, acute, an inch or two inches long, and remain fresh and bright until destroyed by severe freezing. This plant begins to flower in the late spring, and continues to produce its abundant flowers until growth is stopped by cold in the autumn. The flowers are rather larger than those of the Matrimony Vine, and are bright purple. The fruit, however, is its great beauty. This begins to ripen in early autumn and loads the branches until winter. It is oval or oblong, nearly an inch long, and bright scarlet. As it ripens at the time the plant is covered with green leaves, the contrast between the dark green foliage and the scarlet fruit is extremely beautiful, and there are very few hardy plants which can be grown in the climate of the northern states which are more beautiful in autumn or which are more desirable when fruit-effects are desired. It is perfectly hardy, it grows with the greatest rapidity, and can be readily propagated by division, as it suckers freely, or seedlings can be easily raised. It is not particular about soil, and is admirably suited to cover rough banks or rocks, where it may be allowed to grow without support, or to train over fences and other structures.

The character of the Chinese Lycium in fruit is shown by the illustration on page 102, made from a photograph of the end of a branch taken late in the autumn.

Cnicus Hillii.

PROBABLY the oldest botanical name of our eastern pasture Thistle is that of Muhlenberg, *Cnicus odoratus*. It is the *Circium pumilum*, Spenger, and *Cnicus pumilus*, Torrey. It is found from eastern Massachusetts to Delaware, and, while not of great size for a plant of the genus, is noticeable for its large, showy and fragrant flowers. While low it is stout, having large, sparingly branched roots of nearly even thickness. I have not found that any of these were hollow. The involucral scales are unmarked, or marked rarely with a light glutinous line; the anthers have very little acumination, and the tips of the pappus are mostly spatulate and ciliate.

In the year 1867 the late Elihu Hall collected, near Athens, Illinois, specimens of a Thistle which he referred to the above. This passed under the eye of Dr. Gray while making up his account of the genus for the Synoptical Flora. His note in my herbarium shows that he saw that it was different from the eastern plant, although he did not mention it in the Flora. Last year that observant botanist, the Rev. E. J. Hill, collected specimens on the sandy borders of Lake Michigan, and sent me excellent notes which seem to show that it is specifically distinct from the eastern plant. He had previously collected it at Cankakee, Illinois.

Just as these notes were in hand I have received Mr. Hitchcock's excellent Catalogue of the Plants of Ames, Iowa. A reference to page 505 will show that our plant extends to that point. It may reasonably be looked for in other localities.

From Mr. Hill's notes I have the impression that the western plant flowers some weeks earlier than the eastern one.

A comparison of the foregoing with the following description will serve to show the points of difference.

Cnicus Hillii: general appearance much as in *C. odoratus*, but the whole plant of smaller and more simple habit (fifteen to twenty inches high), rarely with more than one head; root perpendicular, fusiform, very slender and hollow (teste Hill) for two to six inches below the crown, then enlarging and tapering to the end, the whole eight to twelve inches long; leaves smaller, less spiny and less divided than in *C. odoratus;* scales of the involucre having a dark, glutinous line on the back; pappus usually slender-pointed, but occasionally a few with narrow spatulate tips; anthers more or less acuminate. From central Illinois to central Iowa.

Wilmington, Del. *William M. Canby.*

Foreign Correspondence.

London Letter.

THE EXHIBITION at the last meeting of the Royal Horticultural Society was of more than ordinary interest. Orchids, Chinese Primroses, Cyclamens and other plants were represented by exceptional specimens, both in regard to their cultural excellence and in their rarity and beauty. The winter we have had here has been all against good horticulture. No one would have been surprised if Mr. Cannell had declared that his Primulas had all gone wrong because of the fogs and darkness. But Mr. Cannell's marvelous exhibition of these plants last Tuesday told a very different tale. The "Swanley strain" of Primulas spoke for itself and spoke loudly through these plants, which were nearly two feet across, a foot high, and many of them with a dozen large many-flowered trusses of blooms as large as a florin, of extraordinary substance, the margins elegantly crisped and the colors superb. Some of the new varieties are almost scarlet, and Mr. Cannell declares that before long he will produce a Primula by the side of which the soldier's coat shall pale. Swanley Blue is a pale violet-flowered variety, and Swanley White is an excellent kind. The largest plants shown were two years old, and had flowered freely and also borne a crop of seeds in their first year. "All the result of common-sense cultivation, aided by our special manure, which is really capital stuff," says Mr. Cannell. But his common-sense treatment for Primulas is specially constructed houses, with hot-water pipes close to the roof as well as below the stages; careful ventilation in damp weather and very careful selection in the matter of varieties.

A group of Cypripediums, mostly hybrids, was exhibited by Messrs. Pitcher & Manda, of Swanley. Fifty-nine kinds were represented, and whilst the flowers of many of them were attractive the majority had no special charm beyond that of novelty; but to many collectors of Cypripediums novelty alone is asked for. Messrs. F. Sander & Co. showed a beautiful group of Orchids, among them a grand plant of *Odontoglossum Edwardii*, with two long, branched spikes of purplish flowers; *Oncidium Brunleesianum*, a pretty little species of the *O. sarcodes* section. When introduced and first flowered in England six years ago this plant produced a spike of no less than 150 flowers. Each flower is half an inch long and wide, the sepals primrose, the petals yellow barred with brown, whilst the three-lobed lip, which is folded behind and tongue-shaped in front, is colored deep maroon. A portion of the original plant was sold for 150 guineas. *Dendrobium Luchianum* and the pure white-flowered variety of *Coelogyne cristata*, known as Hololeuca, were also among the plants sent from St. Albans.

Phajus grandifolius, an old favorite in gardens, was shown exceptionally well by B. S. Williams & Son. It was in a twelve-inch pot and bore no less than fourteen spikes, averaging a yard in height and crowded with flowers. Old though this plant is, it does not occupy as prominent a place among popular Orchids as it merits, for, in addition to its massive beauty, it is as easy to grow as a Gladiolus and as certain to flower. *Cattleya amethystoglossa* (Prinzii) was shown with stems over a yard high and an enormous head of its large, richly spotted, amethyst-lipped flowers.

The following plants obtained certificates:

CATTLEYA TRIANÆ, var. PLUMOSA, remarkable in having a line of crimson down the middle of each of the rose-colored segments, and a lip colored rich maroon.

CYPRIPEDIUM CREON.—A hybrid raised by Messrs. Veitch from *C. œnanthum superbum* and *C. Harrisianum superbum*.

ODONTOGLOSSUM TRIUMPHANS, Whiteley's variety, a large and richly colored variety, much superior to the typical plant, handsome though this is.

IRIS DANFORDIÆ.—A dwarf plant with dull yellow flowers spotted with green. It was scarcely worth a floral certificate.

CHORIZEMA LOWII.—A pretty seminal variety of what is known in gardens as *C. varium splendens*, itself a good, useful greenhouse plant, but a long way inferior to its offspring, which was raised in Messrs. Low & Co.'s Enfield Nursery. As shown, it was one and a half feet high and formed a compact, many-branched elegant plant, every branch terminated by a raceme of richly colored flowers, half as large again as those of the parent and much brighter in color. This is a really pretty addition to a genus of greenhouse plants which are far less difficult to manage than the majority of hard-wooded plants, with which Chorizemas are classed.

HAMAMELIS ZUCCARINIANA is a dull-colored variety of the well-known Witch Hazel, *H. arborea*. The last-named is now a beautiful picture in one of the shrubberies at Kew.

Messrs. Veitch, who exhibited the plant certificated, also showed *H. arborea* in good condition.

Several of Mr. Cannell's Primulas obtained certificates.

The annual general meeting of the Society was held last Tuesday, when the statements made by the President, Sir Trevor Lawrence, with regard to the work and position of the Society gave unqualified satisfaction. With a balance in hand, a rapidly increasing constituency, and general enthusiasm among the leaders of the Society the prospect is exceptionally hopeful. Of the £40,000 required to build a hall and offices for the Society in London £27,000 has already been promised.

Disa longicornu.—Tubers of this interesting Orchid were sold at an auction sale in London last week. Although collected on Table Mountain, and described by Thunberg in 1773, it does not appear to have ever been cultivated or, at any rate, flowered in England. It has small Orchid-like tubers, a stem only two or three inches long clothed with about six leaves, which are oblong, acute, wavy, and three inches long. The scape is six inches long, one-flowered, and the flower is as large as that of *D. grandiflora*, but very different in form. The upper sepal forms a large trumpet-shaped, long-spurred, wide-mouthed hood, and the three lower segments are oblong and spreading. The whole flower suggests a Columbine, and is colored lilac-blue. According to Bolus, this species is found only on Table Mountain, where it grows "among moss or grass in clefts of steep rocks on the sides turned from the sun, where the water drips in early summer, at an altitude of 2,100 to 3,000 feet. It flowers in December and January." The

Fig. 20.—Lycium Chinense.—See page 100.

tubers of these beautiful Cape Disas cannot, unfortunately, be gathered except when the plants are in flower, and consequently before they are anything like mature. To lift any plant, even a Tulip or Hyacinth, when in flower, and at once dry it, would be to run the risk of losing it altogether, but in the case of such delicate plants as these tuberous-rooted Orchids the chances are a hundred to one against their recovering.

Angræcum fragrans is attracting some attention now, a figure of it having been prepared for the *Botanical Magazine* from a plant in flower at Kew, and an account of its economic value will shortly appear in the *Kew Bulletin*. The leaves of this species are made into tea in the Island of Bourbon, where the plant is a native, and sold in Paris in boxes containing sufficient for thirty cups, at 1f. 25c. per box. Cigars are also made from the leaves in Mauritius. There are remarkably few Orchids of any economic value, the most important being Vanilla. The Angræcum is scarcely likely to become of much value commercially, as the plant is small and difficult to cultivate. It may be called a large edition of *A. (Mystacidium) filicorne*, the stems being short, the leaves oblong, three inches long, and the flowers in small racemes, each being an inch across, pure white and fragrant. The leaves when dry have an odor of vanilla.

London. *W. Watson.*

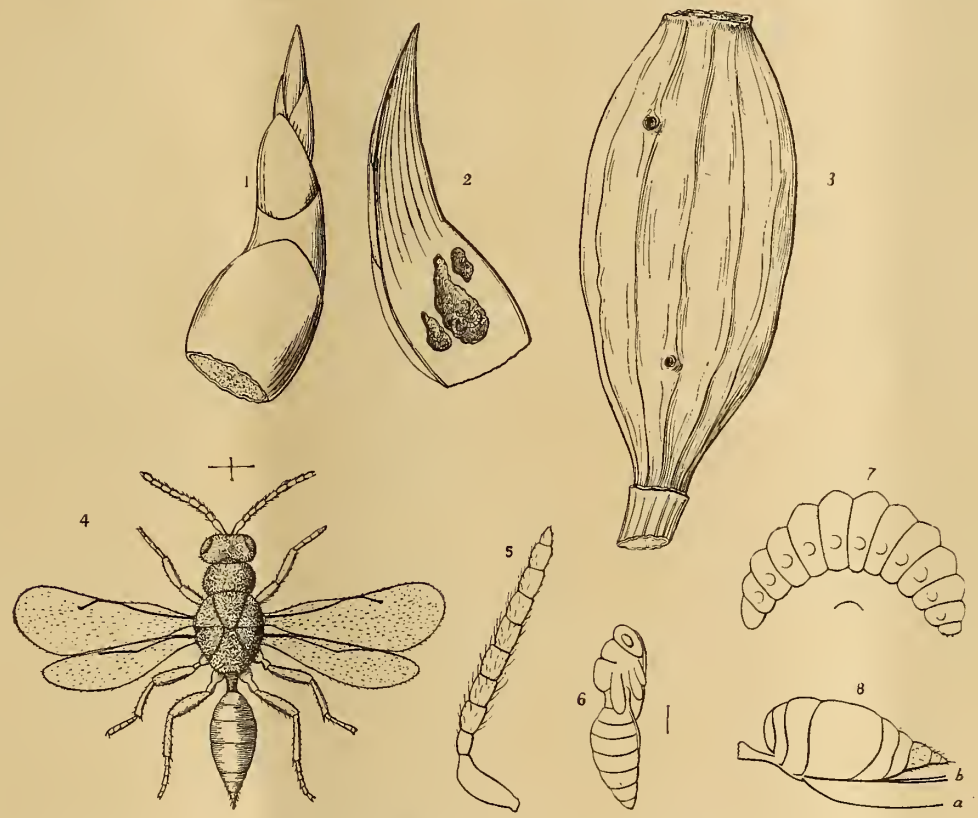

Fig. 21.—An Insect Pest (*Isosoma orchidearum*) —See page 99.

Cultural Department.

Iron-clad Seedlings.

While there can be no question of the fact that the importation of varieties of fruit-trees from north-eastern Europe has been of advantage to the orchard-growers of the cold north, and has given them courage to persevere in their efforts to produce a supply of home-grown tree-fruits, it ought not to be forgotten that some of our most valuable iron-clads are native seedlings. Among these a certain number have sprung from these foreign varieties, and I have no doubt that many more valuable sorts will be thus produced. The Wealthy, for instance, is supposed to be a Siberian Crab seedling—perhaps, and even probably, crossed from the Fameuse. But the equally hardy Scott's Winter, which stands the cold and dry climate of Iowa and southern Minnesota rather better than the Wealthy, is unquestionably a pure product from our common apples of New England. McMahon's White, from Wisconsin, is probably of like origin; and yet, so far as I can decide, after a dozen years' trial, it is as hardy as Oldenburgh.

In growing seedlings with the hope of getting valuable market varieties of tree-fruits, adapted to our northern tier of states and the Canadian provinces, many more failures than successes are sure to be encountered, for we want not merely hardy trees, but meritorious fruits. Yet the mere obtaining of an iron-clad tree is something. Six or seven years ago I had sent to me fifty Pear-seedlings, grown from seeds of standard varieties of the hardier class, such as succeed on the Champlain Islands, near the Canada line. These seedlings were set out in a nursery row, with the object of budding upon them some of the iron-clad Russian Pears. They were left standing three or four years before budding; and each winter all but one of them were killed to the snow line. When the others were budded, close to the ground, with the Bessemianka Pear (which seems to be the hardiest of the Russians), this uninjured seedling was left; and two years later it was, with the budded Russians, transplanted into the orchard. It has now passed through several of the hardest winters on record in north-eastern Vermont without the slightest injury, growing strongly each season from its terminal buds; and it is now as sound and healthy as the Russians in the same row. The chances are, of course, that it will not produce a valuable fruit, but, waiting for a test of that, I still value it, and take pleasure in calling attention to it, as showing that iron-clad seedlings can be grown from the older race of Pears—none of which is iron-clad.

Appeals are frequently made to fruit-growers in the cold north to grow seedlings, and allow them to bear before grafting them. But it is a heavier task than many can be induced to attempt. Of a thousand such seedlings there is hardly a chance that more than half a dozen will be really iron-clad, and of such a possible half-dozen how many could we reasonably hope to bear valuable fruit? Maine is a state of seedling orchards, and has been so for a hundred years, yet Maine has not, among many excellent summer, fall and early winter apples, brought out a single long keeper of noticeable merit. Her commercial orchards are all planted with varieties originating outside of her boundaries. It is probably true that no expert has made a business of examining the seedling orchards of Maine with a view to the discovery of valuable kinds. If my own experience is any criterion, I should say that it would be very desirable to have such a search instituted either by the State Pomological

Society or the Horticultural Department of the State Agricultural College.

Within the limits of a single town in northern Vermont I have in the last twenty-five years come upon three useful iron-clad seedling winter Apples of the old strain, one of which (Scott's Winter) has become a standard sort, advertised by nearly all the great nurseries east and west.

But, with all this, I would not discourage the growing of seedlings. All of us can do a little in that way, and sometimes a great success comes with very little effort. The late Mr. Dudley, of Aroostook County, Maine, got from a few seeds of Oldenburgh, planted in his garden, a large, handsome, productive and very good winter apple of the type of its parent. This experiment (as well as that of Mr. Gideon in producing the Wealthy, and of Mr. Cady in producing the Northfield Beauty of Vermont) has practically demonstrated the error of the position taken by some writers that we cannot expect to get winter varieties from seeds of summer and fall apples. Undoubtedly much the larger number of seedlings will yield early fruit. The proportion of early to long-keeping varieties of apples the world over is very great, and naturally so, since all the wild types are of that sort, and keeping apples are the product of human perseverance in growing seedlings.

What I particularly wish to urge, without discouraging the propagation by seed, is a careful examination of the millions of seedlings already in existence upon farms all over the continent. Unless one goes about among the farmers, especially in what are called the "back towns," he will get very little idea of the immense number of these seedling fruit-trees. Seedlings cost nothing, and many of our poorer farmers, discouraged by the costly and generally worthless trees sold them by peddlers, plant none but seedling trees. The women of our back farms are particularly noted for this. They find a special interest in raising fruit-trees from seed, and thousands of them are quietly proud of growing in this way apples that they fondly believe are "better than any of your grafts." It is true that they are not very good judges on this point, but sometimes they will really surprise one with the excellence of the fruit of some favorite tree, the child of their tender care and patience. Few of these "fill the bill" entirely, yet we must remember that all of our best fruits were once obscure seedlings, many of them brought to notice only through what seemed a chapter of accidents.

Newport, Vt. *T. H. Hoskins.*

Dieffenbachias.

THIS very handsome genus of tropical Arads has now become quite common in cultivation, several valuable additions having been made in recent years, though several of the older species are also well worthy of more extended cultivation. It will, of course, be understood that these plants are not to be recommended for house decoration, as the majority of the Dieffenbachias would suffer from any long exposure to such conditions, but in a collection of stove plants they are remarkably attractive, and, being comparatively easy to grow, may be commended to amateur cultivators as well as to professionals. These plants prefer an open mixture consisting of nearly equal proportions of turfy loam and peat, a moderate quantity of dry cow-manure and some sand, and when given such a compost as this and a temperature of sixty-five to seventy degrees, in a house pretty well shaded, the result is usually satisfactory. They also require liberal watering and syringing when in full growth, so that red spider may not get a foothold, for if this be allowed the beauty of the foliage will soon be ruined. They are propagated by cuttings, which may be made from the tops or from single eyes of the old stem, the first being preferable if specimen plants are desired. A strong top will make a better furnished plant than an eye-cutting; but if quantity is the object, of course the latter is more desirable.

Among the older species *D. Baraquiniana* is very desirable when well grown. It has leaves about a foot in length and from four to six inches wide, these being bright green with a white midrib, and the surface of the leaf more or less spotted with white. The leaf-stalks are also pure white, which adds much to the beauty of the plant. *D. Baraquiniana* is one of the oldest species in cultivation, having been introduced from Brazil more than a quarter of a century ago.

D. Bausei is also a fine variety, and much more dwarf and compact in growth than the preceding. This is a garden hybrid that originated in Europe perhaps fifteen years ago, and has broad leaves that are frequently over a foot in length. Their ground color is yellowish green, and this is blotched with darker green and spotted with white. *D. Bausei* makes a charming little specimen, and is well adapted for cultivation where there is not sufficient space at command to grow the stronger kinds.

D. eburnea is another small-growing species that is worth a place. It has oblong-lanceolate leaves of light green color and much spotted with white. The foot-stalks are pale brown and somewhat marked with white, and the whole plant is graceful and elegant.

D. imperialis is one of the largest of the genus, and has very dark green leaves that are blotched with yellow. These leaves are two feet or more in length, rather stiff-looking, and they have much substance. This species enjoys strong heat, and is a remarkable plant when in good condition.

D. Bowmannii is also a strong grower, and, like the preceding, is a native of America. This fine species produces leaves about two feet in length and half that in width, the color being deep green, more or less blotched with irregular markings of very light green. *D. Bowmannii* was introduced about the same time as *D. Bausei*, and, like it, makes a handsome specimen.

D. Carderii is another attractive introduction of recent years. It is of compact habit and moderate growth, the leaves being dark green in ground color, but much marked with yellowish variegation. It is a native of Columbia.

D. Regina is one of the most striking of the newer Dieffenbachias, the leaves being nearly covered with yellowish white markings. It is of moderate growth, the stem being quite short-jointed and the petioles also rather short, thus giving it a compact habit.

D. nobilis is another good sort, and it produces rather longer leaves than the preceding. These are from eighteen inches to two feet long and about nine inches broad, and much blotched with white near the midrib. This species is quite strong in growth, and, like so many other members of this genus, is a native of Brazil.

D. Weirii is one of the prettiest dwarf species, the leaves being rather narrow and seldom more than one foot in length. Their ground color is dark green, varied with spots and blotches of yellowish green. This is really a pretty little plant, though but seldom seen of late years.

In addition to the species here briefly noted there are several others also worthy of general cultivation. The juice of the Dieffenbachias is more or less poisonous, and is likely to irritate any cut or sore on the hands to which it may be applied, and it is well to exercise proper care in handling the cuttings of these plants.

Holmesburg, Pa. *W. H. Taplin.*

Brunsvigias.

OF the several species of Brunsvigias I have cultivated but two—*B. Josephinæ* and *B. gigantea*, commonly known as *B. multiflora*.

The bulbs of both species are very large; that of my specimen of *B. Josephinæ* is about twelve inches long and five inches thick. Its color is blackish brown and its outer layers are soft to the touch. During the twenty years I have owned this bulb it has not increased in size as far as I can determine. During this time it has been repotted not more than four times, and for fifteen years has blossomed every year but one, it having declined to do so in 1887.

The treatment it has received has been as follows: It is potted in a compost of rotted sods, a little leaf-mould and a little sand in an eleven-inch pot. It passes the summer, from June to September, under a tree, and laid on its side to keep it dry. I do not generally begin to water it until the flower-stalk begins to push, generally the first week in September. When this occurs I place it in the greenhouse, and give it about a quart of water every day until the short days come. From November 10th to March 1st, once in three days is often enough to water it or any other bulb. The flower-stalk is ashy-purple, about an inch thick, and so very brittle that last fall when I lifted the pot suddenly it snapped off, and I had no flowers. If no such mischance occurs the great umbel of blossoms will be fully expanded in about two weeks from the time they begin to appear. In number they vary from thirty to fifty, each being at the end of a pedicel nine inches long, so that the entire flower-head has a diameter of a foot and a half. The individual blossoms are about three inches in length and two wide, of a very elegant shape and of a brownish crimson color. The whole plant is very striking and ornamental in appearance. As in most Amaryllids, the leaves follow the flowers; they attain a length of two feet, with a breadth of five inches.

During all these years no sign of an offset has appeared. Seeds are formed in abundance; they are as large as a small

pea, almost white and sprinkled with minute red dots. They are of the bulb-like appearance noticeable in those of Nerine and *Amaryllis Belladonna*, and, like those, are best sown on the surface of the soil. Those I have tried have germinated readily, but I threw them away as soon as my curiosity on that point was satisfied, for I do not believe that seedlings would attain a blossoming size in less than forty or fifty years. Burchell, in his account of the nearly allied *Ammocharis coranica*, which he found in thousands in Caffraria, declares that from a careful dissection of bulbs eight inches in diameter he does not believe that that size was attained in less than two hundred or three hundred years. *B. Josephinæ* first flowered in cultivation in the gardens of the Malmaison, and was named in honor of the Empress Josephine.

All that has been said of the cultivation of *B. Josephinæ* is applicable to *B. gigantea*. The bulbs of the latter species are almost spherical and light yellowish brown in color; the outer coats are very hard and stone-like and very brittle. The foliage is peculiar, each leaf being about fifteen inches long, very broad, and rounded at the end; shaped, indeed, much like a beaver's tail. The flowers resemble those of *B. Josephinæ* in form, and are produced every year; they are less numerous, and though much brighter in color, are less effective because they are greenish at the base.

Canton, Mass. *W. E. Endicott.*

Snowdrops.

Galanthus Fosteri.—So prevalent is the idea that size is necessarily an element of beauty in a flower that the first view of this new Snowdrop is a disappointment. Herr Max Leichtlin considers this the King of Snowdrops, and thinks that under cultivation it will prove the finest of the family. The fine bulbs with which I was favored last fall were collected ones, and, of course, do not do the variety justice, but, from present appearances, they must improve very materially before they produce flowers to equal those of *G. Elwesi* in mere size. However, this is a beautiful variety of *G. latifolius*, with firm Scilla-like foliage, and sepals which seem scarcely as broad as those of good specimens of *G. Elwesi*. The perianth-segments are pure white, with a slight line of green under the notched edges and a dot of green at the base of each petal—a most charming interior.

Galanthus Elwesi.—This Snowdrop commenced blooming on a south border late in January, and its large but dainty flowers again proved the earliest harbingers of a new garden season. There is a special charm attached to this delicate flower which weather of the wildest does not discourage. The fiercest storms simply toss their beautiful blooms gracefully about, and they cheer one in this gloomy season with their look of contentment under most disheartening surroundings. I have noticed that this Asia Minor variety has been said to be sometimes of a rather delicate constitution, but I can see no indication of this in my border, which contains a few hundred bulbs collected in 1889. They are now in good condition, with flowers large and sepals mostly wide and of good, firm texture. Like most collected bulbs they vary somewhat in form and in bud—I notice some quite spherical, while others approach the long dainty form of *G. nivalis*, though in all cases very much larger.

One cannot have too many Snowdrops. Either in the borders, in the grass, or for naturalizing they are never out of place and never too abundant, and as the heralds of spring one welcomes them year after year with increasing interest. White flowers are never very showy in the garden, and while *G. nivalis* is a gem, *G. Elwesi* is so much larger (yet without a trace of coarseness) that it should always be planted in preference where the greatest effect is desired. These bulbs have been collected in such quantities that there is no reason why the dealers should not reduce the price and give every one a chance to plant them largely.

Elizabeth, N. J. *J. N. Gerard.*

Iris Bakeriana came into bloom in the open border on the 23d of February. This beautiful little Iris, with its blue standards and tigered falls, has been several times described in the columns of Garden and Forest, but its perfect hardiness and natural season of flowering in this latitude do not seem to have been noted. Planted in August, 1890, in a group with several others of the type of *I. reticulata*, this Iris (as well as the others) has been entirely without protection. The garden was continuously frozen from December 1st till some time early in January, and part of this time the bed had a slight covering of snow. Shortly after the change to mild weather the foliage commenced to spear up, and has not been damaged by any of the constant vagaries of the temperature. When showing color a pane of glass was fastened over blooms to protect them from moisture, and at this writing it is doing duty as a snow-shed. One hesitates to speak confidently of any plant on a single test, but, judging from the trial of this Iris during the rather hard winter just past, I think there can be little doubt of its perfect hardiness.

After some experience with *I. reticulata*, however, I am inclined to make the reservation that, as with most naturally early-blooming plants, care should be taken in selecting a suitable location. Snowdrops, Squills and some Anemones may be planted anywhere, as the most trying weather affects them little, if at all; but it seems better to plant such things as these little Irises in a position where they will not start much before their natural season even if the weather should happen to be mild earlier. A good position, I find, is on a border which is slightly shaded from the winter sun by a low picket-fence till late in January. In such a location the earth remains, as a rule, continuously frozen till late in the winter, and when the sun rises to soften the bed the plants are ready to spring into bloom with little danger to fear from sudden changes. But, aside from the interest of flowering these little gems in the open ground, perhaps, until one has some surplus stock, more enjoyment could be had from them if planted in a cold-house, where one could study their dainty beauty with no fear of pneumonia.

Elizabeth, N. J. *J. N. G.*

Phalænopsis Stuartiana.—In the gardens of Mr. H. H. Hunnewell, at Wellesley, Massachusetts, there are several plants of this species now in flower, one of them having an arching scape thirty-one inches long, and bearing fifty-eight flowers. It has five leaves about twelve inches long and three inches across. Some five years ago I cut from the root of one of these plants a piece on which two small leaves were growing, and, placing it carefully in a small saucer with four or five bits of potshreds with charcoal and sphagnum, it has now grown into the plant above described. It was permitted to flower for the first time last year; the scape then had nineteen flowers.

South Natick, Mass. *F. Gould.*

Correspondence.

Orchids at North Easton, Massachusetts.

To the Editor of Garden and Forest:

Sir.—At the gardens of F. L. Ames, Esq., the cool Orchid-houses are particularly gay, even thus early in the season. During a recent visit I noted in particular some exceptionally good varieties of *Lælia anceps*, among them a form of Virginalis called Alba, which is very nearly pure white, there being only a faint yellow blotch in the throat. The variety Williamsii has very large white flowers, with a yellow blotch in the throat, and violet-colored lines radiating therefrom. Sanderiana is often confounded with this plant, but its flowers are smaller, and the throat and tip of the labellum are shaded with violet-purple, with an intermediate bar of white. The whole flower of the variety Winniana is of a deep violet color, the lip being a shade darker than the sepals and petals, while Percivaliana is the very opposite of this, being a very light mauve.

It is still rather early for Dendrobiums, but some rare and beautiful specimens are in flower. In comparison with the flowers of *D. nobile*, those of its variety Elegans are more regular. The sepals and petals and lower part of the labellum are a soft creamy white, in striking contrast with the deep wine color of the interior of the labellum. The variety Nobilius of the same species is a most striking one. The entire flower is a deep maroon-purple, excepting only a small part of the lip. *D. infundibulum*, var. *Jamesianum*, is noticeable for the large size of its flowers, the purity of its white sepals and petals, and its deep yellow tubular throat. *D. Schneiderianum* (*D. Findlayanum* × *aureum*) is the most beautiful of the many hybrids now in bloom. The lobes of the labellum reflex gracefully, with chocolate and orange markings in the throat. The sepals and petals are pale pink, the latter wavy. In the size and color of its flowers and slight fragrance it resembles the seed parent, *D. aureum*, but in length of pedicels, which gives the plant additional grace, it inherits the good qualities of its pollen parent. This is a well-bloomed specimen, bearing forty-five flowers on two stems. *D. micans* (*D. Wardianum* × *lituiflorum*) is another handsome hybrid, in which the flowers are more nearly like those of *D. Wardianum* in shape, the trumpet-shaped labellum peculiar to the seed parent being very slightly developed. In reference to the variety of *D. Wardianum* known as Schrœderi, Mr. Robinson, the head-gardener of the establishment, aptly says that it bears to the type the same relation that the variety Nobilius does to *D. nobile*.

A remarkable specimen of *Vanda cærulea* is now to be seen here. The flowers are over four inches in diameter. The coloring of the petals and labellum is a deep blue; the sepals are lighter, with a still lighter, nearly white, marbling over the whole flower. *Cattleya Trianæ*, var. *Leeana*, is a portion of the original plant. In the size of its flowers it is a monster, some of them measuring eight inches across the petals, with a proportionately large labellum. The petals are lilac-mauve; the lip deep mauve; edges shading lighter; throat with yellow markings. *Cattleya* (*Lælia*) *Exoniensis* is a rare and beautiful hybrid, probably between *Cattleya Mossiæ* and *Lælia purpurata*, somewhat intermediate in character between these plants.

The very select collection of Cypripediums here contains some handsome specimens of many new and rare species, varieties and hybrids. *C. Morganiæ* (*C. superbiens* × *Stonei*) is conspicuous for the sulphur-green petals, with bronzy purple blotchings and ciliated margins. Its general habit is that of *C. Stonei*, with a pouch like that of *C. superbiens*. The fine specimen here now bears three scapes with ten flowers, and as recently as last August it carried twelve flowers on three scapes, and therefore it may be rated as a pretty free bloomer. *C. Mastersii* is a new species. The scape is erect, sixteen inches long, and hairy; the petals deep bronze veined with violet-purple, and pouch bronzy purple. *C. insigne Chantini* (Philbrick's variety) is, without doubt, the handsomest of the varieties of this fine species. It has a deep, arching, dorsal sepal, with reflexed margins. The white nearly covers the whole, and the violet punctation is very delicate. This is sometimes confounded with the varieties Maulei and Punctatum-violaceum, both inferior kinds, with a flat dorsal sepal. *C. Godseffianum* (*C. hirsutissimum* × *Boxallii*), now blooming for the first time, is of very recent origin. The centre of the dorsal sepal is a black bronze on a yellowish green ground. Petals large, wavy at the base, the upper part reddish purple, and the lower sulphur-yellow, with dark spots. *C. Leeanum superbiens* (*C. insigne* × *Spicerianum*) has a dorsal sepal not unlike that of the variety Chantini, but it is larger and almost wholly white, with violet punctation extending across the lower half and continued up the median line to the tip. *C. cardinale* (*C. Sedeni* × *Schlimii*) is a very handsome and almost continuous blooming hybrid in the way of *C. Sedeni*, but brighter; the pouch is more round and the petals are not twisted.

The new and rare *Odontoglossum Harryana* is now in bloom. It is probably the handsomest and most distinct of all the bronze-flowered Odontoglots. The sepals and petals are bronze, with clear yellow tips; base of labellum yellow and purple, with white lines and white tip.

Masdevallias were represented by many quaint and beautiful species and varieties. The *M. Chimæra* group, which have a strange fascination for many people, are here in full force. *M. Roezlii* almost black; *M. Winnianum* purple; *M. rubra; M. aurea; M. Veitchiana*, the ground color of which is orange-scarlet, with the violet hairs suffusing three-fourths of the surface, giving it a peculiarly brilliant hue; *M. ignea* with its varieties, Rubra and Aurantiaca; *M. Lindeni* and *M. Harryana*, conspicuous for violet shades, and *M. Tovariensis* are all represented by fine specimens. *Plurothallus Roezlii* is a curious novelty, with plum-colored flowers. Fine spikes of *Oncidium splendidum*, effectively placed, with the lovely pure white form of *Lycaste Skinneri*, bring my list to a close.

Wellesley, Mass. *H. G.*

Wanted, a Tract on Forestry.

To the Editor of Garden and Forest:

Sir.—The necessity of forestry reform is admitted by all intelligent people who take time to examine the question, but no reform can make much headway until the people at large become convinced of its necessity. The prime need, then, in every such cause is to instruct them as quickly as possible in that which so greatly concerns their welfare.

The two great avenues to the human mind are through the eye and the ear, and of these the first is, no doubt, the most important. That which we see makes, on the whole, the greatest impression. Such object-lessons, therefore, as that contemplated by the Adirondack League Club, referred to in your issue of February 18th, will, of course, be a vast help in forming a healthy public opinion concerning the management of our national forests. The fine example of the city of Lynn, which is now engaged in acquiring a vast and varied tract of adjacent woodland, embracing some 1,400 acres, to be held as a public forest and park for the use of the people forever, is another splendid object-lesson; the enterprise of the little village of Freedonia, New York, which has had the wit to seize the park idea by the right handle and forestall the future by boldly laying out two parks in the very heart of the town. These and other similar examples help along the causes with which they may severally be classified far more rapidly than can the very best of preaching. May such tangible teaching increase.

Yet there is a large and important work to be accomplished through the "foolishness of preaching." The press has done and is doing much. Still it occurs to me that there is need of, or at least room for, special work through such tracts as that one which assisted in the great reboisement of certain districts of France. There, the forests having disappeared through heedless cutting, and the turf been gradually destroyed by the sharp hoofs and the hungry gnawing of the flocks, great and increasing damage from floods began to overwhelm the valleys. To reclothe the heights and restore the equilibrium was found to be impossible until the people—the peasantry who had votes—had been won over. A prize was offered for the best short work adapted to teaching them these lessons, the little book "Studies of Master Peter" being the successful competitor. Some similar work, all the better if shorter, which could be widely disseminated among our rural populations would, I am confident, accomplish much toward producing a right popular view of the vast forest-interests of our land. Who will write one?

Dorchester, Mass. *S.*

[Mr. B. E. Fernow, Chief of the Forestry Department at Washington, has already written some leaflets for general distribution, but we cannot have too many of them nor have them prepared from too many points of view.—Ed.]

A Hand-book of Plants.

To the Editor of Garden and Forest:

Sir.—Can you refer me to some book which contains a description of all the plants in ordinary cultivation? I have examined a work in four volumes which seems to give the information I wish, but it is too expensive and cumbersome for my purpose.

Tarrytown, N. Y. *E. J.*

[Perhaps the best book for such a purpose is the "Hand-book of Plants" by Peter Henderson. The new edition, which was published something like a year ago, is practically a new book, not only because it includes such species and varieties of plants as have been introduced since the first edition was published, but because of the instructions given for the cultivation of various kinds of fruits and garden plants. Of course it is not so full as larger dictionaries like Nicholson's, but it has the advantage of being prepared expressly for American readers, and it will be found as complete as one ought reasonably to expect a book of such a size to be, and much more accurate than manuals of garden plants and practice usually are.—Ed.]

Primula obconica.

To the Editor of Garden and Forest:

Sir.—Ever since the first reports of the poisonous character of *Primula obconica* were published in your journal I have been examining and experimenting with it at times. In so far as structural features are concerned there is little to add to the excellent account by Dr. Thurber (vol. iii., p. 104). All parts of the plant are covered more or less densely with glandular hairs. The secretion is not so abundant at any time as to be viscid, and there is an entire absence of silicified hairs, which he suggests as a possible cause of the injury. There is nothing about this species which is widely different from *P. Sinensis* and *P. veris*, two old plants of gardeners, against which not a breath of suspicion has ever been raised. Figures of the cuticle made under the microscope show but slight differences in the length and profusion of hairs only. Otherwise one figure would stand for all three species.

Although I am moderately subject to plant-poisoning, all trials with *P. obconica* have given negative results, and I know of no one who has suffered, although several here have been frequently exposed.

Without calling in question the accuracy of reported cases, may we not put this Primrose into the list of plants poisonous, if at all, only to such persons as are extremely sensitive, and hence not necessary to be excluded from cultivation?

State College, Pa. *W. A. Buckhout.*

[It was nearly three years ago—that is, in the issue of Garden and Forest for May 3d, 1888—that Dr. James C.

White, of Boston, suggested *Primula obconica* as the probable cause of an inflammation of the skin of the hands and face of persons who had been handling it. In a later number he gave evidence to show that his original suspicion was probably correct. Since that time experience has abundantly established the fact that many persons are subject to an irritation of the skin, more or less severe, from contact with this Primrose.—Ed.]

The Owl and the Sparrow.

To the Editor of Garden and Forest:

Sir.—I am glad to see criticism of M. Naudin's proposal to send us an owl for the discouragement of the English sparrow and the possible slaughter of our native sparrows, wrens, bluebirds, yellow-birds and other insectivorous songsters. Allow me to add an appeal to those school-boys and others who are enthusiastic in collecting birds' eggs. A great deal more knowledge of birds and their ways can be gained by examining the nest occasionally without touching it or the eggs, and by quietly watching the old birds at their work; and by this method of study the unpleasant feeling which comes over one after robbing a bird's nest will be avoided.

Washington. *H. B. A.*

Recent Publications.

Among a number of interesting articles recently published by Mr. John Addington Symonds in a book called "Essays Speculative and Suggestive," are two which should have especial attraction for our readers.

Even a slight acquaintance with the author's previous works would justify the prediction that in the chapter called "Landscape" the subject would not be treated from the most obvious point of view. No one will be surprised to find that it is not an essay on landscape in itself, but on the way in which a feeling for natural beauty has developed in mankind, as shown by the art and the literature of successive periods. "It is an error," says Mr. Symonds, "to believe that the ancients were insensible to the charm and beauty of external nature. Much has been written about their attitude toward landscape and the parsimony of picturesque description in their poetry. Yet sufficient stress is rarely laid upon the difference between the Greeks and the Romans in this matter. Nor has it been made clear enough that classical literature in its later stages exhibits more of what we may call the modern feeling than we find in Homer and the Attic writers." This position is substantially the same as that which was taken by one of our contributors in the series of articles we printed last year on the "History of Gardening Art." However, there are some points of dissimilarity. The difference between the Greeks and the Romans in their feeling for nature was not then explained as Mr. Symonds explains it. But, on the other hand, Mr. Symonds does not dwell upon the fact, then referred to, that descriptive writing of any kind is almost absent from Greek literature. We think that the cogency of the statements in the beginning of his chapter would have been increased had he shown that, as the Greeks, despite the unquestionable strength and acuteness of their feeling for art, have left us no real descriptions of works of art, so it is foolish to argue, from the paucity of their descriptions of natural scenes, that they had no true feeling for their beauty. But nothing could be more clear and charming than the way in which he illustrates that abiding anthropological instinct of the Greek mind, which, leading it to personify all natural phenomena and forces, hardly left a place in literature or in art for the painting of purely natural scenes; and his account of the development of a different frame of mind in the later Latin poets is, in its scholarly quality, combined with its lightness of touch, a passage such as no one else could have written. Equally interesting is his exposition of the reasons why, when Christianity had banished the old delight in terrestrial things, together with the old vast company of imagined beings inhabiting nature, "both literature and the plastic arts decayed. Classical polytheism," he continues, "interpolated a multitude of ideal personalities between the mind and nature. All these were swept away. The soul was left face to face with God." The material world was evil, and there was nothing left but "infinity and fact. What would happen should theology relax her grasp upon the intellect and men once more begin to gaze around with curious delight on their terrestrial dwelling-place?"

It was in the time of the Renaissance, Mr. Symonds believes, that "the intellect of man came painfully and gladly to new life through the discovery of itself and nature." The Latin songs of the thirteenth century, "in so far as these touch nature, reveal a genial thawing of the spirit. They dwell on the charm of spring-time in the country and connect the freedom of the open air with pleasures of the senses. Classical literature is at work as a form-giving influence. The German lyrics of the Minnesingers, the Provençal lyrics of the Troubadours, the Celtic romances of Arthur and his Knights, when these touch nature are in like manner vernal. The magic of the May pervades them; the mystery of the woodlands enfolds them. They are the utterances of generations for whom life has revived." Then comes Dante with his keen feeling for natural beauty, and "contemporaneously with Dante—though Dante hardly shared this movement—there began what is known as the Revival of Learning: that resuscitation of classical literature and art which exercised so potent an influence over the mind of Europe." Inspired by classic example, poets and painters then began to express more plainly a love for nature; but it always was after the classic fashion, as a background for man and his acts, until the very close of the Renaissance period when five great painters gave landscape independent life and importance. These, says Mr. Symonds, were Rubens, Claude Lorraine, the two Poussins and Salvator Rosa; they were the first who "emancipated landscape from its traditional dependence upon human motives and proved that Nature in herself is worthy of our sympathy and admiration." With and after them came the great company of Dutch landscape painters, while "in literature classic standards of taste continued to prevail" until science brought her quota of influence, and, in our own century, poets took the same attitude toward nature that painters had begun to take in the seventeenth century.

It will be seen, even from this brief summary, that Mr. Symonds does not adhere to the usual belief that the modern love of nature is an inheritance from Teutonic ancestors; that the difference which, although it has been exaggerated, does really exist between the ancient world and our own in this respect is a difference in blood, in natural, instinctive habits of mind. He says, indeed, quite plainly, that when the Scandinavians and Teutons were Christianized and absorbed into the fellowship of nations, they "brought with them nothing which could constitute a new condition for the sense of natural beauty. Like the Greeks, they looked at the world from the standpoint of mythology. The cosmic forces were personified in their religous legends as ideal men and women. Norse poetry was ill adapted to fostering that sympathy with nature which had begun to germinate in the latter stages of Græco-Roman civilization." Moreover, he adds, "such as it was, the dominant civilizing energy, that of the Latin Church, laid it under strict interdict." There is no space here to give the reasons why we must dissent from this belief and fall in with the more commonly accepted one which regards the Teutonic mind as more susceptible to the influence of nature, simply and purely as nature, than the Greek or Latin mind. But we think that Mr. Symonds unconsciously shows this very fact when he cites the songs of the Minnesingers and the Celtic romances as exhibiting a true and tender feeling for nature. Undoubtedly, the influence of the classic world was felt in northern Europe before the time which we are accustomed to call the "dawn of the Renaissance"; but neither these poets, nor even Dante, can be said to have been moulded, even if they were touched by it. That there was a distinctively Teutonic influence at work in literature and art all through the middle ages, and that it affected even non-Teutonic nations, seems to us a clearly proved fact; and as clearly proved seems the fact that it meant a new and stronger feeling for natural beauty simply as such. To what, we wonder, would Mr. Symonds attribute the development of architectural decoration from the classic conventionalism of Romanesque times into the often directly imitative, wholly realistic types of the end of the thirteenth and of the fourteenth century?

The second chapter to which we have referred is called "The Pathos of the Rose in Poetry," and again it recalls something that was recently written in Garden and Forest. This time it is the whimsical complaint of Alphonse Karr, cited in an article about him (vol. iii., p. 522), that the Greeks had said one or two pretty things about the Rose, the Romans had added one or two more, and then the world had gone on repeating them over and over until they had become worse than commonplace. Mr. Symonds is not whimsical, and he does not complain of this repetition of ideas or say that it has resulted in commonplaces. He simply shows, in a very delightful way, how two classic poems, one by Catullus and one by Ausonius, have been re-echoed in later days and in different tongues. To quote from this essay would be like plucking off

a couple of petals to show the quality of a Rose, so we leave it to such of our readers as may be fortunate enough to chance upon Mr. Symonds' attractive book.

Notes.

According to the *Economiste Français* about 862,700 tons of coffee are annually produced in different parts of the world, more than half the amount being credited to Brazil.

Pomona is pronounced by Dr. Aldrich, of Ohio, a good Raspberry for the home garden, although the fruit is not firm enough for shipping. The plant seems hardy, and it is productive of large and fine-looking berries of excellent quality.

In an article in the *American Garden* it is stated that Mr. Thomas R. Ballantine, of Norfolk, Virginia, raises 125 acres of Spinach a year, the sowing of which requires two and a half tons of seed, and from which he harvests some 25,000 barrels. Mr. Ballantine grows the Savoy Spinach entirely.

Mr. Edwin Lonsdale, in the *American Florist*, calls attention to the fact that Carnations have received special attention by the Pennsylvania Horticultural Society, which offers premiums for groups of twenty-five varieties in special colors. These premiums are offered for competition both at the spring show, which opens on March 17th, and at the Chrysanthemum show in November next. Premiums are also offered for the best seedling Carnations.

Some time ago Mr. W. E. Endicott stated in this journal that he had hybridized the white form of *Freesia refracta* with *Tritonia crocata*, and the resulting plants bore flowers which were Freesias pure and simple, and yet the Tritonia was the seed parent. Very naturally, such a result has excited inquiry, to which Mr. Endicott responds that he took great pains with the experiment, and is perfectly certain of the fact. He adds that in his greenhouse the Freesia has never set seed.

The League of American Wheelmen has offered $100 in prizes for photographs which can be used to illustrate the unfitness of our present public roads as highways. Some suggestions for subjects are the following: A farmer's team and wagon hub-deep and knee-deep in a muddy road; views of rough and rutty roads; broken vehicles caused by rough roads or steep grades; smooth, hard-surfaced roads with teams hauling loads over them. These object-lessons ought to prove effective aids in the campaign against bad roads.

The rare and showy South African Groundsel, *Senecio petasites*, lately noticed in these columns, has been blooming for some time in the greenhouses of B. P. Cheney, Esq., Dover, Massachusetts. The stems are herbaceous, about three feet high, terminated with a broad umbellate panicle of bright yellow flower-heads. To those who tire of Cinerarias, Cyclamens, Calceolarias and the generally grown winter decorative plants, this is a welcome introduction. It may be propagated either by seeds or cuttings, which develop at the base of the stems.

The Committee on Nomenclature of the Society of American Florists has named sub-committees, to each of which is to be referred questions as to the names of a single plant or class of plants. The following are the chairmen of the several sub-committees: John N. May, Roses; Edwin Lonsdale, Carnations; John Thorpe, Chrysanthemums; E. G. Hill, Bedding Plants; Charles D. Ball, Palms and Ferns; Robert Craig, Miscellaneous Greenhouse Plants; Ernest Asmus, Bulbous Plants; William R. Smith, Hardy Plants. William Falconer, Glen Cove, New York, is General Chairman.

A late bulletin from the New Jersey Experiment Station aims to acquaint the people of that state with the true character of the Black Knot of Plum and Cherry-trees and to stimulate united action for the suppression of the disease, which has practically driven two of our best orchard fruits out of cultivation in many parts of the country. If it is proper to pass laws compelling land-owners to prevent noxious weeds from going to seed on their premises, why not compel owners of trees infected with this fungus to cut off and destroy the diseased branches? The spores of this fatal fungus are surely as much to be dreaded as are the seeds of Canada Thistle.

Last year Professor Roberts, of Cornell University, removed the tassels from every alternate row in a plot which contained forty-eight rows of Indian Corn. The tassels were cut as soon as they could be seen and before they had produced any pollen. In no single case did a row upon which the tassels were left produce nearly as much as the rows on either side of it from which the tassels had been removed. In the aggregate, the number of good ears in the rows of emasculated plants was 2,338, as against 1,551 good ears on the rows where the tassels had been left, while in the former case the weight of merchantable corn was 1,078 pounds, and in the latter 710 pounds —that is, both in the number of ears and in the weight of the corn, the advantage was nearly fifty per cent. in favor of the rows where the tassels had been removed.

In the course of a lecture on "The Geographical Distribution of Plants," recently delivered before the Massachusetts Horticultural Society, Mr. H. F. Ganong, instructor in botany at Harvard University, said: "Man's influence upon the plant kingdom has been far less than it appears at first sight, and it is nearly uniformly unfavorable. The carrying of plants from place to place includes for the most part forms cultivated for food or for ornament, and the majority of them, if left to themselves in their new homes, would soon be exterminated, and hence produce no lasting effect upon plant distribution. In fact, the cases in which man has produced any considerable effect upon the vegetation or flora of a region are extremely few, and the effect is nearly always destructive. The stumps where once a forest stood speak most forcibly of man's power to destroy."

A bill to create the office of Forest Commissioner has been introduced in the Pennsylvania House of Representatives. The officer, to be appointed by the Governor, is to have practical knowledge of forestry, and by the aid of wardens employed by him he is to investigate the condition of forest-lands and have charge of those belonging to the state. He is to enforce the laws which provide punishment for the willful firing of forests, and he is to protect forests from cattle and illegal depredations, and to report annually the extent of damage by fire, cattle, etc. He is to give free information to those who ask for it as to the care of woodlands and the starting of new ones, to gather statistics of forest-products, and to post throughout the state rules for preventing and suppressing fires. The bill is approved by the Pennsylvania State Forestry Association, which is circulating petitions for its enactment, and sending out with these petitions a leaflet in which the reasons for reform in forest-policy are tersely set forth.

An article on "Dates," recently published in the *Illustrirte Gartenzeitung*, of Vienna, says that in north Africa the Date-palm is propagated by offsets, which are separated as they root and afterward planted out on the same spot. The young tree begins to bear blossoms in its fifth or sixth year, but yields fruit in no considerable quantity until a couple of seasons later, and is not in full bearing before the age of ten or twelve years. As the male and female blossoms are borne by different trees, man's help is needed to secure a crop. Hardly any but female trees are cultivated—a single male specimen serving to fructify hundreds of females. When the blooming season arrives—in February or March—and the great broad spathe of the pistillate tree unfolds, the Arab takes a bit of the staminate inflorescence, wraps it in a corner of his burnos, climbs the female tree by the aid of the step-like projections left by the leaves of its earlier years along the trunk, and ties the fragment carefully to the middle of the pistillate spathe. This is done when open flowers are first seen, and then the tree is watched until the blooming season is over, so that, as new blossoms appear, they, too, may be helped to develop fruit, the ones already treated being easily distinguished by the cords used in the tying process. Good judgment must, however, be exercised, especially in the most favorable years, for, if too many flower-clusters are encouraged to develop, the quality of the fruit will be injured. If the owner of a female tree or orchard does not possess a male specimen, he may buy the inflorescence he needs in the market-place, where it sells at a franc or a franc and a half. The harvest begins in October or November, and the fruit is plucked before it is quite mature and allowed to ripen in store-houses, as the nocturnal cold would injure its flavor, the thermometer often sinking at night to zero Centigrade, while during the day it may rise as high as thirty degrees. "Date-bread" is made from the fresh fruit which, freed of the kernels, is compressed into a block so hard that it may be cut like a ham, other fruits, such as Pistachio-nuts and almonds, being often mixed with the dates. This bread is a very nourishing article of food, and very palatable when eaten with ordinary bread. Syrup called "date-honey" is also made by pressure from the fresh fruit; from this syrup a sort of brandy is distilled; and the kernels, when first roasted and then boiled, yield an agreeable drink that is called "Gusmado-coffee."

NEW YORK, WEDNESDAY, MARCH 11, 1891.

TABLE OF CONTENTS.

The Western Arbor-vitæ.

THIS tree has played its part in the exciting drama of early American transcontinental exploration. The little band of travelers under the command of Captains Lewis and Clark, after a long winter passed in the country of the Mandans on the waters of the upper Missouri, left their dreary camp in April, 1805, and pushed on into the vague and mysterious regions which still separated them from the shores of the Pacific, to reach which they had left their homes in the east a year before. The mountain barrier which divides the waters of the Atlantic from those of the Pacific was overcome with comparatively little trouble or hardship, for the pass by which they crossed and which still bears the names of the leaders of the party is one of the lowest and most easily approached of all the natural highways which penetrate the continental divide. But when this was passed, they entered into a region of mighty mountains and of deep and swift-running rivers bordered by forests, through which, except along the rare hunting-trails of the Indians, travel was made almost impossible by fallen timber larger than they had ever encountered before. Here trees were seen which were new to them—a great Spruce, with something of the appearance of a Hemlock, but vastly larger than any Hemlock of the east, and unknown Pines and Firs and many unfamiliar shrubs and flowers, and the Arbor-vitæ, which only caused comment from its great and unusual size, for they did not realize that they had found the giant of its race any more than they realized that the Larch-tree, which they soon met with in great numbers, was not the Larch of the eastern states, but a species which they were the first white men to look upon. The Arbor-vitæ interested them, for in its tall trunks they saw possible relief from the hardships of their daily struggle with the unrelenting forces of the wilderness. It was not, however, until the end of September, the men being worn out with fatigue and hunger, that their leaders determined to abandon their animals and entrust themselves to the rapid and uncertain currents of the river. On that day, having found a grove of Arbor-vitæ of proper size and at a convenient distance from one of the tributaries of the upper Columbia, they proceeded to make five canoes, which on the 10th of October, so industriously did they labor, were ready for use, and which, after many dangers had been overcome, floated the men who first crossed North America to the shores of the Pacific.

Lewis and Clark saw the western Arbor-vitæ at the extreme eastern limits of its distribution; it had, however, been seen a few years earlier on the coast of Alaska and of Puget Sound by Vancouver at the time of his Pacific voyage, and his naturalist and physician, Menzies, had carried a few leaves back to England. It was not, however, until several years later, or about 1820, that it was properly distinguished and described. It was Thomas Nuttall, to whom Weyth brought specimens from the Flat Head River, who gave to this tree the name of *Thuya gigantea*. The name was well chosen. In a region of great trees, of Sequoias, of Sugar Pines and of Douglas Firs, the western Arbor-vitæ holds its own for bigness, sending up a mighty shaft free of limbs for perhaps a hundred feet from an enormous enlarged base tapering gradually, until at twice the height of a man from the ground its diameter may not be more than a dozen feet. Beside this giant, the other Arbor-vitæs of the world appear like pigmies. There are not many of them now, although once they or their ancestors occupied a more important place in the forests of the world than they do at present. The type of the genus, the familiar Arbor-vitæ, inhabits the northern and mountainous parts of eastern America; *Thuya gigantea* occupies similar positions on the Pacific side of the continent; one species, very similar in all the details of its structure to the Pacific tree, occurs in Japan, and another, which is often called Biota instead of Thuya, having been considered at one time sufficiently distinct from our Arbor-vitæ to constitute a genus by itself, belongs in China.

Thuya gigantea is one of the most beautiful trees of the American forest, and in cultivation it is not surpassed, in its young state, at least, by any tree of its class. Economically it is of great importance. Lewis and Clark learned the value of its trunks for canoes from the Indians, who used no other tree for this purpose in all the region where it is found; and it is from the western Arbor-vitæ that the great canoes which astonished the early travelers in Alaska were hewn. The inner bark was used by the Indians for food, and cut into long strips it served to hide their nakedness. The color of the wood, which is dull red, has caused this tree to be called almost universally in the north-west "Red Cedar" from its fancied resemblance probably to the so-called Red Cedar of the east. The wood is very valuable; it is light, soft and easily worked, and so durable in contact with the ground, or when exposed to the elements, that no one has ever known it long enough to see it decay. It furnishes admirable material for the interior and exterior finish of buildings, for fences and for cooperage, and especially for shingles, which are not inferior to those made from any other wood, and which are now sent in large quantities, and of unusually large size, to all parts of the country.

Thuya gigantea, unfortunately, is not hardy in the eastern states, and, like many of the trees of the Pacific forests, it cannot be used to beautify and enrich our plantations. In Europe, however, where it was first planted many years ago, especially in England and in some parts of France, it has grown rapidly and vigorously, and promises to be a useful as well as an ornamental tree.

There has been more or less confusion among cultivators in Europe with regard to the name of the western Arbor-vitæ, and this confusion serves to show the hold on life a mistake of this sort has when it has once been made, and how hopeless are the efforts of scientific men to correct popular errors. There are two of these Thuya-like trees in western America; both are giants and both are beautiful and desirable trees in cultivation. One is *Thuya gigantea*, and the other is *Libocedrus decurrens*, a

tree with something of the habit of a Thuya, but very distinct in all botanical characters, and much more southern in its range. The Thuya was described first by Nuttall; Don, in ignorance of Nuttall's earlier description, described it again as *Thuya plicata*. Then Carrière, taking up a manuscript name of Douglas, called it *Thuya Menziesii*; and so, having to dispose of Nuttall's name of *Thuya gigantea*, and knowing only one Arbor-vitæ from the region, applied it to the Libocedrus, which had been regularly named before by Torrey. For some reason or other Carrière's names have held among cultivators; and when one buys from a European nursery a plant called *Thuya gigantea* he is sure to get *Libocedrus decurrens*, while the true *Thuya gigantea* appears variously as *Thuya plicata* or *Thuya Lobbii*, so called from the collector Lobb, who sent home seeds of this tree to England long after it was in cultivation there, sometimes as *Thuya Menziesii* and as *Libocedrus decurrens*. This transposition of names has been pointed out before, and the synonymy of these trees is fully and correctly displayed in most of the recognized works on conifers; and occasionally the two plants are labeled correctly in European botanic gardens. The correction does not penetrate deeply, and *Thuya gigantea* will continue to be known, no doubt, as *Libocedrus decurrens* in most European gardens and arboretums until Wellingtonia fades into Sequoia.

Some idea of the massiveness and beauty of a trunk of the western Arbor-vitæ can be obtained from the illustration which appears on page 116, although no illustration can give any idea of the beauty of the coloring of the bark, which is one of the chief attractions of this noble tree. The illustration, from a photograph by Notman, represents a tree of medium size in the natural park recently acquired by the new city of Vancouver, in British Columbia, which has already been described in this journal.

How to Begin Reform in Forest-management.

THE Maine State Forestry Association held a meeting in Augusta last week to consider the forest-interest of that state and suggest appropriate legislation on the subject. Mr. B. E. Fernow, Chief of the Division of Forestry in the Department of Agriculture, was invited to be present, but, being unable to attend, sent a letter to Hon. James E. Hobbs, President of the Association, from which we are allowed to make the following extracts:

What the forestry interests of Maine need above all things is the diffusion of more knowledge as to the true value as a resource, and the real nature of the forest, and as to the means and methods of its satisfactory reproduction. Next it needs such protection against fire as that knowledge would at once command, and a civilized community ought not to withhold from any kind of property.

Whatever measures you may propose to meet these needs, I warn you against urging any legislation without proper and adequate means of carrying it into execution. Too many ineffective laws have already been enacted in all the states with regard to this and other interests, much to the detriment of the cause which they were intended to benefit. It is not an easy matter to propose practicable measures for forest-protection as long as forest-property is all held in private hands. Hence it is good policy to proceed slowly until some practicable remedy is proposed and embodied in legislation, when full and proper means to carry out the law should be strenuously insisted upon. A half-hearted execution of the law is certain to retard healthy development of the forestry movement.

I have advocated, and I would advocate now, that the best first step to be taken by any state is to employ a forest-commissioner, whose business it would be to gain the needed knowledge of forest-conditions in his state, and then act upon his proposals for legislation which are based upon this knowledge. His very name and existence, if he be the right man, would stimulate the citizens of the state to study the questions involved, to form an opinion, and to aid in abolishing abuses and improving conditions. He should be in sympathy with the owners of woodlands, and especially with the lumbermen, with whose co-operation alone forest-legislation can be successfully accomplished.

From the legislation of other states in the Union but little can be learned that is very effective. On the other hand, the plan of the Canadian Government, in Ontario, for the protection against fire, may suggest some measures that could be adopted in Maine. Briefly, its provisions are that the Government appoints fire-wardens, at the recommendation of the lumbermen, to act during the dangerous season, preventing and putting out fires and instructing the people in regard to the fire laws. The Government pays one-half, the lumbermen the other half of the expense. The result has been satisfactory to both parties.

I invite especial attention, however, to the fact that the Commissioner of Crown Lands and his office have charge of this service, and that in Maine also somebody, like the proposed forest-commissioner, must be directly responsible and charged with this duty, if it is to be effective. Paper legislation, without a special officer to enforce it, is not likely to put out or prevent fires.

Castiglioni's Travels in the United States.

THIS work* has received so little attention from writers on American botany that a brief notice of the book and its author may be of some interest to those curious in the earlier literature of our plants.

Luigi Castiglioni, a descendant from the ancient and illustrious Milanese family of that name, was born shortly after the middle of the last century, and died in 1832. The various honorable offices held by him during his life, and the distinguished titles conferred upon him, bear witness to his active interest in the affairs of his day.† He was Director of the Royal Mint, President of the Academy of Fine Arts of Milan, Senator of the Kingdom of Italy, Chamberlain of the Emperor of Austria, Chevalier of S. Stefano, P. M., and of the Iron Crown, and a member of many learned societies, including the American Philosophical Society of Philadelphia. He was a devoted student of numismatics and the possessor of a famous collection of Italian coins. Early in life he became much interested in sylviculture, and with his brother, Count Alfonso, afterward associated with him in the authorship of a work on foreign plants useful in medicine and the arts, was instrumental in introducing many valuable trees into northern Italy. In recognition of his botanical attainments a genus of plants was dedicated to him by the Spanish authors Ruiz and Pavon, but, the genus not being well founded, the name has since become a synonym.

In 1785 he visited this country, moved, as he tells us, by curiosity to witness the political birth of a republic composed of distinct nations extending over a vast area, and by the desire to study the natural productions of the land, particularly those of the vegetable kingdom, with the view of introducing the more useful ones to his native Lombardy. He passed three years in traveling through the thirteen states and a portion of Canada, and the result of his observations was published in 1790, shortly after his return to Milan.

The main portion of the book consists of a narrative of his travels, with extended comments on the histories and governments of the states, with notes on the manners and customs of the people and on the natural productions of the country. It is followed by an appendix entitled "Observations on the Most Useful Plants of the United States," in which almost all our common trees and shrubs, and some of the more interesting herbs, are described in alphabetical order after the manner of Marshall's Arbustum. This appendix is accompanied by three plates.

That the author was well qualified for the task his judicious observations on the social and political condition of the young republic, and his careful notes on its geography and natural history, abundantly testify. Though not of the importance to systematic botany that the works of his predecessors, Wangenheim and Marshall, proved to be, his account of our trees and shrubs is in other respects by far the most interesting that had appeared up to that time. As an instance of his sagacity, it is worthy of remark that he distinctly notes and repeatedly insists upon the affinities of our plants with those of Japan and China, a subject which has since played so important a part in the philosophical consideration of the two floras. In vol. ii., p. 156, he says: "It is moreover to be observed that the plants are very similar to those of the eastern coast of northern Asia, the Magnolia, Illicium, Calycanthus, Ginseng and many others, for example, growing here as in Japan and China, thus confirming the assertion of Franklin that the eastern coasts of the old and new continents bear much analogy in their climates,"

* "Viaggio negli Stati Uniti dell'America Settentrionale fatto negli anni 1785, 1786 e 1787 da Luigi Castiglioni. Con alcune Osservazioni sui Vegetabili più utile di quel Paese." Two volumes, 8vo. Milano, 1790.

† See Litta, "Famiglie Celebri di Italia."

and in a foot-note he refers his readers for further proof of this to a comparison of Thunberg's "Flora Japonica" with the "Flora Virginica" of Gronovius. Again, in his account of the Catalpa, p. 212, he remarks: "This is one of the plants common to the eastern coasts of America and Asia which prove the analogy of the two climates."

The three plates give good figures of the Franklinia, made undoubtedly from the specimen in Bartram's Garden, the Poison Sumach and the Bear Oak, though I cannot find that they have ever been cited.

It may be added that the simple grace of his style makes Castiglioni's work one of the most readable of the early contributions to our botanical literature, and it deserves to be known to all lovers of our plants acquainted with his language. It has been so strangely neglected, however, that many to whom the book would be of interest are perhaps ignorant of its very existence, and it may be doing some service, therefore, to call attention to the fact that "the story is extant and written in very choice Italian."

Jamaica Plain, Mass. *C. E. Faxon.*

The Sleepy Grass.

IN contributions from the *United States National Herbarium* (No. 2, issued June 28th, 1890), Dr. Vasey describes *Stipa viridula*, Trin., var. *robusta:* A stout, leafy, densely tufted grass, four to six feet high, growing in thick clumps, with broad and loose sheaths longer than the internodes, and flat, wide blades often two feet long. Dr. Vasey informs me that it is very common in New Mexico, reaching northward through Colorado, probably to the hilly parts of South Dakota. Southward it extends through Texas into Mexico.

In 1879 Dr. Palmer collected this plant in Coahuila, Mexico. He noted that it was considered poisonous to cattle, horses and sheep, having a temporary narcotic effect upon them, and that it was only eaten by strange animals, being shunned by the native animals which have once experienced its effects (*Bull. Torrey Bot. Club*, xiv., 99). Dr. Vasey also noticed that it was not eaten by cattle during the summer, being eaten only under stress of hunger in winter or spring.

In 1888 I received a letter from my friend Dr. M. E. Taylor, of the army, then stationed at Fort Stanton, New Mexico, which I quote in parts: "Hereabout grows a grass . . . the eating of which by horses will, within a few hours, produce profound sleep or stupor, lasting twenty-four or forty-eight hours, when the animals rally and give no evidence of bad effect. It is known among cowboys as 'Sleepy Grass,' and dreaded by them on their 'rounds up,' as their horses are liable to eat it, and cannot then be kept up with the herds. . . . The tradition is that horses having once eaten of it will not touch it again."

This letter was accompanied by another from Mr. J. E. Cree, a stock raiser, whose ranch is near Fort Stanton. From this letter, addressed to Dr. Taylor, I also quote in parts: "The Sleepy Grass invariably grows in the immediate proximity of water, and where the ground is no doubt sub-irrigated. I have never known cattle to suffer. . . . Happening to be with our 'round up' this spring, we camped at Three Bear Springs. That night, although our foreman took precautions to guard against any of our horses getting the grass, we found in the morning that three or four had succeeded. Out of this number it seemed as though one would succumb altogether. He would stand in one position for hours at a time, his head swaying backward and forward as if asleep, and, if I remember correctly, was trembling all over. It appeared to very strangely affect his kidneys, as he had an unceasing desire to pass urine. . . . It was fully seven days before he recovered, and was then weak and drawn. One of the other horses seemed to be all right on the start, but before long it became evident he was also suffering from the effects of the Sleepy Grass, and it was only by a free use of the spurs that he could be made to move along. His recovery was much quicker. . . . I may mention that we have not found a horse that has once suffered ever again to eat it. We had a number of 'Bronchos' this year, and while under its influence one could walk up and catch them. Whether a sedative can be procured from this grass or not, I venture to suggest that some valuable extract affecting the kidneys may be obtained from it."

From the same gentleman I received a letter in 1890, in which he says: "Since I corresponded with Dr. Taylor it has been brought to my notice that cattle are affected in a similar way to horses, and that the curious properties which so affect animals are contained in the blades. Quite a number of our horses have been ill this spring after having eaten it. It usually takes them about a week to recover, during which time they are unfit for work, and specially so during the first three days."

Captain Kingsbury, of the Sixth United States Cavalry, under date of March, 1890, wrote me from Fort Stanton that "the Sleepy Grass affected nearly all my horses at two camping places. It was hard work to make them walk."

A specimen of the grass in question was received from Fort Stanton and submitted to Dr. Vasey, who identified it as his *Stipa viridula*, var. *robusta*.

The similarity of symptoms, whether observed in Coahuila or in New Mexico, is certainly remarkable, and furnishes strong evidence of the substantial accuracy of the observations as reported. It would seem, then, reasonably established that this plant possesses narcotic or sedative properties, affecting principally horses, but also cattle and probably other animals; that animals are not fond of it, but eat it inadvertently or when under stress of hunger; that cases of poisoning occur specially in the spring, when the radical and lower blades first come up, and that the active principle resides in these blades, and perhaps only during that season.

Now let us turn to the species itself, *Stipa viridula*. It is a western grass, abundant beyond the Great Lakes and from British America southward to Colorado. It appears to be common in Oregon and California. It is considered a good pasture and hay-grass by stockmen, both foliage and seed-tops being much liked by cattle. In good land, specially if moist or irrigated, it attains a height of three feet or more and yields excellent hay. Being widely diffused it furnishes a considerable part of the wild forage of the Rocky Mountain-region. This plant has never been accused, so far as I can ascertain, of containing any deleterious principle or of giving rise to any unpleasant symptoms; it is such a common constituent of pastures and hay, and so extensively consumed, that it is not possible it should possess any deleterious properties without attention having been called to it. Here we are, therefore, in presence of a botanical variety possessing marked properties which are absent in the species, an occurrence which, I am inclined to believe, is quite rare among native plants, and might, perhaps, be used as an argument for raising the variety to the dignity of specific rank.

There are some twenty-two species of Stipa in North America. Outside of *S. viridula* few possess economic importance. *S. spartea*, according to Professor Macoun, is the "Northern Buffalo Grass" of the Canadian ranchmen; it "constituted the winter food of the buffalo, and is now the delight of horses in the winter season." In other parts, this species, as well as *S. comata*, under the name of Porcupine Grass, is considered a great nuisance by stock raisers on account of the sharp-pointed and barbed callus which penetrates the flesh of sheep and other animals. *S. occidentalis*, *S. setigera* and *S. pennata*, var. *Neo-Mexicana*, are also mentioned as desirable elements of pastures or as sometimes furnishing hay. None of these, so far as known, possess narcotic or other unusual properties.

Fort Buford, N. Dak. *V. Havard.*

Can the Gypsy Moth be Exterminated?

THE recent action of the Governor of Massachusetts in dismissing the original Gypsy Moth Commission as inexpedient and incompetent, and the appointment of a new commission without remuneration selected from members of the State Board of Agriculture, and to be under its direction, once more brings into prominence the question of the war against this now notorious insect. It seems probable that the commissioners appointed last spring were named rather on account of their political capacity than their entomological knowledge, since not one of them even knew the nature and habits of the insect with the extermination of which they had been entrusted. The advice of entomologists, given gratuitously when asked for, probably prevented some serious blunders. The large sum voted by the Legislature gave ample means for prosecuting the work, and the results arrived at in reducing the pest last season were better than many people anticipated and as good as was to be expected from inexperienced and more or less careless management.

Land-owners naturally made much complaint and opposition to the invasion of their grounds by employees of the Commission for the purpose of searching for the cocoons of the Gypsy Moth, or more particularly for the application of insecticides (chiefly arsenical) to trees, shrubs and other vegetation. The act establishing the Commission gave it power to invade any private place in furthering its object, and the ignorant workmen employed were in many cases apparently very careless in the use of the Paris Green and indifferent as to the thoroughness of their work.

Late in the season an attempt at some sort of quarantine inspection was inaugurated with the idea of preventing the spread of the insect from one town to another. While teams on roadways were examined, at certain points the inspection seemed to be of the most superficial nature, and it does not appear that such modes of conveyance as railroad trains or river boats received any attention.

It is now generally conceded that it must be fully twenty years since the insect was first unwittingly introduced by Mr. Trouvelot while making experiments in silk-culture near Medford. During that time it has been increasing in numbers and annually spreading over a larger area; and in some localities it was noticed as quite injurious during at least two seasons before it came to the notice of entomologists or received official attention. This being the case, the question naturally arises as to how far beyond the present known limits of forty or fifty square miles and in what directions the insect may have been transported during all the years in which its existence was ignored. Whether or not its extermination, which was plainly contemplated by the legislature, can be accomplished, depends largely upon the area over which it has been distributed. If it does not exist in this country outside of the limits where it is now known the task might not be easy, but it would be much simplified.

That the pest may be in other places undetected may readily be supposed, since it has escaped the notice of the numerous naturalists of Boston and vicinity for so many years. Some of the most infested localities were about large manufacturing places, where freight-cars remain for days or weeks while loading or unloading. The habits of the insect are such that there seems every reason to believe that, in the last years preceding its discovery, it has been carried in one or another of its stages with freight to distant points, where, if the conditions were favorable, it is now on the increase, although its presence may not be observed for years. It might be worth while for the Commission to find out some of the places to which car-loads or empty cars have been most frequently dispatched from the infested district in recent years, and to have competent persons visit these places to ascertain whether the pest is there. While there is not the least evidence that it has spread beyond the area now known to be infested, the chances of the pest having been carried far beyond should not be lost sight of. If it is found to have gained a foothold elsewhere, an opportunity would be given for checking it before it becomes as alarmingly abundant as it did at Medford and surrounding towns.

Its advent within the borders of other states would make it a national rather than a state care, but it is questionable whether further special legislation would be advisable except for the enactment or enforcement of such laws as would compel every landowner to keep his property reasonably clear of such pests, so that they would not be a menace to the rest of the community.

To many persons it seems that the prospect for the extermination of the Gypsy Moth is not very hopeful; and from its habits, known distribution and the means that have been thus far taken for its subjection, one can hardly see how its extermination in this country is now practicable, even with the aid of larger appropriations than the legislatures could be prevailed upon to give.

The appropriation and expenditure of the $50,000 already voted, however, will not have been altogether in vain; for, besides the accomplished temporary suppression of the pest, a wide-spread popular interest in entomology has been aroused, and the value of a knowledge of such things has been once more very effectually and practically demonstrated to those who usually belittle such studies. Besides this, the folly and waste of allowing political and personal motives to control appointments in matters of this nature has had one more illustration, if, indeed, any more was needed.

The now famous work, carried on under the direction of Dr. Riley, in overcoming the Cottony Cushion or Fluted Scale in California by the importation of the predaceous Lady-bird beetle (*Vedalia cardinalis*) from Australia, very naturally has led to the inquiry whether there are predaceous or parasitic foes of the Gypsy Moth which could be introduced to keep it in check in this country if the project of extermination should be abandoned. In Europe over a dozen parasites of the Gypsy Moth are known which are the chief preventives of the undue increase of the pest. Owing to circumstances unfavorable to their enemies, the Gypsy Moths are occasionally very abundant and their larvæ exceedingly destructive to vegetation in some parts of Europe.

They are rarely or never so destructive, however, as another closely related insect, *Liparis monacha*, popularly known as the "Nonnen" in Germany, the advent of which would be a much greater evil to this country. The ravages of the "Nonnen" in European coniferous forests have been recognized for hundreds of years, and the serious destruction caused in Bavaria last season showed that it was almost as hopeless to make a fight against this foe to-day as it was two centuries ago. Its extreme abundance and destructiveness is of only occasional occurrence, the numbers fluctuating remarkably from year to year. It frequently happens that insects of this destructive class are almost annihilated by epidemics of fungal or bacterial diseases, the causes and conditions of the development of which are not yet well known. With a better knowledge of them, it is possible that such diseases may at some future time play an important part in the struggle against destructive insects.

The new Commission appointed to prosecute the work against the Gypsy Moth may be depended upon to carry it on in the best and most disinterested manner possible, for although none of the appointees of Governor Russell are known as entomologists, they are men of such wide intelligence that they are certain to solicit and take advice from the very best authorities as to the possibility of extermination, the benefit likely to be derived from the importation of the foes of the pest and the best means and methods of carrying out the intent of the law.

Arnold Arboretum. *J. G. Jack.*

New or Little Known Plants.

New Orchids.

Cypripedium × "Muriel Hollington," Rolfe.—This is a charming little hybrid, raised from *Cypripedium niveum* fertilized with the pollen of *C. insigne*, in the collection of A. J. Hollington, of Enfield. It received an award of merit from the Royal Horticultural Society on November 11th last. As in the case of all hybrids raised from *C. niveum*, the characters of that species largely preponderate, but the spots and especially the folded apex of the dorsal sepal, the nerves of the petals, and the leaves, are all modified in the direction of *C. insigne*. The flower is white, with the lip, petals and dorsal sepal beautifully veined with light purple, the latter organ having a yellowish green disc.—*Gardeners' Chronicle*, January 3d, 1891, p. 10.

Cypripedium × Castleanum, Rolfe, is a beautiful hybrid, raised in the collection of Messrs. F. Sander & Co., of St. Albans, from *C. hirsutissimum* fertilized with the pollen of *C. superbiens*. It somewhat resembles *C.* × *Fraseri*, raised from the first-named species crossed with *C. barbatum*, but is more brightly colored. The characters of the pollen parent somewhat preponderate, but the colors are darker than would naturally have been expected.—*Gardeners' Chronicle*, January 10th, 1891, p. 30.

Cypripedium × Orpheus, Rolfe, is a pretty hybrid, raised in the collection of Messrs. F. Sander & Co., of St. Albans, from *C. venustum* fertilized with the pollen of *C. callosum*. It strongly resembles the last-named species in character, but the dorsal sepal is smaller, more acute, and without the purple veins, and the petals more purple toward the apex, and with fewer warts on the margin, in which respect it approaches the seed-bearing species. It is the first hybrid raised from *C. callossum.*—*Gardeners' Chronicle*, January 10th, 1891, p. 39.

Cypripedium × Alcides, Rolfe, is a large and delicately-colored hybrid, raised in the collection of Messrs. F. Sander & Co., of St. Albans, from *C. insigne* fertilized with the pollen of *C. hirsutissimum*. It is tolerably intermediate in character, though the influence of the pollen parent decidedly preponderates in the shape of the dorsal sepal, petals and lip. The colors are more delicate than would *à priori* have been expected.—*Gardeners' Chronicle*, January 10th, 1891, p. 40.

Kew. *R. A. Rolfe.*

Plant Notes.

Some Recent Portraits.

Sir Joseph Hooker describes, in the February number of the *Botanical Magazine*, a new Magnolia (t. 7157) from Japan, for which he proposes the name of *Magnolia Watsoni*, in honor of Mr. William Watson, our London correspondent and the assistant curator of the Royal Gardens. *Magnolia Watsoni* is described as a small tree, flowering at the time of the unfolding of the leaves, which are four to seven inches long by two to three and a half inches broad, elliptical or obovate-oblong, obtuse or cuspidate, deep green above with yellow margins and nerves, paler, and, when young, clothed on the

lower surface with fine silky appressed hairs. The flowers are solitary, very short-peduncled, and five or six inches in diameter, and remarkable in the broad ring of blood-red filaments which surrounds the pistil. This tree was purchased by the authorities of the Royal Gardens from the Japanese Court of the Paris Exhibition in 1889, and it flowered at Kew in the open ground last year. The flowers are described as possessing a powerful odor, like those of the Calycanthus. This, we suspect, is the plant which Mr. Thomas Hogg introduced into the Parsons' Nursery at Flushing many years ago, where it has proved perfectly hardy. He found it in the mountains of Japan and considered it a mountain form of *M. parviflora*, and it is under this designation that it has been grown and distributed from Flushing, where it flowers every year and has occasionally produced fruit. It is probably distinct from *M. parviflora*, as Sir Joseph Hooker points out, differing from that species in its much larger foliage and in its larger short-stalked flowers. A drawing was made in the Parsons' Nursery some years ago for GARDEN AND FOREST, but has been held in the hope that a figure of the fruit, which is not obtainable every year, might be added to make it complete. The yellow margins of the leaves of the Kew plant are possibly abnormal, as, judging from the source whence it was obtained, the specimen is probably of garden origin.

Other figures in the same number of the *Botanical Magazine* are: *Catacetum fimbriatum* (t. 7158), a showy Brazilian Orchid long known in gardens, having been exhibited at Brussels as long ago as 1848; *Rhododendron scabrifolium* (t. 7159), one of the numerous Rhododendrons recently discovered in western China by the Abbé Delavay, chiefly from the mountains of Yun-nan, which the present species inhabits at an elevation of 8,000 feet above the sea-level. It is a small rigid shrub, hairy all over, with the exception of the bracts, corolla, stamens and style. The leaves are two and a half to three and a half inches long, elliptical or oblong-lanceolate and acute at both ends. The flowers are borne in loose terminal subumbellate fascicles on long slender pedicels surrounded at the base by pubescent yellowish bracts. The corolla is an inch and a half in diameter, and is white, flushed with pink, with a short campanulate tube. The species is rather interesting than beautiful from a garden point of view. *Tricuspidaria dependens* (t. 7160), a small Chilian tree of the Linden family, widely distributed through ten degrees of latitude. It produces handsome pendulous, blood-red flowers an inch and a quarter long, hanging from the axils of the new leaves. *Angræcum fragrans* (t. 7161), an Orchid chiefly interesting for the persistent vanilla-like odor of the dried leaves, which has caused them to be used as tea in Bourbon, the Mauritius, and even to some extent in France, where it is considered digestible, and recommended in diseases of the respiratory organs.

Cultural Department.

The Genus Cycas.

OF the nine genera into which the order *Cycadaceæ* is now divided the genus Cycas is the only one which finds general favor in horticulture. *C. revoluta* is universally popular as a decorative plant; it is also a conspicuous feature in elaborate flower arrangements, especially for funeral occasions in Germany and several other continental countries. In England it is generally grown for the conservatory. It is perhaps the hardiest of all Cycads, and its beautifully glossy green, plume-like leaves are as durable as the leaves of any plant.

It is a native of China, from whence it is said to have been introduced into Europe by Thunberg in 1737. Its trunk sometimes attains a considerable height, as is shown by a specimen in the Kew museum, which is ten feet high. A living plant in the winter garden has a stem six feet high. As a rule, however, before the trunks get to this height they sprout all over their sides and base and break up into numerous heads. Large examples of both the female and male plants are in the Kew collection. The female is common in gardens, and when in flower its central, nest-like cluster of stunted, brown, felt-covered fronds, bearing each three or four orange-colored, egg-like fruits, is both attractive and interesting. The male plant, however, is exceedingly rare. The Kew examples were obtained after much trouble from Shanghai in 1884. The cones are erect, pine-like, and each stem is said to produce three cones at once.

Next in popularity to *C. revoluta* comes *C. circinalis*, which appears to be common in the tropics of Asia, and which has been known in English gardens since the year 1700, when it was introduced by the Earl of Clarendon.

Dr. Trimen states that it is abundant in Ceylon, where its trunk often grows to a height of from fifteen to twenty feet, and is sometimes branched. Some fine trunks were sent from Ceylon to the Colonial and Indian Exhibition held in London in 1886, of which several are now at Kew. One of these is a particularly handsome specimen. Its trunk is eight feet high and fifteen inches wide at the base. The spread of its foliage is eleven feet through, each frond being six feet long, eighteen inches wide, with the pinnæ a foot long, arched, and five-eighths of an inch wide.

C. Rumphii is very similar to *C. circinalis*, as also are *C. Celebica* and *C. Thouarsii*. This last is the only Cycas represented in Africa, where it was found by Kirk on the Zambesi. Dr. Gappy states that he saw in an island in Bougainville Straits a Cycas, probably *C. Rumphii*, "with a stem forty-five feet high, growing solitary in a plantation." This is by far the tallest Cycad I have ever heard of. The largest specimen of *C. Rumphii* at Kew is a particularly fine one. Its stem is less than three feet high by seven inches in diameter at the base, but it carries a head of forty leaves, each six feet long and eighteen inches wide, the pinnæ falcate, fourteen inches long by half an inch in width. I have seen a picture of a plant of *C. Rumphii* in Calcutta, with no less than fourteen heads of leaves and a cone in the centre of every head.

C. undulata of gardens may be *C. Sumannii*, a native of Fiji, and not unlike *C. circinalis*, except that the pinnæ are slightly wavy at the margins.

C. Riumininiana is a most elegant species and a very rare one. The Kew plant has a stem eighteen inches high by four in diameter, twelve leaves, each four feet long, the pinnæ narrow, thin in texture, half an inch wide, and of a bright, glossy green. The fronds are almost as elegant as the leaves of a Cocos. This rare plant was introduced from the Philippines by Mr. W. Bull some twelve years ago.

C. Siamensis is almost as largely grown in France as *C. revoluta* is here. This is partly due to the fact that it is common in Siam and Cochin China, from whence it was introduced in quantity into France about ten years ago. It has large stems, often seven feet high, much swollen at the base; elegant bright green fronds about four feet long, and pinnæ nine inches long. It is supposed to be sufficiently hardy to bear as low a temperature as *C. revoluta*. At Kew, however, it is grown in a stove, having failed in the large temperate house. I do not see how *C. gracilis*, var. *viridis*, of Van Houtte, *C. pluma* of Ball, and *C. Boddamii* of Dyer differ from *C. Siamensis*.

C. pectinata.—This is the handsomest of all Cycas. It is not, however, as easily grown as the better-known species, as it requires a stove temperature, with plenty of sunlight and moisture. Even then its fronds, magnificent though they are when at their best, suffer considerably in winter, and are rarely fit to remain on the plant a second year. The plant represented in the illustration (page 114) was grown at Kew over the tank devoted to *Victoria Regia*. It was in a ten-inch pot, had a stem a foot high, conical in shape, and leaves eight feet long, rich green in color, and as elegant as an ostrich plume. This species is easily distinguished from all others by its semi-erect, arching fronds and by its thin, blunt-tipped, long, falcate pinnæ. It is a native of Sikkim. Sir Joseph Hooker found it in Great Rungeet Valley in 1848, and a sketch of it made by him on the spot shows it with a stout stem at least twelve feet high. The fruit of this species is as large as a Golden Drop plum, and as richly colored when ripe. The male cone is exceptionally large and handsome, being nearly twenty inches long by six inches in diameter, tapering to both ends. It is formed of fleshy, closely packed, overlapping scales, each tipped with a macron nearly two inches long. *C. Jenkinsiana* of Griffith appears to be the same as this.

There are several Australian species of Cycas which are represented only in few collections at present, but which when better known and more plentiful are certain to find favor. They are quite as elegant in foliage as and at the same time distinct from the other species mentioned. The best-known is *C. media*, which is not unlike *C. Siamensis*, and of which Mr. Bull used to have some very fine specimens: *C. Kennedyana*, *C. Cairnsiana* and *C. Normanbyana*.

The most famous collections of Cycads are those at Kew, Herrenhausen (Hanover), Potsdam and St. Petersburg. Mr. Bull has also a good many species; indeed, he is the only English nurseryman who possesses a representative collection of these plants. In massiveness and grandeur the Cycads are not surpassed even by Palms, while many of them are so easily kept healthy that it seems almost difficult to harm them.

The cultural requirements of Cycases do not differ materially from those of the order generally. They do not require

much root-room, but they like a rich open soil, plenty of water when growing, and a little extra food in the shape of liquid manure helps them considerably in the growing season. While some of the species, such as *C. revoluta* and *C. circinalis*, retain their leaves several years and scarcely turn a hair in winter, others are practically deciduous. When the fronds sicken it is wise to keep the roots fairly dry, so as to rest the plants. This usually happens in winter, but by March again new leaves will push up, and these should be encouraged by gentle syringing in favorable weather and an occasional good watering at the roots. Should the stems decay at the base they may be cut off above the decayed part and treated as cuttings. Quite large stems, both of Cycas and other genera, have been renovated in this manner. It sometimes happens that after fruiting a stem will decay at the top, and appear to lose entirely its central bud. Cycads, however, are not like Palms in this respect, for I have seen new growths start from the top of stems which apparently had previously lost everything down to the pith. Should the central bud fail to start again then laterals will almost certainly push out, or even all round the base of the stem just above the roots numerous sucker-like growths will spring up. In fact, one might say that if there is health in even a small portion of the stem of a Cycad there is a chance of its revival. Cycas differs from other genera of *Cycadaceæ* in having a conspicuous midrib extending up the whole length of the pinnæ. Stangeria is the only other genus with this character, but it differs very markedly from Cycas in all other respects.

Kew. *W. Watson.*

Fig. 22.—Cycas pectinata.—See page 113.

Hardy Plant Novelties.

THE season of seed catalogues has fairly begun, and those who study this literature always find something to interest and instruct, and, probably, to perplex, them in the effort to discriminate between desirable novelties and those which are quite as well left alone. It would appear that we are to become better acquainted in future than we have been with the treasures of the New Zealand flora. One of these, *Ranunculus Lyallii*, is now offered by several seedsmen, and if there was but a reasonable hope that seeds of this beautiful plant would germinate easily we should soon be in possession of a good stock. *R. Lyallii* is known as the Shepherd's Lily in its native country, which is in the southern or colder of the two islands known as New Zealand. Some time ago I obtained fresh seeds of this plant direct from its native locality, with the date on which the seeds were collected, but at the end of two years no plants appeared, and I can only find one instance recorded of this Ranunculus having been raised from seed, and this was by Mr. Anderson Henry, of Edinburgh, Scotland. In this place the plants came at the end of three years after sowing. The flowers of *Ranunculus Lyallii* are pure waxy white, four inches in diameter, while the leaves are peltate, often fifteen inches in diameter, with a many-flowered stem two to four feet high. This plant would certainly not be hardy in the colder states, but would be desirable for the cool greenhouse.

Of other New Zealand plants the Aciphyllas are also offered as new. My experience with this genus is not extensive, being confined, in fact, to *A. squarrosa*, the Bayonet-plant, so called

on account of the sharp-pointed segments of the foliage. Four years ago a single plant was received and carefully nursed in-doors until early summer, when it was planted out with other things, but with the first heavy rains it rotted off at the ground-level, and therefore it is to be presumed that until of good size the Aciphyllas would need to be grown in-doors. If this could help them to become established, it is worth trying, as their singular appearance when in flower gives them unusual interest.

Delphinium Zalil when introduced created considerable interest on account of its being the first yellow-flowered species of Larkspur cultivation. We are now offered another species with yellow flowers in *D. Przewalskyanum*. (The secret of pronouncing this apparently impossible name is said to be the insertion of an "i" between its first two consonants.) This species, unlike *D. Zalil*, is a true perennial, perfectly hardy, and a native of central Asia.

Another remarkable plant, not new, but now first offered, is the beautiful Mexican Thistle, *Erythrolæna conspicua*. True, it is only a Thistle, but, judging from the descriptions and figures received, it must possess unusual merit. We are told that it is a biennial plant, but that when treated liberally it grows four to six feet high, much branched, with large foliage crowned with flower-heads of a bright orange-carmine color. Our seed was sown at the commencement of the year, and they are now strong plants, and grow rapidly. In the warmer states this plant would be a conspicuous one for ornamental gardening, but here it would have to be protected in winter the first year, and this detracts somewhat from its value.

We are indebted to Mr. William Thompson, of Ipswich, England, for the reintroduction of *Coreopsis grandiflora*, of Nuttall, and though this very plant has been distributed here as *C. lanceolata* in almost every state, still its identity had not been determined. It has been the subject of note in previous numbers of Garden and Forest, that there were two plants called *Coreopsis lanceolata* in cultivation here, the one vastly superior to the other, and now the better one will be known as *C. grandiflora*. It may be distinguished by the larger and brighter flower-heads and by the deeply pinnatifid leaves, the terminal lobe being much the largest. This, the true *C. grandiflora*, has a large tuft of what would be evergreen foliage in a milder climate than ours, but here it usually gets badly disfigured, although the heart of the plant winters out safely. Those who possess *C. lanceolata* would do well to examine their plants, and if they are correctly named, to get *C. grandiflora*, for both are admissible into even the most select collections, and considerable difference will be found in the duration of the flowering season of the two plants. It has been stated that *Coreopsis lanceolata* ripens seed sparingly in some seasons; this may be true, but I am very sure that Goldfinches find the seed the most palatable food they can obtain in its season, as I once discovered when trying to save a quantity of seed. They did not wait for it to ripen, but seemed to prefer it when approaching maturity, and perhaps it has been through the agency of Goldfinches that the Coreopsis is so often met with as an escape from cultivation in places where it could not otherwise have been found. Seedlings of *C. grandiflora*, if raised early and planted out in good soil, will flower nicely by the end of summer, and will make a fine display the following season.

South Lancaster, Mass. *E. O. Orpet.*

Notes from Cornell University.

Substitutes for glass of various kinds in forcing-houses are from time to time referred to in horticultural journals, but their relative efficiency does not appear to be fully settled. Some trials of these substitutes are now being made at the experiment station here. A section of the forcing-houses recently built was first covered with a strong white oiled paper. A short experience with this material, during several snow-storms and the subsequent freezing and thawing aided by the wind, was sufficient to show its inefficiency, and a cloth covering was substituted for it. The latter is cotton-sheeting of medium quality, costing $2.50 for the 350 square feet covered, and it was thoroughly oiled with raw linseed oil, both to make it more durable and more translucent. It was put on, and the first coat of oil (about three gallons) applied, by two men in a day; a second coat, requiring another gallon of oil, being added a week later.

This covering seems to accomplish all that was expected of it. It apparently retains the heat as well as the ordinary glass roof. More exact investigations, however, are to be made, both as to the loss of heat in this and in the glass houses.

Although, of course, a considerable portion of the light is cut off, the oiled cloth admits a larger amount than would be expected, and it seems from present experience that a forcing-house built in this manner, on account of its cheapness and ease of construction, would be of practical value for the propagation of many kinds of plants, and, perhaps, even for the forcing of Lettuce and some other crops.

Further experiments will be undertaken to decide these questions.

Electric Light in Horticulture.—Experiments with the electric light are showing some very interesting results this winter. One of the forcing-houses is divided by a tight board partition across the centre. Upon one side of this partition are growing a variety of plants with an electric light suspended from the roof in the midst of them. Upon the other side is a corresponding set of plants of the same varieties, growing under conditions as nearly like the first as it is possible to obtain, except that the artificial light is carefully excluded. The light has been in operation about six weeks for five to six hours each evening, except on moonlight nights, when it has run for about two hours.

The difference in growth in the two sections of the house has been very striking with some kinds of plants, especially in the case of Petunias and Lettuce. While in the lighted half of the house the Lettuce crop is now large enough to market, the average size and weight of the plants in the opposite section are but little more than half as great.

The effect upon flowers is also very marked. While the plants of Petunia, Verbena, etc., develop much more rapidly under the light, the flowers when opened last only half to two-thirds as long as in the unlighted section, and begin to bleach and fade very soon after opening.

The flowers in nearly every case turn toward the electric light, and the plants also show a similar tendency. In the winter of 1889-90, when the electric light ran continuously throughout the night, this bending of the plants toward the light was very much more marked. From all sides they reached out their slender branches toward one point, seeming to make an almost conscious appeal for more light. The whole subject is worthy of further investigation, and the experiments are to be continued with varied conditions.

While it is easy to draw hasty conclusions from a few experiments, it does not seem visionary to think it possible that in the not distant future the electric light may become an important adjunct in our large forcing-houses, especially when we consider that, as our present experience seems to show, a crop of Lettuce can be matured ten days or two weeks earlier by its use.

Ithaca, N. Y. *C. W. Mathews.*

Orchid Notes.

Angræcum sesquipedale.—This species is superior to any other Angræcum, and it must certainly be ranked among the most interesting of all Orchids. The plant was known to European botanists as early as 1822, but it was not until 1857 that it was first brought to England in a living state from Madagascar, its native country, by the Rev. William Ellis, whose explorations of this island resulted in the discovery of more than one remarkable plant. *A. sesquipedale* flowered with Mr. Ellis at Hoddesdon, Herts, during the year of its introduction. It created quite a sensation at that time; but this is not to be wondered at, for in addition to the peculiar formation of the flowers, which has always been a matter of interest to botanists, their beauty has never failed to call forth the admiration of every one. The stem of the plant is erect and thickly clad with arching, oblong leaves, about two feet long, notched at the apex, dark green, and arranged in two opposite rows. The axillary peduncles bear from one to four star-shaped, slightly fragrant, flowers of thick texture, and from six to eight inches in diameter. The sepals and petals are broad at the base and taper gradually to a point; lip ovate-acuminate, and elongated from twelve to eighteen inches at the base, thus forming a remarkable, hollow, pendent spur. When the flower first opens the parts are pale green; they all turn to creamy yellow except the spur, which retains the greenish tint; later they assume a waxy whiteness, which is maintained for several weeks, and then they turn to rich yellow before dropping. A specimen grown here presented a magnificent appearance when in bloom last February. The stem of this plant is but twelve inches in height, and it bears only a single, one-year-old branch. But, notwithstanding its small size, eleven full-sized flowers appeared at once on four peduncles. To develop this free-flowering character *A. sesquipedale* should be planted in a basket and suspended from the roof, close to the glass, on the sunny side of a house, which is kept at a stove temperature all the year. Growing Sphagnum, with ample drainage, will be found most acceptable to the roots. Although free access of light is essential at all seasons, yet, to

Fig. 23.—Thuya gigantea.—See page 109.

keep the plant healthy, bright sunshine must be excluded by shading except during the winter months. The plant advances with greater rapidity as it is farther removed from the light, and the foliage then assumes a much more luxuriant color; but this rankness of growth moderates the production of flowers to a large extent. Moist roots and a moist atmosphere are congenial to the plant at all times, but when the flowers appear the supply of water should be reduced.

Lælia superbiens.—The most famous of the early collectors of Orchids, Mr. Skinner, wrote that he discovered this plant in 1839 in Guatemala. The first specimens he had seen were cultivated by the Indians, to whom the plant was

then known as the "Red Flower." Mr. Skinner adds, that in 1840 he found the plant growing in immense quantities about twenty leagues north of the city of Guatemala; that there was hoar-frost upon the ground at the time of his visit to its native locality; and that "St. Joseph's Wand" was the name given to it by the Spanish-speaking people who dwelt there. There are now few collections of Orchids in which it does not hold a prominent place. The plant which flowered with Mrs. Wray, of Cheltenham, in 1844, was probably the first to bloom in England. *L. superbiens* is a strong-growing plant, and, under favorable conditions, soon forms a large specimen. The creeping rhizome is about half an inch in diameter, and produces pseudo-bulbs at intervals of two or three inches. The pseudo-bulbs are oblong, from nine to twelve inches in length, nearly round, tapering toward both ends, ribbed, and, when young, covered with a whitish sheathing. At the top they support one or two oblong, acuminate leaves, about their own length, very thick, and of a dark green color. The peduncles proceed from the summit of the pseudo-bulbs, and vary in height from five to nine feet. They are clothed with the silvery sheathing peculiar to the pseudo-bulbs, and bear from ten to twenty flowers in a globular cluster at the top. The flowers are from six to seven inches across, the sepals and petals spreading, lanceolate (the latter by a trifle the broader), and both of a bright rose color. The lip is as long as the sepals, three-lobed, with the lateral lobes incurved, crimson and yellow, the front lobe broad, spreading, wavy, on the margin, and deep purple with crested lines of yellow. This Lælia thrives very satisfactorily in the airiest end of an intermediate house. It should be grown in a basket, with rough peat fibre, charcoal, and abundant drainage for the roots. It should be kept well up to the light, and should have shade only during the brightest days of spring, summer and autumn. Care must also be taken to restrict the supply of water after the growth has been completed.

Phalænopsis Schilleriana.—Comparatively few Orchids can be called attractive at all seasons of the year; but this is one of the best, and when in bloom during the winter and early spring it can hardly be excelled. This plant was introduced from the Philippine Islands in 1860. The oblong leaves attain a length of eighteen inches in well-grown specimens; they are dark green, with irregular bars of gray on the upper side, and a pale purplish color underneath. The peduncle is more or less branched, and, according to the age and vigor of the plant, from one to three feet in length. The flowers are about three inches across, sepals oblong, petals very bluntly ovate, lip trilobed, the lateral lobes oblong and turned backward, with a yellow callosity at the base, and the front lobe lyre-shaped. Pale lilac, faintly suffused with rose, is the prevailing color, and the lower sepals and lateral lobes of the lip are distinctly spotted with red. All the flowers expand about the same time, and they last in good condition from six to eight weeks. Under careful cultivation this plant is remarkably floriferous. A specimen grown in England bore at one time no fewer than 378 flowers. There are numerous varieties of *P. Schilleriana*, all worthy of cultivation, and in some of them the flowers are fragrant. The odor is agreeable, and it is most sensible during bright weather. *P. Schilleriana* should be planted at an elevation of three or four inches above the top of a well-drained pot or basket, with clean crocks for the drainage, and lumpy charcoal and fresh, clean sphagnum about the roots. It requires a stove temperature, with protection from sunshine, and sufficient water should be given to preserve at all times the luxuriance of the Sphagnum in which the plant is growing. Water should not remain about the leaves for any considerable time.

Cambridge, Mass. *M. Barker.*

Cattleya speciosissima.—This has become one of the most conspicuous of winter-blooming Orchids, and, although a rather shy bloomer, judicious treatment will overcome this objection. For the two winters before the last we had little success in flowering these plants, but this season several of them have behaved to our perfect satisfaction. The size of the flowers varies from six to eight inches in diameter, with a lip from one and a half to two and a half inches across. Their color is hard to describe, as each plant has its special shade, ranging from a light, delicate, flesh-color to a decidedly rich purple, with a dark mauve-purple lip. Again we have some varieties with sepals and petals blotched and veined in the manner of *C. Mossiæ*, var. *Hardyana*. We grow the plants in a house with *C. Trianæ*, so as to have them in winter-flowering quarters. They are in shallow pans and baskets suspended from the roof, although many specimens of the variety Lowii, which bloom as freely as *C. Trianæ*, are left in pots. My practice is to give them all the sunlight possible from the beginning of October until the end of February, during which time they will grow and flower freely. They must be sparingly watered at all times, or they will suffer from "the spot." They never should be watered until they become rather dry. Nor do I give them any "rest" if at all inclined to grow. Some plants that bloomed here last July and August are in bloom to-day again, and probably by next July or August they will flower again. The stems appear to be quite as large as those made during the summer, and in my opinion it does them no harm whatever to flower, if the flowers are not allowed to remain on them too long. A comparatively small amount of fibre and moss, with a little charcoal, will suffice as a compost, as they do not like much around their roots, and, of course, they must be kept far from snails and white scab.

Staatsburgh-on-Hudson. *F. Atkins.*

Greenhouse Rhododendrons are proving much more valuable every year, and Messrs. Veitch are adding new varieties almost every month, many of them superior to the older kinds. A collection of flowers of some of the best varieties was shown at a late meeting of the Royal Horticultural Society, and were generally admired. They comprised Vesta, a large-trussed, large-flowered cream-yellow variety; Nestor, rich yellow; Scarlet Crown, a brilliant red, with large flowers; Balsamæflorum aureum, and about a dozen others. These plants are scarcely ever flowerless. They are always in growth, and as fast as a shoot casts its flowers it pushes into new growth, matures a bud, and blooms again. Consequently upon the same plant occur, simultaneously, young growths, flower-buds and expanded flowers. A dozen plants will yield flowers from January to December.

Kew. *W.*

Clerodendron Thompsonæ.—This fine old plant should not be neglected or displaced by newer favorites. It is suitable for pot culture for conservatory decoration, or it can be grown as a climber, and the flowers are useful for cutting. It is of scandent habit, with large, smooth, dark green leaves, and its large panicles of bright crimson flowers, with pure white calyces, invariably arrest attention. It is easily propagated by cuttings taken in summer. In fall the small plants may be placed under the bench in a warm greenhouse and kept dry. In February or March they should be potted in light rich soil, with plenty of pot-room, as they make roots freely. If shifted whenever pot-bound, they will bloom almost all summer. Old plants require the same treatment. They must be shaded from the sun when growing, as the foliage is very tender. When the blooming season is over they should be freely watered and kept growing until it is time to ripen the wood, when they may have more sun and less water. If wanted for winter-flowering they require a short rest, after which they may be shaken out, repotted and started again. Specimens too large for this treatment will flower better if considerable of the old soil is removed and replaced by fresh compost. If not wanted till spring they can remain in a cool light place, with just enough water to keep them alive through the winter.

Maywood, N. J. *J. S. T.*

Correspondence.

Wild Flowers in California.

To the Editor of Garden and Forest:

Sir.—It has been an open winter in California, with nearly two months of sunshine, but the wild flowers do not seem more forward than usual. To-day (March 2d) I found, along a warm hill-side, where the flowers bloom earliest, the Manzanita (*Arctostaphylos Menziesii*), which is a low shrubby tree here, loaded with its Heath-like blossoms. Stray specimens bloom earlier, but the mass of the bushes are now blooming. My little favorite, *Dodecatheon Meadia*, was in great abundance on some warm slopes. With its dainty Cyclamen-like flowers it is one of our prettiest wild plants. On a shaded hill-side there were several Cardamines blooming. This is *C. pauci-secta*; our best, *C. angulata*, is also in flower in the cultivated fields. The yellow Buttercup (*Ranunculus macranthus*) and *Fritillaria lanceolata* I found well-budded. They are late this season. Certain warm slopes were yellow with the blossoms of a low-growing composite plant, and *Castilleia parviflora*, one of the Painted Cups, is also in bloom. The introduced plant, *Erodium cicutarum*, which we Californians call Alfilleria, is, as usual, among the earliest to blossom. In gardens the Chinese Narcissus is well over its flowering. The scarlet Japan Quince is now in bloom, as are most Narcissi.

Some of my fall seedling Pansies are in blossom. Laurestinus, Polyanthus, Oxalis and Verbenas are becoming quite plentiful. The large Dog-tooth Violets (*Erythronium grandiflorum*) in my bulb-beds are well in bud.

Ukiah, Cal. *Carl Purdy.*

Peaches and Yellows.

To the Editor of Garden and Forest:

Sir.—In a recent number of Garden and Forest, the fact was referred to that Peach-growers in New Jersey and elsewhere claim that they can cure the yellows, and it was stated that this claim has been disproved by experiment. Yet, though the experimental proof is undoubtedly accurate, so also are the statements of the New Jersey growers. The truth is, that much, if not the larger proportion, of so-called yellows in New Jersey is not due to the specific disease, but to the attacks of the root-louse, which, by sapping the roots, gives the yellow appearance. This can be cured by the application of kainit or of tobacco, and it is altogether too sweeping a statement as to the prevalence of this disease in southern New Jersey that is frequently made. Killing the lice cures the yellows, and this is the basis for the claims made by the New Jersey growers.

Rutgers College. *John B. Smith.*

The Nettle-tree in New Jersey.

To the Editor of Garden and Forest:

Sir.—In Dr. Britton's "Catalogue of Plants found in New Jersey" *Celtis occidentalis* is set down as "not very abundant in the Pine Barrens." I have never found this tree in the Pine Barrens, strictly speaking, of Atlantic County. It is to be found, however, in various localities, particularly along or near streams which flow into salt-water. It is especially abundant near Pleasantville, where it grows best on lands which border on and slope toward the salt marsh. The largest tree I have seen here measures very nearly two feet in diameter, and its branches have a spread of forty feet in diameter. I estimate its height at about thirty-five feet. This tree, which is an unusually large one for this region, is a solitary one, and being finely formed, its "peculiar beauty" (as noted in Garden and Forest, vol. iii., p. 42) is especially seen at this time of the year.

I may add that this tree stands near the site of an Indian village and burial-place, and has long been a landmark in the neighborhood.

Pleasantville, N. J. *John E. Peters.*

Viola hastata.

To the Editor of Garden and Forest:

Sir.—The illustration of this Violet in your issue of February 18th, and the note concerning it, reminded me that one peculiarity of this plant is not mentioned in any description of it which I have seen—I mean its glossy, brown-veined foliage. The upper side of the leaves is green, netted with brown veins; the under side is often entirely bronze. If this characteristic color could be retained in cultivation (which I have not yet tried) the plant would be of especial value. The Halber-leaved Violet likes light soil along the sunny borders of woodlands.

Two other Violets of ascertained merit for garden use are worth mention here. *Viola striata* has large velvet petals, cream-white, veined with purple; it is fully as handsome as *V. Canadensis*, and thrives in more open exposures than the latter, but wholly lacks its delicate fragrance. *V. rostrata*, with pale lavender colored flowers bearing curious long spurs, is a somewhat rare species that is charming in the Fern garden.

Geneva, O. *S. F. G.*

Lilium Hansoni.

To the Editor of Garden and Forest:

Sir.—For the sake of accuracy I beg to state that this Lily first flowered at Leiden with a Dutch amateur; I obtained by the agency of Mr. Mater, then manager at Siebold's, a bulb for $20. This was in 1862. The following year I had a few more bulbs at $25 and $32, which I then carefully cut to pieces, leaving at each scale a bit of the trunk or body of the bulb, and I thus obtained by sowing these scales about 150 bulbs within two years. They ranged in size from that of a pea to that of a walnut. As soon as my first bulb divided I sent a bulb to Mr. Hanson, who then flowered it first in America.

Baden Baden. *Max Leichtlin.*

Periodical Literature.

In *Scribner's Magazine* for March, Mr. Samuel Parsons, Jr., has an interesting article entitled "The Ornamentation of Ponds and Lakes," which ought to encourage all who own a stretch of river-front or even the tiniest pond or brook to experiment for themselves in this direction. At least half the knowledge required for such experiments is the knowledge of what not to do, and something of this Mr. Parsons conveys by his account of how he himself failed in his first attempts with aquatic and moisture-loving plants. His account of the way in which he subsequently worked to better advantage on a country-place which, although it was but ten acres in extent, fronted on a broad, placid stream and extended over a narrow strip of land on the opposite side of the water, should, however, renew ambition in the reader's mind. His advice with regard to the advantage of emphasizing Nature's own arrangements of shore line and vegetation is as clear as it is judicious, and the beautiful picture of the stream of which he speaks, with the two tall Poplars accenting a little promontory and the path kept far enough away from the shore not to interfere with the fringing vegetation, greatly helps the impressiveness of his words. We should have been glad, by the way, had he dwelt upon this question of paths, for no fault is more common in the arrangement of ornamental sheets of water than the establishment of paths close to the brink. A formal, artificial look is thus given to the scene and no good purpose is served; for, of course, it is never necessary to come quite close to the water except when a boat is to be taken, and for this special and proper provision can be made at some single spot. When one wishes merely to look upon the water, it is far more delightful to see it over at least a narrow strip of turf spreading out into aquatic or semi-aquatic plants than against a hard line of gravel or stone. We should think the fact self-evident were not instances of what seems to have been a contrary belief so sadly frequent both in public parks and in private grounds. We have too often praised the beautiful aquatic plantations which Mr. Parsons has introduced into the basins of our New York parks to feel any necessity for quoting his own words about them. The pictures which are given of these basins will interest readers who live at a distance from New York; they are extremely pretty and reasonably faithful, although the extent of the basins seems exaggerated, especially where the Bethesda Fountain in the Central Park is shown.

In an article called "Australian Cities," by Mr. George R. Parkin, published in the March number of *The Century Magazine*, he describes the magnificent harbor of Sydney, and then adds: "I doubt if any public pleasure-grounds in the world contain so many attractions as do the park and botanic gardens bordering on the bay. Inclosing one large arm of the harbor, facing another, and looking out upon the waters where navies can float at ease, their position is unrivaled. The climate favors the growth of sub-tropical vegetation as well as that of the temperate zones, and great skill has been shown in making the most of such an opportunity for effective landscape-gardening and interesting botanical experiments. The grounds are large enough to furnish ample room for the thousands who flock to them on Sundays and holidays. Beautiful public gardens are not confined to Sydney, but form a striking feature of Melborne, Adelaide, Brisbane, Ballarat and every considerable Australian town. They enter into the life of the people both for pleasure and for instruction. The services of highly skilled botanists are secured to give them scientific interest. Experiments in acclimatization are constantly carried on, and have a wide range from the advantages of climate. Several have attached to them zoölogical collections of considerable interest. At Ballarat private generosity has added a beautiful collection of Italian marbles. The brilliancy and profusion of the semi-tropical flowers, and the ease with which large numbers of Tree-ferns are reared in light structures of lattice-work, make possible effects in gardening which are very striking to northern eyes."

Interesting descriptions of tracts of country little known or wholly unfamiliar to Europeans are contained in Mr. W. W. Rockhill's article called "Through Eastern Thibet and Central China," published in the same number of this magazine.

The sudden and startling contrasts which are presented in many parts of these regions, and which were noted when we reviewed not long ago Mr. Hosie's account of his travels in central China, are well shown by the passage where Mr. Rockhill says: "As far as Jyékundo I had found the country desolate and stony, with only here and there a little brush growing

in the more sheltered nooks among the hills; but on the morning of the second day after leaving the town we entered a small cañon which opened on the Dré ch'u, and the scene changed as if by magic. Cypress and Juniper, Pine and Birch covered the mountain-sides, and along the brook, flowing between banks of velvety grass, powdered with little pink and white flowers, grew Plum-trees and wild Gooseberry-bushes. Honeysuckle and other shrubs, all in full bloom, filled the air with the fragrance of their blossoms. From the cavities in the tufa rocks hung Fern and creepers, from which the water dripped in glistening drops. For miles the country remained the same, becoming even grander along the Dré ch'u. There the road was high up on the steep mountain, 600 or 700 feet above the broad blue river, and on each side in the background were dazzling peaks of snow." Before reaching Tachien-lu Mr. Rockhill had traveled over seven hundred miles "in a country where no European had ever put his foot," and where only of recent years the Chinese have been able to implant themselves among the hostile natives. After leaving this town the road ran "down a rocky gorge on each side of which the mountains rise almost perpendicularly to a height of over two thousand feet. Wherever possible the soil was cultivated, Maize and Potatoes being the principal crops. Willows, Poplars and wide-spreading Walnut-trees were growing around the little villages and tea-houses with which the narrow rocky path was lined." It seems strange to learn that in this remote region Irish Potatoes are one of the principal articles of diet.

Exhibitions.

Orchids in New York.

THE fifth annual Orchid show of Messrs. Siebrecht & Wadley, which has been open for a week past in Madison Square Garden, has proved interesting on account of the variety of the plants exhibited, and highly suggestive as to the possibilities of effective floral arrangement which are offered by the immense area of the amphitheater. The ground-plan, which was designed by Mr. N. F. Barrett, consisted in the main of geometrical beds, which produced pleasing effects of form and color to one looking down upon them from the galleries, while tall, close hedges which separated the different sections were set so as to open vistas through which visitors who passed from one garden to another near the entrance caught glimpses of masses of flowers and foliage in the distance. The view through the centre was between a double row of Bay trees and terminated in a so-called Italian garden constructed on an incline, from the summit of which a sheet of water fell into a basin of aquatic plants. On one side of this avenue was a garden with formal, Box-bordered beds and masses of Daffodils, Crocuses, Lilies of the Valley, Tulips, Hyacinths and other spring-flowering bulbs. On the other was a garden where Spiræas, Lilacs, Andromedas, Forsythias and other shrubs in bloom were shut in by masses of Long-leaf Pine, Spruce and Red Cedar.

As this was an Orchid show distinctively, the principal display of these plants was massed on four large stands in the centre, while about them were formal beds of Paris Daisies, Cinerarias and Azaleas, with an outer border of Lilies, Roses, Heaths and Cytisus, which, in turn, were backed by specimen Palms and Tree Ferns. Altogether, it was a praiseworthy effort at a design for general effect, and, with the material at command, it was successfully carried out. Perhaps the time will come when a New York Horticultural Society can command all the treasures of the private and commercial collections near the city, and with such resources to draw upon this amphitheater would offer a field for infinite variety of arrangement. Well-grown individual plants would here be most useful. One of the chief attractions at an elaborate exhibition in Philadelphia a few years ago was a Fuchsia; but it was a Fuchsia of such size and vigor and wealth of bloom as one hardly sees in a lifetime. Half-a-dozen Azaleas, developed by years of careful attention into first-class specimens, would have fairly illuminated even so large a space as Madison Square Garden, and many other equally effective flowering plants could be named. At this exhibition the most attractive plants were the Orchids, and Orchids are not effective for massing. They do not show at a distance for what they are worth, and their place in the general scheme might have been better filled by plants of less individual excellence. Perhaps, too, they would have appeared to better advantage themselves if separated and partially screened from the rest of the exhibition and spread out over a more extended space, so that each one would have had opportunity to display its special grace and beauty—an opportunity which was partially lost when they were crowded so closely together. The well-grown Phalænopses shown by Messrs. Siebrecht & Wadley were certainly more effective scattered along the green bank at the east end of the garden than if they had been grouped together on a stage in the centre of the area.

The collection of Orchids shown by Messrs. Siebrecht & Wadley excelled all others in point of numbers, although the remarkable group from the garden of Mr. W. S. Kimball, of Rochester, contained quite as many species and varieties. Smaller than either of these collections, but of choice quality, was that of Mr. Hicks Arnold, of this city, containing such varieties of *Cattleya Trianæ* as Aspasia, Pandora, Splendidissima and others, with *Phajus tuberculosus*, *Cypripedium Leeanum*, *C. Schlimii* and many more of the best of this genus. Mr. Eyermann's collection did not reach the garden in time for the early days of the exhibition, but there was a large and well-selected consignment from Mr. William Matthews, of Utica, New York. The Rose Hill collection was very strong in its abundance of good varieties of *Cattleya Trianæ*, and there were many well-grown plants of *C. Percivalliana* and *C. Lawrenciana*. Besides the Phalænopses, which deserve special mention on account of the vigorous growth of such choice sorts as *P. Stuartiana*, *P. Schilleriana* and the like, the Cypripediums were a great attraction, including specimens of *C. Argus*, *C. Spicerianum*, *C. insigne Chantini*, *C. Harrisianum* and scores more, of the pick of this popular genus.

To name the noteworthy plants in Mr. Kimball's collection would be to make a catalogue of the entire list. There were some sixty varieties of the very best Cypripediums nestling among low Ferns, and over them arched the most delicately beautiful of Odontoglossums and Miltonias. Among his Dendrobiums were *D. Cambridgeanum*, *D. Freemanii*, *D. Findleyanum* and *D. Jamesianum*, and the gem of his Cattleyas was a striking variety of *C. Lindleyana*.

Besides the Orchids, the more striking features of the show were the many tall Cocoanut Palms, some beautiful Pritchardias, and numbers of specimen Ferns and Pitcher plants. The exhibition was well attended throughout.

Notes.

Seventy-eight thousand four hundred and fifty-two potted plants were used last year in decorating the parks and gardens of the city of Berlin.

The *Florida Agriculturist* says that many growers in Florida, having become tired of the shy-bearing Navel Orange-trees, have resorted to girdling them with considerable success.

The longest avenue of trees in the United Kingdom is said by the *Northern Gardener* to be one of Beeches, in Savernako Forest in Wiltshire, which is five miles in length. The longest avenue in the whole civilized world is said to be at Mildura, in Victoria, where the Government of that State have made a wide arborescent walk fifteen miles long, leading almost straight to the extensive irrigation region of the colony.

In a large Pineapple plantation on the Indian River the fertilizer which seems to give the best success contains a large amount of kainit. Captain Thomas E. Richards, the proprietor, does not use much nitrogenous manure because the plants thus fed shoot up breast-high, and then the apple falls over, becomes burned in the sun and is coarse and spiritless. It is found that the fruits do better when they grow on short, stocky stems hardly more than knee-high.

Among the novelties that are occasionally seen in the florists' windows this season are forced plants of the Pale Laurel, *Kalmia glauca*, the small terminal corymbs of lilac-colored flowers being quite attractive. The plant, however, has a rather bare appearance, because the foliage, which is not naturally very abundant, is still more sparse in the forced specimens. The Kalmias are among our most beautiful shrubs, but it is questionable whether this one at least can ever be forced with advantage.

The Japanese *Akebia quinata* has been planted for a great many years in this country, and it has proved one of the best of vines to cover screens and arbors. Professor Georgeson, in the *American Garden*, says that it is largely used in Japan for wicker-work, and that nothing can surpass for this purpose the strong, slender and pliable shoots, which are of almost uniform thickness throughout. As these shoots are long and thin, they do not need to be split before they are used, and articles made from them are stronger and more durable than willow-ware. The Akebia is used in the manufacture of baskets, trays and even of sun-hats.

In the third annual report of the Cornell Agricultural Experiment Station we find noted among the investigations under way: An experiment with the cultivation of Huckleberries, both at the station and upon a piece of land in the eastern part of the state; tests of edible plants of foreign countries to determine which ones give promise in this state; tests in the automatic ventilation of greenhouses, and several other features of greenhouse construction; a large experiment to determine the influence of food, chiefly concentrated fertilizers, upon the variation of plants; a large experiment with hardy foreign and domestic Roses; a systematic study of Horse-radish, with particular reference to propagation and improvement; and at all times the study of the species and the variations of plants under culture. Photography is used freely in all the station work as a means of preserving accurate records.

A timely appeal to the Legislature of Pennsylvania for an Alleghany Mountain park is made in *Forest Leaves*. In behalf of this project a quotation is made from Governor Beaver's last message, wherein it is truthfully said that while it is difficult, now when the state has practically parted with all its lands, to re-acquire them, yet without such actual ownership of the waste land of the central mountain belt of the state it is hard to devise any efficient plan for reforesting it. Tens of thousands of acres, not worth for any commercial purpose the taxes annually levied upon them, and which under the present system of tax rates are used to defraud the unwary, might be made productive to the commonwealth if held and controlled by it. An Alleghany park, including a large portion of the mountain region of the state, might easily be made so as to protect the head-waters of all the rivers which there take rise.

The largest apple-tree in New England, according to the *Boston Journal*, is in the north-western part of Cheshire, Connecticut, and it stands in the dooryard of Mr. Delos Hotchkiss. Its age can be traced by a family tradition to 140 years at least, and it may be twenty or twenty-five years older. It is now of symmetrical shape; the trunk is nearly round, without a scar or blemish; there are eight large branches; five of them have been in the habit of bearing one year, and the remaining three the next. Mr. Hotchkiss has gathered in one year from the five branches 85 bushels of fruit, and his predecessor has harvested 110 bushels from the same five branches. By careful measurement, the circumference of the trunk one foot above the ground, above all enlargements of the roots, is thirteen feet eight inches. The girth of the largest single limb is six feet eight inches. The height of the tree is sixty feet, and the spread of the branches as the apples fall is 100 feet. The fruit is rather small, sweet, and of moderate excellence.

A writer in the New York *Evening Post*, when describing the beautiful effects upon the scenery of the Central Park of the snow-storm which occurred during the last week in February, said: "One effect on some of the Pine-trees was very curious: the long, bristle-like, diverging leaves that surround the terminal buds were matted continuously together by the clinging snow into cups of trumpet-mouth shape, the larger of which might contain a closed fist, and the sight of a good-sized tree with these turned all one way was very striking. Detached beauties and curiosities abounded. A great Beech standing apart near the Ninety-sixth Street gate was a type of all the solitary deciduous trees, the outline of its branch-tips all in soft white losing its firmness and appearing to dissolve into the storm. A tall, full Weeping Beech was like an arrested waterfall of spray. The Dogwoods held up stretched sheets descended out of heaven. The white Birches seemed like mists. The evergreens, struck all through with white, became soft gray. But the strange beauty of the whole view was the great wonder. That moved even the park-keepers to admiring speech, and prompted one of them to ask, 'Where's all the people in New York that pretends to like fine scene-ry?'"

The Fruit-Growers' Association has taken firm hold in England, although its inauguration dates only two years back. Formed for the purpose of diffusing a knowledge of such fruit as may be cultivated out-of-doors in that country, it has already done much toward the extension and improvement of fruit-cultivation. Lectures are given in various parts of the country by qualified members of the Association; exhibitions are held and tempting prizes given, and even professional advice has been gratuitously afforded to those seeking it. The report of the Association has just been published, from which it appears that two delegates, Mr. G. Gordon and Mr. Lewis Castle, were sent to Ireland to inquire into the condition and prospect of fruit-culture in that country. Thirty-six papers have been prepared and read by twenty-two of the leading growers and authorities during the two years of the Association's existence; some of these papers have been printed and circulated freely. As an example of how much good may come from work of this kind, it is stated that over two thousand inquiries by letter were answered by the Association last year; also that the increase in the acreage under fruit-cultivation in England during the last two years is shown by the agricultural returns to be 12,637 acres.

In an address recently delivered in Vienna upon "Persian Fruit-trees," Dr. Stapf, as reported in *Gartenflora*, said that Apples, Pears and Cherries flourish in that country only at elevations of from 6,000 to 7,000 feet above the sea. Persian cherries are small, with reddish or yellowish watery flesh, and an insipid, almost bitter taste. The plums, too, are not very good, but, on the other hand, the apricots are far superior to those grown in Europe. The trees often grow to "gigantic dimensions," especially near Shiraz, at an elevation of from 5,500 to 7,500 feet; and the fruit is very large and of an "exquisite sweetness." Two kinds of peaches are grown, one of the ordinary downy sort and the other a small smooth-coated, delicious variety. Pomegranates are universally seen, being of shrubby habit when wild, but of tree-like size in gardens. One species is devoid of seeds. Walnuts are very widely grown, and near Shiraz an enormous specimen may be seen at an elevation of 8,000 feet, while further north, in the Kohrud Mountains, there are fine large plantations at an equal elevation. Even Fig-trees flourish up to an elevation of 5,650 feet, or higher still in the province of Farsistan, and the White Mulberry follows to almost the same height, while the Black Mulberry, of which several kinds are grown, lags 1,500 feet below it. A singular fruit is supplied by the so-called Oil-Willow (*Elæagnus angustifolia*) which, when cultivated, yields a berry resembling an olive in size and shape, but of a "honey-sweet taste." When gardens are not encircled by walls Poplars and Willows are planted as wind-breaks—*Populus alba* and *P. pyramidalis*, *Salix Persica* and *S. æmophylla* being chosen. Here and there in gardens immense Maples may be seen, and more seldom Elms, among the latter being a remarkable variety (*Ulmus campestris*, var. *umbraculifera*), with a thick spherical head. Elms and Celtis-trees and Ashes are planted in front of the mosques, but Planes and Cypresses are the trees best beloved by the people. The former are especially chosen for avenues, where they are often trimmed so that they grow to an immense height, but develop a head of comparatively small size. The Cypresses are either columnar or spherical in shape, the form with horizontal branchlets never being grown.

The death is announced of Mr. John Dominy, in his seventy-fifth year. Of the English gardeners who have lived in the present century none has distinguished himself more than this quiet, genial and pleasant man, who by his skill as a hybridizer has created many plants of rare beauty. It is to him that is due the credit of first successfully hybridizing Orchids and Nepenthes, and it is to his skill and patience that the world owes such beautiful garden plants as *Cattleya Exoniensis*, *Calanthe Veitchi* and *Lælia Domini*. Dominy passed nearly all his active life in the employ of the Veitches, first at Exeter and then at Chelsea; he was much respected by the horticultural profession, and received in 1880 the large gold floral medal of the Royal Horticultural Society, and when he retired ten years ago from service a substantial testimonial was raised by popular subscription among his friends. He was a man whose works are likely to live long after him and to be admired by generations to whom the name of John Dominy may perhaps be unknown.

Catalogues Received.

C. E. Allen, Brattleboro, Vt.; Flower and Vegetable Seeds and Plants, Small Fruits and Fruit-trees.—David Hill, Dundee Nursery, Dundee, Ill.; Evergreen Trees.—Wm. Elliott & Sons, 56 Dey Street, New York; Flower and Vegetable Seeds.—Ellwanger & Barry, Rochester, N. Y.; Roses.—J. W. Manning, Reading, Mass.; Hardy Border Plants and Hardy Trees.—Samuel C. Moon, Morrisville, Bucks Co., Pa.; Bulbs, Small Fruits and Fruit-trees, Deciduous, Ornamental and Evergreen Shrubs and Trees.—Parsons & Sons Co., Limited, Flushing, N. Y.; Hardy Ornamental Trees, Flowering Shrubs and Vines, Rare and Choice Plants.—Josephus Plenty, 144 Pearl Street, New York; Conservatories, Greenhouses, Vineries, Skylights, etc.—Carl Purdy, Ukiah, Mendocino Co., Cal.; California Bulbs.—John Thorpe, Pearl River, N. Y.; Chrysanthemums.—Siebrecht & Wadley, Rose Hill Nurseries, New Rochelle, N. Y.; Orchids, Palms, Ferns, Roses.—Schlegel & Fottler, 26 South Market Street, Boston, Mass.; Flower and Vegetable Seeds, Bulbs and Plants.—P. E. Transon Bros., Orleans, France; Small Fruits, Fruit and Shade-trees, Roses, etc.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MARCH 18, 1891.

TABLE OF CONTENTS.

Forests and Floods.

In the River and Harbor Act, approved last year, there was a clause ordering an examination of the West Branch of the Susquehanna River, in the state of Pennsylvania, with a view to ascertain (1) whether the navigation of this stream could be permanently improved by the construction of embankments or otherwise, and to ascertain (2) the best practical method of confining the waters of the river during the times of flood to the general course of its channel. Inasmuch as the difference of elevation between the mouth and the head of the West Branch, covering a distance of 125 miles, is more than 400 feet, and since, from physical conditions, the improvement of the channel for purposes of navigation could only be accomplished by means of locks and dams, it is evident that no material and permanent improvement in this direction could be hoped for without an enormous expense, and the engineer who has been making the examination so reported.

We desire, however, to call attention to the portion of the report which relates to the floods of the river. We do this, not because any new facts or arguments are adduced, but because this is an official paper prepared by Major Charles W. Raymond, who is known as an engineer of great knowledge and experience, and who is altogether above being biased by any sentimental considerations. The basin of the West Branch of the Susquehanna occupies a high table-land, and has an area of nearly 7,000 square miles, which is about one-fourth of the drainage of the Susquehanna River and its tributaries, or about one-seventh of the area of the state. Major Raymond gives some account of the floods of 1865 and 1889, the latter of which will be remembered as signally disastrous to life and property; seventy-eight persons lost their lives, and houses, mills, lumber and live stock were swept away, and farms and fertile bottom-lands were covered with sand and gravel. As first among the causes which increase the violence of such floods, Major Raymond names the destruction of forests. In this particular region the lumbering operations have been very extensive. In addition to the ravages made by fire, it is stated that the total amount of lumber, board measure, which has been cut here since 1862 is 5,250,000,000 feet, representing 30,100,000 logs. As for the effect of lumbering operations on this large scale, Major Raymond says:

The destruction of forests from the mountain crests and slopes of a water-shed is undoubtedly the principal cause of the increase of the average magnitude of floods. The evidence collected during the last twenty-five years, establishing this conclusion, is well-nigh overwhelming, and it is verified by repeated observations, not only in the mountainous countries of Europe, but also in our own land. By the removal of the forests from the mountain slopes the ground is robbed of its protecting covering of roots, moss, leaves and porous soil, which forms the forest-floor and serves as a natural storage reservoir, holding back the water of rainfall and melting snow, and compelling it to descend slowly to the channels. By the subsequent cultivation of the lands, ditches and drains are made to facilitate the more rapid discharge from the cultivated surfaces, until the rain rushes down the hill-sides in destructive torrents, gullying the ground and choking the minor lines of drainage with rocks, sand and gravel, and hurrying into the recipient of the water-shed volumes of water which before reached it in a comparatively quiet flow.

Colonel Torrelli affirms as the result of careful observation that four-fifths of the precipitation in forests is absorbed by the soil or detained by the surface of the ground, to be gradually given up in springs and gentle rills, and only one-fifth of the precipitation is delivered to the rivers rapidly enough to create floods. Upon the same slopes and surfaces denuded of their forests the proportions are reversed. That the destruction of the forests in mountainous water-sheds is followed by disastrous floods, where previously such floods were unknown, is not a matter of theory, opinion or probability, but is a well-established physical fact.

Other causes which increase the effect of floods are enumerated; among them artificial constructions, such as bridges and dams, besides the collection of logs, lumber and ice in the stream and upon its banks. But these are of secondary importance. As to methods of prevention, the devices of storage reservoirs and transverse barriers carried across the lines of drainage seem to be inapplicable to this region, for reasons not necessary here to consider, and the principal reliance must be in forests. On this last point the report continues:

The method of prevention by the maintenance and planting of forests upon the head-waters and upper slopes of the affluents of the basin depends for its efficiency upon the ability of forest-covered slopes to retain for a considerable time a large percentage of heavy rainfall, thereby preventing the surcharge of the lines of drainage. In France, Italy, Germany and Austria the systematic planting of mountain slopes, as a means of restoring lost fertility and preventing the inundations following the destruction of forests, is an established fact, followed by results more satisfactory than the most sanguine anticipations. . . . As population becomes more dense and the injuries from these uncontrolled floods increase, the time must come when the execution of a thorough scheme of control will be demanded. This will require the construction of numerous low dams and other inexpensive works to restrain the flow of the more remote tributaries and give the lower valley time to discharge the flood volume; and, besides this, new forests must be planted and maintained.

It is no part of our present purpose to speak of the close and costly survey of this region which would be necessary before any intelligent work on the details of a project of this magnitude could be begun. Nor is this the place to consider whether the general Government should undertake any work so local in its character. But the same forces which have destroyed the forests which sheltered the head-waters of this branch of the Susquehanna have been at work with more or less energy about the sources of every stream whose waters find their way from the Appalachian Mountain system to the Atlantic Ocean or the Gulf of Mexico. Between the Adirondacks and Alabama is a continuous line of such basins as that surveyed in Pennsylvania by Major Raymond, and more serious still is the threat of devastation from the mountain systems of the west, with their greater altitude and steeper slopes.

It is almost disheartening to feel the necessity of reiterating these statements which have never been controverted and rarely questioned, because all that is said and written seems to exert no actual restraint upon the axes and fires which keep steadily at the work of making bare the slopes and crests of our mountains. But reasonable appeals to reasonable men are never wholly lost. If the state of Pennsylvania had a Forest Commissioner who would do for every drainage basin in the state what Major Raymond has done for a single one, such reports presented year after year to the Legislature could not fail in the end to awaken attention. Every state in the Union has immediate use for some intelligent officer to study its forest-interests and bring the various phases of the forest-problem before the people and their law-makers. This step has already been taken in some states, and the proposition is strongly urged in others. In our view, it is a measure which should be at once adopted by all.

It is a matter of regret that Congress has once more adjourned without passing the bill for the enlargement and protection of the Yellowstone Park. Up to the very latest moment the friends of the measure, who have been laboring for it for eight years, had hopes of its passage. They were anxious to have the bill called up, feeling sure that in the committee of conference the amendment added by the railway lobby would be stricken out; but in the rush of business at the closing hours they could not command a hearing. The whole matter must now rest till Congress meets again, and meanwhile the great forest-tracts which it was proposed to add to the park will continue to be devastated by fires, and the noble game will be slaughtered for their hides by skin-hunters. The value of the park, as it is admitted by every one, would be greatly increased if the head-waters of the streams which pour into it could be protected, if the picturesque valleys and panoramic scenery in the proposed extension could be added to the wonders already within the park, and if the favorite breeding-places of the elk could be saved. But the opportunity to secure all these advantages has again been thrown away by the representatives of the people because the representatives of a corporation demanded some exclusive privileges.

The Rose-bush of Hildesheim.

The town of Hildesheim, which lies on the little river Innerste and now contains about 25,000 inhabitants, is one of the oldest in northern Germany. Episcopal rank was bestowed upon it in the year 835; and Bishop Bernward, who occupied his chair from 993 until 1022, was a famous architect and worker in many minor artistic crafts, and signs of his handiwork still remain to interest the traveler. During the thirteenth and fourteenth century the town was especially flourishing and important; it belonged to the Hanseatic League, and retained its title of "free city" until 1803. The Romanesque architecture of the district is very well represented in Hildesheim, and its domestic buildings of later mediæval and Renaissance times are especially famous, being many in number, rich in type, and little injured by restorations. But perhaps the most famous object in the city is the ancient Rose-tree of which we give a picture on p. 127. East of the cathedral lies a two-storied cloister of Romanesque construction; in the centre of this rises the Chapel of St. Anne; and against the wall of the apse of this chapel rises the Rose-bush. Local tradition ascribes its planting to Louis le Débonnaire, the son of Charlemagne, who was crowned in 816 and died in 840. History does not justify this belief, which would give the Rose-tree an age of over a thousand years; but it is confidently asserted, on historical grounds, to be 800 years old. But the stock we see to-day is not the one that flourished during so many earlier centuries. Late in the last century the Rose died down to the ground, and its present height, about thirty feet, represents the one hundred and ten years of growth from the ancient root. This in itself seems a respectable age for a Rose-bush; but if its entire life is included, the Hildesheim tree is certainly the oldest as well as the most famous in the western world. And if an antiquity as great is claimed for others in the Orient, the assumption rests, we must believe, on less well-ascertained facts than those which German historians can cite.

Chamisso.

Few poets are dearer to the popular heart in any land than is Adalbert von Chamisso in Germany; and while school-children there learn his ballads as they do those of Schiller and of Uhland, his fame has been carried into other lands by the prose story of Peter Schlemihl, "the man who lost his shadow." But how many people now remember that Chamisso was not only a poet, but a scientific man of wide accomplishment who added largely to the knowledge of his time, and was the friend and colleague of Humboldt, Johannes Müller and Ehrenberg?

It seems odd, with his patriotic ballads in mind, to learn that Chamisso was born in Champagne, in France. His father was of the noble lineage of Boncourt, and was one of the great throng of *émigrés* whom the Revolution drove to seek new homes in alien lands; and the boy Adalbert, born in 1781, and brought at a very early age to Berlin, there received his education and became a page in the royal household. Later he served in the Prussian army, was taken as a prisoner of war to France in 1806, and returned there afterward for brief periods, during one of which he was instructed in botany by the son of Madame de Stael. Even as a child he had shown a strong inclination for the study of nature, and when he again established himself in Berlin at the age of thirty, he entered the university as a student of medicine, worked in the zoological museum, investigated electricity and magnetism, as well as mineralogy and geology, and, in short, for three years pursued science with unusual breadth of range and intensity of application. In 1815, highly recommended by his teachers, he was appointed to accompany Von Kotzebue on the famous voyage of exploration in the ship Rurik, the ultimate aim of which was to discover a north-east passage from the Pacific to the Atlantic Ocean. This voyage lasted three years, and, though the arctic passage was never attempted, many and varied lands were visited which then were little known to science, including Teneriffe, Brazil, Chili, the Sandwich Islands and California, as well as numerous points in the far north. The name of Chamisso Islands within the arctic joins with several others to perpetuate the memory of the poet and his companions in this voyage. Under difficulties even greater than those which, fifteen years later, embarrassed Darwin during his voyage around the world, Chamisso, like Darwin, worked diligently in many branches of science while on the Rurik, brought home large and varied collections, and published an account of his experiences in a book, cast in somewhat popular form, called "Views and Observations during a Voyage of Discovery." In 1818 he was appointed assistant in the Botanical Institute at Berlin, and held the office until his death in 1838. In 1835 he became a member of the Academy of Sciences upon the nomination of Humboldt and Kunth. A botanical text-book for schools which he wrote had great success in its time, and a species of plants belonging to the unwilting Amaranths was, in his honor, named Chamissoa by Kunth.

Chamisso's favorite plants are said to have been those of the water, especially the *Potamogetæ;* but nothing that grew escaped his keen attention, and he distinguished himself during his very first days on the Rurik by discovering on the English coast near Plymouth a little plant, *Centaurea nigrescens*, which no local botanist had noticed. Heavy rains or burning heats prevented him from making the best of his time in certain countries which he visited and where the stay of the ship could not be long; but nearly the whole flora of the Radak chain was collected by him, and on the coast of California, then almost virgin soil to the botanist, he made many interesting discoveries, including a now familiar flower, which he named for the surgeon of the Rurik—*Eschscholtzia Californica*. Seeds of this he brought home, and to him must be traced its introduction into European gardens. So generously did he distribute his collections among his fellow-savants all over Europe that much of the service he rendered to botany has never been placed to his credit. But, as has been said, other branches of science—zoölogy, geology, anthropology, folk-lore, linguistics, and more besides—likewise engaged his attention; and he not only collected largely, but thought profoundly and suggested many new theories, in some of which he has been confirmed by the investigations of later days. For example, his theory of "propagation by alternating generations," based on a study of those very low forms of aquatic life called the Salpæ, went unheeded when he gave it to the world. But the labors of Steenstrup and Johannes Müller afterward confirmed it, in so far at least that Steenstrup declared that the honor of having led the way to an understanding of the different methods of generation characteristic of the lower organisms belongs "to the accurate and

ingenious investigator Chamisso." Indeed, one who follows Chamisso through all the fields of science in which he labored will often find him advancing ideas which later writers have either wholly or partially incorporated into theories that now command general acceptance, while the name of their first founder is forgotten by all except a few specialists. But my object has only been to show that the poet whom the world knows so well was "lined," as the French say, by a scientific man of much distinction; and perhaps those who think that an interesting association adds to the charm of even Nature's loveliest products will be glad to remember, whenever they look at the California Poppy, that it was discovered and named by the author of "Peter Schlemihl," and of the many charming ballads which mitigated the drought and dustiness of their first steps in the study of the German language.*

New York. *M. G. Van Rensselaer.*

Recent Botanical Discoveries in China and Eastern Burma.—IV.

Pedicularis.—Despite the wonderful variety displayed by this genus of plants, it has never yet received much attention from gardeners. The species may be difficult to cultivate, as they almost all grow in pastures in thick turf, and are, perhaps, in an early stage of development at least, root-parasites, like many of the allied genera. Looking through some of the illustrated periodicals, such as the *Botanical Magazine*, which has now appeared uninterruptedly for 113 years, we find that only three species have been figured, namely, *Pedicularis Canadensis* (t. 2506); *P. mollis* (t. 4599), an Indian species, and *P. megalantha* (t. 7132); also an Indian species, figured in the last completed volume. The last is really an ornamental plant, of which there are many in the genus, especially among the numerous Indian and Chinese species.

If gardeners have neglected this genus of herbaceous plants, botanists have not, as it has been monographed over and over again. The species are spread all around the northern hemisphere, from the arctic regions southward, in America, to the Andes, but not south of the equator. One of the species mentioned above, *P. Canadensis*, ranges from Canada to Florida and the mountains of central Mexico. In Europe the species are less numerous than in America, only two being found in Britain, and hitherto, I believe, no species has been found in Africa. In Asia they abound from the arctic regions southward to Ceylon and Burma; and they are especially numerous and ornamental in the mountains of India and China. So recently as 1888 Mr. C. J. Maximowicz† has monographed the whole genus, and since then Dr. D. Prain, Curator of the Calcutta Herbarium, has been engaged on a fully illustrated monograph of all the Indian species, only the letterpress of which has reached England at the time of writing this. Maximowicz enumerates 250 species, including a few imperfectly known ones; and Prain seventy Indian species, being nearly double the number described in Hooker's "Flora of British India" no longer ago than 1884. Finally, I have between ninety and a hundred in the "Index Floræ Sinensis," including several remarkable species previously undescribed. Mr. Maximowicz, in the monograph referred to above, gives a brief history of the literature of the genus, from which we learn how greatly the number of species has been augmented by comparatively or quite recent explorations. The Russian botanist, Steven, compiled the first monograph of the genus, which appeared in 1822, and contains descriptions of forty-nine species. Bunge followed in 1843 and 1846 with ninety-nine species, and Bentham in 1835 and 1846 with 109 species. The Russian explorers of central Asia and north-western China added a great many new species, bringing the total up to rather more than 150 in a synopsis by Maximowicz in 1877, with additions in 1881.

In 1886 the late Dr. Asa Gray described twenty-eight species in his "Synoptical Flora of North America." As already stated, Maximowicz's monograph raised the number to 250 species in 1888, and the great accession to the previously known species in this monograph was mainly due to the exertions of two French missionaries, Delavay and David, in western China. No fewer than forty-eight Chinese species were described for the first time; and the "Index Floræ Sinensis" adds descriptions of ten more.

All the species of Pedicularis are herbaceous plants, and apparently mostly perennials, though it is probable that some of them, perhaps a considerable number, flower only once. They vary in stature from two or three inches to four or five feet, and the leaves are alternate, opposite or verticillate, and present infinite variety in form and cutting, many of them being exceedingly elegant. The flowers, too, which are produced in clusters or spikes, or singly, are equally variable in size and color, and are very curiously formed, the tubular portion of the corolla being often very narrow and very long, and the upper lip often assuming the shape of a beak or proboscis, which is sometimes curved upward, sometimes downward, sometimes twisted, and sometimes very much elongated. In other species the upper lip is merely hood-shaped, or consisting of two lobes similar in size and shape to those of the lower lip, or in a few instances it is even shorter than the lower lip, or almost obsolete. The prevailing colors are shades of red and purple, but there are pure yellows and white, and commonly the flowers are spotted with another color.

Before passing to the Chinese species a few words respecting some of the more remarkable Indian species may not be out of place. Foremost comes *P. megalantha* (*Botanical Magazine*, t. 7132), because it is already in cultivation. It has rosy purple flowers two inches and a half long, with a very narrow tube, and a broadly lobed lower lip enclosing the incurved, beak-like upper lip. This has been successfully cultivated by Mr. George Wilson, the well-known English amateur horticulturist of Weybridge. I may mention that the plant figured in Regel's *Gartenflora* (1878, p. 195, t. 943) under the same name is apparently a different species, though closely allied, having clear yellow flowers, with a comparatively short tube. Noteworthy among other species of this section, which on the whole is the most ornamental section of the genus, are *P. bella*, *P. labellata*, *P. siphonantha*, *P. Perrottetii* and *P. bicornuta*. These must all be very beautiful plants. *P. bella* is a dwarf plant, from one and a half to three inches high, the large flowers springing from a tuft of leaves close to the ground, and constituting about two-thirds of the whole height. This little gem grows gregariously in Sikkim at altitudes of 15,000 to 16,000 feet, and although the color of the flowers is not given in the descriptions it is evidently a very ornamental species. Judging from dried specimens, it is an annual. *P. Perrottetii* is a native of the Nilgherry mountains, in southern India, and has the longest flowers of any known species; in fact, considerably longer than those of any other species. The whole plant is usually less than a foot high, and often not more than six inches, and in the finest specimens I have seen the white flowers are fully five inches long. *P. bicornuta* is an exceedingly handsome yellow-flowered species, a native of north-west India and Afghanistan, ascending to altitudes of 9,000 to 13,000 feet. The flowers have a comparatively short tube, but they are broad and showy; and the stems of this species are often a foot high, and studded with fully expanded flowers throughout their length. In this species the upper lip has the curious beak-like form inflexed, and twisted and bipid at the tip; hence the specific name. The Indian *P. tenuirostris* is also remarkable for the long proboscis-like upper lip.

Coming to the Chinese species, we find equal variety, though none perhaps with flowers quite so long as those of *P. Perrottetii*. On the other hand, there are some quite peculiar Chinese types. Especially remarkable among these is one to which I have given the name of *Pedicularis vagans*. It is a native of Mount Omei, in the province of Szechuen, at an altitude of 4,000 to 5,000 feet, and has long-stalked, radical leaves, about a foot long, and so like the fronds of a small Lastrea or Aspidium as to be easily mistaken for a fern, especially before the development of the flower-stems. The latter are long, slender and weak, and evidently clamber over other plants. In shape and cutting the leaves borne on the flower-stems are very similar to those of the white thorn, *Cratægus Oxyacantha*. The flowers are not large, and apparently inconspicuous, though their color is unknown. As an ornamental plant, however, *P. vagans* is far surpassed by many of the new Chinese species. Among them *P. superba* and *P. Rex;* the latter, having a large, hood-shaped upper lip, is also found in eastern India. Two other fine Indian species also occur in western China, named *P. labellata* and *P. Elwesii;* both dwarf plants with numerous stems, the latter having very large, dark purple flowers.

P. Przewalskii, in stature and size of flowers, resembles the Indian *P. bella*, described above; but the singularly beaked upper lip and broadly lobed lower lip of the corolla give the

* Most of the facts in this article have been drawn from an address delivered in 1888 at Berlin by Professor Dubois-Reymond, printed in the *Deutsche Rundschau*, and translated in the *Popular Science Monthly* for December, 1890. The portrait which accompanied the translation showed the youthful Chamisso—Chamisso the poet—with strong features, somewhat like those of Schiller, although less pronounced, a smoothly shaven face and long, thick, light hair falling in curls on the shoulders.

† While writing this I have received the news of the unexpected death of this distinguished botanist. It was known to us that he was in bad health, but we were quite unprepared for the sudden event, which has deprived Russia of her foremost botanist, and the botanical world of the highest authority on the flora of central and eastern Asia.

flower the appearance of a large-beaked bird with outstretched wings, only the beak is turned over the back. The flowers appear to be of a beautiful bright red. *P. Chinensis* has white or pale yellow flowers, with an exceedingly slender tube three inches in length. *P. muscicola*, as the name denotes, grows among moss. It is of very slender habit, with solitary axillary flowers, about two inches long, and of a deep purple red. *P. macrosiphon* is a closely allied species with even longer flowers. But almost all of the species are beautiful, and I must break off here.

Kew. *W. Botting Hemsley.*

New or Little Known Plants.

Bessera elegans.

SUMMER-BLOOMING bulbous plants succeed as a class in our climate, and deserve more general attention at the hands of cultivators than they receive. A few intelligent and enthusiastic amateurs grow them successfully, and obtain a great deal of pleasure and satisfaction from doing so; but, with the exception of some of the hybrid Gladioli, such plants are practically unknown in most of our gardens.

The pretty liliaceous *Bessera elegans*, which is represented in the illustration on page 125, is one of the best plants of this class. It is a native of the mountains of southern Mexico, and, if treated like a hybrid Gladiolus—that is, if the bulbs are lifted in the autumn and stored during winter in a dry place and replanted in the spring—it can be grown with perfect ease, and will repay the little care it requires with its bright flowers, which open in succession during fully two months of the late summer and early autumn. They are vermilion red, variously marked with white on the inner surface of the perianth-lobes and on the tube formed by the enlargement of the bases of the filaments which characterizes this genus. The beauty of the coloring of the flowers is intensified, too, by the bright purple of the anthers.

Bessera elegans was introduced into Europe many years ago, and has been described under two or three different names based on slight variations in the color of the flowers. Very little has been heard of it, however, in cultivation of late years until a year or two ago, when one of the seedsmen of this city succeeded in obtaining a supply of the bulbs, which are now offered for sale.

Our illustration is made from a plant furnished for the purpose by Mr. Atkinson, gardener to John L. Gardener, Esq., of Brookline, Massachusetts.

New Orchids.

Cypripedium insigne, var. longisepalum, Rolfe, is a distinct and very remarkable variety of the well-known *C. insigne*, which appeared in a batch of the ordinary form imported by Messrs. F. Sander & Co., of St. Albans. Its chief peculiarity consists in the long and narrow sepals, which measure two and a half inches in length by only one inch in width. The dorsal one is also unspotted and with the white opical area reduced to the smallest dimensions. The lip and petals are normal in character.—*Gardeners' Chronicle*, January 17th, 1891, p. 72.

Cypripedium × Celia, Rolfe.—This is a very pretty hybrid raised in the collection of Wm. S. Kimball, Esq., of Rochester, New York, by Mr. George Savage, probably between *C. Spicerianum* and *C. tonsum*. The record of parentage was unfortunately lost, but there is abundant evidence of the former in the hybrid, while characters of the latter are apparently present in the leaf, dorsal sepal and staminode, if not also in the petals, and it is known that the two species were hybridized together.—*Gardeners' Chronicle*, January 24th, 1891, p. 104.

Dendrobium niveum, Rolfe.—This is the *Dendrobium Macfarlanei*, Rchb., f., which, unfortunately, must bear a new name, there being a species of the same name described seven years earlier by F. Mueller, also from New Guinea, and belonging to the section Aporum. *D. niveum* is a magnificent species, with pure white flowers which measure four and a half inches in diameter. It has again been introduced from New Guinea, this time by Admiral Fairfax.—*Gardeners' Chronicle*, January 24th, 1891, p. 104.

Cypripedium × Berenice, Rolfe, is a fine and handsome hybrid, raised in the collection of Captain Vipan, of Wansford, from *C. Roebelenii*, a variety of *C. Philippinense*, fertilized with the pollen of *C. Lowii*, and thus the first hybrid whose parents both belong to the racemose-flowered group. It is generally intermediate in character, and combines the characters of the two species in a very pleasing manner. The petals are drooping, narrow, over five inches long, and spirally twisted.—*Gardeners' Chronicle*, January 31st, 1891, p. 136.

Restrepia striata, Rolfe.—This is a most distinct and pretty species, with the habit of *R. antennifera* and its allies. Instead of being spotted, however, the lateral sepals are striped with seven sharply defined maroon lines on a yellow ground, the lines being a little narrower than the intervening spaces. It exists in two or three collections, but I am not sure who first introduced it. Schlim met with it and sent home a drawing, but probably no living plants. Messrs. Hugh Low & Co. introduced plants from the Cauca range, in New Granada, which flowered in January, 1890, but at Glasnevin it flowered nearly a year earlier, though whether from the same source I am unable to say. It is a very charming little species.—*Gardeners' Chronicle*, January 31st, 1891, p. 137.

Plant Notes.

Some Recent Portraits.

Monsieur Carrière, in the issue of the *Revue Horticole* for February 1st, figures a Cherry under the name of *Prunus Capuli*, which is occasionally met with in French gardens. It is, we suspect, only a form of *Prunus serotina*, and not the Cherry of western tropical America and Mexico. Judged by the figure, it resembles very much that form of *Prunus serotina* which occurs in some parts of New Mexico and Arizona, and which has usually been referred by American botanists to the Mexican *P. Capuli* of De Candolle, which itself may be found to be not specifically distinct from our common Wild Cherry of the northern states. Unfortunately, sufficient material does not exist in herbaria to determine satisfactorily the specific characters of the Mexican and Central American Cherry, which may be expected, however, to differ from the tree found farther south.

A full-page illustration in the *Gardeners' Chronicle* issued on February 14th is made from a photograph of a field of Daffodils grown in the Scilly Isles, and gives a better idea of the extent and importance of the cultivation there of these flowers than any description could. It appears that in 1887 and 1888 as many as ten tons of flowers, principally Narcissi, were exported from Scilly into England. The business, however, has increased, and is increasing very rapidly, and last year the maximum export of flowers on any one day reached the total of fifteen tons. Such a field of flowers as this picture portrays would be worth a trip across the Atlantic to see.

The colored plate of *The Garden* published on the 14th of February is devoted to a beautiful Mexican Ipomæa, generally known in gardens as *Mina lobata*, a plant remarkable for the structure of the flower, the limb of the corolla being shaped like an oblong five-cornered bag, the base being turned so much upward by the tube as to be hidden from view. The inflorescence is racemose, upright and arranged something in the manner of that of the Borage family; the flower-buds are a bright rich crimson, changing from orange to pale yellow as they open, and as the flowers appear at all stages at the same time produce a charming and unusual effect. *Mina lobata* can be started in a warm house in the spring, and then planted out against a fence or arbor, and will then grow rapidly to the height of twelve or fifteen feet by midsummer and flower profusely. The racemes are usually branched, twelve or eighteen inches long, and sometimes produce thirty or forty flowers, which are each about an inch long. Seeds are produced when the season is long enough, and germinate readily, or the plant can be propagated by cuttings.

Foreign Correspondence.

London Letter.

Auction Sales.—An enormous number of plants of all kinds are now distributed in London by means of public auction sales. A few years ago the only salesman of note was Mr. J. C. Stevens, whose weekly sale in his rooms near Covent Garden Market was limited almost exclusively to Orchids, and generally newly imported plants only. Now Mr. Stevens has two or more sales of Orchids every week, and Messrs. Prothero & Morris have at least the same number of Orchid sales in their rooms at Cheapside. Besides these there are several sales every week of bulbs, Palm-seeds, fruit-trees, Roses, herbaceous

plants and all kinds of hardy trees and shrubs. These are mostly offered by samples sent to the auction rooms, the vendors undertaking to forward the plants direct from their nurseries to the buyers. In this way nurserymen find a ready means of disposing of surplus stocks, and although some of the prices realized are not remunerative to the growers, it frequently happens that higher prices are obtained in the auction rooms than would be asked in the nursery.

Fig. 24.—Bessera elegans.—See page 124.

Great quantities of Orchids have already been disposed of by auction this year notwithstanding the unfavorable weather. *Lælia grandis* was offered by the thousand last week; enormous masses of *Dendrobium Dalhousieanum*, *D. Wardianum*, *Vanda Sanderiana* and other choice tropical East Indian Orchids have also recently found a ready market in the auction rooms. This week brings quantities of newly imported plants of the pretty new *Odontoglossum Noezlianum*, which may be called an orange-red *Mesospinidium vulcanicum*, and is likely to prove a good garden Orchid. There are also other novelties and rarities which will shortly find their way to the auction rooms, but which I am not in a position to name at present. On the whole this means of distributing plants has its advantages both to vendor and purchaser. At the same time it offers an opening to dishonest dealers who prey upon the ignorance of many who attend these sales. We sometimes hear of wonderful things being bought at an auction sale for "a mere song"; but we rarely hear of the heart-breaking disappointment of the purchaser who gets only rubbish for his pains, and, sometimes, big prices. These things, however, must be at auction sales of all kinds.

A Fatal Year.—A winter which will certainly stand out among the bad winters of this century has been destructive not only to many good plants, but has killed off many good men besides. This week we have lost three of the leading lights in the English horticultural world. Mr. John Dominy, who served Messrs. J. Veitch & Sons over forty years, and who raised not only the first, but many of the finest, hybrid Orchids we possess, died suddenly last week, at the age of 75. The genial, clever manager of the Clapton Nurseries, Mr. Frank Casey, fell dead at a railway station only a few days ago, and last Tuesday the venerable secretary of the Gardeners' Benevolent Society, Mr. E. R. Cutler, died suddenly at Wimbledon. The first and third men were ripe in years, and have left behind them a record of good work which will not soon be erased; but Mr. Casey was scarcely beyond the middle age, and died in harness.

Three Good Garden Palms.—*Chamædorea elatior* is a Palm of quite exceptional value. Among the many species of this genus in cultivation it is the only one that may be grown in an ordinary greenhouse temperature. It forms a tuft of bamboo-like green stems, about eight feet or less in height, and each stem bears an elegant head of dark green pinnate leaves. From its habit of throwing up stoloniferous offsets freely from the base, it may be propagated by division in the same way as answers for Rhapis. At the French exhibition,

two years ago, there were some magnificent specimens of this Palm shown from Algeria.

Phœnix Rœbeleni has behaved perfectly in the exceptionally trying conditions that have prevailed during this winter, the plants at Kew being now as healthy as one need wish. I anticipate considerable popularity for this Palm and hope that the quantities of seeds mentioned by Mr. Roebelen, its discoverer in Siam, will soon find their way into gardens. Like the Chamœdorea this Phœnix may be multiplied by means of offsets.

Rhopaloblaste hexandra is an elegant Palm in the way of *Geonoma gracilis*, and, apparently, as easily grown as that popular species. It has been in cultivation some years at Kew, having been obtained from Java. Mr. Bull offered it among his new plants of last year, and published a characteristic figure of a young example in his catalogue. The genus is related to Ptychosperma, and is composed of three species, natives of the Malay Archipelago. *R. hexandra* ultimately forms a stout, erect stem, bearing a wide-spreading head of arching, feathery, pinnate leaves. Plants only a foot high are pretty in foliage and habit. It requires stove treatment.

A Hybrid Brownea.—Several hybrids have been raised in gardens from the cultivated species of Brownea, the best of them being the result of a cross between *B. macrophylla* and *B. grandiceps*. This was raised by the late Mr. Crawfurd, of Lakelands, Cork, and flowered by him several years ago. Mr. Crawfurd had formed a fine collection of Browneas, which, after his death, were divided between the botanic gardens at Glasnevin and Kew. The hybrid above named is now flowering freely in the large Palm House at Kew. The plant is twelve feet high, has large pinnate leaves like those of *B. macrophylla*, and large terminal clusters of salmon-red or flame-colored flowers. The individual flowers are larger than those of *B. grandiceps*, being almost as large as the flower of *Lapageria rosea*. There are about sixty flowers in each head, but they are packed so tightly together that they do not appear to be so numerous. *B. macrophylla* differs from all other Browneas in its habit of producing its large clusters of brilliant red flowers on the stem, never at the ends of the branches. A figure of it was published in *Botanical Magazine* (t. 7033). In *B. grandiceps* the flowers are always terminal. For large tropical houses this hybrid will prove at least as useful as *B. grandiceps*, perhaps the best known of all. The large specimens of Browneas in the Palm House at Kew never miss flowering freely in February and March. Besides those above named we also have in cultivation *B. coccinea*, *B. Ariza*, *B. capitella*, *B. coccinea* × *latifolia*, *B. Ariza* × *grandiceps*, and *B. Leopoldii*.

A tall, single-stemmed plant, long cultivated under the name of *B. princeps*, was flowered by Mr. Crawfurd in 1888. It proved to be a Talisia, a genus of *Sapindaceæ*, very far removed from *Leguminoseæ*, the order to which Brownea belongs. A figure of the Talisia, which Professor Oliver named *T. princeps*, was published in Hooker's *Icones Plantarum* in 1889. It was introduced by Linden many years ago as *Brownea princeps*, and by Loddiges as *B. erecta*. It has also been called *Theophrasta pinnata*. In the Kew Palm House there are a pair of tall specimens, one of which is forty feet high, with a magnificent head of foliage.

Cultural Department.

Chrysanthemum Queries.

A FEW weeks ago, Mr. John Thorpe read a paper on Chrysanthemums before the Massachusetts Horticultural Society, and from it we have already made some quotations. After the paper had been read, many of those who heard it made inquiries on various points suggested in the discussion, and Mr. Thorpe replied. We give below a selection from these questions and their answers.

"What is known of the new, early varieties offered by European growers?"

This is a matter of importance to those who have no greenhouses, but it should be said that, with one or two exceptions, the early-flowering varieties raised in Europe have not given satisfaction, because of their inability to withstand the excessive heat of our summers. It will be reasonable to expect a few of the many early varieties offered by Delaux to succeed, but just how many, time and experience alone can tell. The moist and temperate climate of France and England, where Chrysanthemums do well out-of-doors, is very different from ours. If we desire to secure a series of early-flowering varieties, which will withstand the vicissitudes of our climate, we must raise our own seedlings and save none but the sturdy ones which prove their ability to endure our trying weather. Delaux claims that his set will begin to flower as early as July 15th. We have already several pompons that would flower by that date if they only could be induced to grow. What we need is a series beginning to flower not earlier than September 1st, of stout, compact growth, bright, healthy foliage, with good-sized flowers of distinct and desirable colors. M. E. Nichols is a variety having some of these good points; it is a sturdy grower, it has thick, leathery leaves, the flowers are of medium size, but rather undecided in color, and it blooms about October 5th. Harvest Queen is a good white, and so is Madame Lacroix, and they bloom about October 15th; the flowers of the two last named are much better, however, when grown under glass.

"Which is the best early variety for cut flowers for market?"

That depends upon what color is desired. The best white is Jessica, the best yellow Rohallion, followed by Gloriosum five days later, or about October 15th. It is astonishing how much difference five days make in market prices.

"What variety remains longest in perfection?"

Different flowers, according to the time of year. The duration of bloom varies from twelve to twenty days. By judicious selection and special cultivation, Chrysanthemums can be had in bloom from January 1st to December 31st; the blooms probably will not all be of the first quality as to form, size, substance and color as they are when flowered in autumn, but they will have enough good points to make them acceptable. For ten years I have never been without Chrysanthemum flowers. We have only to remember that they are herbaceous plants, which, when they start to grow, keep on until they produce buds and flowers. It should not be inferred, however, that much is gained by this interfering with their natural time of flowering. Strawberries are best in June, and Chrysanthemums are best in November.

"Is it wise to award prize medals for new varieties upon the exhibition of the first flowers, or should awards be deferred until the superior character of the new plant has been established?"

The first year my seedling, Mrs. Cleveland, flowered I considered it a capital prize. It was propagated and sold the following spring, and when it flowered the second year, instead of proving itself a gem of the first water, it fell as low as the third class. Seedlings should always be tested more than one season, and no prize should be awarded to any until its superiority in character and habit is fully established. It is unwise for a grower to offer to the public any new plant or flower until its merits are shown to be greater than those of existing kinds, especially when varieties are so numerous, and in many cases so excellent.

"Is there any remedy for the little insect-hopper that so injures the plants out-of-doors during summer?"

Professor E. V. Riley, of the Department of Agriculture at Washington, has taken a great deal of interest in the investigation of this enemy, which attacks not only Chrysanthemums, but Asters, Golden-Rods and other composites. The female stings the stems of the plants to deposit her eggs, causing a disorganization which is shown by numerous excrescences.

The best preventive I know is a solution of one ounce of bitter aloes in four gallons of water, and with which the plants should be syringed twice a week from July 1st to the middle of August.

"Can the Chinese incurved varieties shown here take rank with those grown in England?"

There are many of the finest old-style, incurved flowers, such as Queen of England, Mrs. Shipman and Princess of Wales, that do not do at all well here, whereas in England they are most popular and give great satisfaction. I have yet to see a really first-class dozen of these kinds in America. Climate must account for this, as we have as much skill and as good appliances as any country has. I have never seen two dozen of these shown on one stand in America that would rank as second, or hardly as third-class in England. The specimen-plants of the old incurved kinds are not equal in quality to the cut flowers. That famous variety, Mrs. Rundle, and the two sports from it, always appear in competitive groups. Two out of the three Rundles will be found in any competition of six varieties, and in nine or more varieties it is almost a certainty that all three will be shown.

"Where did the best twelve Japanese varieties originate—in Japan, America, France, or England?"

Probably the best twelve now are direct importations from Japan, but by next year, or the year after at the farthest,

The Rose-tree of Hildesheim.—See page 122.

twenty-four American-raised seedlings will be in cultivation, that will beat twenty-four from any other country. This is because so many are engaged in raising seedlings and also because the standard of requirements has been raised. There are now a great many seedlings on probation, and if they prove as good as when seen last season, they will give us these additional good varieties.

"What are the very best late kinds to have in flower at Christmas?"

Mrs. Humphreys, Ethel, Mrs. H. J. Jones, and Governor of Guernsey are late-flowering kinds. But it depends largely upon the manipulation of the plants. For example, if the plants are allowed to become very dry in August, and the wood ripens, they will flower by the middle of November; but if they are kept growing, and the wood remains soft several weeks later, they will then flower in December. It is not a question so much as to when the cuttings are taken as it is how continuously they are kept growing after they are rooted, up to, say, eight weeks before they are required to be in flower. Perhaps it would be better to take cuttings later rather than very early of late-flowering kinds.

"What are the best six varieties for market cut flowers?"

I should rather name a hundred, since the grower would doubtless want them coming into the market from September 1st to January 1st, in all the popular colors, such as yellow, white, pink, bronze and red, with a few fancy or parti-colored varieties. Then, as Chrysanthemum flowers last about fifteen days, for the 120 days between September 1st and January 1st it would take eight varieties at least for one color alone; therefore it will be seen that at least thirty or forty sorts are required to fill the bill.

Mr. Thorpe gave the following list of Japanese Chrysanthemums as being of great merit: Twelve from Japan direct—W. H. Lincoln, Volunteer, Lilian B. Bird, Mrs. Alpheus Hardy, Louis Boehmer, Kioto, Mr. H. Cannell, Christmas Eve, E. G. Hill, Comte de Germiny, G. F. Moseman, Robert Bottomley.

Twelve American seedling varieties—Violet Rose, Mrs. M. J. Thomas, Minnie Wanamaker, Harry E. Widener, Ada Spaulding, Carrie Denny, G. P. Rawson, Excellent, Maunda, Miss M. Wheeler, Mrs. Bowen, and Cyclone.

Twelve varieties raised in France—Belle Paule, Ceres, Etoile de Lyon, Margot, L'Incomparable, M. Bernard, Roi des Japonais, Madame C. Audiguier, Val d'Andorre, Boule d'Or, Alcyon, Jeanne Delaux.

Twelve varieties raised in England—Elaine, Eynsford White, Sunflower, Martha Harding, Joseph Mahood, Fair Maid of Guernsey, Carew Underwood, James Salter, Mrs. Falconer Jameson, W. Mathews, Stanstead Surprise, William Robinson.

Hardy Plants from Seed.

NEARLY all hardy plants may be raised from seed in the open air, with greater or less satisfaction. For the mere purpose of keeping up stock of easily managed, vigorous kinds, it is in no way necessary to incur the additional labor of raising them under glass; generally speaking, they require as much labor and attention, when so treated, as more expensive plants. With a numerous group, such as Delphiniums, which rarely bloom the first year from seed, and some, such as the herbaceous Pæonies, that are slow to germinate, even when raised under glass, there is really nothing to gain, in point of time, by raising them in a more troublesome way; and unless we have reason to suspect that, on account of long keeping, the vitality of the seeds is low, and that they would therefore have a better chance under glass, all of them may be sown out-of-doors. New and rare subjects, however, and choice species and varieties, that it is desirable to make the most of, had better be sown under glass; and some Pentstemons, late-blooming Phloxes, Œnotheras, Verbascums and Gaillardias, which, if sown early, bloom the first year. For sowing out-of-doors a sheltered border should be chosen, and one that is easily accessible from all sides. The seeds should be sown thinly and watered carefully. Seedlings may be transferred to nursery beds as soon as they are large enough to handle.

The luxury of a hot-bed, or even a cold frame, for raising plants from seeds, has many advantages, and will well repay any who can afford it. If a hot-bed is used, a cold frame should be handy to place the pots or pans of seedlings in as fast as they germinate, because the close conditions essential to germination are detrimental to the healthy condition of the seedlings after that stage. Sand or coal-ashes are equally good as a plunging medium in hot-beds. Good light loam is the best soil to use, from which the rough portion has been separated by a coarse sieve; and this refuse is very useful to place over the drainage. The soil should be pressed firmly, and the seeds, except the largest, covered thinly. The frame had better be kept rather close, and some kind of shading used, instead of much airing, which only dries up the soil. When the weather becomes settled in May, seedlings, as fast as they can be handled, may be planted in nursery beds; excepting only such as grow slowly, or Alpine garden subjects, which had better be put in shallow boxes, and kept where they can be cared for. These nursery beds should be covered with light litter or Pine-leaves the first winter.

Wellesley, Mass. *T. D. Hatfield.*

Tree Ferns.

THE Ferns of arborescent growth include many of the most noble and graceful species in this vast order, and wherever sufficient space is at command some Tree Ferns should find a place. Many of these plants may be grown in a moderate temperature; in fact, some few of them will stand a slight frost without injury if they have been grown in a low temperature generally, so that the fronds are of stout texture. Their chief requirement as to soil is a good open mixture, and this may be composed of about equal portions of peat and loam, or a little excess of peat may be used if the loam is heavy, and sufficient coarse sand may be added to make it quite gritty. The material should be quite coarse and fibrous, for, although Tree Ferns require firm potting, the soil should always retain its open character, and sufficient drainage material of either pot-sherds or charcoal, or both, should be used. If the specimens have attained considerable size the growth will be strengthened by tying sphagnum moss around the trunk from the surface of the soil upward, and the moss being kept damp will soon induce a growth of fresh roots all around the trunk, and in a short time these will form a perfect mat in the moss, and then find their way down into the soil.

During the summer syringing overhead is practiced by some growers, but if the atmosphere of the house is kept moist by frequently dampening the floor end underneath the benches the syringing will not be essential; and, indeed, unless done by an experienced man, it had better be neglected altogether. Among the species to which the name of Tree Ferns may properly be applied the following are a few of the notably handsome plants which are easy to manage:

Dicksonia antarctica.—This is one of the most widely known of its class, and deservedly so, for, though specially interesting when it has attained large size, it is also remarkably handsome while small. It has tripinnate leaves of dark green color, the upper side being quite glossy while the lower is much lighter in color. In Australia it sometimes attains a height of thirty to thirty-five feet, and is crowned with a majestic head of fronds that are ten to twelve feet in length. Many stems, some of them of quite large size, have been imported from time to time, and among these may be mentioned some nice plants about ten feet in height, which can now be seen in Horticultural Hall, Fairmount Park, Philadelphia. These have been established there for several years, and are now a marked feature of the Fern-house.

D. squarrosa.—This is much smaller than the preceding and forms a more slender stem, which has the peculiarity of sometimes branching when old by means of young plants formed on the stem. It produces fronds from three to six feet long and somewhat rigid in habit, so that they stand out at right angles to the stem. The fronds are tripinnate and dark green.

D. Schiedei.—This most graceful Fern may be more easily recognized by many under its old name of *Cibotium Schiedei*, and it is one of the most attractive and elegant Tree Ferns in cultivation. It makes a stem but slowly, and consequently is not likely to outgrow its quarters in that respect very soon, but the fronds are very large, often reaching a length of ten feet or more. They are bipinnate, the pinnules being long and pendulous, light green above and glaucous beneath, and the crown of the plant as well as the stipes are thickly covered with long silky brown hairs.

The Alsophilas comprise another fine group of arborescent Ferns, many of which are quite large growers, and several of them suitable for cool-house culture. The most widely known of this genus is *A. australis*, a fine greenhouse Fern, with bipinnate fronds that sometimes attain a length of twenty-five to thirty feet. It is a rapid grower and requires an abundance of water, especially if placed out-doors in the summer, for which purpose it is well adapted if it is placed where it can be protected from the sun.

A. ACULEATA.—This is a smaller Fern, with a stem some five or six feet in height, armed with long, sharp thorns, as are also the stipes. Its fronds are tripinnate, and of a size proportionate to that of the stem. It comes from tropical America, and makes better growth when cultivated in a warm house.

A. EXCELSA is another of the large species, and reaches a height of thirty feet. It bears some resemblance to *A. australis* in general outline, but is even more hardy than that fine species. Its fronds have much substance, and it may be used out-of-doors in summer, as well as for house-decoration.

A. REBECCÆ is of much more recent introduction than those named above. It is a cool-house species from Australia. Its fronds are bipinnate and dark green in color, and the plant attains a height of about eight feet.

THE CYATHEAS include such good plants as *C. dealbata*, with large fronds that are quite finely cut and almost white beneath; *C. medullaris*, a very large Fern, with fronds ten to twelve feet long, stipes almost black, and the crown of the plant covered with black chaffy hairs; a good plant for cool treatment; *C. Dregei* and *C. princeps*.

As has been said, young plants of *Dicksonia antarctica* are suitable for even a Fern-house of very modest dimensions, but there are small Tree-ferns besides well suited to small houses. Some of the best of these are *Bleechium Brasiliense*, *Lomaria gibba* and *L. cycadoides*.

Holmesburg, Pa. *W. H. Taplin.*

Clianthus Dampieri.

THIS plant, also known as the Australian Glory-pea, is a truly beautiful one when in flower, but, as is well-known to all who have attempted its cultivation, there could scarcely be a more fickle subject. Much has been written on the treatment of this plant, and, curiously enough, those who have succeeded with it are all equally emphatic in commending their several methods, which, it is hardly necessary to add, are widely different. It is not because I have discovered any new way of treating this plant, but from the fact that seeds were sown last September in a cool greenhouse, and a plant produced therefrom is now in flower, that I am tempted to record the fact that others may do likewise. The seeds were few in number, and were sown in a four-inch pot, and when the pot was full of roots the ball of soil, without any disturbance, was shifted into a six-inch pot, and as red spider does not seem to have attacked the plant, it is still in good health, and other flowers are showing for future display. To those unacquainted with the plant, it may be well to explain that the prevailing color of the flower is bright red, the lower part or keel bearing a strong resemblance to a lobster's claw, to which it has often been likened. The upper half of the flower is almost black, with a small blotch of white. This is the typical plant. There is also a variety known as *C. marginatus*, in which the color of the claw is white, margined with red, giving the plant a most distinct appearance. An excellent colored figure of this variety appeared in the London *Garden* a year ago. It appears that Louis Viewig, of Quedlinburg, Prussia, has hit upon the plan of grafting *C. Dampieri* upon the much hardier and more easily grown *C. punicens*, which gives it a much better constitution and longer life. Grafted plants are offered at very low prices, and should be worth the notice of some of our enterprising nurserymen and seedsmen. It may also be remarked that the white-margined variety has been named "Deutsche Flagge," the colors being red, white and black. Those who attempt the cultivation of the Clianthus should use light soil composed of loam, leaf-mold, a little charcoal, and enough sand to make the soil porous, and when potting it on they should take care not to injure a single root-fibre. Gareful attention also should be given to the watering. *Clianthus punicens* is itself a very beautiful plant. Years ago I remember to have seen a fine plant growing out-of-doors in a sheltered position on a south wall, which every summer flowered profusely, and was a beautiful object. *C. punicens* could not be grown here in New England in this way, but is well worth trying in a greenhouse, however limited the space, as it could be planted out and trained up the rafters, and if freely syringed red spider could be kept away much more easily than would be the case with *C. Dampieri*, the foliage of the latter being densely clothed with a woolly covering, and therefore an excellent refuge for this minute pest.

South Lancaster, Mass. *O. O.*

Chrysanthemums.—Mine are now well established in three-inch pots, and are breaking after the first stop. I shall repot about the 20th of March into six-inch pots, and about the first of April shall remove into a cold frame, which will be kept only warm enough to be frost-proof. My plants are thus kept healthy and stocky, and are thoroughly hardened by the time I put them into ten-inch and twelve-inch pots, the final size, in May. For the last shift I use good heavy loam, previously enriched, with a sprinkling of oyster-shells, as our soil is almost devoid of lime; coal ashes answer just as well. I return the plants to the frames so as to be able to cover them with sashes in case of heavy rain, which soddens and sours the soil.

Wellesley, Mass. *T. D. H.*

Lilium Wallichianum superbum.—The introduction of this superb Lily will again call attention to that group of Indian Lilies of which *L. Nepalense*, *L. Neilgherrense* and *L. Philippinense* are representatives. It is well known to cultivators of Lilies that the members of this group have always been difficult to manage, the trouble being that they are very excitable, delicate in growth, and make but few roots. From information I have just received it is evident that this new variety of *L. Wallichianum* does not manifest the weakness of its relatives. A plant which grows six feet high and carries eleven flowers and requires scarcely any support, is certainly a vigorous one and different from the ordinary run of Indian Lilies. It must be borne in mind that this group will not endure rough treatment, and demands the protection of a greenhouse from September to May. If *L. Wallichianum superbum* ever gets cheap enough for florists to grow in quantity, what a magnificent Easter Lily it will be! The coloring of its immense trumpet-shaped flowers is most beautiful—a rich golden yellow and white inside, bronzy brown and white on the outside.

The type, *L. Wallichianum*, was introduced into England forty years ago.

Pearl River, N. Y. *John Thorpe.*

Euphorbia jacquiniæfolia.—This useful old plant, with its long slender sprays of rich crimson flowers, is very ornamental in the greenhouse now, and for cut flowers it is unsurpassed. It does well with the same treatment as that given to the Poinsettia; in fact, I grow the two on the same bench and treat them exactly alike, except that the Euphorbia is not cut back quite so severely as the Poinsettia, although, while growing, I pinch it back quite freely to make it more bushy.

Chorizema cordatum.—This is a showy greenhouse plant with Pea-shaped flowers, colored orange and red, and produced freely in long terminal racemes. It flowers in early spring, and delights in a light rich soil, with plenty of water while growing. When it has made its growth it should be kept a little drier until fall, with abundant sunshine to ripen the wood. When repotted in autumn it should be cut back quite severely and set in a warm, sunny position. As soon as the new growth begins a good supply of water will again be required.

Maywood, N. J. *J. S. T.*

Correspondence.

The Wissahickon Woods.

To the Editor of GARDEN AND FOREST:

Sir.—The articles that have appeared in GARDEN AND FOREST from time to time, on communal forests, and the care and management of municipal forests, have been instructive and interesting to American readers. The land tenure here is so different from that prevailing in Europe that it might be very difficult, if not impossible, for the Government to own and cultivate land in the older states. If the Government undertook to buy the holdings of the people a great expenditure of money must be made.

All municipalities require open-air spaces. Philadelphia enjoys excellent facilities in this respect. Fairmount Park was created (1) for the protection of the water-supply of the city, (2) for the maintenance and preservation of pastoral scenery, and (3) as a pleasure resort. Philadelphia's only available water-supply is derived from the Schuylkill River. Pumping stations and subsidence reservoirs have been constructed from time to time to utilize this supply. The growth of the city along the river front, and the erection of large woolen and cotton works, have seriously impaired the supply. The present Fairmount Park was secured as a preventive measure against the pollution of the streams within the county limits. Two thousand seven hundred acres of land were thus set aside; still the purity of the water was found to be below the standard. The cause was sought for. The Wissahickon, the main affluent of the Schuylkill within the county limits, was found at fault. A belt of land five miles long on either side of the stream was secured. All the mills, nearly twenty in number, were purchased and removed.

The Wissahickon is one of the most romantic of American streams. The slopes on each side are high and abrupt. "Self-guarded by these rock battlements, it retains that primeval character, in which, let us hope, it will always be preserved. Along its banks trees and vines hang down to the water's edge, and numerous springs drip from the rocks. Its unbroken quiet, its dense woodland, its Pine-crowned hills, its sunless recesses and sense of separation from the outer world, contrast strongly with the broad meadows, the open-flowing river, and the bright sunshine, which characterizes the adjacent region. It is a chosen spot."

If left open to the public as it now is, without adequate police supervision, its natural beauty must soon fade. The younger growth will be tramped down, and in a few years its charm will be gone. A systematic care of these densely wooded hills, and a wise financial management, will preserve this most natural of all spots to the country forever. A large amount of the present growth has reached maturity. A careful and scientific thinning might be of the greatest advantage. Some system might be carried on ; regeneration under shelter wood, either in compartments or single trees, or a combination of seedling and coppice forest. At the present time, when a tree falls, that is the end ; no other tree takes its place. This should not be so, for in a very few years there will be no woodland left.

If we can profit by European experience, this forest might be so managed as to pay the expenses of its maintenance. Mr. Pinchot, in his excellent article in Garden and Forest (vol. iii., p. 398), says : "But the interest of the citizens of Zurich in the Sihlwald is far from being centred in the substantial return which it makes to the city treasury. Its second interest lies in the qualities of a great city park, which it unquestionably presents. It has been the wise policy of Herr Meister to maintain throughout the forest a network of well-kept roads and paths, to place occasional benches along them, to keep the beauty of the landscape unharmed, and in general to make the Sihlwald thoroughly and pleasantly accessible. In so doing he has secured its future by demonstrating to the people the utility and value of their ownership. The question naturally arises whether the multiform advantages to be derived from such a city forest in Switzerland might not be enjoyed in America ?"

Why not make the Wissahickon woods the municipal forest of the city of Philadelphia ? Let it become the first American Sihlwald. It will be of inestimable advantage to the city. The water-supply will remain pure, and it will yield a revenue large enough to meet the expenditures for maintenance and salaries of expert foresters. A great advantage would be gained even if no surplus is derived. By united action on the part of the people the city fathers might no doubt be convinced of the benefit to be derived from such a forest. A great expenditure need not be made at first, and in a few years the forest might become self-supporting. A demonstration here of the advantages derived from a scientific supervision of a municipal forest would not only prove a blessing to Philadelphia, but might serve as a stimulus to similar movements throughout the country.

Philadelphia, Pa. *J. W. Harshberger.*

Winter Flowers in California.

To the Editor of Garden and Forest:

Sir.—The few words from Mr. Purdy in your last issue prompt me to send some notes of the plants that are blooming in my yard this last day of winter. There are eighty-eight in all, and since New Year's on almost any day fifty plants might have been counted in flower, though only in a few cases freely blooming. The finest single plant at present is *Doronicum Caucasicum*, with the clear yellow of its ray and disk, and the fresh pale green of its leaves. After this comes *Aubrietia purpurea*, then *Triteleia uniflora* with its variety Alba, and a white-flowering Allium, which I suppose to be *A. Neapolitanum*. Another mass of white is made by a wide-spreading *Iberis sempervirens* and a group of Empress Candytuft, while *Phlox subulata*, with its white variety thrown into contact, spreads over the ground like heavy splashes of color from a brush, and makes a pretty edging to several beds. *Phlox amœna*, slightly taller than *P. subulata*, would doubtless make quite as attractive a plant as the latter, but the specimen I have has not had time to grow so as to exhibit its full value. *Lobelia Erinus* and the Heliotropes are flowering with nothing but the eaves of a gable to protect them. There is always sufficient frost here to kill these plants when exposed. This winter, however, has been a mild one, no snow appearing on either of the ridge-walls that enclose our valley until this month, and then only upon the highest elevation of the one to the eastward, Mount Hamilton, the site of the Lick Observatory. This forbearance on the part of the weather has perhaps saved a rectangular mass of thirty by thirty-six inches of *Mahernia odorata*, just now completely covered with buds. This plant is really a trailer, and, it seems to me, would appear well falling over a wall, or down a stony incline. The Hellebore does well here without protection, and many kinds of Oxalis would certainly pass the winter unharmed. One plant of *O. cernua* was somewhat affected by frost last month, but has now nearly recovered, while other plants of the same species seem not to have been touched. *Teucrium frutescens* is a beautiful plant of a gray-green aspect, the upper part of its leaves very dark green, the lower part, with the stems, silvery, and the flowers pale blue. Over the plant I have is cast the spray and golden balls of a variegated *Coronilla glauca*, and the combination is not inharmonious.

Six of the plants in flower, the Ox-eye Daisy being one of them, merely show a few flowers, probably left over from the previous season, but all the rest are making their regular spring display. Several plants are already out of flower—the white and yellow Crocus, the Snowdrop, Winter Aconite and *Phlox procumbens*, while the Narcissi are rushing rapidly through their too short season.

With favorable weather *Alyssum Wiersbeckii* will, within a week, eclipse all other yellows with its abundant bloom, and the Peach, whose branches touch the house-wall, will have every twig decorated with rosy blossoms. This Peach-tree loses all of its leaves by a fungal, or insect attack, early in the spring, and is afterward reclothed, the second dress being retained well into winter, and the last leaves falling unfaded about the first of January.

One word is needed for the Correa, which is now seen at its best. A lady, who yesterday saw it for the first time, exclaimed, "Why, it is really finer than the Fuchsia," and she came, too, from Santa Cruz, where the Fuchsia ranks with the showiest of the garden shrubs, and is a year-long bloomer. Though my specimen was bought for *C. alba*, it is clearly not that species, as its flowers are pendent, rose-colored without, paler within, and its truncate calyx, though with a somewhat irregular border, has no distinct teeth. The flowers of *C. speciosa* are erect, and the pendent ones of *C. virens* are green, while *C. pulchella* has scarlet flowers, so that it is hard to identify my plant. But, whatever its name, its beauty is something to be thankful for during these last winter days even in California.

Santa Clara, Cal. *B. P. Leeds.*

An Ancient Sunflower.

To the Editor of Garden and Forest:

Sir.—My horticultural dictionary tells me that the Sunflowers are "natives for the most part of North America, although a few are found in Peru and Chili." Yet in an article by a learned German author, recently published in the *Deutsche Rundschau*, I read that there is a window in the apse of the Church of St. Remy, at Rheims, which dates from the twelfth century, and on which the Virgin Mary and St. John are represented standing beside the cross and wearing halos, around whose outer edges are pictured flowers of the Helianthus, "all turning toward the Saviour, their true sun." Can you tell me what flower it may be which thus resembles the Helianthus closely enough to be mistaken for it and could have been familiar to Frenchmen of the twelfth century ? I cannot believe that the writer can have mistaken for a glass-painting of so archaic a period as the twelfth century one produced at the much later time when, it seems, the true Sunflowers were introduced into Europe.

Philadelphia. *L. H. G.*

Periodical Literature.

An article on "The Flora of the Desert of Atacama," written by Mr. Thomas Morong and published in the February *Bulletin of the Torrey Botanical Club*, is especially interesting to the general reader from the facts it gives with regard to the way in which Nature adapts her products for life under the most unfavorable conditions. "It seems," says the author, "like a contradiction in terms to speak of a desert vegetation, and especially one upon a territory so bleak and desolate as the Atacama, which is distinguished by the number of its hideously barren hills of rock and its sandy wastes. And yet this desert bears a flora quite extensive and very interesting in its character. Over 500 species of plants have been gathered within its borders, and probably as many more might be detected upon a close research. One naturally wonders by what chance such a flora can be brought into existence and how it

can live after being once started. In explanation, it must be said that this region is not absolutely rainless, although it is nearly so. There is an occasional winter rain, or rarely two or three showers in the course of a winter, occurring at long intervals. Generally such rains are barely enough to moisten the ground, but that little is sufficient to cause the seeds, which are lying dormant in the sand, or the bulbs beneath the ground, to germinate. Once up, the seedling is kept alive by the dews which fall nightly upon the earth, and by the mists that hang around the hills every morning in the winter and spring-time. In this way these growths obtain moisture enough to enable them to reach maturity. Besides this the Atacaman plants have acquired several peculiarities which admirably adapt them to their conditions of life. One of these lies in the power of the seeds to live for many years in the dry sand without germinating. They have been known to retain their vitality for ten years and then to sprout at the touch of rain." Microscopic investigations show that such seeds have a "special weather-protection." They prove in every case to have "unusually thick walls and a copious supply of albumen around the embryo. . . . . While seeds are thus fortified against protracted drought, tubers and bulbs are equally well equipped by the large amount of water or milk which they store up. I found many of the bulbs that I collected so full of juice that I could squeeze it out in a stream by hand. Another peculiarity of the herbaceous flora evidently acquired is the early age at which the plants begin to flower and fructify. As if aware that they have only an ephemeral life, and that what they have to do must be done quickly, they are scarcely above ground before they put forth blossoms. Many species may be seen in flower when hardly an inch in height, and go on flowering until they reach the stature of two or three feet—if they can survive so long, I was continually deceived by this habit, naturally supposing that the wee things must be different in species from the plants that I had seen elsewhere only as tall and robust when in flower. A little more experience, however, convinced me that these Liliputians were merely taking time by the forelock.

"Still another adaptation is the extraordinary number of seeds formed by many plants and scattered over the soil in which they grow. This habit is not confined to species which usually yield great numbers of seeds, but seems common to all the desert flora. Thus a little Violet which seldom attains a height of three inches, common about Caldera, often exhibits from thirty to forty pods full of seeds upon a single plant.

"One other apparent adaptation deserves mention. It is said that a majority of the desert plants are shrubs, or, at least, are suffruticose, and this accords with my own observation. I found that such growths are in the habit of shedding their leaves in the summer instead of winter, thus reversing the ordinary process of nature. By this means they reduce their vital expenditure to a minimum at a season when they need to husband their utmost strength in order to resist continued dryness. This leaves them free to exert their full powers at a period when they are most likely to imbibe the revivifying moisture. Aided in this by their thick, long and knotty roots, and close, non-evaporating bark, these shrubs, which seem to be nothing but dead stocks in the summer, can withstand even several years of drought."

Many of the desert plants which Mr. Morong describes are curiously grotesque in habit, but bear very beautiful flowers. Such is *Cynanctum viride*, an Asclepiadaceous shrub which lies close against the sides of rocks; "the stock, which manages to survive the summer, is short and stumpy, with a thick head like an old Pollard Willow, from which it sends out new green shoots whenever the winter rain falls." An Evening Primrose (*Œnothera Coquimbensis*) commences to flower "when not much larger than a needle, continuing the process till it is two feet high." A Calendrinia is commonly called the "Guanaco's foot," from the resemblance of its leaves in shape to the hoof of the animal; "this elegant flower throws up a tall branching stem, each branch bearing on long naked peduncles several large and brilliant purple blossoms, a conspicuous object upon the desert. . . . In clumps around which the sand is often heaped in ridges as if against a wall occurred an odd-looking, yellow-flowered shrub of the *Apocyneæ* (*Skytanthus acutus*), popularly named *Cuerno de cabra*, or Goat's horn, from the singular habit which its long, pointed follicles have of twisting themselves into the shape of a pair of goat's horns. The resemblance is so exact that every one calls them by that name at first sight. In similar situations is found an Ephedra, vulgarly '*Pingo-pingo*,' the naked sharp-pronged stems of which seem just in place in such a region. We frequently rode through mounds of sand in which clumps of these two shrubs were completely buried."

The Cacti of this region, says Mr. Morong, are among the most curious he had ever seen. "The most noticeable of all belongs to a genus created by Philippi, and is, I believe, confined to this desert, named *Eulychnia breviflora*. It throws up from a cluster of roots numerous columnar stalks about as large in diameter as a man's arm, and armed with innumerable long, unequal, needle-like spines. The flower is on the summit of the stalk, not unlike a large cup in aspect, the lower part of which is covered with crinkly velvet hairs of a lavender hue, above which rises a single row of stiff white petals, including a host of delicate stamens. Another Cactus of the Melon variety, not over eight inches high, and not unlike a pineapple in shape, has its spines twisted about the stem, so that they resemble a bird's nest, inside of which the small red flowers hide like eggs." An Alstroemeria, "which exhibited great lilac flowers, the petals streaked with blue veins and yellow blotches"; a shrubby Euphorbia, five or six feet in height, with large white flowers and an excessive amount of milky juice; a delicate vine, *Tropæolum tricolor*, "which climbs upon shrubs in thick masses, profusely decorated with spurred corollas, whose bright tints of orange, red and blue offer a standing invitation to all the humming-birds that live in its vicinity," and *Euphorbia Copiapina* are among the other interesting plants described as inhabiting different parts of the Peruvian desert. The last-named "has a multitude of short stems which rise directly from a huge underground tuber, and lie in a circle upon the ground. The stems, leaves and flowers are lurid in hue, as if burnt by a tropical sun, and the tuber, in aspect much like a big turnip, is full of milk. Other things might perish in that rainless climate, but such a tuber would be preserved for many years in the dry sand."

Notes.

Stachys tuberifera, the Chinese vegetable introduced a few years ago, is said to be growing in favor where it has been tried in England.

We have received an excellent photograph of a striking variety of *Dendrobium nobile* which is now in bloom in the houses of Mr. Charles J. Carpinder, New Brunswick, New Jersey. Its flowers are said to be much larger than those of the type, and the coloring is remarkably distinct and beautiful.

The cultivation of the Pecan is said to be increasing in Texas every year. A farmer near Fort Worth has just planted a grove of forty acres. The demand for the best variety of Texan nuts seems to be unlimited, and the trees will probably grow much more rapidly under cultivation than they do when left wild. Single trees have been known to earn for their owners from $40 to $80 a year.

In his famous "Natural History of Selborne," first published in 1789, Gilbert White speaks of a vast increase in the production and consumption of vegetables as having occurred within the memory of people then but middle-aged, and he adds: "Potatoes have prevailed in this little district by means of premiums within these twenty years only, and are much esteemed here now by the poor, who would scarcely have ventured to taste them in the last reign."

According to Mr. S. D. Willard, the best-paying Pears during two years past have been the Bartlett, Duchess and Kieffer, the latter excelling all as a profitable orchard sort. One grower with 214 trees on little more than an acre received a total of more than $3,000 for three successful crops, and this last season's yield brought $1,313.50. No pear is more rapidly gaining favor as a canning fruit, its elegant appearance always giving it a good sale. So far the tree has been free from blight.

The memorial stones in Japanese grave-yards, says Sir Edwin Arnold, stand very close together, for, as a rule, only the ashes of the dead are interred. On the stone are inscribed not the names that had been borne in life, but some appellation, most often fancifully poetic, conferred by the priests after death. At the foot of the stone a little cup is hollowed out to contain water in case the spirit should return and wish to drink; and on either side stands a Bamboo joint containing sprigs of the *Shikimi* or Evergreen Anise (*Illicium religiosum*).

At a small party given recently in Indianapolis, the *Indianapolis Tribune* says that the hostess departed from the customary serving of ices in glasses, and had them in real calla lilies. The large spadix was removed and the flower contained quite as much ice as the ordinary receptacle. When the cup so filled was laid on an exquisite plate the effect was very attractive. Callas filled with bunches of sweet English

violets make a beautiful decoration, when piled in pyramid form on the centre of a dinner-table. They are also equally pretty placed at each plate.

The so-called "military zone" which encircles Paris is a strip of ground about 2,500 feet in width lying between the outer base of the old fortifications and the populous suburbs which have grown up during recent years. No one is allowed to build upon this strip, and for the most part it is occupied by market-gardens, which play a large part in supplying food to the great city. As its value for building purposes has, however, become very great, and as the present military governor of Paris favors the erection of a new chain of forts beyond the suburbs, it is possible that these fertile gardens may soon give place to solid blocks of houses.

The *Journal of Horticulture* speaks a good word for *Gypsophila paniculata*, not because it is a showy plant, but because of the value of its spray of minute flowers in giving lightness and elegance to bouquets. It is perfectly hardy here, making a long fleshy root, and when once established it will take care of itself for years. There are other kinds of perennial Gypsophilas which are valuable for this same purpose, and the little annual *G. muralis* is also most useful. This last plant is particularly suitable to use in small vases of Sweet Peas, as it seems to float about the flowers like a mist, and adds to their color an airy grace which can be secured in no other way.

"If the art of gardening," once wrote the poet Schiller, "is at last to turn back from her extravagances and rest with her other sisters, it is, above everything, necessary to have clearly before you what you require. . . . If this is done, there will be found, in all probability, a very good middle course between the formality of French gardening taste and the lawless freedom of the so-called English style. . . . It is certainly tasteless and inconsistent to desire to encompass the world with a garden-wall, but very practicable and reasonable to make a garden, satisfying all the demands of a good husbandman into a whole which shall seem characteristic alike to the eye, the heart and the understanding."

In the "Thoughts" of the French writer Joubert, published near the beginning of this century, we read the following intelligent comment upon the desirability of introducing at times a formal element into gardening art: "When a regular building commands the garden which surrounds it, it ought, so to say, to radiate regularity by throwing itself round itself to all distances whence it can be easily seen. It is a centre, and the centre ought to be in harmony with all points of the circumference, which is itself nothing but the development of a central point." There is a little exaggeration in the phrase which follows, yet we have seen instances where it would not be too severe: "Those irregular gardens," says Joubert, "which we call English gardens, require a labyrinth for the dwelling."

Last week the Judiciary Committee of the Senate of the state of Massachusetts gave a hearing to the advocates of the bill for the Preservation of Beautiful and Historic Places upon which we have before commented. Strong addresses were made in favor of the bill, and it received a hearty endorsement from the Appalachian Club, the State Horticultural Society and many eminent men and women. A letter was read from the poet Whittier, who said: "The movement is made none too soon. Barbarism, vandalism and greed have had their own bad way too long, and have done, and are still doing, irreparable mischief. Access to our seaboard is becoming difficult. Some of our best beaches are desecrated. Poison water gas is killing fine old shade-trees in our villages. It is time to call a halt."

Special Agent Andrew Cauldwell writes to the Commissioner of the General Land Office that the Trustees of the "Kaweah Colony" have been arrested for cutting timber in the Sequoia National Park created under Acts of Congress last year. Owing to the heavy snow-storms no trees have been cut since the first of December, but there is a possibility that operations will be renewed when the snow melts. The Agent has had copies of the rules for the government of these reservations posted in conspicuous places on all the roads leading to them, and he promises to use every means in his power to protect them from trespass until a guard from the army can be stationed there. The trial of the arrested trespassers takes place next month, and if they are proved guilty their prompt conviction would probably prevent any further depredation upon the timber of these reservations.

An English correspondent writes that *Rhododendron arboreum, R. grande* (*argenteum*) and *R. Nilagericum* are now magnificently in flower at Kew. The first-named is represented by a pyramid of foliage twelve feet high, studded with hundreds of bunches of brilliant crimson flowers; *R. grande* forms a tall flat-topped shrub or small tree, with large leaves, silvery on the under side, and huge trusses of large bell-flowers, which are rose-red in bud, ivory white when open, with a blotch of dull crimson at the bottom of the bell. *R. Nilagiricum* is like *R. arboreum*, but the flowers are rose-colored. *Camellia reticulata* is again a gorgeous picture of flowers, the fog having made no apparent difference to this species, although the garden Camellias have suffered more or less severely from its effects. There is no Camellia equal to this for ornament, all the others looking stiff and artificial in comparison.

The expression of a desire to own "a small house and a large garden" has been attributed to many writers, but the credit really belongs to Abraham Cowley, who lived from 1618 to 1667. In a letter to John Evelyn he wrote: "I never had any other desire so strong, and so like to covetousness, as that one which I have had always, that I might be master at last of a small house and a large garden, with very moderate conveniences joined to them, and there dedicate the remainder of my life only to the culture of them and the study of nature. But several accidents of my ill fortune have disappointed me hitherto, and do still, of that felicity; for though I have made the first and hardest step to it, by abandoning all ambitions and hopes in this world, and by retiring from the noise of all business and almost all company, yet I stick still in the inn of a hired house and garden among weeds and rubbish; and without that pleasantest work of human industry, the improvement of something which we call (not very properly, but yet we call) our own. I am gone out from Sodom, but I am not yet arrived at my little Zoar."

The news comes very unexpectedly that Maximowicz, one of the most judicious and accomplished systematic botanists of our time, and the great authority on the plants of eastern Asia, died in St. Petersburg, where he was the keeper of the Imperial Gardens, on the 16th of last month. His career began many years ago with a long journey in Manchooria, of which he made a careful botanical examination. He published the botanical results of this journey in St. Petersburg in 1859 in a stout quarto volume under the title of *Primitæ Floræ Amurensis*, with illustrations made from drawings by his own hand. Later, Maximowicz traveled in Japan, where he made large botanical collections which have been distributed among the principal herbaria of the world and have thrown the best light on the flora of that empire, which Maximowicz has studied assiduously for years with the intention of writing a comprehensive Japanese Flora. A vast amount of preliminary investigation was done toward this work which, however, Maximowicz, overwhelmed with the richness of the collections which for years have been poured in upon him by a multitude of Russian travelers in the little-known regions of central and western Asia and which no one else could work up so well, never saw his way to begin. His labors, however, in this field will lighten the burden of the botanist who undertakes to prepare a Flora of Japan and who will find the best sources of information in the critical notes which Maximowicz has published from time to time since 1866 under the title of *Diagnoses Plantarum Novarum Japoniæ et Manchuriæ*, and in which he has described many new species of plants and elaborated many large and difficult genera. Other important works from his pen are monographs of the Rhododendrons, the Hydrangeas and the Buckthorns of eastern Asia. Maximowicz wrote in Latin or German, but he was master of English as well, which, strangely enough, he learned on the Amour River, and the letters with which he favored his American correspondents were remarkable for their terseness and accuracy of expression. His death leaves a serious gap in the small group of systematic botanists of the first class.

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MARCH 25, 1891.

TABLE OF CONTENTS.

The Silver Maple.

THE Silver Maple is one of the largest and most beautiful trees in a genus peculiar for the beauty of its species. To many people, perhaps, who know it only as a shade or street-tree, the Silver Maple does not always appear to be a handsome or desirable tree. Planted, as it has been very generally, for such purposes it often has a weak and overgrown appearance, as if it had outgrown its strength; the branches are brittle and easily broken by wind and snow, the foliage is often thin, and the leaves fall early. This is the Silver Maple to people who know it in towns only and who see a tree in the wrong place, and where all the conditions are unfavorable to the development of its beauty. There are trees, like the Scarlet Maple, the River Birch and our eastern Larch, which seem to flourish as well when they are placed in unnatural conditions of soil and surroundings as in the situations in which they grow naturally, and which thrive as well on a hillside as in their native swamps. The Silver Maple is more fastidious. Unfortunately, it grows very rapidly, and even in unfavorable situations few trees will attain a greater height or a thicker stem in the first forty or fifty years of their existence. It is this rapidity of growth that has made the Silver Maple a favorite with people who are in a hurry to obtain immediate effects and do not care to look very far ahead; and at one time it was planted in the northern states, especially in cities and their suburbs, in immense numbers, without much regard being paid to the fitness of the position selected for it.

The Silver Maple is an inhabitant of low, sandy river-banks, and it is on river-banks only or in low meadows that it displays its beauty; and the lover of trees, if he would see it at its best and would realize what the Silver Maple becomes when all conditions favor it, should float down one of the large streams which flow into the tributaries of the lower Ohio. Here may be seen the river-forests of the Mississippi-basin in their full richness and beauty, and Maple-trees unequaled in majesty and grace by those of any part of the world. In the rich alluvial soil which forms the low banks of such streams, the Silver Maple rises sometimes to the height of a hundred and twenty feet, with a trunk three or four feet in diameter. Ten or fifteen feet from the ground this divides usually into three or four stout, upright, secondary stems, which are destitute of branches for a considerable height above the division of the main trunk and then ultimately separate into many slender branches with slender, pendulous branchlets, the whole forming a wide and majestic head. The bark of the trunk on the old trees is bright reddish brown, more or less furrowed by deep, longitudinal fissures, while the surface separates easily into large, thin scales. On trunks of young trees and on the branches of old ones the bark is quite smooth and light gray, faintly tinged with red. The young branchlets are bright chestnut-brown, with a smooth and lustrous surface, and are marked with large, pale spots. The winter-buds are rather small and are covered with bright red, imbricated scales, with a conspicuous fringe of pale hairs on the margins. The ample leaves are often six or seven inches in length, rather less in width, and are deeply five-lobed by narrow sinuses, with acute, irregularly toothed divisions, the middle division being often larger than the others and somewhat lobed. They are thin and membranaceous, and borne on long, slender, bright red petioles they dance with the slightest breath of wind, displaying in turn the bright and cheerful green of their upper surface and the silvery whiteness which clothes their lower surface. In autumn they turn pale yellow.

The flowers of the Silver Maple, like those of our Red Maple, appear late in the winter, or in very early spring, long before the leaves; they are produced in sessile axillary fascicles on the shoots of the previous year, or on short spur-like branchlets developed the year before from the wood of the preceding season. The sterile and fertile flowers appear in separate clusters, sometimes together on the same tree, but more frequently on different trees. The buds from which they open are aggregated into compact clusters, and are covered with thick red and green scales fringed on the margin with long rusty brown hairs. The flowers are greenish yellow and have no petals; the calyx, which is five-lobed, is slightly hairy on the outer surface and is long and narrow in the sterile, and short and broad in the fertile flower. There are from three to seven stamens; in the sterile flowers the slender filaments lengthen until they become two or three times as long as the calyx when the pollen is discharged from the anthers, while in the fertile flowers the filaments do not lengthen after the bud opens, and the anthers wither or fall off without opening. The ovary, which is reduced to a minute point in the staminate flower, is covered with hairs. It is possible that perfect flowers with a fully developed ovary and stamens may be found, as such is the usual order of nature in the case of flowers which have become generally unisexual by the abortion of one of their organs, but if such flowers exist, they are uncommon. The ovary of the fertile flower develops into a large fruit with long broad wings, which are sometimes nearly straight and sometimes shaped like a scythe. The fruit ripens at the end of a few weeks after the flowering period, if it is not destroyed by spring frosts, as is often the case, for the Silver Maple, enticed into opening its flower-buds by the succession of a few warm days in late winter, pays for its temerity with the loss of its fruit. Sometimes only one of the two samara, of which the fruit of the Maple is made up, is developed, and it is not an uncommon thing to find a tree producing one-sided fruit, the second and undeveloped ovary appearing as a rudiment at its base. The seed of the Silver Maple, if it happens to fall on moist open ground, germinates immediately, and produces plants which grow sometimes to be nearly a foot high before winter and strong enough to have in their favor the chances of surviving the hardships to which all seedling plants are subjected. In this habit of early flowering and quick development of the seed of

our Silver and Scarlet Maples, a habit which is peculiar to them, may be found, perhaps, a wise provision for their perpetuation. These two trees grow on low river-banks or in swamps—situations which are often submerged for a considerable part of every year, especially in winter and early spring. If the seeds of these trees ripened in the autumn, like the seeds of other Maples, and did not germinate until the following spring, they would run a serious risk of being water-soaked and of losing their vitality. Now, however, they reach the ground at the very best period of the whole year for quick germination. The water has receded from about the trees, leaving a moist open surface, warm, but not yet baked by the sun of early summer. It is a question which we do not pretend to answer, whether these trees acquired this habit of ripening their seeds early in the summer in order to maintain their existence in the low situations where they grow, or whether, the habit having been previously acquired, they were gradually driven to the swamps because their seeds were unable to germinate on the drier uplands at the period of the year when it reached the ground and could only germinate in soil from which the water had recently receded, and was, therefore, full of moisture.

The Silver Maple is widely distributed in eastern America; it is found in the north from the valley of the St. John's River, in New Brunswick, to southern Ontario, and extends southward to western Florida and westward to eastern Dakota, Nebraska, Kansas and the Indian Territory. It is not found very near the Atlantic coast or in the high Appalachian Mountains. It is very common, however, west of the mountains throughout the Mississippi-valley, where it is one of the largest and most generally distributed of the river-trees.

The Silver Maple is often called also the Soft Maple, a name which it owes, probably, to the brittleness of its slender branches, for the wood of this tree is not soft, but hard, strong, close-grained and valuable, furnishing excellent material for the floors of houses and for furniture. It was the Swedish traveler Kalm who first distinguished the Silver Maple, and sent it to his master, Linnæus, who named it *Acer saccharinum*, a name which has unfortunately become more associated with another of our Maples than with the tree to which it properly belongs.

The Silver Maple has been cultivated in Europe since 1725, and flourishes there not so well, perhaps, as on the banks of its native streams, but better than many of our American trees; and in American and European nurseries a number of varieties with more or less cut or divided leaves, or with leaves blotched with yellow or with white, or with more or less pendulous branches, have appeared. None of these varieties, however, are very distinct or in any way materially better or more beautiful than the wild tree.

The Silver Maple is a valuable tree in ornamental planting only when it can be placed in deep, rich and moist meadow-land or by the banks of streams or lakes over which it can spread its long and graceful branches and display the beauty of its brilliant foliage. Its beauty as a meadow-tree is shown in the illustration on page 140, which represents a young planted tree, fifty or sixty feet in height, growing near Boston.

The Value of Good Roads.

IN the issue of this journal for December 17th and 24th, 1890, we gave some extracts from the report which Mr. J. B. Harrison, one of the Forestry Commissioners of New Hampshire, was about to present to the Legislature. These extracts set forth the value and functions of mountain-forests in relation to climate, soil and water-supply, as well as their use in furnishing beautiful scenery as an attraction for summer tourists. The broad prospects among the New Hampshire hills, as well as the pure air and clear flowing streams, with the game and fish in woods and waters, are just as truly natural wealth and sources of revenue as are fertile soil and abundant water-power. They invite summer travel, as similar attractions draw thousands of tourists every year to Norway and Switzerland. These resources, neglected as they are, brought visitors into New Hampshire in the year 1889 who left five millions of dollars in the state. If a genuine effort were put forth to heighten these attractions and make them available, there can be no doubt that these summer visitors could be increased manyfold. For the full utilization of these advantages good roads are essential, and on this point the Commissioners make some recommendations which we quote from the published report:

If we had in our mountain regions as good roads and paths as have been constructed in European countries, whereby more of our mountain scenery could be brought to view, and more of our mountain passes, ravines, gorges and lakes be rendered accessible to the tourist, which are now known only to sportsmen, searchers for timber, and the bold climbers of the Appalachian Club, the large revenue from summer tourists might be doubled, quadrupled, or increased indefinitely. This great interest urgently calls for better roads and paths than it now has, and for more of them, so that in time every mountain pass shall be accessible by a good highway, and every important lake and summit, and other place of special interest, can at least be reached by an easy foot-path or bridle-path.

This opinion has a basis other than that of mere sentiment. It rests upon the more solid ground of profitable utility. If properly constructed and cared for, such roads and paths would prove as remunerative as our average highways. When completed they would afford, in connection with those now in use, circuitous drives of great attractiveness, opening new areas to the lumberman, and new sites for mountain houses, and influencing summer visitors to prolong their sojourn in the state.

If such highways were carefully projected and gradually constructed, at the rate of a few miles each year, their cost would not be burdensome, and they would eventually make known to the world the scenic treasures of our mountain region, many of which are still unknown and inaccessible to tourists. In these attractions New Hampshire has natural resources possessing a cash value as real as that of her waterfalls or her soil; resources which she can and should develop for the benefit of the thousands of summer visitors who annually come within her borders, and for the pecuniary advantage of her own people. The last Legislature made seventeen different grants of money to aid in the construction and maintenance of public bridges and highways, mostly in the mountain regions, amounting to $20,700. It is important that there should be system and foresight in the expenditure of such appropriations. The Swiss and Norwegian roads, so inviting to tourists, have been planned with much care and built with great thoroughness. Their surfaces are hard, their grades are easy, and they are, in all respects, pleasant and safe for travelers. Thus made, they are more expensive at first, but in the end they are more economical, as well as much more satisfactory in use, than the mountain roads to which we are accustomed in New Hampshire.

Memorial Trees.

ELEVEN years ago a man who had watched with great interest the development of Cornell University from its very beginning intimated his desire to present to it some memorial to express his interest and love for the institution. He had not the wealth, by means of which others had enriched it with costly buildings, but he appreciated the beauty of trees, and he conceived the idea of manifesting his love for the University by planting a row of Elms along the eastern avenue of the campus. He was enabled to carry out his generous purpose, and the trees are already attaining noble proportions. The giver has passed away, but the gift promises to remain for many a year, a living witness to his generous spirit. At either end of the long line is a firmly bedded stone, upon which is chiseled the simple inscription, "Ostrander Elms. 1880."

May not this example stimulate other public-spirited citizens to adorn their town-squares or village-streets with beautiful and unobtrusive memorials of this character? In what more delicate and permanent form can a man of moderate means express his appreciation of the beautiful in nature, and his desire to bless those who are to come after him?

Recent Botanical Discoveries in China and Eastern Burma.—V.

Rehmannia.—An examination of the copious specimens of this ornamental genus, collected by Dr. Henry, led to an increase in the number of species, including two described for the first time, and the raising of *R. glutinosa*, var. *angulata*, of Oliver, in Hooker's "Icones Plantarum" (t. 1589), to specific rank. At the same time the forms are so numerous that *R. glutinosa*, *R. angulata*, and what I take, from the description, to be *R. Piasezkii* of Maximowicz, are not quite satisfactorily definable from dried specimens; and I am doubtful whether I have correctly referred *R. Chinensis*, as figured in the *Botanical Magazine* (t. 3653) and in the *Botanical Register* (t. 1960), to *R. glutinosa*. A comparison of the two figures cited reveals considerable difference in the coloring, which is of a kind that recalls the American genus Salpiglossis, of which it is no very distant relation. The plants figured differ from the wild dried specimens from north China in having more decidedly leafy flowering-stems—a result, probably, of cultivation. Both *R. angulata* and *R. Piasezkii* are usually taller-growing plants than *R. glutinosa*. Among the specimens referred to *R. Piasezkii* are some between two and three feet high, and, judging from their vigor, this species probably reaches as much as four feet in height under favorable conditions. On the other hand, it is sometimes reduced to a single flower; yet that flower is larger, with a wider corolla, than in any of the specimens of *R. glutinosa*. Some of the specimens are described as having white flowers, but one from the Ningpo District is said to have magenta flowers and to be an exceedingly showy plant. In shape and size—three inches long—the flowers remind one forcibly of those of *Lophospermum scandens*. *R. angulata* differs in the lobes and teeth of the leaves being pointed instead of rounded. The flowers are variously colored—red, scarlet and orange being combined in the same flowers. A very pretty plant of this affinity, which I have doubtingly referred to Rehmannia, and called Oldhami, after its first discoverer, comes from Formosa, where Mr. W. Hancock collected good flowering specimens in 1885. He found it growing on dripping rocks under the shade of coarse vegetation. It has light-colored flowers (judging from dried specimens only) with dark blotches on the lobes, and in size and shape they are much like those of a medium-sized Pentstemon. Finally, there is a remarkable new species which I have described under the name of *R. rupestris*, in allusion to its natural place of growth on the face of cliffs or rocks. It has been raised at Kew from seeds sent home by Dr. Henry, and it has been drawn for the *Botanical Magazine*, so its characteristics will soon be familiar to persons who see that periodical. *R. rupestris* differs conspicuously from the other species in the thick leaves being clothed with a thick, white, woolly felt, which was strongly developed in the cultivated plant. In a pot it assumes a curious habit, putting forth thick fleshy branches which take a downward direction, concealing the pot. The yellow flowers of the cultivated plant were not so showy as those of the other species; but one of the specimens is said to have had pink flowers. The Chinese name signifies "cliff-cabbage," given to it probably on account of the large rosette formed by its broad radical leaves. From the foregoing notes it is manifest that the genus Rehmannia merits the attention of the gardener.

Calorhabdos.—A somewhat lengthy name, signifying beautiful rod, given first to a single Himalayan species; and now five Chinese species are known, from dried specimens at least. I am not aware that any species of Calorhabdos has ever been cultivated, but should they prove hardy, they are promising plants for introduction in shrubberies and half-shaded situations. Botanically, they are closely related to the Veronicas; in habit, they are mostly like the trailing *Vinca minor;* and four out of five of the Chinese species have the small white, pink, red or purple flowers crowded in short, catkin-like spikes, borne in the axils of the usually thick, cordate or lanceolate, toothed, alternate leaves. A figure of *C. latifolia* is given in the "Index Flora Sinensis" (*Journal of the Linnean Society*, xxvi., t. 4), which will afford a better idea of the type of plant than a long description. One of the Chinese species, *C. axillaris*, also inhabits Japan, and should be easily procured.

Paulownia.—The last member of the *Scrophulariacæ* I have to mention is the arboreous *Paulownia Fortunei*. This is not absolutely new to science, having been described by Seemann as long ago as 1867, from imperfect specimens collected by Robert Fortune, to whom we are indebted for so many beautiful plants from the far east. Seemann had only a portion of an inflorescence, bearing three or four flowers, and may therefore be excused for having referred it to the *Bignoniaceæ*, under the name of *Campsis Fortunei*. There are two such specimens in the Kew Herbarium; one bore Seemann's name, and the other was labeled *Paulownia imperialis*. With ample specimens from the two distant provinces of Kwangtung and Shantung, collected by the Rev. B. C. Henry, an American Missionary, and others, it was at once manifest that we had to do with a second species, differing from *P. imperialis* by its much elongated, cordate, almost caudate leaves, glabrous and smooth on the upper surface, and clothed with a very short, dense, white felt on the under surface; and in the longer, more curved flowers. It is described as a tree twenty feet high, and would, probably, flourish better in North America than in England, where there is usually not sufficient sunshine to ripen the wood.

Kew. *W. Botting Hemsley.*

The Arborescent Yuccas of California.

THE genus Yucca is represented in California by three species, neither of them, however, peculiar to the state. Indeed, they are the most northerly outliers of the genus, which has its greatest development in northern Mexico.

Two of the three attain to the size of trees, *Y. brevifolia* being the largest. It is wholly confined in California to the Mojave desert, of whose peculiar and interesting flora it is the most conspicuous member. On the north its limit is defined by the Tehatchipi Mountains, while the San Bernardino range confines it on the west. South and east its range extends beyond the boundary of the state to the valley of the Virgen, in south-western Utah, and to the Colorado plateau of Arizona. All this great district is a parched desert, and here at elevations of from 3,000 to 5,000 feet above the sea, on gravelly slopes and mesas, *Yucca brevifolia* finds a congenial home. Intermixed with a scrubby Juniper (*J. occidentalis*), it covers many hundred square miles with straggling forests, whose gaunt aspect makes even more cheerless the arid and desolate region they occupy.

The trees reach the height of twenty, and even thirty feet, with a trunk diameter of over a foot. The upper third of the trunk is furnished with a number of contorted branches, which form an irregular and often grotesque head. The leaves are about eight inches long and half an inch wide, rough and very rigid, the edges serrulate, and the extremity armed with a spine. Only those at the ends of the branches show by their ashy green color that the tree is living; the older ones are closely reflexed to the branches and bleached by the sun. The lower portion of the trunk is bare and brown.

Although this tree was noticed by Frémont in 1844 it was thirty years later before its flowers were made known. These were first observed by Dr. Parry in 1874 in southern Utah, and described by him in the *American Naturalist* for March of the succeeding year.

They are produced near the ends of the branches in short and rather dense, sessile panicles. The perianth has none of the grace and elegance characteristic of the genus. The texture is thick and leathery, the color dirty white, and the narrow segments are confusedly crowded. A disagreeable odor adds to the unattractiveness of the flower. April or May is the time of flowering, according as the season is early or late.

The fruit is dry, with a somewhat spongiose pericarp, the withered remains of the perianth persisting at the base. Good specimens are four inches long and nearly two in diameter. Although truly indehiscent, the ripe fruit manifests a tendency to the capsular structure by the replacement at what would be the dissepiments of the thick texture of the pericarp by a thin membrane, which occasionally splits. They are opened here by birds, which are perhaps in search, not so much of the seed as of the larvæ which abundantly infest them.

The seed has the black color and the flat, orbicular shape common in the genus. They are about a quarter of an inch in diameter and a line thick. The tree apparently produces its flowers every year, but is very irregular in perfecting its fruit, which is abundant in some seasons, but in others is an entire failure throughout large districts. In 1876 I traveled many miles through the Yucca-forests of the Mojave, finding but a single group of less than a dozen trees which had produced fruit that year.

The wood is coarsely fibrous, and is without any present economic value. It was at one time thought to be available as a material for paper fibre, and a factory was built in the desert, where it was prepared for shipment to England to be used for that purpose. The enterprise was apparently unsuccessful, and was soon abandoned.

In Utah this tree is called the Joss, Josh or Joshua, a name probably given it by the Mormons, and the meaning and

derivation of which are alike unknown. It is more properly known in California as the Tree Yucca. It has nothing to recommend it for cultivation, and does not succeed even in the San Bernardino Valley, only a score of miles from its native home.

Yucca baccata, the second arborescent species of the state, shares with several others the popular name of Spanish Bayonette. The territory it occupies includes the region to which *Yucca briarfolia* is confined, and extends beyond it both east and west. In the former direction it reaches well into Texas, while in the latter it extends over most of the four southern counties of California. With this wider territorial range it also flourishes under a greater diversity of altitude and climate, but is, withal, strictly confined to the zone of aridity. It is reported to form extensive open forests in some parts of Texas; but this is not the case in California, where it is solitary, or, at most, in small groups. It reaches its best development in the deserts, both as respects size and numbers. The trunks are either single, or two or more form a common base, and are from five to fifteen feet high and a little over six inches in diameter. The branches are few and short, and, like the trunks, clothed with the dead and reflexed leaves. Only those at the extremities are living, as is the case with most tree Yuccas. The leaves are two or three feet long and nearly two inches in width, and have on their edges a few coarse loose fibres. Sometimes the plant is acaulescent, but, perhaps, never truly so in mature specimens.

The flowers are produced in the month of March, or even earlier, near the ends of the branches, in a nearly sessile, broad panicle. They are large, campanulate in shape, of a white color, often shaded with purple, and of a peculiarly wax-like texture. They are very beautiful, either when seen in moss or more closely examined as individuals. Thus examined, they are found to derive an added elegance from the thick, snow-white filaments and ovary, the former tipped with bright yellow anthers, and the latter with the green stigmatic appendages.

This Yucca seldom ripens its fruit in this region. It is baccate in structure, cylindrical, and four or five inches long when mature. It is said to be sweet and edible. The Indians obtain a coarse fibre by macerating the leaves, which they use to manufacture mats and cordage. In time it may come to be utilized by civilized man for similar purposes. Although producing a beautiful flower and growing readily in cultivation, it has little value for that purpose, because of the extreme slowness of its growth—many years, probably, being necessary for a plant to attain a blooming size. *S. B. Parish.*

Plant Notes.

The Fruit of Akebia quinata.

THE handsome and hardy Japanese climbing plant, *Akebia quinata*, has become common in our gardens, where it is admired for its abundant dark green, digitate leaves, which are peculiarly noticeable in the late autumn and in the early winter, as they remain on the stems with little change of color until long after nearly all other deciduous plants have lost their foliage; and for the abundant and curiously formed rosy purple flowers. But very few people in this country or in Europe have ever seen the fruit of the Akebia or realize what a beautiful object it is. The illustration on page 137, made from a specimen which was produced last year in the Arnold Arboretum, will give an idea of the shape and size of the fruit, but will not, unfortunately, convey any idea of the beauty of its color.

The flowers of Akebia are unisexual, but are produced together in the same pendulous raceme. The females, which vary in number from one to three on each raceme, are borne on long, slender pedicels from its base, and are two or three times as large as the males, which are more numerous and are collected together on very short pedicels at the apex of the raceme. The long stems of the female flowers cause them to hang with or below the males an arrangement which seems admirably suited to insure their fertilization by pollen carried from the adjoining male flowers, either by the wind or by insects. But, for some reason or other, fruit is very rarely produced and only on certain individual plants which continue fruitful year after year, while other plants growing with them under exactly similar conditions remain barren. In 1864 *Akebia quinata* produced fruit with the aid of artificial fertilization in the arboretum at Segrez, in France, for the first time it was claimed in Europe, and a figure of it was afterward published by Monsieur Lavallée in his *Arboretum Segrezianum* (t. 28).

The first record of this plant having fruited in this country appeared in the *Gardeners' Monthly* in 1876 (xviii., 324), where it is stated that one of the two plants placed a few years previously by Mr. William M. Canby, of Wilmington, Delaware, in front of his house had produced fruit. Two years afterward fruit appeared on a plant in the garden of Captain H. D. Landis, at Chestnut Hill, near Philadelphia (*Gardeners' Monthly*, xx., 326); and plants are known on Long Island which have fruited every year for a number of years, and the fruit has been exhibited at the county fairs on the island, as I have been informed by Mr. William Falconer, of Glen Cove, who sent the fruiting plant to the arboretum. It is part of a plant in Mr. Charles A. Dana's garden, and was obtained by division. It is interesting that the fruitfulness of this individual appeared the year it was planted in the arboretum. Mr. Canby writes: "There are two Akebia-vines growing over the porch in front of my house; they have been there for nearly twenty years, and have had more or less fruit on them every year from the time they were well grown until this last year, when the flowers were destroyed by the late frosts. Very frequently there is no fruit, but usually each vine has from half a dozen to twenty each year. The baccæ which develop are most frequently one, often two, less commonly three or four, and rarely five. In the latter case, when they become ripe and open, the whole object has a striking appearance.

The fruit of Akebia is technically a berry or a collection of berries, slightly joined at the base, each developed from a free ovary. The individual berry is oblong, four to six inches long, cylindrical, and not unlike the fruit of the Papaw in shape. It is dark purple, mottled with a beautiful shade of blue, and covered with a glaucous bloom. The flesh is thin and dry, and splits open when fully ripe on its inner face, disclosing a fleshy placental mass of semi-transparent whitish pulp, in which the showy black oval seeds are imbedded in great numbers. This is attached at the back by a line following the dorsal suture, and in drying rolls up. The cylindrical, pulpy mass is the edible part of the fruit, and is eaten in Japan; it is insipid, however, and not very palatable, and Akebia-fruit will probably never be valued in this country except as an ornament. It is, however, so very showy that nurserymen should take advantage of the fruit-producing tendency of certain individuals and propagate from them rather than from those which are not fruitful. *C. S. S.*

Some Recent Portraits.

FIGURES of the cone and foliage (t. 7162, 7163) of *Encephalartos Altensteinii* open the March issue of the *Botanical Magazine*. This is a noble south African species said to become sometimes arborescent. The orange-brown cone produced in the garden of Mr. W. H. Tillett, of Norwich, described as eighteen inches long and thirty inches in circumference, is extremely ornamental, as is the habit of the plant with its graceful pinnate leaves.

Two species of Masdevallia are figured in this issue, *M. macrura* (t. 7164) and *M. punctata* (t. 7165). The former is a discovery of Roezel's in New Granada, and was described many years ago; the flowers are purple on the exterior, orange or yellow within, and remarkable for the presence of prominent nerves covered with numerous dark purple warts in the interior of the perianth. The narrow yellow tails of the sepals vary from four to six inches in length. *Masdevallia punctata* is a small plant with small orange-brown flowers, and is most nearly allied to *M. swertiæfolia*, belonging to a small group of the genus in which the lip is superior. The native country of this plant is unknown, although it is supposed to be from the mountainous regions of New Granada. The remaining plate is devoted to *Clematis Stanleyii*, already figured in our columns.

A fruiting branch, with figures of the scales and a section of the leaf of the beautiful *Abies religiosa*, accompanied by a

portrait of a small tree growing in England, appears in the issue of the *Gardeners' Chronicle* for March 7th. This is the Mexican Fir-tree, through the forests of which travelers visiting the city of Mexico by rail now pass near the summits of the mountain ranges which are crossed before the valley of Mexico is reached. It is a very beautiful tree, but, unfortunately, is not hardy in the northern and eastern states. It might be expected, however, to flourish in California, and it would be interesting to know if any large specimens already exist there. The specific name given to this tree was selected because the Mexicans are fond of decorating their churches with its branches.

The colored frontispiece of the March number of the *American Garden* is devoted to a cluster of fruit of *Akebia lobata*, and serves to illustrate the third number of Professor Georgeson's instructive papers on the economic plants of Japan. *Akebia quinata* is well known in gardens, but this second species, for some unexplained reason, appears never to have been introduced into those of America or of Europe. Its home, Professor Georgeson tells us, is in the

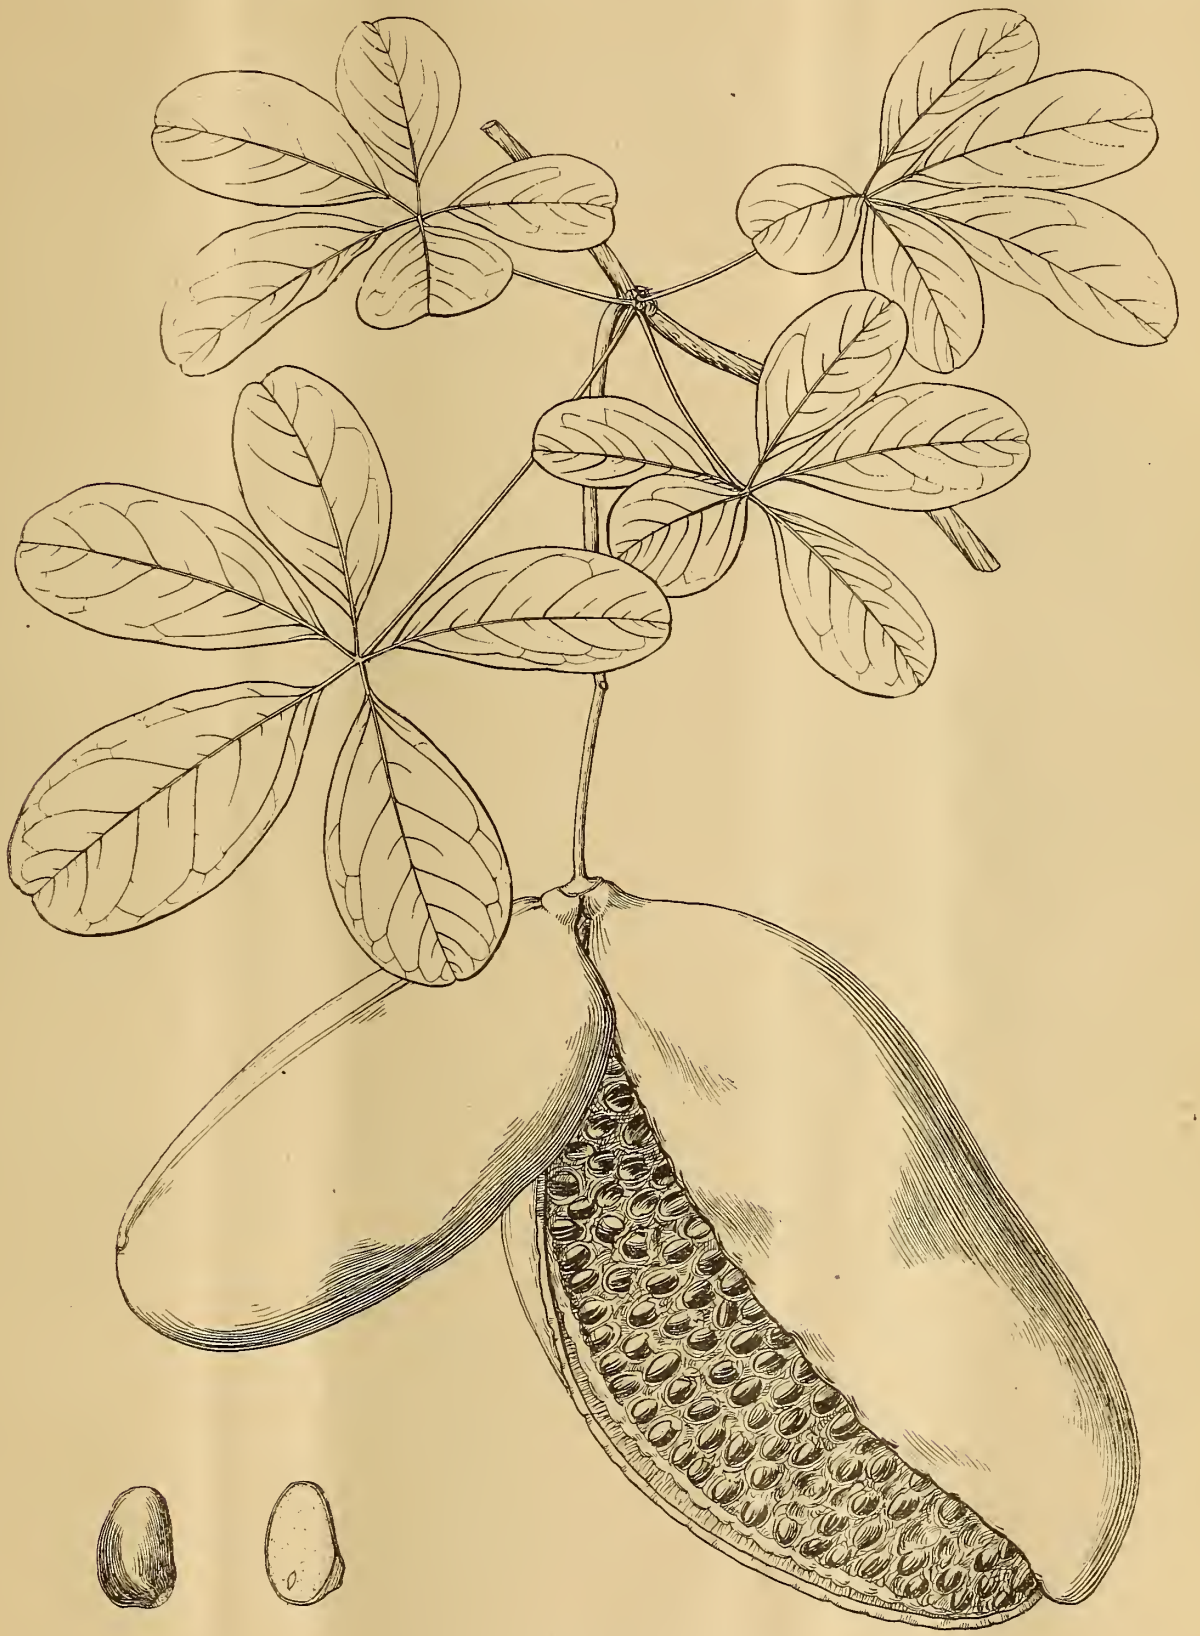

Fig. 25.—A Fruit of Akebia quinata.—See page 136.

mountains of northern Japan. It might, therefore, be expected to prove hardy anywhere in the United States. "It is," he says, "a more rapid and vigorous grower than the former species. I found some very fine vines of this kind in the lower mountains in the northern part of Iwati prefecture, which is well up toward the northern point of the main island. One vine especially attracted attention by its size and load of fruit. It grew in a spot of rich soil, mostly leaf-mold, by the side of a spring in the edge of a wood where it rambled over a thick growth of tall bushes and small trees, within an area of a square rod." As this plant was known to Siebold who, with Zuccarini, published a figure of it in the Flora of Japan, it is certainly curious that the horticultural collectors who have ransacked Japan so thoroughly of late years have failed to send home any seeds of a plant which, if we are to judge of its value by that of its relative, is likely to be of first rate importance in our gardens, especially if it proves more fruitful than the better known *A. quinata*.

Foreign Correspondence.

London Letter.

Lindenia.—It is now six years since this monthly publication was started by the Messrs. Linden, of Brussels. It is devoted exclusively to Orchids, of which 272 pictures, mostly well executed, have already appeared. An English edition has been started this year, of which part II. has lately been published. With such powerful and established competitors as Warner and Williams' *Orchid Album* and *Reichenbachia*, besides *The Garden* and the *Botanical Magazine*, Messrs. Lindens' venture will have to be smart to succeed in England. Certainly nothing could be better than these first two parts, both with regard to the excellence of the drawing and colors of the plates and the interest of the letterpress. Orchidists are to be congratulated upon the number and quality of the periodicals now devoted to illustrating and describing all the best garden Orchids. The plants figured in the parts of the English *Lindenia* already published are as follows: *Cattleya Rex*, which is supposed to be a white-petaled *C. Dowiana*, and which is a most beautiful plant, is represented in the plate; *Cochlioda Noezliana*, a delightful Orchid, similar in habit and flowers to *C. vulcanica* (better known as *Odontoglossum vulcanicum*), differing in having bright scarlet flowers, with a purple-tipped column. I may note here that at the auction sale to-day the plants of this Orchid offered by Messrs. Shuttleworth & Co., although small and newly imported, realized as much as ten guineas each; *Peresteria aspera*, shown as having the pseudo-bulbs of *P. elata*, and a short, drooping raceme of fleshy, cupped flowers, not unlike those of *Acineta densa* in size and shape, but colored tawny yellow, with numerous reddish spots. *Cattleya Warocqueana*, var. *amethystina*, the flowers of which are as large as those of the largest *C. gigas*, and colored deep purplish rose, with a large amethyst-colored lip, deep yellow in the throat; *Catasetum saccatum* is beautifully figured, and is described as "a splendid species, one of the largest of the genus. The sepals are over two and a quarter inches long, marbled and almost suffused with purple brown on a light-green ground. The petals are a little shorter and similar in color. . . . The lip is a remarkable organ, three-lobed, strongly fimbriate, green suffused with brown, white round the mouth of the saccate spur." *Cattleya granulosa*, var. *Buyssoniana*, remarkable for its uniformly cream-yellow sepals and petals and its white and crimson labellum. *Odontoglossum Clœsianum*, a large-flowered form of *O. crispum*, with numerous large, red-brown blotches. It is described as a probable natural hybrid between *O. crispum luteopurpureum*, but on what ground is not clear. The eighth plate represents a pretty mass of the elegant little *Phalœnopsis Lowii*. Except the Phalœnopsis, all these plants are the introductions of the Linden Company.

Horticultural Appliances.—At the Crystal Palace, Sydenham, an exhibition of considerable interest to gardeners was opened on the 3d, and will continue till the 31st of March. It is devoted to greenhouses, heating apparatus, various tools—in fact, to all kinds of garden furniture and machinery. On the whole the exhibits do not comprise anything of exceptional novelty for the professional gardener or well-informed amateur. Nevertheless, it cannot but prove useful to the thousands who daily visit this popular resort, and who are more or less interested in garden work, but are ignorant of the latest improvements in the way of tools and garden appliances generally. For this reason exhibitions of this kind are desirable wherever horticulture is general.

Lilium Harrisii.—The Bermuda Lily has become of enormous importance to flower-growers in England. The market-gardeners in the London districts alone import millions of it yearly. In one nursery some hundreds of thousands are planted every year, and are treated so as to come on in batches, so that the flowers are available from March to October. In Mr. Iceton's nursery at Putney I saw lately house after house filled with this Lily, while in frames and beds were many thousands more in various stages of growth. The bulbs had been planted singly in five-inch pots in strong loam. The stem on each bulb of the many thousands which will open their flowers in about a fortnight, so as to be ready by Easter, was as thick as a man's thumb, from four to five feet high, leafy down to the base, and crowned with a cluster of plump buds. I counted the buds upon many of the stems, and found the average to be six flowers per bulb. With the market-growers it does not pay to attempt to use the bulbs of this Lily a second year; they are therefore sold for a mere song or destroyed after having flowered. The three Lilies generally grown by the London market nurserymen are *L. candidum*, *L. eximium* and *L. Harrisii*. Grown as Mr. Iceton grows them—at first plunged in fibre or ashes outside, then removed to unheated frames, and from thence to warm, moist, light houses, where they stand pot thick, their roots saturated, their heads almost touching the glass—they are an immense success.

Kentias.—The most popular decorative Palms in England are the several species from Lord Howe Island, which were originally described as Kentias by Mueller, and subsequently altered to Howea by Beccari. In gardens, however, they are still generally known as *Kentia Forsteriana* and *K. Belmoreana*. Besides these names there are *K. Mooreana*, *K. rupicola*, and *K. australis*, but the plants in gardens which bear them appear to be merely varieties of one or the other of the two first named. These are grown in hundreds of thousands by London nurserymen, and are sold in all sizes, from plants a foot high in three-inch pots, to big specimens fifteen feet high. They are superior to most other Palms, from the fact that their leaves are not easily injured, and they remain on the plants for many years, so that a specimen fifteen feet high often still retains the leaves which it had when small. They are not injured by being huddled closely together, so long as they get plenty of moisture and warmth. This gives them great value as plants for temporary decoration, and their seeds are now imported by the hundredweight, many of them being disposed of at the auction rooms.

There exists some confusion among growers with respect to these two fine Palms, many being of opinion that they are merely varieties of one species. The following extract from a report on Lord Howe Island by Mr. J. Duff, of the Sydney Botanic Gardens, may throw some light upon the matter. He says:

"Baron Mueller, in the fifth volume of his 'Fragmenta,' describes four distinct species of Palms indigenous to Howe Island, while Mr. Bentham, in the 'Flora Australiensis,' only enumerates three species, stating that he finds 'no difference in the male flowers and fruit of *K. Forsteriana* (the Thatch Palm) and *K. Belmoreana* (the Curly Palm), and that their distinctness remains to be ascertained.' Both Palms flower exactly alike, *i. e.*, they produce their flower-spikes generally from the axils of the lowest row of leaves, but occasionally young, undeveloped flower-spikes spring from the axils of the leaves above them. The seeds [fruits] of the Curly Palm are oval and a greenish yellow color when ripe, while those of the Thatch Palm taper to a point at both ends and are dark crimson when mature.

"The chief specific distinctions, however, are: The Curly Palm bears its flower-spikes singly, which average five to six feet in length, while those of the Thatch Palm consist of five spikes in a row, united together at the base, of an average length of three to four feet.

"The fronds and pinnæ of the Curly Palm are recurved at the apex and the pinnæ are nearly erect at the base, the Thatch Palm having less recurved, darker green fronds and broader, pendulous pinnæ, which distinctions are observable even in the small seedling plants.

"The Curly Palm is the most abundant and wide-spread species, as it extends from the beach to an elevation of about 1,200 feet, while the Thatch Palm is confined chiefly to the beach.

"At an elevation of about 1,000 feet the large Mountain or Umbrella Palm (*Kentia Canterburyana*) is met with growing in patches from this height to the summit of the mountains, to which the small Mountain Palm (*K. Moorei*) is also confined."

It is remarkable that these Palms, which are wild only in this small island, should prove under cultivation so indifferent to treatment as to grow under all sorts of conditions, if only they can obtain heat and moisture.

London. *W. Watson.*

Cultural Department.

Rose Notes.

THE season about to close has not been satisfactory to most of those who grow Roses for cut flowers; there have been many failures, and in many instances the failures are unaccountable. Careful growers, as well as careless ones, have been tried to a greater or less extent by the failure of some variety or varieties to come up to the high standard of excellence now generally established. Of course some of these losses may be directly traced, as usual, to either overfeeding or overforcing. An instance of the latter I observed a few weeks since, when a house of Brides, that in the early part of the season had been very promising, was apparently struck all at once by disease in the form of the "yellows," and at the time of my visit most of the foliage had turned nearly the color of the Golden-bedder Coleus, and, of course, the house was completely ruined either for flowers or for stock. In this case it was plain that the house had been kept too warm in order to hasten the flowers for the holiday trade, and it therefore seemed reasonable to infer that this caused the sudden breakdown of the plants some six weeks later.

The growers of early hybrids, too, seem to have had their full share of misfortunes, for many of the early crops were not nearly up to the standard. Mrs. John Laing and Ulrich Brunner continue to retain their popularity, some very fine blooms of the latter having been in market for weeks past. The early Mrs. Laings were not remarkable, many of them being more or less malformed, but really good flowers of this variety were always in demand.

Captain Christy is a hybrid Tea that should be more widely grown, for when in good condition its good size and its exquisitely tinted flowers of delicate flesh color are highly attractive. Unfortunately, Captain Christy is a somewhat shy bloomer when forced, but still a few such flowers as we sometimes see, cut with stems eighteen inches to two feet in length, will well repay for the space and trouble they require.

Another old Rose that deserves attention is Maurice Bernardin, a seedling from General Jacqueminot, and sent out some thirty years ago. It is bright crimson, of good size, and also a free grower and bloomer. Maurice Bernardin forces very well, too, but has the disadvantage of blooming in clusters frequently, and it therefore becomes necessary to disbud in order to secure good flowers when forced. As an out-door Rose this variety is a very satisfactory one, the color being very fine.

Eugénie Verdier is also a good out-door Rose, its silvery pink flowers being of good shape and size, and the shade of color is a very pleasing one.

Since the novelty has worn off Duchess of Albany does not seem quite as popular, and, though a lovely Rose when in perfect condition, yet this variety certainly has not displaced La France, and in many instances the experience of the florists during the present season has been that they could sell two La France roses for every Duchess of Albany they disposed of.

Good flowers of Madame Hoste have been in demand, and, generally speaking, this has proved a useful Rose; and it is a prolific one, too, though the flowers are to a great extent produced in crops, and the foliage seems quite susceptible to mildew.

The old stand-by, Bon Silene, has also been much used in some cities this season, and while it cannot compare in the matter of size with some of the newer introductions, still the color is attractive, and when well grown it makes a charming corsage bouquet.

The most noted new Rose of American origin, Waban, is finding a ready sale among the trade, the stock prepared for the first delivery (April 15th) being now exhausted, and orders are being booked by the agents for a second delivery, which is promised to take place May 15th. This Rose has already been described in the columns of Garden and Forest, but it may be well to repeat that it is a sport from Catherine Mermet, much deeper in color than its parent, and in growth and habit very similar to that well-known variety. It originated in a florist's establishment in Massachusetts, and is being simultaneously distributed by several wholesale agents in various parts of the country.

Young Roses for future planting should now be growing freely, and should not be allowed to become starved for want of repotting. A stunted condition is often invited by a little neglect in this essential, and once in such a condition it is hard to get the plants out of it. Thorough syringing will also be required every bright day, for the sun is now strong and evaporates much moisture in the day. Pot-grown hybrids will take an abundance of water, and applications of liquid manure from time to time will increase the size of the flowers and general vigor of the plants.

Plants of this class are now much used in decorations, Anna de Diesbach and Magna Charta being two favorites for this purpose, while the well-known hybrid China, Madame Plantier, is also used with charming effect, its pure white flowers being produced in great abundance. The latter variety, however, needs to be brought on slowly in order to secure the best result, for when forced hard the flowers have very little substance.

The pruning of out-door Roses should not now be postponed, as it should be done before the sap rises.

Holmesburg, Pa. *W. H. Taplin.*

Hardy Narcissus.

IN English gardening periodicals the complaint is now current that bulbs of Narcissus, planted in the open ground late last fall, have been kept perfectly dormant all the winter owing to the unusual severity of the season, and fears are expressed for the crop of bloom and welfare of the bulbs, owing to insufficient root action. Although this is a complaint of English growers alone, still we may gather some useful hints from it which may help us when planting time comes again. It is perfectly safe to say, that as soon as the value of a permanent bed of out-door Narcissus is generally recognized these charming spring bulbs will be planted in large quantities. But failure, or partial failure, is almost sure to confront the cultivator in the first attempt unless certain precautions are taken at planting time, and of one of these precautions the complaint referred to forcibly reminds us. Nine-tenths, perhaps, of the Narcissus planted each year are newly imported bulbs, for which we have to depend upon dealers who get them with their other bulbs in fall, and by the time these get to the planters the season is far advanced and sharp frosts are upon us, rapidly robbing the soil of its store of warmth laid up during the summer. Such was my own experience last fall when planting an extensive permanent bed of Narcissus in the open ground. Fortunately the difficulty was foreseen, and, after planting, a covering of twenty-four inches of dry leaves was placed over the whole bed, and it was scarcely completed before snow was upon us, and hard frosts. It was a long time before the thick blanket of leaves was wet through, and consequently the soil did not freeze, and an examination to-day proves that the growth made by the bulbs is ample at the root to support the leaves and flowers when the time comes for them to appear. There is no doubt that the covering of leaves served as a protection from cold above and prevented the escape of warmth from the soil. As soon as the weather permits the covering will be carefully removed and the bulbs will be in flower a very short time after, as they are now pushing through the soil.

There is one other way to ensure success with a new planting, and this is by obtaining American-grown bulbs. In this way the beds may be planted as early as the middle of July, and better at that time than later, for, owing to the strong sunshine, the foliage will have already turned yellow, and root action will have ceased. This action begins again, however, about the end of August, and it would be better to buy imported bulbs than home-grown ones lifted after the roots have commenced to grow, as the best roots and the principal feeders would be injured beyond help by removal, and a second start would have to be made at the expense of the vital forces stored up in the bulb.

To a beginner the difference in shape and size of home-grown Narcissus bulbs and imported ones is perplexing; the latter have very short necks, while of those grown here such kinds as Sir Watkin and Horsfield's often have necks that make the bulb measure six inches in length; this is brought about by the different systems of planting. Our climate makes it necessary to plant much deeper than is the custom in Europe. If we planted as shallow here the plants would be above the soil in fall, owing to the much greater heat here at that period.

As already mentioned, our planting is intended to be a permanent one. And in summer, plants of annual duration will be planted between the rows, such as Mignonette, Asters and other kinds for cutting, and in fall, when the first sharp frosts have killed these, the beds can be cleaned and a good top dressing of well-decayed manure spread on them. The

heavy fall rains will wash this down to the roots and nourish them when they are most in need of help. It will be found necessary every third year to lift, separate and replant the bulbs, owing to the rapidity with which they multiply. In heavy soils the bulbs would soon become so cramped in the soil as to render them flowerless owing to imperfect development, but in lighter soils this would not be so likely to occur. There should be no excuse for a scarcity of Narcissus-flowers in gardens, when it is well understood how perfectly they are adapted for permanent planting, either for naturalization or for the decoration of flower-beds and borders. With a proper selection of varieties they can be had in the open ground from Easter onward for six weeks. The earliest kinds might be so planted that the protection of a frame could be given, and in this way Easter flowers might be assured even in late seasons, but last year there were plenty in the open ground from newly planted bulbs without the least protection.

Fig. 26.—The Silver Maple.—See page 133.

Spring Flowers.

MARCH is a month of anxiety in the hardy-plant garden. The losses usually noted at that time may be the result of hard conditions earlier in the year rather than the constant changes incidental to the month, but at this time we may usually first take note of the losses. With all the continued cold of the past winter the destruction among hardy plants seems less than during the previous much milder season. The few mild periods have started a large proportion of bulbs and hardy herbaceous plants into some activity, and the garden is full of interest. In selecting plants for the hardy garden care should be taken to secure as many as possible of an arctic habit, by which I mean those which spring rapidly into bloom in a few days after the frost releases its hold on the ground. The flowers of these plants are not only among the most beautiful and apparently delicate of any season, but there is a never-ending wonder and charm in their surprising annual appearance. They know their master, and when the sun rises but a trifle they rise to his greeting.

It adds much to the interest of a garden to discover at every mild time throughout the year at least a stray flower or two. Even in our latitude the frost is seldom so persistent that flowers may not be had out-of-doors in warm spots nearly every month in the year. December is usually the barest time, as the ground is then apt to be continuously frozen. This year Snowdrops were in bloom in January in the border, and are still in mid-season. *Anemone blanda* was a close second in February. These plants, I find, are very reliable winter-bloomers, and some established plants in a snug corner are very bright and charming on a sunny day. They range in colors from a not very clear white to a deep pure blue, and the foliage is deeply cut and of a bronzy hue. Some roots of *A. blanda alba* in a border only a few feet distant are only just now starting into growth, so much difference does location make in time of flowering. It would be well to plant *A. Apennina* with *A. blanda*, as this variety follows closely, and would extend the blooming-time of the bed several weeks. My colony of *A. blanda* had a good baking during the summer, and received a mulch in the fall. The latter condition seems important, as they are stronger where the mulch still covers them. From some indications, I am inclined to think that in well-drained soil under deciduous shrubs they would be quite at home.

A Taurian variety of *Scilla bifolia* is proving an excellent early Squill, quite as early as the Anemone. This has flowers of as deep a blue color as *S. Sibirica*, and the blooms are entirely weather-proof, as becomes an early riser. Another Taurian Squill has much larger foliage and of a more true blue shade. This, while scarcely later, is somewhat damaged by hard weather. Muscaris are showing their inconspicuous but lasting flowers, while Chionodoxas are slowly appearing, *C. Sardensis* being most forward. It is rather peculiar that a pan of these in a cold frame are not as forward in bloom as those in the open, though the foliage is more advanced. Winter Aconite (*Eranthis hymelis*) gives a cheerful glint of color, and a stray hardy Primula may be found, though the latter is scarcely a winter flower, like the double Daisy, *Bellis perennis*, which sometimes ventures out in a mild spell, for which temerity they are punished by the first sharp frost. Hellebores seemed such a success out-of-doors last season that mine were plunged in the border early in the year, but without much confidence that the result would change the opinion that they are cold-frame plants—in my garden at least. Looking them over the other day, I found the Lenten section quite ready to bloom, but the Christmas Roses (*H. niger*) entirely dormant, with buds still at the crowns. Perhaps your correspondents, who have bloomed them in the open so many years in succession, have garden conditions more favorable than mine to these desirable plants.

Elizabeth, N.J. *F. N. Gerard.*

Notes from the Harvard Botanical Garden.

Salvia Bethellii.—This excellent variety of *S. involucrata* was obtained from seed some years ago by the English gardener after whom it is named. In many respects it is superior to the species; the habit is more compact and bushy, the flowers more numerous, and of a richer color. No other Salvia flowers so persistently; no other presents such a neat, attractive appearance when in bloom. The entire plant rarely exceeds three feet in height, and it is furnished with dark green, velvety ovate-acuminate leaves, from six to seven inches long, on petioles one-third their length. The flowers are borne in a large, dense, pyramidal, verticillate, erect raceme, with two caducous, ovate bracts, of the same color as the corolla, at the base of each whorl. The corolla is a deep reddish crimson, two inches in length, tubular, flattened, contracted at the top, expanding again in a two-lipped limb, the upper lip densely hairy, and the lower one bearded beneath. Cuttings prepared from the young growth are very easily propagated with bottom heat. They should be rooted in spring, however, so that the plants may be grown in the open ground during summer. They should be taken up and potted in August, or early in September, and afterward treated as Chrysanthemums and other soft-wooded plants that are grown out-of-doors. *S. Bethellii* cannot endure the slightest frost, and it delights in a sunny position and a free circulation of air when under cover.

Tetranema Mexicana.—This is a charming little perennial, scarcely more than six inches high. It was first cultivated in Belgium, some fifty years ago, and is the only member of a genus which is closely allied to Pentstemon. The stem is very short, and thickly clad with opposite, oblong, crenate leaves. The axillary peduncles, bearing the reddish purple flowers in dense corymbs, are produced freely during the summer months. Although much smaller, the flowers in form bear some slight resemblance to those of the Foxglove; and this likeness has been considered sufficient to justify the name of "Mexican Foxglove" for the plant. This name, however, is rather inappropriate. When a Foxglove is mentioned, we turn, naturally, to look for the aspiring stems; but in *Tetranema Mexicana* we find instead a plant of comparatively humble proportions. It is beautiful, but not stately like the Foxglove. Its small size, however, combined with a compact habit, renders it very useful in edging groups of larger greenhouse plants, and its pretty flowers never fail to please. The plant thrives luxuriantly in rich, sandy loam, and it is easily propagated by division or from seeds. The latter are borne in great abundance, and the plants produced from those sown in summer will bloom as profusely in winter, under pot culture, as those obtained from spring-sown seeds usually flower in summer.

The Black Calla.—It is only a year or two since an American firm distributed roots of a plant to which this name was given, with *Arum sanctum* added as a botanical name. The latter name was new, and the impression was thus conveyed that the plant also was new. Some of the roots had been sent here, and the development of the inflorescence was awaited with much curiosity, until the plant turned out to be one which had been cultivated as *Arum Palæstinum* (the correct name) more than a quarter of a century ago. It was introduced from Jerusalem by the Messrs. Veitch, of London, in 1864, and flowered at their nurseries during the following year. *A. Palæstinum* attains a height of from one to two feet, and resembles the common Calla Lily (*Richardia Æthiopica*) in general aspect. The long, drooping spathe is greenish on the outside, and blackish purple on the inner surface; the upper part of the conspicuous spadix is of the same blackish purple color. The fragrance of the inflorescence has been described as similar to that of the Violet; but to most people it calls to mind the odor of decaying Musk-melons. The plant is of no practical utility in garden work, but it may be grown as a curiosity. The treatment given to ordinary Callas will suit it very well.

Cambridge, Mass. *M. Barker.*

Chrysanthemum Queries.—II.

THE following questions, with Mr. John Thorpe's replies, are a continuation of those which we published last week:

"Has the constitution of the Chrysanthemum been impaired by long-continued crossing?"

No; on the other hand, the American-raised seedlings of the past three years are of a decidedly more vigorous habit than those of former years. Raisers of seedlings have now reached the point where they throw away all weakly seedlings, unless they have some new and striking feature which it is desirable to develop in future generations. When my seedlings are about four months old, being generally then in three-inch pots, I discard all plants of puny growth and constitutional weakness, thus doing away with all subsequent trouble, and often the temptation to keep a weakling when in flower.

"How shall we secure a race of Chrysanthemums that will endure our trying climatic conditions?"

If, at any time during May, 500 seedlings are planted in the open ground to which is given fairly good cultivation, there will come a time when some of these plants begin to weaken—that is, they make no progress—and as the trying summer lengthens many others will drop behind, until, probably, at the end of September, your 500 seedlings have a representa-

tion of fifty healthy and vigorous plants only. It is these fifty home-raised plants, then, that have the constitution and the vigor you desire to propagate. We ought to raise American plants for American gardens. A great many of the European novelties in all plants are failures here. It is not that they are worthless originally, but because the conditions they are subjected to are not to their liking. They were born and bred in other surroundings, and, as a rule, are better adapted to them. This, however, is not a rule without exceptions.

"Can strong plants be grown from the cuttings of a weak one?"

When cuttings are taken fairly early, it makes no apparent difference whether from a strong plant or a weak one of a given variety, provided always that they are properly treated afterward. A cutting no thicker than a knitting-needle, if well cared for from the start, should be as strong two months later as one that was originally as large as a lead-pencil. Some believe that permitting a plant to produce only a few flowers tends to strengthen the plant, and the fact is it costs the plant less effort to elaborate one flower than it does fifty. If a plant is allowed to carry all its flowers without disbudding, what a task it has! A single shoot of some varieties has as many as forty buds formed, and when we consider that each flower, when open, carries from 140 to 150 florets, it will be seen that the strain on the plant is a very severe one.

"Is the production of a blue Chrysanthemum possible?"

I do not see why it is impossible, and I hope yet to see a genuine blue Chrysanthemum. The old botanists declared that we could not have blue, yellow and red in the same species of plant. But we have blue, yellow and red Hyacinths, and I see no good reason why we should not get the same colors in the Chrysanthemum. The original colors of the Chrysanthemum-flower were limited to a pale yellow, white and a very weak lilac shade, and from these have been elaborated all the colors and shades we now enjoy in this flower. This has been accomplished by very slow and persistent work in selection and cross-fertilization and by the tendency of the plant to sport. Notice how the yellow shades have been intensified and how many shades there are. The lilac has become pink of pure quality. Cullingfordii oftentimes, when the flowers are closely shaded, presents us with nearly a pure tone of red. The most pronounced purple we have to-day comes from the lightly tipped, incurved Princess of Wales, in the form of a sport named Violet Tomlin. It is a true purple, and we cannot get purple without blue. To those who are hard at work watching the tendencies and developing new forms of the Chrysanthemum, the sudden appearance of a blue one would prove no great surprise. Raisers of seedlings frequently see signs of a new departure four or five years before it actually takes place. A blue Chrysanthemum may first be obtained from a sport.

The Influence of Pollen upon Fruit.—Among many experimental studies which have here been made of Tomatoes growing under glass the past winter, trials of pollinating in various ways have yielded, especially in one case, very interesting and suggestive results. One flower of a cluster was pollinated upon one side of the stigma with the least quantity of pollen which it was practicable to apply; to another flower of the same cluster was at the same time given a superabundance of pollen over the whole stigmatic surface. The two resulting fruits have grown and ripened side by side. The one grown from abundant pollination developed to a normal size, and, when cut through transversely, showed the usual even distribution of placentæ and seeds. The one scantily pollinated, on the other hand, reached only about one-fourth the size of its mate, and when cut like the other, seeds were found on only one side of the fruit; the other side, however, had grown almost symmetrically with it, but, instead of being filled with seeds, contained only the enlarged placentæ, making the fruit nearly solid on that side. This suggests an important field for further study in relation to the influence of pollination upon the development of fruit and related subjects, and it has practical bearings of no little importance.

Cornell University. *C. W. Mathews.*

Saxifraga Burseriana major.—This is an extremely pretty Saxifrage, and is well worth the attention of the gardener. It is a very old plant—at least the typical *S. Burseriana* is—having been described and figured in Jacquin's "Miscellanea" as long ago as 1778. The variety Major is far superior to the type, and has flowers about twice as large, although even on the same plant great variation in this respect is observable. The plants are almost perfectly hardy in England, but it is safer to have them kept in a cold frame during vigorous winters so that the pure white flowers may not be nipped off before their expansion in January and February.

Correspondence.

Protection from Field Mice.

To the Editor of Garden and Forest:

Sir.—I wish to ask through your columns for advice as to the protection of trees, young and old, deciduous and evergreen, from the depredations of field mice. We have had snow on the ground for fourteen weeks, and, as the last of it is now disappearing, the ground is covered with a complete network of their runs. Their nests have been made of the grass under the snow, and they are now easily seen, but the late occupants have migrated. Their work, however, remains. Apple-trees, twenty-five years old, are completely girdled by them so that not a vestige of bark remains where they have been at work, but worse damage has been done among choice trees and shrubs recenly planted. A fine young Copper Beech is stripped of bark for quite two feet above the ground level. The damage was not visible until the snow cleared away, and then the ruin was beyond repair.

South Lancaster, Mass. *O. O.*

[A good way of protecting trees from mice is to tramp the snow hard about the trunks after every storm during the winter. The mice cannot push through the snow when it is packed. If the bark of the tree is washed late in autumn with some preparation distasteful to the mice this will often answer as a protection. Aloes, gas-tar, carbolic acid and sulphur are used for this purpose. After the injury has been done scions are sometimes laid over the girdled space, with their thin ends inserted under the bark above and below and carefully waxed and wrapped. This conservative surgery will in many cases save the tree.—Ed.]

"Insect Lime" for the Gypsy Moth.

To the Editor of Garden and Forest:

Sir.—The reference by Mr. J. G. Jack, in your issue for March 11th, to the almost explosive appearance in destructive numbers of *Liparis monacha* (nonne) in Germany, when discussing the war against an allied species of the Gypsy Moth in this country, leads me to send you a few brief notes from a paper which I read two weeks ago before the Entomological Society of Washington on the former subject almost on the very day when the Gypsy Moth Commission held its sessions in Boston.

It seems to be the world's practice for each community to go on trusting to its own experiences rather than profiting by that of others, exactly as it does in the forestry problem.

What these insect pests mean to a forest-administration will be understood when it is stated that the last ravages of the above-named "nonne" involved an area of over 100,000 square miles, the premature cutting of 55,000,000 cords of wood, and the most inconvenient disarrangement of working plans, which, in a forest-administration, are necessarily laid for 100 or more years in advance.

Many thousands of dollars were spent last year, and many more will be spent the coming year, not in exterminating, but in checking, the pest, until natural causes, like fungus diseases and parasites, will reduce it to its usual limited existence. Many remedies have been proposed and tried, and where such large areas are concerned and such values involved, they were, of course, tried without stinting expense and without losing sight of their practicability. In one district of 2,000 acres of Spruce-forest not less than $12,000 were spent experimentally.

The only really effective remedy was found in the application of bands of "insect lime," a glue specially prepared and extensively used in Germany. This preparation, applied in various ways, is useful against quite a number of insects. It would no doubt be applicable against our Canker-worm; against the Bag-worm, Fall-web-worm and Tussock Moth, and has been found most effective against the Gypsy Moth in its native country.

In this latter case the "insect lime" is best applied toward the end of the winter—that is, just now—upon the patches of eggs which this insect is in the habit of attaching to the outer bark of the trees. The glue, of course, prevents the hatching

of the eggs. The price of this preparation, which is specially manufactured in varying composition by several firms, is $2 per 100 pounds.

Against the "nonne" and other similar caterpillars, which wander up and down trees, a band of insect lime, two inches broad and a quarter of an inch thick, is applied around the trunk, breast-high, after the rough bark has been removed. With improved machines for scraping the bark and applying the glue, and which do the work three to five times as fast as it can be done by hand labor, the cost per acre of Spruce-forest was $1.80, of which $1.25 was for the material; it is, therefore, a cheap remedy. The bark scraper is a simple instrument of the plane type, and the banding machine, an apparatus to put on the glue quickly and of proper size, does not cost more than 50 cents, if purchased from the inventor. I am prepared to give addresses of the firms manufacturing the insect lime and the machines, if wanted, and further details in regard to their application. The effectiveness of the bands is due to the fact that the caterpillars, be it on account of the disagreeable smell (tar-oil) or of their objection to soiling their coats, are absolutely unwilling to cross the barrier, and can be gathered below the band and killed, or die from starvation. The insect lime must, of course, have the capacity of keeping fresh and maintaining its consistency for two or three months in all weathers, and this is the secret of its preparation.

The absolute success of this application as a preventive rather than a cure, and its freedom from the objectionable features which attach to the spraying of arsenic and other poisons, etc., certainly recommend it at least for trial in this country.

Forestry Division, Department of Agriculture, Washington. *B. E. Fernow.*

Exhibitions.

Spring Flower Show at Philadelphia.

THE exhibitions of the Pennsylvania Horticultural Society are always attractive, and the Spring Flower Show, which was held last week, was rather happier in arrangement than usual. Nothing could be much better than the bank of foliage in front of the stage, with the graceful line of Palms rising above masses of green, and just enough of color from flowering plants to relieve it from monotony. In front of the stage, but separated from it by a walk, was a considerable space, covered with flowering plants and shrubs, Azaleas, Hydrangeas, Cytisus, etc., which was very effective, both by itself and in connection with its background. Why are not plants on exhibition arranged on the floor oftener than they are? This is the natural position for the greater proportion of them, and certainly, in this instance, if some of the specimen Palms and Ferns in the great collections had been placed on the floor they would have appeared to better advantage than on the stages, not only because the point of view would have been better, but because the valance around the staging was by no means decorative in itself, and it certainly did not add to the beauty of the plants, either in the way of harmony or contrast.

Apart from the ordinary plants on exhibition there were two groups which attracted great attention. The first of these was Dr. Williams' collection of dwarfed Japanese trees, of which much has been written. The specimens exhibited were said to range from fifty to a hundred years old, and yet they were hardly more than two feet high. What was interesting about them was the contorted and weather-beaten look which gave them a really venerable aspect, in spite of their minute proportions. One of them was a Pine, and the others seemed like different forms of Thuya. The second group consisted of several wagon-loads of Cactuses which Mr. Blanc had sent down from his immense collection. About 300 varieties were here represented in 500 specimens. Many of them were in flower, although this is not the season for them, and many more were carrying highly ornamental fruit. Besides the Cactuses there were some striking Aloes, Agaves, Euphorbias, and Mesembryanthemums. Among the most remarkable of the plants were two Anhaloniums and the so-called Bishop's Head (*Estrophytum myriostigma*). The genus Cereus was represented by some extraordinary and fantastic varieties of *C. flagelliformis*, *C. formosus* and *C. tuberosus*. Of Echinocacti the most interesting were *E. Arrigens*, *E. cornigerus*, *E. turbiniformis*, *E. Texensis* and *E. candidus*. Of the neat little Mammillarias the best were *M. echinata*, *M. elephantidens*, *M. lasiacantha*, *M. micromeris*, *M. pusilla* and *M. sanguinea*. Many other genera were equally well represented, and to large numbers of visitors the display was a revelation of the remarkable variety in form and in size and in habit which these grotesque and beautiful plants assume.

The foyer was bright with blooms of Roses, while of Orchids the best were those of Mr. C. F. Evans, whose plants were hung from the short stumps of branches of a dead Cedar, which was draped with Vines and Ferns. It would be hard to find better Roses than the Ulrich Brunners of Messrs. Pennock Brothers, Edwin Lonsdale and John Burton. In fact, this Rose seemed to justify the reputation which it enjoys about Philadelphia of being the most perfect of all Roses for forcing. Madame Luizet and Mrs. John Laing seemed to be of equal merit as usual, while the Jacqueminots and Wootons and Baroness Rothschilds were remarkably good. The exhibitors already named, with Messrs. Kift & Son, Heron & Nisbit took the principal prizes in Roses. *Lilium Harrisii* was abundantly displayed, and those by W. K. Harris, Michael Sammon and other growers left nothing to be desired. There were but few plants, however, of the more beautiful *L. longiflorum*, which always appears to excellent advantage in comparison with the Bermuda Lily, on account of its much firmer and more gracefully poised flowers.

The collections of choice and rare greenhouse plants from the gardens of the Messrs. E. W. Clark, George W. Childs, A. J. Drexel and H. A. Dreer were, as usual, the central features of the exhibition of this class of plants. One rarely sees anything better than the splendid Pritchardia exhibited by James Long, gardener to Mr. Drexel, or the great Livistona and the *Microlepia cristata* which Mr. Hughes sent down from Mr. Childs' collection. The premium for a new and rare plant went to the gardener of Mr. Drexel for *Spathiphyllum pictum*, who also took a premium for Palms and Ferns.

The Carnations attracted a good deal of attention, and a certificate of merit was justly given to E. G. Hill & Co., of Richmond, Indiana, for a remarkable collection of seedlings, many of them of immense size and of clear distinct colors. Mr. H. E. Chitty, of Paterson, Edward Swain, Avondale, and Charles T. Starr, of the same place, all showed new departures in Carnations, and, undoubtedly, the group, taken altogether, was the finest ever seen in Philadelphia.

Special mention ought to be made also of the new greenhouse Azalea, called Vervainiana, which was shown by Mr. James Dean, of Bay Ridge, New York, for the first time. The flower was double and richly variegated from white to deep crimson. Near by these was also a group of hardy Azaleas of especial merit, which were shown, for the first time in this country, by Pitcher & Manda, of Short Hills, New Jersey. The flowers were of good size and of distinct colors, and they promise to be valuable additions to the shrub-border.

Recent Publications.

Monographie der Abietineen der Japanischen Reiches. By Heinrich Mayr. Munich, 1890, pp. 1–104, with seven colored plates and analyses.

Dr. Mayr, who is now well known in this country, where he has traveled extensively, by his remarkable work on the forests of North America, has devoted some part of the last three years, during which he has occupied the chair of Silviculture in the Imperial University of Tokio, to studying in their native forests the various forms of *Abietiniæ*, in which they abound. Dr. Mayr, so far as relates to the grouping of the species of these trees, follows in general lines the authors who have written before him on this subject. He proposes, however, several new species detected by him during various journeys made in the Japanese forests. These are *Abies umbellata*, a tree which appears to resemble the now well-known *A. brachyphylla*, if one may judge from the plate; *Picea Hondœnsis*, belonging to the group of which *P. Ajanensis* is the best-known representative; *Pinus pentaphylla*, a large and interesting white Pine of the mountains of the central island, where Dr. Mayr discovered it, and related to our *Pinus Strobus*, but with shorter and smaller cones, as they appear in the plate. A Larch from the Kurile Islands is distinguished as *Larix Kurilensis*, and the little Pine which has been regarded a variety of the Cembran Pine of Europe is now considered distinct from that widely distributed species under the name of *P. pumila*.

The attention which is given to the description of cultivated varieties of different Japanese conifers adds particular value and interest to this work for the cultivators of trees, as descriptions will be found in it of many varieties cultivated and esteemed by the Japanese which the tree-lovers of America and Europe now hear of for the first time. Of *Pinus Thunbergii*, for example, nine varieties are described; of *P. densiflora* more than twenty varieties are recognized; of *P. parviflora* six, and of *P. pentaphylla* two; in all, some forty varieties of Pines, of which more than half have already been

distinguished in Japanese works of dendrology, the others now being first characterized by Dr. Mayr.

The views which the author expresses with regard to the specific rank of Japanese conifers may not be all adopted, but his work, based as it is on observations made in the field by a dendrologist of great experience and equipped with trained powers of observation, is a most important and valuable contribution to the knowledge of trees. It would, perhaps, have been more generally useful if the characters of the different species and varieties had been written in Latin instead of in German, and the absence of an index, an inexcusable omission in a work of this sort, makes the pursuit through its pages of synonyms a serious and laborious undertaking.

Notes.

Mrs. S. T. Rorer, principal of the Philadelphia Cooking School, has prepared a neat volume of nearly 200 pages, entitled "How to Cook Vegetables." The book is not for sale, but is very appropriately used as a premium by W. Atlee Burpee & Co., the Philadelphia seedsmen.

The clear red flowers of *Erica carnea*, the Mediterranean Heath, are among the first to greet the eye in Central Park. A colony of these plants covering a rod or so along the bridle-path, opposite Eighty-first Street, is now making a cheerful show as their bright blooms are seen among Trailing Juniper, *Enonymus radicans*, and Scotch Heather, *Calluna vulgaris*.

A plant of *Androsace sarmentosa* in bloom has been sent to this office by Mr. George C. Woolson, who flowered it in one of his cool houses at Passaic, New Jersey. It is one of the prettiest of the genus, and carries a globular cluster of bright pink flowers on a stem rising two or three inches above a rosette of gray-green, softly pubescent leaves. It will probably prove hardy, and, if so, it will be a welcome addition to our list of early-flowering plants.

No. 2 of Volume II. of the *Memoirs of the Torrey Botanical Club* contains an account of the "Spring Flora of South-western Virginia," written by Miss A. M. Vail, who, some months ago, recorded her observations in Garden and Forest. The paper is annotated by Professor N. L. Britton, who describes as new *Clematis Addisonii*, *Pentstemon lævigatus*, var. *canescens*, and *Senecio aureus*, var. *angustifolius*. The same number also contains a paper by Mr. Arthur Hollock, on the "Autumn Flora of South-eastern Virginia."

Bartram's Garden, the first botanical garden established in the New World, and long the most famous spot of its kind in the United States, has, principally through the energy of Mr. Thomas Meehan, been acquired by the city of Philadelphia as one of its smaller parks, and the city has now taken possession of it and appointed a superintendent to preserve it. An interesting account of the garden, and of its founder, John Bartram, and of his son, William Bartram, appeared in the *Public Ledger* of Philadelphia on the 16th of the present month.

Writing to a friend in this country, under date of March 7th, Mr. W. Thompson of Ipswich, England, says: "The worst of our winter is over, I trust, but it is still cold, and plants are backward for us. Pear-trees are making a wonderful show of buds, which looks like the promise of a good fruit-year, although it does not follow that flowers will be perfected in fruit. But we have lost many plants reputed to be hardy, and what have survived may be regarded as hardy beyond all doubt. *Polemonium pauciflorum*, one of Mr. Pringle's plants, has stood well, to my surprise."

Mr. W. Junker, writing recently in *Petermann's Mittheilungen* about the journey he made five years ago between the Albert and Victoria Nyanzas lakes, spoke of the vast Papyrus-swamps which line the banks of the streams, and said that the natives use their stems to construct floating bridges or, where the river is too wide to be bridged, rafts, which are propelled across. In another account of the same region, given lately by Mr. Jackson, it was said that the British East Africa Company is trying to develop the large tracts of country it controls, by planting, in favorable localities, valuable timber-trees from India, as well as by importing colonies of Persians and Indians to start useful plantations of other sorts.

A circular from Mr. Thomas Meehan, which we have just received, states that he is determined to revive the publication of the discontinued "Flowers and Ferns of the United States" in monthly issues. Under the title of "Meehan's Monthly" this publication will contain, in addition to the colored plate of some wild flower, notes on various features of general gardening. The whole will be illustrated with wood-cuts. In the conduct of this monthly Mr. Thomas Meehan will be assisted by his sons, Thomas B. Meehan, J. Frank Meehan and S. M. Meehan. The first number of the periodical will commence in June, and its price has been fixed at two dollars a year. Mr. Meehan's return to horticultural journalism will be welcomed by many readers of the *Gardeners' Monthly* who felt something like a personal bereavement at the discontinuance of that excellent magazine.

The *Jackson* (California) *Ledger* notes the fact that the trees which were planted at the Experiment Station, located on the foot-hills, were obtained from nurseries along the coast, in interior valleys and on foot-hills. The stock was, in each case, thrifty and strong, and all seemed to start under the same conditions, but there is already a marked difference in favor of the trees from nurseries where the conditions of climate and soil are similar to those of the station. These trees have altogether outgrown those which were involved in a sudden change of conditions, and this seems to indicate that, in selecting a young orchard, it would be always advisable to procure trees from a location where the conditions resemble, as nearly as possible, those of the place where the trees are to have their permanent home.

At the nurseries of H. Meyers, Passaic, New Jersey, we observed last week that *Meconopsis Nepalense*, an Indian Poppy, was coming up strong from plants which had wintered with no other covering than some loose litter. These plants came from seed sown last spring in partial shade. It is something of a surprise to find this Meconopsis so hardy. Another plant of the Poppy family, *Eomicon chionantha*, which has already been described in these columns, was flowering in the greenhouse, and it will probably survive our winters out-of-doors. Among other hardy plants flowering in cold frames or in the greenhouse were *Alyssum spinosum*, a trailing species with glaucous foliage and yellow flowers; *Aster alpinus*, and its white variety, with flowers as large as a half-dollar, on stems four inches long; *Geranium tuberosum*, with finely cut foliage and flowers after the style of our common native species; and *Erpetion reniforme*, the Australian Violet.

The death of Mr. John B. Russell, which occurred at Indianapolis on the 11th instant, removed one of the pioneers of American horticulture. Mr. Russell was born at Cambridge, Massachusetts, July 23d, 1801. He was a printer by trade, having been instructed in that art at the famous University Press, in his native town. In 1823 he started a printing establishment in Boston, where he printed the *Christian Register*. In 1824 he purchased the *New England Farmer*, and conducted it in connection with a seed business at 52 North Market Street. His interests now brought him in contact with agriculturists and horticulturists from all parts of the country, and ultimately his offices became an acknowledged rendezvous, where matters of interest to the cultivators of the time were discussed. It was here that the idea of forming a horticultural society was first mooted, and the first public suggestions on the subject were made in an article which appeared in the *New England Farmer* of January 9th, 1829. In that month the office of the *Farmer* was removed from the third to the second story, and the society, when formed, occupied a part of the room vacated by Mr. Russell, and the *Farmer* became the organ of the society, and so remained until its publication ceased in 1846. The society was incorporated in June, 1829, and Mr. Russell at once commenced practical work as general agent of the society, and continued it until 1832, when he sold his interest in the Market Street establishment. After leaving there he engaged in another publishing enterprise until 1839, when he went to Cincinnati, where he became general and commercial reporter for *The Gazette*, which position he held until 1858. Later he was clerk at Washington to the Commissioner of Pensions, and in 1868 he was appointed Librarian of the Department of Agriculture. He retained this position until ill health compelled his retirement. Mr. Russell was the last surviving corporator of the Massachusetts Horticultural Society. Although hardly a surprise, on account of physical infirmity and increasing years, his death is much regretted by those about Boston who know of the good work he accomplished when laborers in the field of horticulture were few. There is much to interest readers of the present day in Mr. Russell's "Reminiscences of the Massachusetts Horticultural Society," which appeared in *Tilton's Journal of Horticulture*.

GARDEN AND FOREST.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, APRIL 1, 1891.

TABLE OF CONTENTS.

The Movement for Better Roads.

THE agitation for improved systems of road-construction and road-maintenance has become so general throughout the country that it may be fairly said to have attained the dignity of a popular movement. The subject is calling forth articles by writers of authority in our leading magazines and weekly journals, in the bulletins of scientific societies and state experiment stations, and in pamphlets issued by various associations organized for economic reform. The Governors of half a dozen states have felt impelled to invite attention to the importance of the subject in their annual messages; in several of the states, notably in New Jersey, laws have been enacted during the winter which overthrow the traditional methods of highway repairs, and in other legislatures bills are under consideration, with a probability that they will become laws, which provide for state aid and expert supervision in the maintenance of highways, and it is proposed in more than one instance to use the direct-tax money which has been returned by the general Government to individual states as a permanent fund for the improvement of country roads.

The sentiment in favor of reform in this matter would be still more urgent if the mass of the people had any experimental knowledge of the superiority of good roads over poor ones. When farmers can be shown by actual practice that good roads, by enabling them to double their loads, add to the value of everything carried away to sell, save minutes or hours every day which amount to days and weeks in the year, and bring them closer to markets and amusements, and schools and churches, they will urgently demand a reform which promises to add so much to their comfort and profit. And they will be still more eager for this improvement when they find that it costs one dollar to keep in repair a good macadam road instead of the five dollars which they have been paying in taxes to maintain the same length of dirt road, upon which, even when in fair condition, three horses are required to haul the load which one can draw on a properly metaled surface.

But one of the special duties of this paper is to invite attention to the value of natural beauty, and we wish here to emphasize the arguments quoted last week from the report of the New Hampshire Forest Commission. Every census shows that the population of our cities is growing at a more rapid rate than that of the rural communities; and every year the proportion of the city population which escapes to the country for summer rest and recreation increases quite as rapidly. The people of the country enjoy and appreciate natural scenery, no doubt, but to those who have been confined to blocks of stone for eight or ten months of a year it has a charm of freshness and novelty that brings intense delight and unspeakable refreshment. Good roads not only help the country on its way to the city, they invite the city to enjoy the pleasant prospects of the country. The bit of New Hampshire road-bed on page 152, reproduced from a photograph by Dr. W. H. Rollins, of Boston, is by no means a model of construction, but the illustration altogether is its own excuse for being. The happy brook as it flows out into the sunshine from under the shade of lofty trees and the hint of forest-covered hills in the distance unite to make a bit of scenery which every one will recognize as a typical one in the New England hill-country. Such prospects are to be found there by the hundred, and only the instinct of an artist is needed to select a view-point from which the landscape will present a richness of composition, a harmony and balance which make a perfect picture. Such scenery is a part of the natural wealth of any region. It is not only a priceless inheritance of delight to the eye and the imagination, but it has a productive value in attracting strangers. The building and maintenance of good roads and paths in such a country are investments which will bring even more abundant pecuniary return than they will in strictly agricultural regions. Indeed, there are many parts of the world which are famous for their natural beauties alone, and the only way to make these attractions available is by perfecting their system of public roads.

One who is preparing a home in the country will always find that it is as profitable to secure the counsel of a landscape-gardener, if his grounds are to be laid out to the best advantage, as it is to take the advice of an architect in the construction of his house. Indeed, as has often been insisted on in these columns, the two ought to work together from the very outset; for just here the training of the landscape-gardener will be found of especial value in selecting the precise location of the building. But a great many houses throughout the country have not been designed by architects, and, of the grounds about them, not one in a hundred has been planned in accordance with professional advice. Of course, many of these houses are ugly and inconvenient, and the same is true of their surroundings. But we have all seen country houses which look as if they were made to live in, and in which their occupants find life a pleasure; and these houses nestle cosily in the exact spot where they belong, and are so naturally connected with it, by shrub and vine, that they seem to have developed there as an integral feature of the landscape; and yet no professional designer has ever aided in planning either house or grounds.

Such "house-scenes," however, are not likely to come by chance. They are the result of thought and taste. They are the expression of careful study and long labor by some one, although the labor has been one of love, for there is no more fascinating occupation than a serious attempt at designing the home-acre. In no other way than by actual practice can the amateur appreciate how much is meant by the word "design." At every step he will find problems to puzzle him which an expert might solve at

once. But, after all, if one is in earnest to make the most of his situation the task will always be delightful, and the result will often be most satisfying. Any one can learn how to propagate and plant and make trees and shrubs grow if he takes time enough and interest enough, and, perhaps, the best course is that usually adopted by amateurs, which is to begin and profit by mistakes. But only the select few can make pictures with this material after they know how to grow it. Only "the prophetic eye of taste" can see how a landscape will appear in twenty years—after saplings have expanded into trees and a bleak hill-side is converted into a forest. Fewer still are they who can create an ideal scene which will be worth waiting twenty years to realize while it is growing in beauty and interest every day. Very instructive would be a series of pictures of the grounds about some country house, beginning with a map and view of the place in its original condition, and followed by a succession of illustrations taken every year in which the development of the scene to its ultimate fulfillment could be traced.

In this number we begin the publication of some sketches of the trials and joys of an amateur in landscape-designing, which will in some degree supply the place of such a panorama. If a faithful record of failures as well as of successes is given, the articles will prove as helpful as they are entertaining. They certainly will find sympathetic readers among that large class of persons who have at some time been lured into an effort to model and decorate a portion of the earth's surface in accordance with their personal views, and who, of course, have never outgrown their interest in such matters, for the garden-habit, when once fixed, is never completely overcome.

Rafinesque.

MR. THOMAS MEEHAN has lately printed in the *Public Ledger*, of Philadelphia, some new and interesting information about the Sicilian botanist Rafinesque, one of the most brilliantly endowed naturalists who have studied the flora of North America—a man who, from personal peculiarities partly and partly from the literary and scientific eccentricities of the latter part of his life, was not appreciated by his contemporaries in this country or valued at his true worth by the generation which followed them; and it is only in our time that naturalists are beginning to realize the breadth of Rafinesque's mental equipments and the justness and value of many of his observations. His theory, for example, now universally acknowledged, that new species and genera are being continually produced by derivation from existing forms, appeared the utterances of a madman and entirely outside the teachings of the theological faith which before Darwin's time had not lost its hold on scientific thought. The burial place, even, of this remarkable man long remained unknown, and it is only recently that it has been located in an obscure lot in Ronaldson's Cemetery, at the corner of Ninth and Catharine Streets, in Philadelphia. The plan of removing his remains to a more honored spot and of marking his resting-place with a simple monument will be approved by every American naturalist.

Rafinesque's will, rescued from oblivion by the energy of Mr. Miller Reeves, of the *Public Ledger*, throws much light on the history and character of the man, and in bringing to light his domestic history gives a clue, perhaps, to the cause of some of the eccentricities of the latter years of his life. It is not very creditable to the intelligence and public spirit of the Philadelphia of fifty years ago to find that "one who evidently lived to do good as he understood it—who supposed he would have, when he made his will, not only something for his family, but enough to warrant a thought of benefiting orphan girls—should die in a garret on Ray Street, between Third and Fourth Streets, in the midst of his great collections, with nothing but a hard cot for furniture and no living soul at hand to close his eyes," and that "the medal he hoped should forever remain in his family should be summarily tossed into the mint as old gold; while the manuscripts, which should be judged by 'The Medical Flora of the United States' a truly valuable work even to this day—manuscripts on which he had depended for legacies and reputation—should have been sold for $5 only, while even the herbarium paper brought over $20; and that his great collections of books and objects of natural history—costing $7 to catalogue, $8 to clean, $6 to carry and $4 to help fill eight wagon-loads to the auction mart—should have only realized $22.29."

Rafinesque was evidently of opinion, when his will was written in 1833 (he died in September, 1842), that he was a man of means. In it he bequeaths his "immortal soul to the Creator and Preserver of the universe, the Supreme Ruler of millions of worlds soaring through space, to be sent to whatever world He may deem fit and according to His wise laws." Secondly, he provides that his body should be cremated, that it "may not contaminate the earth and be the cause of disease to other men." In the third clause he leaves his personal property, consisting chiefly of scientific collections, books, patents, secrets and claims, to his sister, Georgette Louisa Rafinesque, married to Paul Lanthoes, of Bordeaux, and to his daughter, Emily Louisa.

The fourth clause of the will is, perhaps, the most interesting in the light it throws on the personal history of the testator. "While residing in Sicily," it relates, "I deemed myself lawfully married from 1809 to 1815 to Josephine Vaccaro, although the decree of the Council of Trent forbade our regular marriage. In 1811 was born my daughter Emily, and in 1814 my son Charles Linnæus, who died in 1815. But on hearing of my shipwreck in 1815, Josephine suddenly married Giovanni Pizzalour, a comedian, and dissipated the property I had left in her hands. She also refused to send me my daughter, for whom I sent in 1816 and 1817 two brigs in succession to Palermo, the Indian Chief and the Intelligence, wherefore I have ever since refused to notice her and do not leave her a single cent of my property, as she has another family by a living husband."

The sixth clause provides that his books, maps, engravings and collections of natural history, etc., shall be sold and the proceeds used by his executors to print and publish "my manuscripts, sketches and maps in the cheapest form in America or Europe in English or French, unless the copyright can be sold. These posthumous works of mine to be sold at an advance of one hundred per cent. and one hundred copies at least to be printed. The proceeds of these copyrights or sales are to form the fund of my inheritance, to be equally divided between my sister and daughter."

The eighth section names a number of these unpublished works, namely, "The History of American Nations," "Travels and Researches," "Tellers or History of Mankind," "Monuments of America," poem on "Instability," "My Biography," and places them in the hands of Professor John Torrey, of New York, and of Professor Jacob Green, of Philadelphia, his executors. Number seventeen provides that the gold medal, which was so summarily turned into the mint, and which had been awarded to Rafinesque by the Geographical Society of Paris, shall be left to his nephew, Jules Rafinesque, on condition that it is to be kept in the family of Rafinesque "as an honorable record and as a reward of merit."

Section twenty-one is pathetic in view of the amount derived from the sale of the collections and manuscripts. It provides that "if the proceeds of my estate and posthumous works, patents and inventions should exceed the sum of $10,000, or 50,000 francs, I direct that the interest, whatever it is, be put at compound interest in a savings-bank for the benefit of the first female orphan school which shall be established in the United States as near as possible on the plan of Gerard's Orphan College for boys, and if none is established within ten years after my decease, I give the same excess to the first free library that shall be established in fire-proof buildings in the United States."

An inventory of the estate with the executors' accounts is filed with the will. This last shows that when the estate was settled, after all the collections and books had been sold, including the $6, which seems to have been all the ready money Rafinesque had at the time of his death, the estate was indebted to the executors to the amount of $13.43.

How We Renewed an Old Place.

IN describing some very humble attempts to bring order out of chaos in a bit of one of "the unreclaimed farms of Massachusetts," my object is partly to acknowledge a debt to Garden and Forest for the many practical suggestions which have been a help in bringing harmony and beauty out of neglect and desolation; and at the same time to show its readers the pleasure and interest of endeavoring to create, under its inspiration, a garden and forest of one's own.

The experiments that I relate are by no means completed, and the mistakes made will call for sympathy, as the successes will claim congratulations; but to those who will kindly go with me

along the way we have come, at all events the story ought to show what can be done with moderate expense, by the aid of such excellent publications as are now within reach of every one, and how, by loving labor, the old may be made to add charm and dignity to the new, while the new lends purpose and meaning to the old. What has given so much delight in doing, must, it seems to me, give pleasure when told, and it is in this hope that I venture to detail our very simple experience.

I.—THE OLD PLACE.

In the very heart of old New England towns there may often be seen some dilapidated house falling into ruins, surrounded by half-dead fruit-trees and straggling shrubs, while an adjacent garden, once productive and blooming, runs to waste beside it. Its gates are off the hinges, the fences falling to pieces, the hedges untrimmed, the flower-beds smothered in weeds, coarse burdocks and rampant wild vines encumber the ground and run over into the highway, the trim paths have disappeared, the out-houses are toppling over; forlornness and abandonment speak in every line of the decaying house, the former gentility of which renders its decline still more melancholy.

It was such a dreary old place as this which attracted our attention when we first came to settle in Massachusetts. Why such a desirable spot should have fallen into disrepute was always a surprise, for the situation in itself was excellent, the estate running for nine hundred feet along the main street of the town, and lying about half-way between the two villages known in popular parlance as The Plain, and Broad Bridge, so that it was only a quarter of a mile from the post-office of one, while the railway station of the other was within a ten minutes' moderate walk for a man. Moreover, it commanded one of the loveliest inland views possible, and had an unusual variety of surface to make it interesting, as well as a fertile soil for grass and garden.

The view was what particularly appealed to us, for it comprised a charming stretch of salt meadow with a blue stream winding through it like a ribbon, skirted by low, heavily wooded hills, with a distant glimpse of houses overtopped by the masts of the shipping in the harbor. From the higher levels of the farm one could catch a glimpse, when the leaves were off the trees, of a strip of blue sea, and Boston light could plainly be seen revolving after sundown, while of a still evening the monotonous roll of the waves upon the beach could be clearly heard.

The old house, which we vainly tried to find habitable, had stood for 200 years, and must have been a fine dwelling in its day; its rooms, though low-ceiled, being spacious and numerous, and their outlooks picturesque. It was ill-planned for modern comfort, but many of its contemporaries in this ancient town are still occupied, and by a little alteration made very comfortable; still, owing to neglect and ill usage by tenants, the owners having long since moved away, it was in a condition of hopeless disrepair. The floors had settled, and the walls with them, until, in some of the lower rooms, there were gaps beside the beams of the ceiling in which rats or squirrels had made their nests, so that supplies of nuts were to be seen safely stored away in the holes. The window-panes were broken, the shingles moss-grown and ragged, the chimneys falling into ruins and the sills had rotted away. Moreover, the road that wound by the door had been so raised by the accretion of 200 years that the part of the place around the house lay in a hollow, and, there being no one to complain, the town dug water-ways and coolly drained the road over the surface of the ground, so that after a spring freshet piles of sand were to be found all over the grass, giving the farm a water-logged aspect that added to its disrepute.

From this, and from the fact that, situated as it was between the two villages, it formed absolutely a part of neither of them, to us an advantage rather than a drawback, but to the town's-people an objection; it resulted that when the farm was put up at auction, some ten years ago, no purchaser could be found at any price. Finally, convinced that the land was worth more without the house than with it, the owner took it down, and, to the great amusement and consternation of the old farmers who despised the spot, we bought the place for a moderate sum, having convinced ourselves by careful examination that it would at least give us an occupation for the rest of our natural lives to get it into condition, and as that was what one of us wanted, we were disposed to try what could be made of it, and confound our critics.

Then arose in the village a murmur of disapprobation and superior wisdom, such as is apt to follow any purchase in a New England country town.

"What does the doctor want of that forlorn old hole? Only a salt-ma'sh to look at, and the road a-drainin' right into it all the time. Ain't no place to put a house; too shady and wet where the old one was, and ef he goes up on the hill he'll jest blow away. Used to be a good farm in the old man's time; best garden spot in town, but pretty well run out now; and the fences! It'll take all he'll earn to keep them fences in repair; half a mile o' fencin' ef there's a rod."

And so the croaking went on behind our backs, and sometimes to our faces, with only a word of good-will now and then from people who recalled the charm of the old place when it was in the hands of the family, and hoped that something of it might in time be restored.

We ourselves, left face to face with our bargain, went over the land, now our own, and took heart of grace as we planned our first improvements, and decided on a site for the house. When we took an account of stock this is what we found:

A curiously shaped piece of land, something like the state of Maryland, omitting the eastern shore. The long front of about nine hundred feet, lying upon the main street, at its southern end was nearly six hundred feet in depth, but this part of the place was a barren gravelly hill, which had been pastured until nothing was to be found upon it but a thin, wiry grass full of white weed and a growth of short briers. In the autumn it was a blaze of Golden-rod. The hill sloped steeply to the north and north-east, so that the side of it was exposed and cold, the wind sweeping up across the meadow from the sea in bleakest gusts. This we at once determined was the place to plant Pines, with a view to a subsequent forest. At the foot of the hill was a fertile swale of excellent grass-land, which intervened between it and a second rise of land, which was the termination of another gravelly hill, through which the main street had been cut, leaving upon our side a small knoll, from which the ground sloped in every direction, making a perfectly drained and slightly elevated spot for a house, an excellent, but rather limited situation, perfectly barren of trees, and requiring much grading.

On the north side of this knoll was another abrupt slope, and then the ground swept on below the level of the highway, gradually narrowing, as a back street, running obliquely, came to intersect the main road at the northern extremity of the place, where was an Apple-orchard of immense old trees whose bending boughs swept the ground; and in the very point a wilderness of Locusts and Wild Cherries.

The site of the old house, shaded by some fine Elms and White Ashes, was too near both streets to be at all desirable, though the shrubbery and the tangled remains of an old flower-garden rendered it very attractive, but at the rear the salt-marsh was in too close proximity, and about half an acre bordering on the back street was so overflowed at times by salt-water that it would only afford a crop of marsh-grass.

The neighborhood of this meadow was thought to be one of the drawbacks of the spot by many; but, knowing that it was perfectly wholesome, and certainly beautiful, to us it was only an added advantage, so long as the gravelly knoll gave us so good a foundation for our dwelling.

Our first problem, the fences, we determined to deal with by planting Willows. The barren hill-side was to be screened with Pines, and our manner of procuring and setting these will form the subject of my next paper.

Hingham, Mass. *Mary C. Robbins.*

Notes on North American Trees.—XXV.

63. *Acer grandidentatum* is a small tree, of the Sugar Maple group, scattered in a few rather isolated situations in the central mountainous region of the continent from western Montana, where Nuttall discovered it many years ago, to northern Mexico and western Texas. It has small, pale leaves, only two or three inches across, deeply three-lobed, with mostly acute or sometimes obtuse lobes. The flowers and fruit are not to be distinguished from those of the Sugar Maple, except that they are sometimes a little smaller, and I can find no good characters by which to separate this western tree from our eastern Sugar Maple, to which it appears joined, botanically and geographically, by a tree of the Gulf states with small obtusely lobed leaves, often pale on the lower surface, and with small flowers and fruit. This is the *Acer saccharinum*, var. *Floridanum*, of Chapman ("Fl. S. States," 81), which is found from western Florida to western Texas, where I have collected it on the banks of the upper Cibolo River,

not very far from the town of Bœrne. This passes, on the one hand, into the mountain form of the west which reaches the Guadaloupe Mountains of Texas, and on the other into some of the small-leaved forms of the variety *nigrum* of the Sugar Maple of northern Alabama and of Tennessee. Considered in this way the Sugar Maple is the most variable of our species, always within certain limits, and the most widely distributed in its range, with the exception only of the Negundo. The fact that the Sugar Maple sometimes bears stipules, as was recorded by Professor Gray many years ago (*American Naturalist*, vi., 767; vii., 422), is interesting, as the presence of these organs has not been noticed in other Maple-trees, although I find, sometimes, a minute caducous fringe of white hairs on the enlarged base of the petioles of Negundo which appear to be stipular in character. On some individual trees of the Black Maple in Indiana and in central Michigan these large and well-developed puberulous foliaceous stipules are not uncommon. An illustration of them appears on page of 149 this issue, made from specimens for which I am indebted to Professor W. J. Beal. These stipules are said to appear constantly, year after year, on the same trees, but, in spite of this, can hardly be depended on to distinguish the Black Maple, even as a variety, as the individual trees which produce them are confined to a few isolated localities, and they are not present, so far as I have been able to examine them, on trees in other parts of the country.

The Black Maple in the extreme form, which appears in central Michigan for example, is certainly a very distinct tree. There it often has large, thin, three-lobed leaves with broad shallow sinuses, the sides of the basal sinus overlapping so that they seem almost peltate. The leaves are villous or densely pubescent on the lower surface, and sometimes furnished with large foliaceous stipules. Their sides drop, as Professor Bailey has pointed out (*Botanical Gazette*, xiii., 213), when they are fully grown, like pieces of old limp cloth, giving to the trees a heavy dull appearance which makes it easy to distinguish them at a considerable distance. But this is the extreme form, and many intermediate forms occur which connect it with our common eastern Sugar Maple and make it impossible to look on the Black Maple as a species.

The question of the correct specific name of the Sugar Maple is not easily settled. Linnæus bestowed upon the Silver Maple the name of *Acer saccharinum*. The identity of his *Acer saccharinum* is made clear by his description published in the first edition of the "Species Plantarum" and by the specimen upon which this description was based preserved in his herbarium. Wangenheim, some years later, when he described the true Sugar Maple, misled probably by the vernacular name, transferred to this tree the name of *saccharinum*, already appropriated to another tree. Here began the error which has been continued by nearly all writers on our trees. The next name given to the Sugar Maple, about which there can be no question of identity, is Michaux's, *Acer barbatum* ("Fl. Bor.-Am.," published in 1803). Marshall had published in 1785 his "Arbustum Americanum," in which *Acer Saccharum* is described, and it is held by some authors that this is an older name of the Sugar Maple than the *A. barbatum* of Michaux, and that being a different word from *saccharinum*, the Sugar Maple must be called *Acer Saccharum*. A name, however, cannot be adopted as long as any doubt exists as to the identity of the plant to which the author applied it, and in this case it is not at all certain what tree Marshall had in mind when he described his *Acer Saccharum*. He enumerated six Maple-trees; of the identity of three of these, *A. Pennsylvanicum* (*A. striatum*, Lam.), *A. Negundo* and *A. Canadense* (*A. Pennsylvanicum*, L.), there is no doubt. The others are *A. glaucum*, the "Silver-leaved Maple," which he describes with flowers of a deep red color, adding that "it is perhaps the *A. rubrum* of Linnæus." "The leaves," he says, "are five-lobed, somewhat toothed or deeply and irregularly sawed on their edges. They are pellucid green on their upper side and a bright silver color on their under." This may be either the Scarlet Maple or the Silver Maple, the color of the flowers indicating the former; *Acer rubrum*, of the identity of this there can be no question, as the flowers are described as scarlet and pedicelate; and *A. Saccharum*, by which Marshall may have intended the Sugar Maple, the only other species of his region which he had not described, provided his *Acer glaucum* can be held to be the *A. saccharinum* of Linnæus; but Marshall's description of his *A. Saccharum*, the only thing we have to depend on, cannot be made to cover the Sugar Maple, as he says it flowers in the manner of the Scarlet Maple, which seems to imply a species with precocious flowers, either the Scarlet or the Silver Maple, and as the flowers are said to be of an "herbaceous" color, it is probably the latter, a view which is strengthened by the name, *Saccharum*, probably a misprint for *saccharinum*, rather than the Latin substantive. But as the identity of this plant cannot be satisfactorily determined, for Marshall left no herbarium, the only safe way is to pass over his name entirely and take up that of Michaux. If this view is adopted, our Sugar Maple becomes *Acer barbatum*, Michaux, and its varieties *Acer barbatum*, var. *nigrum* and var. *Floridanum*.

67. *Negundo aceroides.*—There seems no sufficient reason for retaining the genus Negundo, established by Moench, who dismembered Linnæus' genus Acer in doing so. American authors, following Torrey and Gray, have adopted Negundo, although Professor Gray as long ago as the appearance of the second volume of his "Genera Illustrata" suggested that Negundo was hardly distinct from Acer. He continued to retain the genus, however, in later publications, and in this was followed by Bentham and Hooker in the "Genera Plantarum." Other and later authors, including Maximowicz, Baillon, Koch and Pax, have reunited Negundo with Acer, and I shall follow them in the "Silva of North America," as Negundo only differs from Acer in its pinnate or ternate leaves and in the linear anthers of our species, and take up the Linnæan *Acer Negundo* for our Box Elder. The California tree, which cannot be separated specifically from the eastern form, will have to be known then as *Acer Negundo*, var. *Californicum*. Viewed in this way, the genus Acer may be divided into two sections, as proposed by Maximowicz:

1. Acer.—Flowers polygamous or dicœcious, petalous or apetalous. Leaves simple.

2. Negundo.—Flowers dicœcious, apetalous in the American species. Leaves pinnate or ternate.

Charles S. Sargent.

New or Little Known Plants.

Viburnum dilatatum.

THIS shrub is widely distributed and very common in some parts of Japan, and is not rare in central China. It is rather remarkable, therefore, that it has so long escaped the attention of American and European gardeners, as in the autumn, when its brilliant red fruit covers the branches, it is, perhaps, the most ornamental plant of the genus known in gardens, and by far the best of the recent additions to the list of shrubs which can be cultivated in the open ground in this climate.

Viburnum dilatatum was introduced into England several years ago by the Veitches, in whose nurseries, near London, it flowered in 1875, their specimens supplying the material from which the figure, published the next year in the *Botanical Magazine* (t. 6215), was made. It apparently did not fruit in England, and was soon lost from cultivation. Seeds of this Viburnum were received in 1880, at the Arnold Arboretum, from the Agricultural College at Sapporo; the plants raised from this seed flowered a little in 1888, but it was not until two years later that they produced fruit in profusion and displayed their true ornamental value.

*Viburnum dilatatum** is a stout shrub, growing to the height of eight or ten feet, with spreading, pale, warty branches, clothed, when young, with short rigid hairs and rather obtuse reddish brown winter-buds covered with thick, pale tomentum. The leaves vary from two to five inches in length, and are often as broad, or broader; they are orbicular, or orbicularovate, or obovate, coarsely toothed, and often end abruptly in a short obtuse point. They are dark green above, paler below, the two surfaces covered with white hairs, and are destitute of stipules, and borne on short, stout, hairy peduncles. They turn very late in the autumn, here, to a dull yellow color, and remain on the branches until the beginning of winter. The flowers are white, short-pediceled, a third of an inch across, with a pilose calyx with short, obscurely toothed and circular lobes, and a rotate corolla hairy on the back of the lobes; and are produced in many-branched sessile

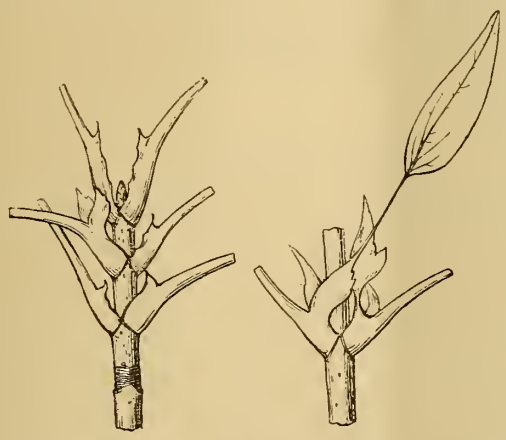

Fig. 27.—Stipules of the Black Maple, var. nigrum.—See page 147.

or pedunculate hairy cymes, four to six inches broad, and open, in Massachusetts, toward the middle of June. The fruit ripens in September; it is ovate, much flattened, a third of an inch long, and crowned with the remnants of the persistent calyx and style. It is very abundant in large broad clusters, and is bright red, or red slightly tinged with orange, and remains on the branches here until the beginning of winter.

Viburnum dilatatum resembles, in general habit, our common eastern *Viburnum dentatum*. It requires deep, well-drained, rich soil, in which it grows rapidly, soon forming broad masses of handsome foliage. The illustration on page 150 is from a drawing, made by Mr. C. E. Faxon, from one of the plants raised in the Arboretum.

Choosing Varieties of Apples.

MUCH which is written upon the subject of the choice of varieties for an orchard fails to commend itself fully to my judgment. Of course general recommendations can have no more than a general character; but, necessarily, such should not be too sweeping or without suggestion of exceptions.

The most frequent advice given is to plant but a few standard sorts and to avoid setting much early fruit. Such advice is common from those who have most widely erred in both particulars; but these persons are not likely to view the situation impartially. A good deal of money can be made by the right man, rightly located, in growing choice early varieties as a specialty. There is a large consumption of mild-flavored, mellow, early apples, and this can be indefinitely enlarged by supplying the market with well-grown early fruit in perfect condition. To do this business rightly, and to the best advantage, not only must choice productive kinds be planted and carefully tended, but such apples should be treated as carefully as choice peaches, and a market secured in advance. The most careful picking, packing and subsequent handling are essential, and cold storage ought to be provided as a protection against temporary gluts. Even the earliest varieties, if gathered properly at just the right time, may be held without harm in cold storage for several weeks if necessary. But it is rare that this is required with strictly choice fruit.

Very unwise, it seems to me, is the constant warning against varieties which are not of the highest quality. Many buyers of fruit have no great delicacy of taste, a faculty easily destroyed, when originally possessed, by some prevalent habits, the chief of which is the habitual use of narcotics and stimulants. The delicate, finely flavored apples, favored by connoisseurs, have not "taste" enough for the majority of buyers. Such persons require a degree of acidity which would be called "screeching" by more refined palates. The public generally are attracted by size, color and moderate tenderness of flesh.

In putting out an orchard we are counseled rightly, as a rule to set only standard sorts, well established in general repute. But there is such a thing as going too far in this direction. I am convinced by much experience and long observation that an orchard of one or two varieties is much less likely to produce full crops than one in which there are a dozen sorts, of different seasons, promiscuously planted. There need not be many of the sorts least in demand, and when we understand the true conditions we may furnish our orchards with abundant pollen without the risk of much unsalable fruit. Popular sorts noted as heavy and regular bearers when planted alone, of which Oldenburgh is a conspicuous instance, are desirable to some extent in every orchard; but as all varieties are not in bloom at once, the late bloomers which are apt to have a scanty yield of pollen would do best if accompanied by strong bloomers of the same blooming season. Probably the largest orchard in Vermont has proved a financial failure, as I believe, by neglect of the precaution here indicated; and I am inclined to the belief that the few orchards which gave full crops in 1890 did so because they were of mixed varieties, embracing a good share of freely polleniferous sorts covering the whole blooming season.

While the public is undoubtedly shy of unknown sorts of little exterior attractiveness, it is not necessarily so with a new variety of fine appearance and fair quality. This is shown by the quickness of several new sorts to win approval. The Yellow Transparent is a conspicuous instance of this; and from my own experience with the Wealthy, I do not believe there will be any difficulty whatever in finding a good market for it. Those to whom this variety was shipped from my orchards last fall seem to be anxious to buy all that can be supplied hereafter.

It is different with unattractive apples, and I would never advise extensive planting of such, except in the case of a high local repute, gained through a series of years. Some of the choicest dessert apples grown, and among them some sorts well known and widely distributed, and productive withal, have never been easy to dispose of in the general market. Peck's Pleasant is a variety of this sort.

The vogue of some apples seems entirely unaccountable to many who have written on the subject. The most extensively grown apple in America, Ben Davis, or New York Pippin, is a conspicuous instance. In the valley of the Mississippi and its tributaries it is the omnipresent fruit from December to May. It is large, it is productive, it is handsome, and a good keeper. It can be so grown as to be a fairly good apple,—equal, perhaps, to the average Baldwin; but, as we find it generally, it seems to well deserve the savage criticism visited upon it, even by men who are growing it for market by the hundred acres. But, as a living dog is better than a dead lion, and as there are few productive, long-keeping apples suited to our great valley, which are, at the same time, attractive to the eye and reliable in productiveness, it is not surprising to find Ben Davis holding its own there, and even intruding, as at present, into our eastern markets.

Newport, Vermont. *T. H. Hoskins.*

Points in Chrysanthemum Culture.

Protecting Plants in Flower.—A few years ago, when I described my so-called "Snug Harbor," I had no idea it would become so generally used as it now is throughout the country during late October and early November. It is simply a frame-work of wood, built on the model of a greenhouse—either equal span, three-quarters span, or half span. Before the plants are in flower, the sides and ends are covered with any kind of burlap, scrim, or other canvas. This is secured in position by being stretched tightly, and then held by

* Thunberg, "Fl. Jap.," 124.—Siebold and Zuccarini, "Fl. Jap. Fam. Nat.," ii., 171.—Miquel, "Prol. Fl. Jap.," 154.—Franchet and Savatier, "Enum. Pl. Jap.," i., 200.—*Bot. Mag.*, t. 6215.—Maximowicz, *Bull. Acad. Sci. St. Pétersbourg*, x., 664.—Forbes and Helmsley, *Jour. Linn. Soc.*, xxiii., 351.

nailing laths over it at bottom and top and horizontally at distances of about four feet. The roof is also of canvas on rollers, so that it can be removed during fine days, the rollers being secured by ropes, whether the canvas be up or down. This method of protection has given great satisfaction, but, like all experiments, there is generally room for improvements. A glass roof, formed of ordinary hot-bed sash, six feet by three, and costing about two dollars each, is now recommended together with a canvas to let down over on hot days and frosty nights. The canvas sides are to be kept as in the original plan. This canvas roof covering will keep out fully seven degrees of frost, providing, of course, everything is snug and tight. The temperature of a greenhouse, glazed with large glass and without any fire heat, will be found as cold as the outside temperature within three degrees when the thermometer registers thirty degrees or lower; the canvas, therefore, affords very great protection from frost.

Growing the Plants.—Where it is practicable, the best plan for growing plants for such structures is to set them where they are to remain. They should not be planted before the first of May, and plants from three-inch pots are better than larger ones. Where old plants are used, no more than two shoots to each one should be allowed to grow, their distance apart being determined by the style of cultivation which is intended. If the plants are to be kept low and bushy, two feet six inches each way will be near enough; if there is head room sufficient for them to grow as high as five feet without being bushy, twenty inches apart will do. The plants should be pinched about the end of June, and as soon as they have broken, three of the strongest shoots should be selected and all the others should be rubbed off. The plants must be staked neatly and kept tied, so as to prevent their being broken or whipped by winds. Early in September the best buds should be selected and all lateral ones removed. It is entirely a matter of taste how many buds are allowed to remain; if the very largest flowers are desired, then from four to eight buds are enough; but for medium-sized, smoothly-finished flowers each plant will carry ten to twenty.

Fig. 28.—Viburnum dilatatum.—See page 148.

A New Style of Paper Pots.—Where it is not convenient to grow the plants in the structure they are to flower in, there are several ways of treating them: in pots plunged in the ground, or planted in the open ground and then removed just before the flowers open. This may be the most convenient way to give them the necessary attention during summer. Last season, in growing about a hundred plants, I made use of a new device and was delighted with the results. About the middle of June I had holes dug, a foot deep, a foot wide, and three feet apart. On the bottom of each hole was placed a piece of inch board nine inches square. A block of wood, the shape of a flower-pot, ten inches high and nine inches in diameter, with a piece of old inch hose nailed across the top for a handle, formed a core around which was wrapped two thicknesses of ordinary sheathing (tarred) paper; this core was then placed in the holes on the boards, and the soil taken out was rammed tightly about it, so as to make the paper solid against it. The block was then removed, leaving the paper in form of a pot. Good soil of turf and rotten manure was then filled into the paper cases, and plants from four-inch pots were set in them. These plants did not require water oftener than three times a week, whereas plants in pots had to be watered often three times a day. In October, when I lifted the plants, they had complete balls of earth about the roots, exactly as if they had been growing in pots all summer. It is an economical and very convenient way of taking care of Chrysanthemums, the cost of the paper being quite nominal.

The Best Varieties.—A good selection can be made from the following list to flower with protection without artificial heat:

Yellow—Gorgeous, Gloriosum, President Hyde, Chevalier Domage, Mr. Bunn, Mrs. F. Clinton, Aureole (Bouch), Dr. Delaux, Sunflower, Rohallion.

White—Mademoiselle Lacroix, Ivory, Lady Selbourne, Elaine, Domination, Avalanche, Blanc Précoce, Bertha Flight, Madame F. Bergman, Shasta.

Bronze—Madame F. de Cariel, William Robinson, M. Edouard André, L'Incomparable, Comte de Germiny, Source d'Or.

Pink—Bouquet Fait, Elenore Bares, Ada Spaulding, Mrs. Hicks Arnold, M. Brunet, M. Boyer, M. Lawson, Excellent, La Triomphante.

Red—George Gordon, M. H. Payne, Dr. Tanner, Bras Rouge.

Purple—John Thorpe, Louis Wielle, M. Bernard.

Where protection is given and artificial heat is available, of course a much larger variety may be selected as flowering from the 5th of November to the 20th. There is in the market a kerosene-oil stove, having about two by one and a half feet of heating surface, which is very cheap, safe to use, and capable of keeping frost out of a structure, say twelve by twenty feet, up to November 15th or 20th.

The following are among the best varieties for such treatment:

Yellow—H. E. Widener, Kioto, G. P. Rawson, E. G. Hill, W. H. Lincoln.

White—Minnie Wanamaker, Eynsford White, M. J. Thomas, Pelican, L. Canning, The Bride.

Pink—I. C. Price, Madame Baco, Alcyon, Miss M. Wheeler, Mrs. A. Blanc, Lilian B. Bird.

Bronze—G. F. Moseman, Carew Underwood, Edward Molyneux, Mrs. Bowen.

Red—Cullingfordii, Mrs. A. Carnegie, Bohemia, Mrs. W. Barr, Mrs. E. W. Clarke.

Early Flowering Plants.

In transplanting plants which bloom early in spring, one should not expect much from them the first year, unless great care is used to take with them plenty of soil, and unless they are moved before they have advanced far in their spring's growth. Even with this extra precaution, there are some that would do better if left until July. Among these are the Dog's-Tooth Violets, Spring Beauties, Wind Flowers, *Dicentra cucularia*, *D. Canadensis*, etc. Such plants almost always do better if left until they have gone to seed. The same can be said of the Trilliums, so far as their first season's growth is concerned; but when Trilliums are set in early spring, they make a better growth the second year than they do the year after they are transplanted in autumn. They usually produce medium-sized foliage and flowers, and thus save their vitality to establish themselves for a vigorous growth the second year. But when the transplanting is left until the leaf-bud begins to show itself above ground, the plant seldom makes a healthy growth, and on account of stunted foliage and broken root-fibers the bulb does not store up full strength for the second year.

In the middle or last of summer, after their stems have died down, there comes a dormant period for many early-blooming bulbous plants. It would seem that during this season would be the most suitable time for transplanting. If the plant is left until after the autumn growth has begun, there is then, in transplanting, a certain loss of vitality to the bulb, which has been used in starting this growth. Many of the fibrous roots are broken, and new ones must be formed. By transplanting during the dormant state, there is little or no loss of strength.

Southwick, Mass. *F. H. Horsford.*

Phajus grandifolius.

Although this noble plant was introduced into our gardens over a century ago, not a single good specimen of it was to be seen at the great exhibitions held in different places in this country during the last few weeks. *Phajus grandifolius* is an evergreen terrestrial Orchid, producing under good culture large, handsome, obovate-lanceolate leaves, two feet and a half long and nearly seven inches wide, and tall scapes seven feet in height, each carrying twenty-five to thirty very fragrant and beautiful flowers. There are usually two scapes from each pseudo-bulb, and often as many as a dozen fully expanded flowers on each at the same time. The sepals and petals are white on the outer surface and a chocolate brown within. The base of the lip, which is folded over the column, is white, stained with yellow on the throat and disk; the sides of the convolute portion flushed with crimson both outside and in.

P. grandifolius blooms during the winter months, and remains in bloom over two months in an ordinary greenhouse temperature. It is also well adapted for decoration, either as a pot plant or cut flower. To obtain large quantities of fine flowers, a liberal treatment is necessary; the plant is of easy culture and will amply repay any amount of attention and care. After flowering it should be kept rather dry and in greenhouse temperature, but never allowed to flag. Early in May the plants should be repotted, divided if necessary, the greater part of the old soil shaken out, and the roots trimmed if necessary. Strong, single growths make nice plants, and two or more may be put into a large pot for a specimen plant. Ample drainage must be allowed, as the plants, during the growing period, require copious supplies of water. Good fibrous loam and rotted manure with a dash of bone flour makes a good compost, and if the loam is inclined to be retentive, a little sand or broken charcoal may be added to keep the soil porous.

A somewhat higher temperature is necessary during growth, about seventy-five to eighty-five degrees, which can generally be maintained during the summer months in a greenhouse. Syringe every day with clean water and shade from direct sunshine. Occasional watering with liquid manure is also beneficial. After growth is completed, considerable reduction of water at the roots and moisture in the air must be made, as an excess at this season will cause blotches in the leaves and decay about the flowers.

Dongan Hills, Staten Island. *W. T.*

Hardy Plants from Seed.—In Mr. Hatfield's notes on this topic he states that nothing is gained by sowing seeds of such vigorous-growing plants as Delphinium under glass, as they rarely bloom the first season. This does not seem to be a happy illustration of what he wishes to say, since all the vigorous-growing Delphiniums will flower the first season. Last week I sowed twelve of the named double and single varieties under glass, and these I certainly expect to bloom the coming summer, and if they had been sown earlier, say in January, there would have been two crops of flowers, such as old-established plants yield, one in June and another later in September. It may be well to notice that there are a few species, principally North American, that require more than one season to be strong enough to flower, but these are not common in cultivation at present, and at best are not nearly as attractive as the older and better-known garden varieties. The following species have always flowered with me the first season: *D. cardinale*, *D. nudicaule*, *D. Cashmerianum*, *D. grandiflorum*, *D. formosum*, *D. exaltatum* and *D. crassifolium*. The beautiful garden forms which are the offspring of *D. formosum*, *D. grandiflorum* and others are the best varieties we have for decoration, and both double and single kinds are easily raised, and come fairly true. The double varieties seed sparingly, but from a few good kinds better varieties can be raised than the imported named varieties. While advocating early sowing

A Country Road-side in New Hampshire.—See page 145.

under glass, it is far from my intention to disparage the sowing under other conditions, but certain it is that these and other plants, even alpines, all pay for being pushed along early in the year. Unless alpine plants are raised early, while we have control of temperature, later in the season we often lose the plants.

South Lancaster, Mass. *E. O. Orpet.*

Pruning Out-door Roses.—As a rule, all Roses in the garden are pruned in spring before the sap starts. The Teas, many of the Bourbons, the Hybrid Noisettes, the Bengal or China Roses, and all others of comparatively weak growth, should be severely cut back; but vigorous kinds, like most of the Hybrid Perpetuals, need only a moderate topping besides the thinning out of the branches. Close pruning of the strong sorts occasions a great growth of wood, but few flowers. Many Roses are more or less injured for blooming every season by a too free use of the knife, notably the various Briers, climbers and native sorts. The Sweet Brier and Austrian Brier are much better when let alone than when closely pruned. There is a beauty in their free growth which is entirely marred by pruning them; and the little increase in the size of their flowers which might result from shortening in the branches does not compensate for the loss of their free growth. The Prairie Rose (*R. setigera*), like all climbing Roses, should be sparingly pruned, and the Dwarf Wild Rose *R. lucida* had better be left untouched.

Germantown, Pa. *J. Meehan.*

More Nematodes.—In a single large greenhouse recently visited, the three following plants, grown in large quantities, were found in a sickly condition: Begonias, Geraniums (Pelargoniums) and Salvias. The Begonia-plants were of considerable size, and some of them had lost a large share of their foliage. The remaining leaves had a wilted but water-soaked appearance, not easy to describe, and quickly fell from their attachments by the slightest touch. There was no sign of a Fungus upon the surface of, or within, the leaf, but upon picking a piece of a diseased leaf apart it was at once found, under the microscope, that countless eel-worms, or nematodes, were present in all parts of the leaf-tissue. It is not a new thing for these microscopic worms to infest the Begonia, but it is rare to find them so abundant and destructive. In a mass of variegated leaved Pelargoniums, perhaps half of the leaves over a considerable area had turned brown and had a disagreeable slimy feel. It was evident that when one such dead leaf had fallen upon a healthy one the disorder was quickly communicated to it. Here again, upon examination, no trace of any Fungi could be found, but, instead, there was an abundance of nematodes. The infested foliage was so transparent, due to the removal of the coloring matter, that by looking through the leaf with the microscope the worms could be seen in all parts of the tissue. The fact that Pelargoniums are subject to attack by nematodes has not been reported heretofore, so far as I know. In the bed of Salvias the leaves were generally blotched, sometimes more than half being dead, but the living and diseased parts were separated by a well-defined line; in other words, the blotches were angular, and in shape governed by the veins of the leaf. The dry brown patches when dissected yielded a full quota of nematodes. The Salvia-leaves, in general appearance, resemble those of the Coleus, noticed some months ago. This justifies us in adding the Salvia to the long list of greenhouse plants that are subject to nematode invasion.

Rutgers College. *Byron D. Halsted.*

The Cultivation of Beans.—The root system of the Bean' while extensive, is but slightly branched, and has but few rootlets. While it is a most persistent and searching collector of moisture and plant-food, gathering a full supply from a soil so poor that the roots of most plants would fail to get anything from it, yet it is comparatively slow in action, and seems unable to meet any sudden extra demand, and to be very sensitive to and slow to recuperate from injury by cold, excess of water, a mutilation from soil-cracking or injudicious cultivation. The entire plant, at every stage of its development from seed to seed again, is peculiarly liable to injury from adverse conditions of moisture and heat. If the seed is planted in earth which is too dry and hot it will malt and fail to grow, even when the soil is afterward made cool and moist. If it is put into ground which is but a little too cold and wet, it will rot; a few hours in a soil saturated with water will kill the roots, or if the plants are subjected for a few days to excessive wet or cold they will be checked beyond possibility of recovery. If the plants, when in bloom or young pod, are wilted by excessive heat and drought, from the injury of the roots by deep cultivation or pulling of long weeds, or because of the sapping of the food and water-supply by the growth of weeds, they will blast and fall off, carrying with them all hope of a profitable crop. As to the best time for planting, no fixed date can be given. It is useless to plant when the ground is in unfavorable condition as to warmth and moisture. Better delay planting until the 20th of July, and then give it up altogether, rather than put in the seed when the soil is too wet, dry, or cold. In general, Beans should be planted just after Corn—that is, just as it is getting a little past the best time for Corn-planting.—*Professor W. W. Tracy, in American Agriculturist.*

Correspondence.

"Insect Lime."

To the Editor of Garden and Forest:

Sir.—Mr. Fernow's recommendation of "Insect Lime" for a variety of our common pests, in addition to the "Gypsy Moth," is perhaps suggestive, and worthy of careful consideration, but it is apt to produce the same misconception as to its range, which long existed, and still exists, as to the effect of tin collars or oil troughs on tree-trunks. The band of "lime" would, undoubtedly, be effective against canker-worms, for here the female is wingless, emerges from an underground pupa, and must climb up the tree-trunk to reach the branches. She cannot pass a sticky band around the trunk, nor any similar obstruction, and if she oviposits below it, neither can the young larvæ. This fact makes the canker-worm an easily controlled pest. It is otherwise with the Fall-web worm, Bag worm and Tussock moth. The female of the web-worm is winged, emerges from a pupa enclosed in a cocoon, flies to the tree, oviposits on a leaf, and the young hatch and feed, intensely ignorant of the dangerous sticky band around the trunk. To be sure the larvæ sometimes wander when full-grown, seeking shelter to pupate; but, if they were stopped from coming down the trunk, they would simply pupate above the band, or the larva would allow itself to drop to the ground from the nearest projecting leaf or branch. In the case of the bag worm it would serve as a protection, where the trees were free from the pest in the first place. Here the female never leaves the bag in which the larva fed, and, after impregnation by the male, becomes an egg-sac purely. These eggs remain secure in the bags during winter, suspended from the twigs of the tree, and in spring they hatch; the young larvæ, already on the tree, and finding it unnecessary to leave it or go anywhere near this "lime." The Tussock moth is as safe, for here too, though the female is wingless, the eggs are laid in fall, quite usually far up on the trunk, or in a folded leaf, which is attached to the twig with silken threads. But, in the case of the last-mentioned species, winds will often cause the larva to drop, or, in its wandering instinct, when full-grown it drops voluntarily, and then a "lime" band would be effective. Still, it is only a very partial remedy, and does not begin to compare in effectiveness with winter collecting and destruction of egg masses, as recommended by me in a recent number of Garden and Forest. Concerning the "Gypsy Moth" I have nothing to say, since I have had no personal experience with it.

Rutger's College. *John B. Smith.*

The Western Arbor-vitæ.

To the Editor of Garden and Forest:

Sir.—I was much interested in reading the article on "The Western Arbor-vitæ" in the Garden and Forest for March 11th, 1891, but was surprised to see the statement, on page 109, "*Thuya gigantea*, unfortunately, is not hardy in the eastern states, and, like many of the trees of the Pacific forests, it cannot be used to beautify and enrich our plantations," since I know of at least three very fine specimens which are in excellent condition, and appear to be perfectly at home. One is in my own grounds at Morrisville, Pennsylvania—a tree about thirty years old, thirty feet high, and one foot in diameter of trunk at three feet from ground. Another tree, nearly as large, stands in the grounds of William Parry, at Parry, New Jersey. There is also a fine specimen in Central Park, New York City, of several years' growth, but I cannot give its dimensions.

While all three of these specimens occupy positions where they are slightly protected from heavy winds by other trees of large size, they do not show any symptoms of weakness or

tenderness, but are growing very rapidly, and making handsome, symmetrical trees.

I think it is a tree entitled to a conspicuous place in any good collection of large evergreens.

It can be propagated by cuttings, although not as readily as some of the other Thuyas; also by grafting on *Thuya occidentalis*.

If grafted, it should be worked low and planted deep, so as to get the tree eventually on its own roots.

Morrisville, Pa. *Samuel C. Moon.*

[It is interesting to know that this fine tree exists in the eastern states, and that it can be grown here in sheltered positions. It must be remembered, however, that a few isolated specimens, a few years old only, do not furnish satisfactory evidence that an exotic tree is capable of adapting itself permanently to new surroundings and of growing to a large size and to old age. There are two or three stunted specimens of the Big Tree of California in Central Park, and there are several larger specimens of the same tree in the city of Rochester, in this state; it would be very unwise, however, to plant the Sequoia anywhere at the east, except as a curiosity, on the strength of these specimens. Several of the Pacific coast conifers grow very well in the east for a number of years, especially if they can be placed in sheltered situations. None of them, however, are very reliable, and are more than liable to succumb to a succession of severe winters. Exceptions are the Weeping *Pinus ponderosa*, at Fishkill in this state, of which a portrait appears in our issue for October 10th, 1888; the fine plant of the Sierra Nevada White Fir (*Abies concolor* or *Lowiana* or *Parsonsiana*, as it is sometimes called in gardens), at Flushing, on Long Island, and a few plants of the Lawson's and the Sitka Cypresses in the neighborhood of Philadelphia. None of these trees are either very old or very large, and their survival through twenty or thirty winters does not prove the value of these species for general planting in the east. Correspondents in the eastern states will do us and our readers a favor by calling attention to other instances of Pacific-coast conifers proving hardy here.—Ed.]

The Owl and the Sparrow.

To the Editor of Garden and Forest:

Sir.—If, as Mr. Naudin has suggested, our little European owl is introduced into the United States for the purpose of destroying the sparrow, the fact should be borne in mind that there are two of these animals, constituting either distinct species or different races. It is only the representative of these nocturnal birds which inhabits the south of Europe which has established itself in the neighborhood of dwellings to the extent even of building his nest under the eaves of houses. It is this southern bird that modern ornithology designates under the name of *Athene meridionalis*, and has identified with the owl which accompanied Minerva in her visit to the ancient Greeks. In the central and north of Europe we have in place of this bird the true *Stryx passerina* of Linnaeus, a rather stronger bird, and very different in its habits. This northern bird does not inhabit cities nor villages or the neighborhood of human habitations. It is much less numerous than its southern relative, and selects for its home wild and uninhabited regions, the borders of forests, uncultivated slopes, and mountains covered with trees. The logic of events, therefore, removes it decidedly from the domestic sparrow, leaving it to prey upon, if it desires to vary its ordinary diet of mice, the field sparrow, an inoffensive species of which no complaint is made in America.

If the attempt to acclimatize the chevêche in America is made, it will be necessary to procure it from Italy, where it is known under the name of "civetta," or from the south of France, and not from England or from Germany where the chevêche is called "steinkauz." And here another question presents itself, Can this bird of southern Europe support the climate of Massachusetts or even that of New York, accustomed as he is to the mild winters of the Mediterranean countries?

Your correspondent, N. H. C., appears to me to be right. Will the chevêche, once established as an American citizen, show sufficient intelligence to devote its energies to the extermination of the sparrow and leave the native birds alone, and then, when he has exterminated the imported sparrows, what is he going to live on? Videant consules ne quid detrimenti res publica capiat.

Berlin. *C. Bolle.*

To the Editor of Garden and Forest:

Dear Sir.—My little owl does not appear to have had much success with the readers of Garden and Forest. Their fears with regard to it, however, seem to me exaggerated. This little bird is too feeble to attack poultry, and its specialty in the order of nature is to wage war on sparrows and mice, which it pursues into their holes. The truth is, that in Europe, where this bird is found, the damage done by sparrows is greatly reduced; and that this owl does less damage to ordinary birds than cats, which could often be dispensed with to advantage, as they inflict serious injury on birds, to say nothing of the fact that they sometimes go mad and are then very dangerous.

Antibes, France. *C. Naudin.*

Viola ocellata.

To the Editor of Garden and Forest:

Sir.—In your issue of February 4th appears a cut of *Viola ocellata*, which bears so close a resemblance to a species found here on the south side of a spur of the Blue Ridge that I am inclined to believe it the same. The cut is good, so far as it goes, but the variety here grows in dense clumps, often twelve inches in diameter by eight inches to a foot in height, covered with hundreds of exquisitely beautiful, cream-white flowers. The perfume is almost imperceptible, but a faint odor is exhaled which a keen scent can detect. Several years ago, being in these mountains, I collected a few plants, brought them home and planted on the east side of my flower-garden, since which time I am forced to destroy them by the hundred every year to prevent their taking entire possession of the ground. My plants bear flowers with long stems, many of them eight inches long, and this renders them valuable for cut flowers. We often mix them with the fragrant *Viola odorata*, and so delude the possessor with the belief that both varieties are odorous. The plants make a beautiful border, and, being evergreen, never lose their attractiveness altogether. The flower has a pale, delicate lavender splash on its three lower petals.

Spartanburg, S. C. *J. S. R. Thomson.*

[*Viola ocellata* is confined to the Pacific side of the continent, and it can hardly be the plant referred to by our correspondent. This, judged by the young plants, not yet in flower, with which she has favoured us, is probably one of the white-flowered varieties of the European Violet (*V. odorata*) which has become naturalized, and is now widespread in some parts of the south Atlantic states.—Ed.]

Notes from Milton, Massachusetts.

To the Editor of Garden and Forest:

Sir.—Although extraordinary care is often given to the propagation of tropical plants they may be successfully rooted on a common gravel bed, such as is used for staging plants. During a recent visit to the greenhouses of N. P. Kidder, Esq., Milton, Massachusetts, I observed that the gardener there, Mr. Martin, roots almost everything in this way. Mounds of gravel are pulled together containing a little grit and also some clay, just sufficient to hold the material together and retain moisture. At the time of my visit such plants as Crotons, Dracænas and Pandanus were being rooted, and many others were shown me which had been propagated in the same way. The cuttings are shaded by plants, and all the water they get comes from syringing.

I have before referred to the value of deep pits with glass roofs about level with the ground. Further evidence of their great usefulness was given here. All kinds of plants may be stored in them which will endure a night temperature of about forty-five. They are mostly used for Cinerarias, Calceolarias, Ericas, Azaleas, Camellias, Cytisus, and also for the later batches of Holland bulbs.

The white *Epacris palludosa* is here grown well. This is probably the best variety for cutting. It is often supposed that imported peat is necessary to grow these well, but Mr. Martin's plants are grown in leaf soil and loam only. His later treatment consists in cutting back severely; abundance of water during the growing season, and a shady place during the

hottest weather; more exposure to sun-heat is given toward fall, in order to get the flowering shoots well ripened.

Mr. Kidder's well-known specimen of *Cypripedium insigne* is a grand sight when furnished with about 100 blooms. It has been exhibited in Horticultural Hall, in Boston, with 110 blooms. It is planted in the form of a semi-globe, measuring four feet six inches over its semi-circumference, and is very even in growth. *C. villosum* is represented here by a fine specimen in a twelve-inch pan, carrying thirty flowers. This is a robust and very satisfactory species to grow; very handsome and distinct, and a peculiar waxy lustre pervades the whole flower. This, with *C. barbatum*, has been the parent of many handsome hybrids.

C. callosum, a recent introduction, very much resembled a fine specimen of *C. barbatum Warneri*, flowering near by. On comparison the latter seems the handsomer—the dorsal sepal is larger, the violet striping is lighter, and a still further distinctive feature is a rainbow band of mauve separating the green from the white portion of the sepal.

C. hirsutissimum, apart from the growth of short hairs, which covers the flower as well as other parts of the plant, shows no striking peculiarity either in form or in coloring. Both the dorsal sepal and pouch are a dull reddish brown, the petals being the most conspicuous part of the flower. They are long, measuring in this case over five inches across, wavy at the base, with a band of mauve running longitudinally.

Les Plantes Potagères; Description et Culture des Principaux Legumes des Climats Tempérés, par Vilmorin-Andrieux et Cie. Deuxieme edition. Paris, 1891, pp. 1–730.

French horticulture is supreme certainly in the vegetable garden; and vegetables are better grown and better marketed in France than elsewhere, and better cooked, we can say in passing without fear of contradiction; and the reader, therefore, anxious to inform himself of all that is new in the way of garden vegetables and their cultivation, and of the salad plants, of which the French make so much account and the rest of the world make so little, will naturally turn for information to the writings of French horticulturists on the subject. The work whose title is printed above and which has just been reissued in a new and considerably enlarged edition will first attract his attention, for although it bears on the title-page as author the name of the commercial firm which for a hundred and fifty years has been prominent in European horticulture, it is really from the pen of the senior member of this firm, the President of the Botanical Society of France, the Secretary of the French Agricultural Society and a recognized authority on the subject of which this volume treats.

It is only eight years since the first edition of this work was published, but so great have been the additions to the number of varieties of useful vegetables which have appeared lately that a second edition became necessary if the work was to retain its value as a manual of the subject. Frequent and rapid modifications are inevitable in the case of a work treating of cultivated plants, especially leguminous plants which, as they appear in the vegetable garden, are mostly annuals or biennials—that is, plants in which generations succeed each other rapidly, displaying new characters which often become fixed into new varieties. There is hardly a year, therefore, perhaps hardly a day, in which some new vegetable form does not appear in the gardens of the world, forms which are often susceptible of being made permanent, and sometimes worthy of being preserved. The reproach is often laid at the door of horticulturists in general, and of seedsmen in particular, that they insert in their catalogues too large a number of varieties of the same plant. It should be remembered, however, when this reproach is made, that horticulture to-day is incomparably more specialized than it was twenty years ago. Even then there were excellent reasons in favor of the multiplication of races, the special tools provided for different horticultural operations. Such reasons are much stronger to-day than they were at that time. Besides the differences of form, of color and of taste which often make the special value of a race of vegetables, their variation with regard to more or less abundant production, to earliness or lateness in maturing, and to the greater or longer time any crop can be prolonged, offer economic questions which must have a great influence in deciding favorably or otherwise the claims of each particular race of such plants. It will be acknowledged, of course, that it is a matter of capital importance for a market gardener to sell his crop of any given vegetable at the exact time when the price is the most advantageous for him. This makes it desirable to develop and fix races having the power to mature early and to mature the whole crop simultaneously, thus leaving the ground free for a succeeding crop of another character. This is demanded in modern market-garden practice, which must allow products to be sent for a long distance to the centres of consumption, thus placing in competition various climates and leaving to each a short time in which to perfect under the best conditions its special products.

It is interesting to note that a large number of recent additions to the list of vegetables cultivated in France have been obtained from North America, especially potatoes, beans, corn, squashes and tomatoes. These last, which, twenty years ago, were practically unknown to the French public in general, have now become one of the most popular vegetables in France, and are sold in the streets of the principal cities every autumn, in immense quantities and of excellent quality.

Monsieur Vilmorin finds that "the Americans bring to their horticultural operations the alert and practical spirit which characterizes all their enterprises, and apply themselves at once to create, in each centre of production, the races best adapted for the end they have in view, and for local conditions."

A word as to the form in which this work is cast will, perhaps, best indicate its scope and value. It includes plants which are usually cultivated in the temperate parts of the world, to be eaten in a fresh state, and also those which serve as seasoning, and includes a good many which have now disappeared from the vegetable garden, but which are mentioned as vegetables in some of the old books of horticulture. It should be mentioned, perhaps, that some plants which are not considered vegetables in this country, such as Strawberries and Melons, find their place here also. Each article devoted to one or several allied plants, cultivated as vegetables, begins with the botanical name applicable to all the plants grouped together in the article; that is, the name which designates the genus and species to which all the forms, more or less modified by cultivation, can be referred. The races of peas, for example, however numerous they may be, appear under the general name of *Pisum sativum*, Linnæus. All the races of beets under the general name of *Beta vulgaris*, Linnæus, etc. In this connection Monsieur Vilmorin remarks that "the fixity of the species, whatever its absolute value may be considered in the system of creation, is very remarkable and worthy of admiration, regarded only from the point of view of the period through which human investigations extend. Species cultivated since the earliest historic times, and exposed to all the modifying influences which might be expected to follow in the case of plants raised, generation after generation, from seed, in spite of their removal from one country to another, and the alteration in the character of their surroundings, preserve their distinct existence, and, although assuming continually new forms, never pass the limits which separate them from allied species."

After the generic name the vernacular names appear under which the plant or group of plants is known in France and in England, Germany, Spain and Italy, and, sometimes, also in Portugal and Holland. This is followed by a short historical account of the plant and the name of its native country, etc., as far as it is known; then the character of the plant, that is, whether it is annual, biennial, or perennial. This is followed by a description of the species, directions for its cultivation in the climate of Paris, and the manner in which it is used. After this comes a more detailed description of each variety with its synonyms, each variety being illustrated by a small woodcut in the text. As an example, the Egg-plant may be taken. This appears as Aubergine, the *Solanum Melongena*, Linnæus, or *Solanum esculentum* of Dunal, of the family of the *Solanaceæ*. Fifteen French synonyms for Aubergine are given, arranged alphabetically in a paragraph by themselves. This is followed by another paragraph, giving the English, German, Dutch, Italian, Spanish and Portuguese names. After them appears the word "annuelle," showing that the plant is an annual, the remainder of the paragraph being devoted to a description of the wild type, followed by the statement that there are 250 seeds in a gramme, weighing 500 grammes to the litre, and that the germinating power of the seed will last for six or seven years. The next paragraph is devoted to instruction upon the cultivation of the Egg-plant, and this is followed by a paragraph upon the uses of the fruit, all this making an introduction to the account of the ten varieties which are considered the most valuable. A similar plan is followed throughout the work in the case of each group of vegetables, which are arranged alphabetically under the French names.

Some idea of the completeness and value of this book as a work of reference will appear when it is stated that in the case of Lettuce (*Lactuca sativa*) more than a hundred varieties are described, while peas, tomatoes, and some other popular vegetables are treated still more fully. It must be remembered, too, in considering the merits of this work, that it is not a compilation, and that the estimation of the value and the knowledge of the characters of the different plants described is based on information obtained in long series of experiments carried on by the author and his assistants for years, and conducted in the spirit, and with the appliances, of strictly scientific investigation. When the amount of work, of which this volume is the record, is considered, it is not hard to understand why the French have made such progress in the improvement of races of vegetable-plants, or why they stand at the head in such matters. The value of the book is increased by tables, in which are given the number of seeds of the different vegetables described, in a given weight, and the average and extreme period during which they retain their germinating power, derived from actual experiments; and also a very full index in which, besides the French and Latin names, those of the other modern languages appear as well as all synonyms.

Notes.

An enterprising dry-goods firm in Philadelphia paid some $500 for decorating their store for the spring opening in the early part of last week. Just before Easter they began to sell the plants to their customers for Easter presents. The result was, that they not only had their decoration for nothing, but realized a handsome profit on it.

The prices of oranges in southern California have nearly doubled, owing to the report that the crop has failed in Italy. Three-fourths of the California crop has been sold on the trees for prices higher than those which have been realized for many years, and the fruit is so abundant that the railroad companies are pressed for facilities to handle it.

A recent bulletin, by Professor Beal, of the Michigan Agricultural College, contains a few of the seeds of six of the worst weeds in that State, so that farmers will be the better able to identify them in examining their clover and grass seeds. The six plants which are credited with this bad eminence in Michigan are Canada Thistle, Red Root, Moth Mullein, Toad Flax, Rib Grass and Narrow Dock.

The Yosemite National Park now embraces parts of forty-two townships, covering about 1,500 square miles, or 960,000 acres, from which is to be deducted the Yosemite grant of 36,000 acres. About 700,000 acres of the National Park is mountainous, well watered, and heavily timbered with Pine, Fir, Spruce, Hemlock, Tamarack, Oak, Cedar, Madroña, Laurel, Sequoia, and Mountain Mahogany. Two hundred and sixty thousand acres are composed of mountain-valleys, meadows, lakes, etc.

The very first entry in the first book of the Plymouth Colony Records is an incomplete list of the "Meersteads and Garden-Plotes of those which came first, layed out 1620." The persons here referred to are, of course, the famous band who were brought by the Mayflower on her first voyage. They had been grouped in nineteen families, and the houses to which these "Garden-Plotes" were attached were built along both sides of what is now Leyden Street in Plymouth. "Meerstead," usually spelt "Merestead," is an old word for farm.

We have received, from a correspondent in Santa Barbara, a spray of the Black Wattle (*Acacia decurrens*), and, in spite of their long journey, the flowers are still bright and beautiful. The trees are very floriferous, and the long racemes of clear, yellow flowers, hanging among the pale green and finely cut foliage, present a very beautiful appearance. The tree is graceful and symmetrical, and it is now attracting great attention in California on account of its economical value. Its bark is so rich in tannin that it is now being planted in Australia and New Zealand by the thousand acres.

In a recent issue of the *Botanischen Centralblatt* it is stated that Dr. Dieck, the well-known dendrologist of Zoeschen, Germany, brought home some very interesting plants from those districts of Pontus and Western Caucasus which he visited last summer. Among them are living specimens of about seventy varieties of Roses, and specimens of *Acer Trautvetteri*, of *Rhododendron Ungeri* and *R. Smirnovi*, of the remarkable Chestnut-oak of Koch (*Quercus Pontica*), and of the genus Orphanidesia, belonging to the *Ericaceæ*, which had never been collected since it was first discovered by Balansas. Most of those plants, it is announced, Dr. Dieck will be prepared to distribute during the coming spring.

A Bulletin, recently issued by Professor E. W. Hilgard, contains brief descriptions of the Port and Sherry Grapes which are now known to be growing in California. Of the Port wine varieties six are named, and of the Sherry and Madeira varieties nine are described. An essential advantage possessed by these grapes over those of the Claret and Bordeaux types is, that they resist, to an extraordinary degree, the influences under which wines made from grapes of the latter types become vinegar. Instead of this they undergo, under the continued action of warm air, the change to the true Sherry and Port flavors.

One would hardly expect from Edgar Allan Poe a panegyric on the art of gardening, yet who has written more sympathetically of the art than he in this passage from the *Domain of Arnheim?* "No definition," it runs, "has spoken of the landscape-gardener as of the poet; yet it seemed to my friend that the creation of the landscape-garden offered to the proper muse the most magnificent of opportunities. Here, indeed, was the fairest field for the display of imagination in the endless combining of forms of novel beauty, the elements to enter into combination being, by a vast superiority, the most glorious which the earth could afford. In the multiform and multicolor of the flowers and the trees he recognized the most direct and energetic efforts of Nature at physical loveliness. And in the direction or concentration of this effort—or, more properly, in its adaptation to the eyes which were to behold it on earth—he perceived that he should be employing the best means, laboring to the greatest advantage, in the fulfillment not only of his own destiny as a poet, but of the august purposes for which the Deity had implanted the poetic sentiment in man."

The industry known as "truck-farming" has been made, for the first time, the subject of the census investigation, and a preliminary report, prepared by Mr. J. H. Hale, has been received at this office. Truck-farming, as considered in this bulletin, is distinguished from market-gardening by the fact that it is carried on, in favored localities, at such a distance from market that transportation by water or by rail is required. Market-gardening proper is confined to local markets, where the grower uses his own team for transporting his products to the retailer or the consumer. Truck-farming, as a business, is largely the creature of the transportation companies, and it has grown up almost entirely since the year 1860. During the census year it required the labor of 216,765 men, 9,254 women and 14,874 children, aided by 75,866 horses and mules, working $9,000,000 worth of implements upon 534,440 acres of land, valued at $70,156,300; and the total production, after paying freight and commission, amounted to $76,517,155. The total acreage of some of the leading vegetables grown on truck-farms is as follows: Asparagus, 37,970; Cabbage, 77,000; Spinach, 20,000; Celery, 15,000; Water Melons, 114,000; Peas, 56,000; Sweet Potatoes, 28,000; Tomatoes, 22,000; miscellaneous vegetables, 82,000.

From correspondents in several of the principal cities we learn that the volume of the Easter flower trade throughout the country has been larger than usual and that prices have been fair in spite of unfavorable weather in many places. The practice of making presents of growing plants has increased so of late years in many cities, notably in Boston and Philadelphia, that florists have been compelled to open temporary stores in addition to their regular places of business to accommodate the increased trade. Some of these retail dealers have disposed of as many as a thousand pots of Easter Lilies, not to speak of a great variety of other plants in bloom. There are few changes in the list of flowers grown and sold for this festival. The larger and coarser *Lilium Harrisii* seems to have quite crowded the old Ascension Lily, and it undoubtedly will continue to hold its place as an early-flowering plant, although there is an increased demand reported for *Lilium longiflorum* in some places. In this city the only thing in the way of novelty among Easter plants observed was Garden Anemones. Large pots of these plants in bloom are very beautiful, and they are practically new to the flower-buying public here. In the decorations of churches and other large places it is gratifying to see *Acacia pubescens* used more largely, as its delicate inflorescence helps to relieve arrangements which otherwise would appear heavy. Few Palms, beside the ordinary trade varieties, were noticed in Easter decorations, but an increased use of Araucarias was very apparent.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, APRIL 8, 1891.

TABLE OF CONTENTS.

A Botanic Garden for New York.

THE educational equipment of a modern city of metropolitan pretensions, as has been pointed out more than once in these columns, cannot be considered complete without a public garden, administered by a man of science in a scientific spirit, as a station of scientific investigation and public instruction. These views have gained a foot-hold in the community, and there is, at this writing, every prospect that the bill "to provide for the establishment of a Botanic Garden, a Museum and Arboretum in Bronx Park" will be enacted by the present legislature, it having been passed successfully through all the preliminary steps. By this bill the park commissioners of the city of New York are directed to set aside 250 acres for a private association which asks to be incorporated to carry on the garden. The purpose of the association is to establish and maintain a Botanic Garden, Museum and Arboretum for the collection and cultivation of plants, flowers, shrubs and trees; for the advancement of botanical science and knowledge, the prosecution of original researches in botany and kindred subjects, for affording instruction in these subjects, and for the exhibition of ornamental and decorative horticulture and gardening; for the entertainment, recreation and instruction of the people. In the list of the incorporators appear the names of some of the most intelligent and public-spirited, and some of the wealthiest men in this city; and it is safe to say that, if they are thoroughly in earnest in their desire to bestow upon the city a great botanical establishment, and if they realize what such an establishment should be, there need be no serious anxiety for its future.

The site selected for the proposed garden is an excellent one; the territory it provides is ample, its surface is pleasantly varied, and its situation has the advantage of being near enough to the centre of population to be readily accessible, and, at the same time, sufficiently remote to be beyond the injurious influences of the vitiated atmosphere of the city. The corporation is to raise the sum of $250,000, with which to establish the garden, and when it has done this the park commissioners of the city are to expend a sum, upon which the income is $15,000, in preparing museums, herbarium buildings, lecture halls and structures for the cultivation of exotic plants, and to construct and maintain the drives through the garden and arboretum, and provide for their policing.

The sum which the city is asked to expend on buildings seems ample for many years at least, but if the general excellence of the plan is to be criticised at all it is in the meagre amount which the new corporation is expected to expend. The city is to build and maintain roads and to spend $400,000 or $500,000 in providing buildings, but when this is done the corporation will hardly be in a position, with an income of only $10,000, to carry on and gradually develop a great herbarium, library and museum, to plant an arboretum, to stock greenhouses with representatives of the tropical flora of the world, to establish gardens of hardy perennial and annual plants, to keep up rock-gardens and shrubberies, water-gardens and bog-gardens, and all the other departments of a modern botanical establishment.

A botanical garden is a museum, and, like all museums, its value depends on the capacity of the man who controls it; it is useful or inefficient in proportion as its head understands the true aim of a museum and has the patience and executive force to carry out his ideas. The man who is equipped to organize a garden in this city which is eventually to occupy an area of 250 acres, and is to place it in such a position among the scientific establishments of the world that its claims and importance will be recognized, is not easy to find; and he will be able to command a salary which will make a large hole in the income of the fund of $250,000. The gradual building up of a herbarium and library, the heart and brain of every scientific garden, and their administration will consume the rest, so that unless a much larger sum of money is provided than the promoters of this scheme now seem to have in mind, there is great danger that the garden will languish, and that those persons now most interested in it will become discouraged. We say this not to add in any way to their discouragement, but only to emphasize what we have said before—that the establishment of a great botanical garden is a serious and difficult undertaking. A garden of this sort is one of the most complicated things a man can be called on to manage; it costs a great deal of money, its growth must be slow, and those who plan such an establishment and labor for it in its inception cannot hope to gather the fruits of their labor. Art is long and the span of human life is short. But it is one of the most hopeful signs of our civilization that men occasionally appear who are really unselfish and are willing to work for the public good without hope of great reward and without expectation of seeing their labors bear fruit in immediate tangible results. The man who lays the foundation of the great garden which is now contemplated, and which we believe our children will live to see firmly established in the Bronx Park, will be a man of this character. It was such a man who came to Kew Gardens just fifty years ago; and since it is by Kew that the promoters of botanical establishments are accustomed to measure their ambition, it will be useful to explain in a few words what Kew is and why it has become what it is.

Fifty years ago the British Government, principally at the solicitation of the then Duke of Bedford, a man famous in his time for his enlightened enthusiasm in gardening which made Woburn Abbey one of the great gardens of England, determined to convert the old gardens and pleasure-grounds surrounding the royal palace at Kew into a public botanical establishment. Sir William Hooker was invited from Glasgow to manage it. He brought with him a European reputation as a botanist, unflagging zeal, industry and enthusiasm, a fund of sound Scotch common sense, the friendship and confidence of all naturalists, and the largest botanical library and herbarium which had at

that time been made. These last he presented to the nation; his reputation and the importance of his collections at once attracted botanists to Kew from all parts of the world. Their visits benefited the establishment, and plants, specimens and books poured into it from all sides. The scientific character of Kew was thus established, and it is this high character that has given it the lead it has long held among the gardens of the world. Sir William Hooker gave the remainder of his long life to Kew, and devoted all his energies and resources to its welfare. His son, a man more famous than the father, succeeded him, and under his administration Kew gained wonderfully in every direction, especially in popular favor. The second Hooker retired from Kew a few years ago full of honors, handing down the administration of the garden and all the family traditions to a connection by marriage, under whose wise and broad management it is growing now still more rapidly than ever before in usefulness and beauty. In no other spot in the world can so many different plants be seen growing; the museums of economic botany are unequaled, the herbarium is the most extensive that men have ever made, and the library is unsurpassed. This is the work of fifty years, carried on by men of extraordinary ability and world-wide reputation, working under the most exceptionally favorable circumstances and with the whole British nation behind them. Kew has received many gifts of great value, and is receiving such gifts every week. It costs, however, to carry on the establishment, which, by the way, does not cover much more than half the area to be occupied by the New York garden, $75,000 or $80,000 a year. The cost of all sorts of garden labor in England is not more than half what is paid for such labor in this country, and everything connected with a garden costs less there than it does here. If, then, Kew furnishes the ideal at which the promoters or the projectors of the new garden aim, they must realize that this can be reached only by the expenditure of a great deal of money, and that even with all money needed such results as the people of New York have the right to expect can only be brought about slowly and with the aid of unusually favorable conditions. Something can be accomplished with $250,000, but this amount is only a beginning, if New York expects to rival London, or St. Louis, or Boston in its Botanic Garden.

Pruning Shrubs.

OUR climate is so favorable to the growth of deciduous, flowering shrubs that they are steadily growing in use and favor in American gardens. The time will come when we shall learn to give them good deep soil, and allow them enough space to develop into their best form. The time will come, too, when they will suffer less serious mutilation at the hands of unskillful laborers who feel called upon to "trim them into shape" every spring. Directions for proper pruning have often been given in horticultural journals, and although the principles which underlie correct practice have been set forth so plainly that no one need err, the necessity of repeating these instructions again and again is apparent to all who take note of the cruel treatment to which many shrubs are subjected.

In the first place, it should never be forgotten that pruning is a weakening process. It takes away from the plant a portion of its vital machinery, and when the cutting is severe the loss of vigor is serious. As an example of this, florists are learning that the present demand for long-stemmed Roses is a tax upon the vitality of the plant, and they have found that they are selling not only flowers but the life of their plants, and after one crop has been taken the bush needs a long rest to recuperate its exhausted energies. Last summer the luxuriant foliage upon some White Maples in a city street was pointed to as a proof that pruning added vigor to the trees. During the previous winter it is true that the limbs had been sawed off nearly to the trunk; but the mass of leaves on the slim twigs which had put out in great numbers from every adventitious bud on the stumps of the amputated limbs was only a proof that nature was making this extra effort to supply the nutritive organs of which the tree had been robbed. This spasmodic output of leaves was not a sign of health, but a signal of distress. Of course, pruning is necessary for many purposes. The removal of dying limbs is remedial. It may be of more importance to increase the fruitfulness of a vine or tree than to promote its longevity, or it may be necessary to change the form of a shrub or tree in order to adapt it to its position and surroundings.

The usual reason offered for the severe pruning of shrubs is that it makes them more floriferous; but the work is often done at such a time and in such a way that it destroys all hope of flowers for the year. A little examination will teach a novice that the shrubs which are to bloom early this spring made all their preparations for it last year. The flower-buds were formed on the wood which ripened last summer, and they were nicely covered up to protect them during the winter. This can readily be proved by cutting off some twigs from a Peach-tree or Thunberg's Spiræa and placing them in water in a jar which is kept in the sunlight in any ordinary living-room. In a short time the buds will open and the flowers will appear, and the experiment could have been successfully made at any time during the winter. Now, when these limbs are cut back severely at this season of the year all the flower-buds are cut away, and we need expect no flowers this year. If we wait until after these early-flowering shrubs like the Forsythias are through blooming, and then cut back the wood which has borne the flowers, new branches will be thrown out to make up for the part which has been taken away. These branches will ripen up during the summer and form flower-buds for blooming next spring. Hence, the first rule to be observed in pruning early-blooming shrubs for the sake of their flowers is: Cut back the growth in late spring or early summer as soon as the flowers have fallen, and never do this pruning in autumn, winter or early spring.

On the other hand, there are shrubs like the Altheas and the Hydrangeas which bloom late in the season, and in these the flower-buds are formed on the wood which grows the same summer. It follows that if these were pruned in early summer the effect of destroying the flowers would be almost as bad as winter pruning would be in the case of the early-flowering shrubs. But if the last year's growth is now cut away before any of the new wood starts the plant will put forth more shoots which will bear flowers in autumn. In the case of such shrubs, therefore, the pruning should also be done after the flowering season—that is, in late autumn, or better in the early spring.

These rules are very general, and they do not cover all cases, as, for example, there are some early-flowering shrubs which do not make their flower-buds on the shoots which were made last year, but on short spurs from the older wood. It may be also said that pruning for flowers alone is not altogether judicious, for shrubs are in bloom but a few days or weeks at the most, and a good gardener will give heed to their general appearance throughout the year. For this reason it is good practice to encourage the shrubs to develop into their best natural form, and this is not done by cutting them back with the simple view to increase their flowers. The proper course is to thin out the feebler and overshadowed branches, so as to give the stronger ones a better chance to develop, and to cut back cautiously, so as not to interfere with their natural and most beautiful form. They will then give pleasure all the year through, not only when in flower and when in full foliage, but even in the leafless season; for shrubs have a distinct and peculiar beauty in the winter, not only from the graceful outline of their spray, but from the delicate color which comes from the mingling of the varied tints of the bark on the branches—a color which seems to rest upon and float about them like a nimbus or halo. All this beauty at every season can be marred by careless shearing, or, what is still worse, by a painstaking effort to cut the shrubs into formal shapes. There is never any justification for clipping them into geometrical forms, like cones or cylinders or spheres; nor for shaving off their tops at the same level as if they were parts of a hedge fence. This means the destruction not only of the beauty, but of the health of the plant.

The one pleasure which is common, constant and universal to all parks results from the feeling of relief, experienced by those who enter them, on escaping from the cramped, confined and controlling circumstances of the streets of a town; in other words, a sense of enlarged freedom is to all at all times the most certain and valuable gratification afforded by a park. The scenery which favors this gratification is therefore more desirable to be secured than any other, and the various topographical conditions of a site, thus, in reality, become important very much in the proportion by which they give the means of increasing the impression of undefined limit.—*Olmsted and Vaux, in Report of Brooklyn Park Department, 1866.*

The Colonnade in the Parc Monceau, Paris.

THE Parc Monceau has already been described in GARDEN AND FOREST,* so it is needless again to tell how it originated, or to note the general characteristics which, despite the introduction, in inappropriate situations, of an excessive multitude of bedding-plants, make it the prettiest of Parisian pleasure-grounds. We now desire simply to call attention to the picture on page 163, which shows a portion of a long, curving colonnade, shaded by trees and luxuriantly draped in Ivy, that stands on the edge of an oval basin of water. It is the most charming and individual feature of the park, and seems especially interesting when we find that it was not built in willful imitation of a ruin, but is a veritable relic of former days. It dates from the best period of the early Renaissance, though, singularly enough, its exact origin is not known. According to one tradition, it was brought from the destroyed Château de Raincy; according to another, which is more generally held, it was part of a great rotunda which Catherine de Medici commenced to build, north of the Church of St. Denis, to receive her own mausoleum and that of her husband, Henri II., and which was torn down in the beginning of the eighteenth century. In his book on "Paris in Old and Present Times," Mr. Philip Gilbert Hamerton writes: "Nothing can be more elegant than this colonnade. . . . In its present situation it seems like a remnant of antique architecture in some graceful picture by Claude, and one is grateful for the good sense that has saved it from destruction. Lalanne once made a very poetical charcoal drawing of it, which has been reproduced in the series of his charcoals. This is one example . . . of the happy combination of architecture with foliage and water. Set up in the British Museum these columns would signify comparatively little; but with graceful foliage and a mirror of water they are charming."

Some of the beautifully proportioned columns, with their delicate flutings and rich Corinthian capitals, can be more plainly seen than those which our picture presents; yet it would be hard to find more charming objects than these. No plant is more classic in its effect or in its historical associations than the Ivy, and it adapts itself as well to the stately simplicity of a piece of classic work like this as to the broad simple rugged masses of a Norman castle-wall or to the slender arches and elaborate carvings of a ruined Gothic abbey. It is a misfortune that, in the dry climate of our northern states, Ivy does not grow so well as it does even in the northern parts of Europe. But in sheltered situations, and especially in southern localities, it well repays the gardener's care. It is not so free and spreading in habit as the Virginia Creeper, yet it does not, like the so-called Japanese Ivy, cling so tightly to its supports that it becomes a close-fitting garment rather than a drapery; and over both of these it has the advantage of keeping its beautiful dark green foliage throughout the winter. Moreover, it grows as well when trailing on the ground as when climbing a wall or column, and this peculiarity is very useful when the gardener is trying, as so often is desirable, to connect an architectural feature integrally with its natural surroundings. Beautiful borders of Ivy are constant features in European pleasure-grounds, and our picture shows how such a border can serve the artistic purpose just referred to while forming a delightful object in itself. When trees instead of columns are draped with Ivy, and it is then allowed to run out over the grass, whether in a formal or a naturally luxuriant way, the effect is equally charming.

We would also call attention to the fine effect of the statue on the little island which occupies the centre of the basin. Had it been stood in a commonplace fashion in the middle of the island, it would have been much less impressive than it now is, reflected with its massive pedestal in the silent water, supported by the tree-trunks just beyond it, and backed by the low mass of shrubs. There is no one point where we have more to learn from the French than with regard to the placing of statues in the open air.

Winter Studies of the Pine Barren Flora of Lake Michigan.—I.

IT is the common practice of those who study plants in their native wilds to observe them mainly during their season of growth. A stroll in the woods in winter, or a botanical excursion when the ground is covered with snow, seems out of place and without adequate reward. But the trees and shrubs in winter, the mosses and lichens which cling to their trunks and limbs or grow beneath their shelter, and the humbler plants with evergreen or persistent leaves offer inviting subjects for study. Acquaintance with a plant is not complete till it is seen in all its phases. The evergreens may not exhibit any essential change of garb in summer and in winter, but they seem more isolated now and contrast more impressively with their deciduous-leaved neighbors. The leafless branches of the deciduous trees also show features of form and covering and teach lessons which are concealed when they are thickly clothed with foliage.

There is also a stillness in the woods in winter which is most impressive. This is due largely to the absence of animal life, and the feeling of loneliness is deepened by the plaintive murmur of the wind among the Pines. The cawing of the crow or the harsh cry of the blue-jay almost startles by its suddenness. But the sense of loneliness soon passes away, for though the currents of life in the forest-vegetation are in suspense the trees themselves are here, ready to furnish lessons and companionship.

One of the first plants to catch the eye in the Pine Barrens, where the soil has sufficient strength to bear it, is the Climbing Bitter-sweet (*Celastrus scandens*). It does well in the moist sands near the lake, holding to the small trees by its twining, rope-like stems. In the early winter its branches are spangled with fruit, the open valves of the orange-colored pod spreading out like a border and exposing the scarlet aril which covers the seeds. Few sights are gayer at this season than the bright fruit, set in a background of the sombre, leafless branches of the vine and its supporting tree. Near by is another climbing vine, the Greenbrier; its dark green, prickly stems clambering over the shrubs and contrasting with their duller hue like a line sharply drawn across them.

There are other shrubs with red or yellowish fruit often met with in the sands or beside the sloughs. Among them are four species of Rose, their stems usually red or reddish in the winter, with a hue more pronounced than in the summer. The hips of *Rosa blanda* and *R. humilis* are apt to be shriveled and dull, not so lasting as those of *R. Carolina*, which keep their form and colors, being plump and bright, and clinging profusely to the bushes in winter. In the wetter ground, where the latter grows, or along the lake-shore, clumps of *R. Engelmanni* are seen, with its oblong fruit still in good state of preservation and rivaling that of *R. Carolina* in abundance. The hips are not generally so ruddy, but have a yellowish tinge. Just before Christmas I looked for the scarlet fruit of the Winterberry (*Ilex verticellata*), but failed to find any, though it was plentiful on the bushes late in the fall. Probably the birds are responsible for their barren look, for they are fond of the berries. But it is not always thus, for the numerous clumps of Ilex by the borders of ponds will display their red berries in the winter, as the common name affirms.

Not so tempting nor so worthy of notice are the clusters of small, whitish berries of the Poison Ivy (*Rhus Toxicodendron*), a common plant in the sands, especially along the roads and cattle-paths. It is almost always the erect form of the plant, a foot or two high, which we see, or the one which runs along on the ground, sending up short branches. It retains its fruit all winter, for this may be found late in the spring, or well up to the time of flowering again. Doubtless it partakes of the poisonous properties of the plant, so that birds avoid it, for I have never seen it eaten by them. Its dun color does not make it prominent like the bright-colored fruits which allure birds, even if it is edible by them. The Stag-horn Sumach (*R. typhina*) is a more attractive shrub than its poisonous relative, and quite common by the borders of woods and in their open spaces, its crimson leaves making it one of the most brilliant features of autumn. The large thyrsoid clusters of fruit, clothed with crimson hairs, still cling to the ends of many of the stout, straggling branches, and serve to make it a conspicuous object in the winter also. The blunt, clumsy branches, dark with sooty bark and hairs, are in marked contrast with those of any neighboring shrub. In handling them one instinctively looks at his fingers to see if they have been blackened by the twigs. The buds are also curious, being deeply set in the midst of a large leaf-scar, and capped by a covering of light russet hairs, thus looking like a blunt cone surrounded by a broad, flat rim. The rudimentary leaves, buried under this copious coating of hairs, seem as if protected against arctic cold. The Fragrant Sumach (*R. canadensis*) is frequent on sandy banks and knolls. It usually occurs in patches of a limited area, but thickly covers the space it occupies. It is a dwarf shrub, but a foot or two high, and is a pretty object at any time of the year—in spring yellow with numerous flowers, in summer clothed with handsome, trifoliate leaves, interspersed with clusters of downy, red fruit; in autumn showy with richly colored foliage; grayish

* See Vol. II., December 11, 1889.

in winter and speckled with little spikes of flower-buds. These appear as the leaves fall off. They resemble small aments and will bear close inspection. They are formed of reddish brown rhomboidal buds, symmetrically arranged on the axis of the cluster. Each bud has a fringe of light-colored hairs, and a dark centre, sharply contrasting with this pale border, and looking as if set in a frame of hairs. The tiny spikes have a checkered appearance, and viewed in mass give to the plants a delicate charm.

The most common evergreen shrub is the Bearberry (*Artostaphylos Uva-ursi*), literally covering the surface of some of the sand-ridges near the lake, and abundant in places farther away. The globular berries, dark red or brown, still hang to the vines, but the varied colors of the leaves are their chief distinction. In sheltered localities some of the thick obovate or spatulate leaves remain of a shining green, but the greater part have assumed tints of brighter color. The typical colors, aside from green, are crimson, purple and vinous, and there are all gradations in the shades connecting these. The nearer leaves, near the ends of the stem and branches, are mostly of the brightest colors, especially the crimson shades. These colors often give to the ground a very gay appearance, as if covered by a carpet of variegated pattern, the splashes of color being extensively intermixed. When the stems rest upon a slope the effect is striking, or even brilliant. The stems are slender and whip-like, branching but little. They sometimes have a length of four or five feet, particularly on the slopes of ridges near the shore of the lake, where they run along the surface of the sands and attain their greatest vigor. Gathered at this season, or late in the fall, after the leaves have changed, they serve admirably for decoration. The leaves remain attached to the stems a long time in the dry heat of a house, and retain their colors well, so that they can be kept upon a wall from one season to another.

Englewood, Ill. *E. J. Hill.*

How We Renewed an Old Place.

II.—PLANTING WILLOWS AND PINES.

WHEN one has nearly half a mile of boundary to define around his four-acre lot, the question arises how it can be enclosed with the least expense and trouble, and in such a way as not to disfigure the grounds. With this problem we had now to deal.

The front upon the main street, thanks to the sociable fashion of our day, it would be quite proper to leave open, with only such screen of shrubs and trees as we should decide upon when the house was built, and the lawn properly graded. Part of it was already well hedged in with ancient bushes which straggled about, where the old house stood, in most admired disorder. But all along Winter Street, as the lane behind us is somewhat ambitiously designated, the fence was tumbling down, and the whole garden spot lay uncomfortably open to view, as well as to the cold east winds that blow across the meadow from the sea. We decided that here a row of Willows would come in admirably, as there would be plenty of rich moist soil for the young trees to root in, and with such a protection the wind-swept garden would in time be warm and secluded, while the silvery foliage would be a harmonious setting for the emerald meadow, and the sapphire stream.

This idea we carried out the week after we made our purchase. A friendly farmer neighbor, compassionating our folly in starting such an enterprise, but anxious to see what we would make out of the place, kindly offered to give us as many cuttings as we wanted, so one bright day in June he appeared upon the scene with a cart-load of Willows, a crowbar, and a hatchet, and, with a man or two to help him, before night he had cut and driven firmly into holes, easily punched by the crowbar in the soft soil, some five hundred bare stakes, every one of which in a few weeks put forth a crop of roots and leaves.

The stakes, sharpened at the end, were about three feet in length, one foot of which was driven into the ground, and firmly stamped into place. It was found better in driving them to have them set at an angle of about twenty degrees, with the tops pointing toward the south, so that the stems did not receive the full force of the midday and afternoon sun. We used the common White Willow (*Salix alba*), which abounds along swampy road-sides everywhere in New England.

These trees have all thriven well, though, owing to the marsh being salter in certain places than in others, some have grown less rapidly than their companions. The fear of the salt-water led us into the error of planting one row of trees at first inside the fence, and at some distance from it, where the presence of Clover and English Grass showed that the top soil was fresh. Subsequently, when they were well rooted, we removed them to the outside along the highway, where they now begin to make an agreeable shade, and an effective screen. The annual dumpings of sand made by the town along the edge of the road, to maintain its level which constantly tends to sink into the marsh across which it has been carefully built, seem to help the trees, which continue to send out surface-roots as the ground rises about them; and though some of them during their first seasons had a sorry time of it in dry, hot weather, they ultimately pulled through, and are no longer sources of anxiety.

The most exposed portion of the place being thus provided for, we turned our attention to the barren hill-side, which was a pretty hopeless-looking spot for trees of any kind. This elevation, some forty feet high and running back nearly 600 feet from the main street, seems to be the bank of some former water-way; at least I like to fancy that the odd terraces, which break its otherwise even slope, represent the gradual subsidence of some body of water which must once have filled the gorge, when the present meadow was an arm of the sea. Gravel and sand, mixed with moderate-sized cobble-stones, are its constituent parts, nothing like a boulder having come so far down. We have often regretted that some of the noble rocks which abound on the other side of the street, farther up the former stream, were not on our hill to form a feature in our landscape-gardening, marked as they are with the scratches which show the grinding of some primeval glacier.

Over the rough foundation of our hill a thin soil has formed itself; fairly deep on the level top where the plain begins, but constantly washed off down the sides into the swale below. It seems hardly possible that trees can ever have grown here, nor are there the smallest traces of any in or upon the soil; but here we resolved that trees should grow; and again the farmers mocked at such a wild idea, and looked forward with sombre satisfaction to our discomfiture.

But how to set about it?

To plow the surface, unless we could yoke a goat to the plow, seemed impossible, since we had just seen a man and a horse and a dump-cart roll together, in a confused but unharmed heap, from the top to the bottom, on account of an incautious step off of the level. Even if we could have plowed the ungrateful soil, of what use would it have been, since there was nothing to bring to the surface but stones? Cultivation being apparently out of the question, the trees would have to take their chance, and a wretched chance, too, for the south shore of Massachusetts Bay is subject to long and severe droughts and to several months of hot weather in the summer.

But here we were upheld by our authorities. An excellent book on forestry gave us some consoling statistics, and later, GARDEN AND FOREST was invaluable in its suggestions. We found that in reforesting hills in France and Switzerland that had been swept bare by avalanches, a north-east slope proved the most favorable exposure for the growth of young Pines, and, if we had nothing else, we had plenty of north and east, with the winds thrown in; so, if that was the sort of thing that they liked, why, bring on the Pines, and let them have all they want of it.

But by the time we got round to this job, as the farmers say, the season for spring-planting of Pines was over, and an exceptionally dry and burning summer was in full blast, and the very grass on the hill was crisped and dry. Our impatience, however, was too great to permit us to wait for another year to begin our experiment. We had read some accounts of August planting of Pines, and determined to have our little fling on the spot, and find out for ourselves whether it was a good time or not.

So we waited, as anxiously as the prophet Elijah, for the first sign of rain, and when at last the brassy heavens veiled themselves in cloud about the middle of August, we started off after trees—not the pampered darlings of a nursery, used to water and rich soil, but the hardy road-side denizens of dry pastures and sand-hills. We picked out the driest and sandiest spots to dig them in, so that if their roots discovered nothing to feed upon in their new locality, they would, from long habit, have got used to short commons, and could adapt themselves to the situation.

Before going out we had the men dig holes over the surface of the side hill with a grub-hoe, banking up the thin soil at the lower sides of the holes with sods, so as to make little dams to retain the water; in these holes we set the trees we selected, which were not over three feet high, but stocky and well rooted. When possible we took up the dirt with them, keeping their roots moist, and well shaded in the cart, and no more were brought at a time than could be set in two or three

hours. After they were all planted, with great labor and trouble, we gave our nursery a thorough watering, and then, except on two or three subsequent occasions, when things looked really desperate from drought, they were left to take their chance. Luckily that year the rains began to fall soon after they were set, and the autumn was a very wet one, so that a good many of the little trees were living in the spring; greater part are flourishing bravely, making a fine show in winter against the snow. In summer they shade so completely into the unkempt green background of the hill that, unless seen in profile, they are barely visible, even when five feet high, and very bushy. Still farther back we have tried setting out very small Pines, and have sown the ground in autumn with countless Pine-seeds, and nuts of all sorts, which come up

Fig. 29.—Phyllanthus pallidifolius.—See page 162.

but another batch, set in the latter part of May the following year, owing possibly to the very heavy rains of 1888 and 1889, did so much better, that we shall always be disposed to give the preference to spring planting in the future.

Of some 150 Pines set out upon this barren northerly hillside, under these cruel conditions, about eighty survive, a few of which are still leading a precarious existence, while the satisfactorily enough, and do bravely for a month or two, but suffer dreadfully in July and August. They are a fruitful source of anxiety and disappointment, because they cannot make up their minds whether to live or die. The young Oaks are especially trying in this respect, for when we have fairly given them up for lost, they thrust out a feeble little leaf and make a fresh effort at existence, but at this rate a millennium

will be too short for them to get their growth in. I have read somewhere that an Oak grew from an acorn in this commonwealth of Massachusetts, forty feet in fourteen years, but if these hill-side acorns achieve fourteen feet in forty years we shall feel we have not lived in vain.

"What do you do to make trees grow?" I asked an Englishman who was coaxing along a rebellious Butternut to some show of vigor.

"Oh!" said he, "I just talks to 'em, and tells 'em to grow, and they grow."

Mindful of this advice, I do not fail to exhort these recreant acorns, but no teacher of a primary school ever had a worse time in getting a shoot out of a young idea, than do I out of this infant class of refractory nuts and seeds.

New or Little Known Plants.

Phyllanthus pallidifolius.

THIS plant, which is a native of Java, is more often met with in gardens, under the name of *Reidia glaucescens*. It belongs to a vast genus of the Euphorbia family, with four or five hundred species scattered over the warmer parts of the world's surface. The name is formed from two Greek words, meaning leaf and flower, and was given to these plants because, in some of the species, the flowers are produced from the edges of what appears to be the midrib of a long compound leaf, but which is really a branch, the organs which look like leaflets being true leaves.

Phyllanthus pallidifolius will not, perhaps, interest people who find little to admire in plants which do not produce large and showy flowers. It is a small shrub of graceful habit, with bright fresh green foliage, pale and glaucous on the under surface, as beautiful as that of many Ferns. It is, for this reason, well worth cultivating in collections of stove-plants. The flowers, which are graceful and pretty, are produced during the summer and autumn in great profusion, and hang from the branches on long, slender, bright red pedicels, the males solitary or a few together from the axils of the lower leaves, the females solitary toward the ends of the branches. They have no petals, but the sepals are yellow, with fringed margins, and are marked with bright red at the base. This plant, like the others of the genus which are occasionally cultivated, flourishes in a compost of sandy loam, mixed with a little fibrous peat, and requires thorough and careful drainage. It may be easily increased by cuttings struck with bottom heat.

Our illustration on page 161 is from a photograph of a plant in the collection of Mr. J. L. Gardner, of Brookline, Massachusetts.

New Orchids.

Cochlioda Noezliana, Rolfe.—This is a charming novelty, of very graceful habit, bearing a branching panicle of medium-sized, orange-scarlet flowers with a yellow disc. It was introduced by Messrs. Linden, L'Horticulture Internationale, Parc Leopold, Brussels. A plant was exhibited at a meeting of the Royal Horticultural Society on November 11th last, when it was awarded a botanical certificate. It is dedicated to Monsieur John Noezli, its discoverer. According to an advertisement in the *Gardeners' Chronicle* for February 28th last (page 258), the species is a native of the Andes of Peru, growing at an elevation of 9,000 feet above sea-level. It belongs to a small genus closely allied to Odontoglossum, under which genus and Mesospinidium the species are generally known in gardens.—*Lindenia*, vol. vi., p. 55, t. 266. (English edition, vol. i., p. 9, t. 266.)

Peristeria aspersa, Rolfe.—An interesting species, allied to *P. Rossiana*, Rchb. f. It was discovered by Monsieur Bungeroth on the declivities of the Sierra de Marawaca, one of the most elevated mountains of the Parama chain, in Venezuela. This collector sent specimens to Messrs. Linden, L'Horticulture Internationale, Parc Leopold, Brussels, in whose collection it flowered last year. The flowers are borne in short racemes of about ten each, the color light brownish yellow, densely spotted or speckled with innumerable small spots of reddish brown, and the lip of a darker color, bordering on crimson.—*Lindenia*, vol. vi., p. 57, t. 267. (English edition, vol. i., p. 11, t. 267.)

Schomburgkia Sanderiana, Rolfe.—This is a very handsome Schomburgkia, introduced by Messrs. F. Sander & Co., of St. Albans, about three years ago, and now flowering for the first time. It is a plant of medium size with hollow pseudobulbs, very rigid leaves, and a lax, somewhat branched, panicle of rosy carmine flowers. It is allied to *S. Humboldtii*, Rchb. f., which, however, is easily distinguished by its much more elevated and acute keels, and other differences.—*Gardeners' Chronicle*, February 14th, p. 202.

Cypripedium × Creon, Veitch.—A new hybrid raised between *C.* × *Œnanthum superbum* and *C.* × *Harrisianum superbum*, the latter being the seed-bearer. It is about intermediate in character; the dorsal sepal is dark red-brown, with a white margin, and the petals and lip pale red-brown. It was awarded a first-class certificate by the Royal Horticultural Society on February 10th last. It is curious to note that both the parents are themselves hybrids.—*Gardeners' Chronicle*, February 14th, pp. 214, 215.

Bulbophyllum inflatum, Rolfe.—This is a very remarkable little Bulbophyllum, which was received from Sierra Leone in 1887, and flowered in the Kew collection in 1889, and again in the following year. It is closely allied to *B. comatum*, Lindl., a species from the same country, not known in cultivation, though quite distinct in its inflorescence. The racemes are like pendulous, egg-shaped masses of yellowish green, hairy flowers. This peculiarity is owing to the shape of the rhachis, which is swollen in a remarkable manner, forming a solid, fleshy, ellipsoidal body, an inch long by half as broad, on which the flowers are densely arranged. The hairs on the flowers are remarkable in their origin. Each sepal is strongly keeled, and it is these keels, particularly those of the lateral sepals, which break up into long hairs, while the margins of the sepals are almost or quite smooth. The name is given in allusion to the peculiar swollen rhachis. It is a very free-flowering little species.—*Gardeners' Chronicle*, February 21st, p. 234.

Kew. *R. A. Rolfe.*

Cultural Department.

Some American Oxalis.

I BEGAN many years ago to collect bulbous and tuberous plants, and the genus Oxalis has been a favorite of mine from the beginning, but so incorrect are the names that are supplied with the bulbs that the trouble of identifying the species has been almost equal to the pleasure of possession. It would seem that the names of South African kinds, and of Mexican kinds, however confused among themselves, might be kept distinct, but they are not, for the only firm (an Italian one) which now has the names *O. Jacquiniana* and *O. vespertilionis* on its lists, sends two Cape species to those who order those kinds, though both are Mexican.

About forty sorts are indigenous to Mexico and Central America, including *O. stricta*, which is found the world over, and of these not more than five or six are obtainable. One more of the group, *O. Drummondi*, I am glad to find offered this spring by Gillett and Horsford, from whom we always expect something interesting.

The bulbs of the American section are not hard and solid like those of the Cape, but of a much looser structure, and are soft enough to yield readily to the pressure of the finger and thumb. All the kinds are summer-blooming. *O. lasiandra* has been in cultivation in this country longer than any other Mexican sort, having been introduced many years ago by James Vick, who saw it used as an edging in European gardens. Its flower and leaf stalks reach a height of twelve or fourteen inches, and, as their growth is not so tufted as in the other kinds, they look somewhat weedy before the season is over, the tall stalks, with the remains of the early blossoms, lying out in all directions. Nevertheless the plant is well worth growing. Its leaves are composed of from five to nine long, narrow, dark-green leaflets, radiating like the leaves of *Cyperus alternifolius*, altogether unlike those of any other Oxalis I have ever seen. The flowers are bright rosy crimson, of medium size, and produced in clusters.

Oxalis Deppei is a very fine species. Its foliage is light green, of the familiar clover-leaf form, each leaflet being marked with a broad chocolate-colored mark like the letter V. The flowers are light crimson, and are produced all summer. The foliage of this and the following kinds is very dense and tufted, and, of itself, no slight ornament to a garden.

O. tetraphylla has four leaflets instead of three to each stalk; their color is much darker than in *O. Deppei*, and the blotch is deep brown. When the leaflets are unfolded the four combine in such a way as to make a nearly perfect square. The flowers are lilac, with a white centre, and, like those of the other species here described, are produced in abundance from June until frost appears.

O. latifolia has flowers much like those of *tetraphylla*, but the leaflets, which are arranged in threes, are very broad, and have a deep, wide notch in their outer sides.

O. lilacina is another species much resembling *tetraphylla*. Its flowers are a little smaller, and a little lighter in tint, and its rounded leaflets are in threes. No one who has one of these needs the other, unless he desires to grow as many species as possible.

I have two other species under the name of *O. elegans*. One is undoubtedly a variety, *O. hirta*, a South African species; the other, though evidently American, being much like the species already named, in time of blooming and general appearance, is very unlike the true *O. elegans*, which is a Peruvian species of great beauty, if we may trust the figure in the *Botanical Magazine*.

O. umbrosa is a very pretty species to plant in clumps or lines, as its foliage is very dense and very bright and fresh in color. It has no zone of brown as most of the other kinds have. Its flowers are white.

The Committee on Nomenclature of the Society of American Florists will do horticulture a service if they will stop the sale of this species under the name of *O. Deppei*, as is now done by many dealers.

All of the species described in this article are very susceptible to cold; the least frost kills the tops, and, of many hundred bulbs left out over winter, not one has lived until spring. In growing these sorts care must be taken not to plant *O. tetraphylla* and *O. latifolia* near any other sorts, as they send out subterranean runners to the distance of twelve or eighteen inches, each bearing a new bulb at the tip—a habit of growth which results in mixing the kinds if they are closely planted. The other kinds make their new bulbs in a cluster at the crown of the plant.

All of these kinds have a translucent root, shaped like a carrot. These are eaten in Mexico, but they have a disagreeable smoky flavor, very unacceptable to a civilized taste.

Canton, Mass. *W. E. Endicott.*

Fig. 30.—View in the Parc Monceau, Paris.—See page 159.

Odontoglossum nebulosum.

WHETHER it is that this large-flowering species is somewhat difficult to grow satisfactorily, or that it does not produce its handsome blooms in greater abundance, it does not seem to be so highly appreciated as some smaller kinds, and it is rarely that a good word is spoken in its favor in the horticultural press. The flowers, which are borne on strong erect scapes, are from two and a half to three inches across, having white sepals and petals, the lower half of which is decorated with chestnut-brown blotches of irregular shape, and somewhat paler on the sepals; the roundish, wavy-edged lip is also white, with some large chestnut blotches in front of the bright yellow, two-lobed crest, which has sometimes small red spots all over it. The pseudo-bulbs are of moderate size, ovoid and flattish, with two sharp edges, and bearing two deep green lanceolate leaves, each about six to nine inches long, on the summit.

Great variation exists among the flowers, the result no doubt of cultivation. In some forms the sepals and petals are large and well-arranged, the chestnut blotches standing out prominently on the white ground; in others the segments are small

and badly shaped and of a dirty greenish white color, which gets confused with the blotches. Three varieties are recorded. One of them, Candidulum, was introduced over thirty years ago, it is said, by Messrs. Low, of Clapton, a form with no blotches on the sepals and petals, and only one or two, or even none, on the lip. This seems to be the same as the plant sometimes called Candidissimum. The variety Pattisonianum is not well known. Reichenbach described it in 1868 as having large white flowers, and as being a native of Oaxaco, whence it was introduced by Baron Karwinski. The name commemorates Dr. Pattison, who was the first to flower this plant, and *Phalænopsis Luddenanniana*, in England.

About 1833 the typical *O. nebulosum* was found growing on the trunks of Oak-trees in Oaxaca, Mexico, by Baron Karwinski, but it was not until the severe winter of 1837–38 that it found its way into cultivation in England through the means of Mr. Bateman, and then the first consignment did not last long, as the plants were coddled in a too high temperature, in accordance with the inexperienced views of Orchid-growers of that time. Some years later two other well-known plant collectors—namely, Galleotti and Ghiesbreght—obtained plants of this species, and the latter sent a consignment to Monsieur Linden, in whose establishment at Ghent it flowered in 1856. Since this time it has often been imported, but not in great quantities.

A temperature varying from sixty to sixty-five degrees Fahrenheit in winter to seventy or seventy-five in the height of summer is suitable for *O. nebulosum*. In late spring-time growth begins, and constant attention to watering is requisite from this time and onward during the summer months. The plants should be shaded from the sun when it becomes very hot, and plenty of air ought to circulate through the house without causing one to feel a draught. The usual compost of rough fibrous peat, with a little fresh sphagnum moss and charcoal, in combination with first-class drainage, is required in order to grow strong, healthy plants, with a fair show of flower-spikes.

Isleworth, London, W. *John Weathers.*

Zonal Pelargoniums for Winter Blooming.

PERHAPS the so-called Geranium is more widely known and grown than any other garden plant, and its dazzling colors are seen everywhere in summer. But its true value is never known or thoroughly appreciated until it is used for decorating a conservatory or window-garden in winter. In the summer season a sudden storm will destroy its masses of flowers in an incredibly short time, and days must elapse before the plants regain their fair appearance; but this is not the case with specimens protected from the weather, which produce an uninterrupted and brilliant display through the dull winter months. Besides this, it is only with such treatment that the best color of each individual variety is secured, and the infinite variety of tints, from the deepest crimson to the purest white, is defined. It is true that there are certain varieties which are most useful when grown out-of-doors during the summer, while others are only valuable for conservatory decoration. It is therefore necessary to have a selection from both classes if we would have a continuous bloom.

Many people think that greenhouse space had better be reserved for something better than Zonal Pelargoniums, and, therefore, those plants which are used for bedding in the summer are simply kept alive during the winter in a starved, kept-over condition. But if the best winter-flowering varieties are selected, and have an opportunity given them to develop, they will prove worthy of the most careful attention.

For successful winter-flowering Geraniums must be grown especially for the purpose, just as roses are grown. Strong cuttings should be taken from April to June, according to the size of the plants desired, and their duration of flowering, and inserted singly in small pots of sandy loam. Cuttings may also be rooted in sand and afterward potted, if care is taken that they should neither be dried up nor drenched with water. As soon as they have made a new growth, and the small pots are filled with young and active roots, they should be re-potted into four and a half or five-inch pots, using this time, as a potting soil, two parts of fibrous loam to one of thoroughly rotted manure. An old spent hot-bed, where leaves have been liberally used in making it, is an excellent manure, and so is a spent mushroom-bed. Of course, if the loam is stiff it will be necessary to add some sand to keep the soil open, and the pot should be carefully crocked and drained, because these plants need frequent watering in hot weather. Over a layer or two of crocks in the pot a thin layer of cinders that have been sifted through a sieve with a half-inch mesh will serve to keep the soil out of the crock and, at the same time, keep earth-worms from the soil, as they do not like to travel through the sharp cinders. The plants should be placed in an ordinary frame, on a good cinder ash bottom, and protected from drenching rains and wind and scorching sun. When planted out they need all the sun they can possibly get, but, while in pots, they will dry out so much more quickly that it is preferable to shade them a little to prevent the roots from drying, for this would give them a serious check.

The plants should be pinched back to make them bushy, and all flower-stalks should be picked off as soon as they are large enough to handle, and early in August those which are meant for early flowering should have their last shift into nine or ten-inch pots, in which the soil may be rather coarser than that in which they have been growing. They should be kept out-of-doors, watered well and well guarded against the ravages of caterpillars, which are apt to eat the under side of the leaves, and disfigure them. They should be housed in September, although, if the weather is dry, they may remain out longer, but the plants will suffer if the weather is damp and cold. A warm, airy and light house is best for them, and the temperature should be kept at from fifty-five to sixty-five degrees. They will need a few stakes, which are slightly spread, and the shoots should be tied so as to keep the centre of the plant open. The pinching of the flower-buds should be discontinued, but any strong-growing roots should be pinched back. After the pots are filled with roots weak liquid manure should be given occasionally, and also a top-dressing of well-rotted manure and a little bone-flour. Good plants in six-inch pots may be had from cuttings struck in June.

The following is a good list of varieties suitable for the conservatory or window-garden:

Single-flowered Varieties.—White: Queen of the Whites, Improved, International, Lily, Mrs. Benedict. Pink: Lady F. Russell, Mrs. Joynson, Norah. Salmon: Countess of Derby, Mrs. D. Saunders. Purple and Magenta: Richard Dean, Dr. R. G. Tucker, Lord Churchill. Crimson and Scarlet: Mr. H. Cannell, Brilliant, H. Cannell, Jr., Hyacinth, Rev. H. Harries, Lynette, Judge Brown, Fiery Cross.

Double-flowered Varieties.—White: La Cygne. Salmon: Queen of the Fairies. Scarlet: Golden Dawn, M. Bruant. Pink: Mary Geering, Glorie de France. Deep Crimson: Black Knight.

Dongan Hills, Staten Island. *W. Tricker.*

The Best Chrysanthemums in England.—The yearly analysis of the leading Chrysanthemum-blooms shown at the numerous English exhibitions is always interesting to those who make a specialty of this flower everywhere. While American varieties are becoming very numerous and taking year by year a leading place in our exhibitions, no grower can afford to neglect the varieties among which our English friends find the prize-winners. Comparatively little interest seems to be taken here in the Chinese incurved section, no stand of these worthy of notice having ever been seen at any of our shows. As a matter of interest we note the leading twelve varieties of 1890 at English exhibitions in the order of their rank: Miss M. A. Haggas, Miss Violet Tomlin, Empress of India, Queen of England, Lord Alcester, Golden Empress of India, Jeanne d'Arc, Lord Wolseley, John Salter, Princess of Wales, Prince Alfred, Golden Queen of England. As compared with former audits, this shows a falling off of Empress of India, which variety has occupied the foremost place for a number of years. The leading Japanese varieties show the usual shifting of places. The first dozen were: Etoile de Lyon, Sunflower, Avalanche, Edwin Molyneux, Madame C. Andiguier, Mademoiselle Lacroix, Val d'Andorre, Maiden's Blush, Jeanne Delaux, Stanstead Surprise, Mr. Ralph Brocklebank, Stanstead White. Eight of these varieties are introductions of 1886 and later. Whether the new kinds are really so superior to the older varieties, or simply that their novelty causes them to be grown more largely, only future exhibitions will show. It is curious to observe the almost entire absence of American varieties from the list of sixty-three varieties, Volunteer (Henderson) being Number 45, and Florence Percy (Allen) Number 46. The latter variety, like Mr. Ralph Brocklebank, is not highly esteemed with us, as it always comes very thin.

Elizabeth, N. J. *J. N. G.*

Ipomœa pandurata.—This plant is going the rounds of the catalogues as the "Perennial Morning Glory," and it will probably be widely distributed this year. It is quite safe to say that all who buy the plant will also buy experience. It is also true that the plant is very beautiful, a perennial and quite

hardy, being a native plant, and, according to Gray, found from Connecticut to Illinois and southward.

I well remember finding it wild for the first time and bringing specimens to the late Dr. Thurber for name. His words I repeat as nearly as my memory will permit: "Don't plant it, or if you do, don't try to dig it up, for if you do you will have a task that will last for years." His advice sufficed for me, and it was left to ramble over its native hedgerow where it was very ornamental. The plant has a very thick root which penetrates deeply, and every particle of this root, when broken off, will grow, so the more one tries to dig it up the more persistently does it appear over a wider area. But if one plants it where it is to remain to be gazed at for a lifetime, it would probably not spread or cause trouble. But there comes a time, in the history of most plants, when it seems best to remove them, or replace them with something else, or to dispense with them altogether. When that time in this Ipomæa's history arrives, trouble is to be apprehended. The moral is to plant the vine on a back fence or hedgerow, and not in any dressy part of the garden.

S. Lancaster, Mass. *O. O.*

Tomatoes under Glass.—In providing for a second crop of these, a trial is now being made of some unusual methods. Instead of raising seedlings to take the place of the old plants from which a crop had been removed, a large portion of the earth was removed from the boxes in which they grew, and the plants were coiled around in the boxes and covered with fresh earth, the ends of the plants being left projecting above the surface. In another lot the old plants were cut down nearly to the surface of the ground, and a single shoot was allowed to grow up from the stem. In both cases the young shoots, having all the roots of the mature plant to support them, have grown with great vigor. Both of these methods, but especially the second, seem to indicate at present that a considerable reduction in the interval between successive crops may be made by their use, as the plants have far outstripped, in growth and flowering, the seedling plants of the usual size which were transplanted beside them at the same time.

The Forest.

Prairie Forestry and the Timber Culture Law.—I.

THE proposed repeal of the Timber Culture Law, with no provision suggested whereby Government will offer any encouragement for the planting of trees on the treeless prairies, has led me to look into the question of how far the law has been instrumental in promoting tree-planting on the wind-swept plains. I began the study of this question with the impression that I had only to consult the records of the Government Land Office to find incontestable proof of the wisdom and value of the law. Such incomplete data as I have been able to secure have not inclined me toward the enthusiastic support of the measure in its present form, but I do not believe the figures warrant the repeal of this important law unless Government is ready to adopt a comprehensive system for the conservation of forests on the public domain, and attempt the planting of timber of its vast treeless plains. Little has been accomplished in the way of successful tree-culture under this law, much less would have been done had Government offered no inducement to the settler to plant trees.

In the land offices at Huron, Watertown, Mitchell, Aberdeen and Yankton 53,499 entries have been made under the Timber Culture Law. Had every entry thus made represented a different piece of land this figure would indicate the presence of 534,990 acres of trees on 53,499 sections of land, for but one timber-claim can be located on a section. But the figure first given represents the total number of entries, and when a claim is relinquished the land is returned at once to the public domain and is again subject to entry. The statistics of the Land Office are very faulty in this, and no data are obtainable by which the exact number of different pieces of land entered as timber-claims could be known. The Mitchell office reports 15,231 entries, 4,000 relinquishments and 920 proofs. The 15,231 includes all entries that may have been once or twice relinquished, and hence does not give a correct idea of the acres held under the law; neither do the 920 proofs thus far made afford a basis for estimate, because probably the majority of tree-claims are not yet old enough to be proven up. The Aberdeen office reports 7,287 entries, and the Register estimates 5,319 cancellations.

The authorities of the General Land Office at Washington estimate that ninety per cent. of all the timber-culture entries in the country are either fraudulent or failures. The final proofs submitted at the offices named above number 2,890, making about five per cent. of the entries; this would seem to prove the estimate a good one. But, granting the very great number of failures, the Timber Culture Law has placed on the prairies of South Dakota 28,920 acres of timber, every acre of which contains at least 675 trees; 2,890 groves on lands that otherwise would probably have remained treeless for an indefinite period. It is true that many of the claims on which proof has been accepted are far from being ideal groves, either in the quantity or quality of the trees that compose them, but a single winter in this windy state will teach that every tree that grows is worthy of respect.

Nearly all the settlers of Dakota came from the regions far better adapted to tree-culture than their new home. Naturally, when they saw the luxuriant growth of grass that covered the prairies, they concluded that the Timber Culture Law offered the easiest and cheapest means of securing land. Government designed to cover the naked prairies with groves, the ameliorating influence of which should be apparent in increasing ratio as the trees grew older. From the standpoint of the law the settler's first duty was to cultivate his trees and make his plantation a success; but he saw in the trees only one element of value, a means of securing a quarter section of land for a very small amount of money and effort. He soon found that the ten acres of trees, which brought no money return, demanded care and time which could be made an element of profit if put on the remaining acres of his claim. Every part of his tree-claim was a source of income but the ten acres which gave him title to it, and these were a constant expense. A very great number of those who made entries regarded the ten acres of trees as the one incumbrance on the land thus secured, and all such people naturally gave what they considered the least possible care to the trees that would insure them a title to the land. Many people believed that very little cultivation was necessary for trees (indeed, there is still prevalent a popular belief that too much cultivation is ruinous), and when to the wrong ideas of the inexperienced new-comer is added a lack of interest in trees for their own sake, the chances for success would be greatly against him. At the time when the greater part of the timber-culture entries in South Dakota were made, from 1880 to 1885, it was honestly believed by many settlers that trees would grow with very little care. When the trees died, as the great majority of them did, the planter attributed the failure to an "off year," and did not learn that no part of his land demanded so much attention as the ten acres that he had especially promised to care for.

The two causes for the many failures in tree-culture in this state are the planter's ignorance and his failure to cultivate intelligently. From what I have seen of tree-claims during my residence in the state I can testify that wherever trees were well planted and intelligently cultivated success was attained. I know of successes in the most unfavorable parts of the state, and failures are common in those parts of the state having the most rain-fall.

The great number of relinquishments have been in the hands of men who have been badly disappointed. Instead of being the cheapest way of securing Government land, any one who has proved up a tree-claim is very apt to say it is the most expensive land he owns. Congress was honest in making the law, and settlers thought they had a rare bargain. But both were deceived.

Correspondence.

Notes on Nomenclature.

To the Editor of Garden and Forest:

Sir,—Nearly all botanists are thoroughly in unison with the present vigorous movement to place botanical nomenclature on a firm footing, in so far as this can be effected by the identification and establishment on the principle of priority of the oldest names of groups and species. Much has already been accomplished in this direction in recently published catalogues, notes, special papers, and notably in Professor Sargent's "Silva of North America" as far as published.

It is true, however, that in two or three peculiar cases the principle of priority has not, as a matter of fact, been rigidly adhered to; although in the particular instances referred to the avoidance of extraordinary combinations was doubtless a reason for not carrying out the law.

Dr. Britton, in his "Catalogue of New Jersey Plants," in referring to the question of reinstating the oldest specific and

varietal names, distinctly states that the "names adopted are based strictly on the principle of priority of publication, the oldest specific or varietal name available being retained in whatever genus the plant is located, or whatever its rank as species or variety."

Professor Sargent, in discussing this point, assumes the same attitude, and states that he has "adopted the method which imposes upon a plant the oldest generic name applied to it by Linnæus in the first edition of the 'Genera Plantarum,' published in 1737, or by any subsequent author, and the oldest specific name used by Linnæus in the first edition of the 'Species Plantarum,' published in 1753, or by any subsequent author, without regard to the fact that such a specific name may have been associated at first with a generic name improperly employed."

In the range of the "New Jersey Catalogue," the author was called upon to consider the specific names of three species—Box-elder, Catalpa, and Sassafras—in the disposition of which we have illustrated the first exceptions in this work to the otherwise rigidly adopted law of priority. Other authors of subsequent publications, in disposing of these plants, have done no less than follow an accepted authority, and have maintained *Negundo aceroides*, Moench; *Catalpa bignonioides*, Walter, and *Sassafras officinale*, Nees. The new Silva, so far as now published, has not, of course, reached these questionable points; nor are we at liberty to anticipate what the author's decision is, or will be, when these cases are reached. We believe, however, that there can be but one decision, that of adopting the law without exception.

We do not wish to be understood as criticising Dr. Britton's position, for he has doubtless critically surveyed the ground upon which this question is raised, and for a good reason chosen to record an exception to the general law of priority already adhered to strictly by zoölogists, though, as it seems, not as closely by botanists. His reason, however, for not, in these instances, taking up the oldest specific name for the Box-elder and Sassafras, cannot, we believe, be for lack of evidence to identify with them Linnæus' earlier names—*Acer Negundo*, *Laurus Sassafras*, and *Bignonia Catalpa*.

But the time has arrived, it would seem, when what may by some be considered as valid objections, in fact positive reasons for calling a halt in the adoption of a certain type of specific name, must be waived, at least if we would appear consistent with the object—stability of nomenclature, toward which we are tending and for which so much hard work has been and is to be done.

The principal errors to be avoided in creating new and in reinstating old names need not be detailed here, but chief among them is that of employing a name which shall, if specific, be distinct from any other used in the same genus. Considering this, therefore, as the primary object in the application of a name, it practically matters but little what the combination finally becomes, by properly locating the plant, so long as it is distinct. It will not be any more easily remembered or better serve to avoid confusion with other names, whether we call it *Negundo aceroides*, or if we restore the oldest specific name, *Negundo Negundo* (Linn.) In other words, a name is a name, and although in the form just given not the most perfect, nevertheless quite as satisfactory as the many specific names in use which either have no meaning at all, or in their significance attribute to a plant a character positively not possessed.

But in urging the necessity of following strictly the law of priority in such cases as that of the Box-elder, we wish not to be understood as recommending the creation of new names in which the generic and specific members are exactly alike, but as referring in the opinion here expressed only to names already published, and therefore unalterable. Furthermore, the framers of the botanical code, in seeking to avoid the creation of such names as *Negundo Negundo*, adopted an article which prescribes that, "In constructing specific names, botanists will do well to give attention to the following recommendations"; and the one which covers this point is, "Avoid specific names having, etymologically, the same meaning as the generic name."

Doubtless this article, together with a natural repulsion felt for so redundant a combination as *Negundo Negundo*, has led botanists to stop short in the restoration of such specific names. But the principle urged in the code, and the spirit of those seeking to carry it out, is that each plant shall bear the "most ancient" designation, "provided it is consistent with the essential rules of nomenclature." And in examining the ground on which inconsistency may be charged in taking up, for example, *Negundo Negundo*, it is obvious that in such an attempt one would be perfectly in line with all of the "essential rules." For it is possible, if not quite fair to suppose from the language of the rule just quoted, that it had for its object only to prevent the original construction of a specific name like its genus; presenting, therefore, an entirely different case from the present difficulty, which is not "constructing" a specific name, but forming a combination in which the "most ancient" name published is applied to the species; so that whether foreseen or not this peculiar difficulty was clearly overlooked, and not provided for in the code.

Aside from the point here raised for settlement, many other troublesome questions have arisen in the attempt to re-establish obsolete names, and, so far as the botanical code furnishes sufficient authority for such difficulties, there is perhaps no reason for departing from accepted decisions. But it seems there are cases which have required further authority, for which botanists have had recourse to laws adopted by zoölogists, particularly ornithologists. In other cases, even a perhaps sufficient law in the botanical code has been discarded for one of the zoölogists' covering the same ground, but with different limitations. An example of this is the somewhat general adoption by botanists of the zoölogists' method of citing the original author of a specific term (when taken from its original genus) in a parenthesis, with the author of the combination outside; whereas, the botanical code requires only the latter name.

It seems, therefore, inasmuch as authority for minor cases has already been derived from the zoölogists, that we can do no better than follow their advice in the present difficulty and adhere without exception to the law of priority, a decision, too, which must tend to still more harmonize the usages of botanists and zoölogists.

If, then, we are to be guided by the zoölogists in the question of taking up for the Box-elder, Sassafras and Catalpa the oldest specific names, which would give for *Negundo aceroides*, Moench (1771), *N. Negundo* (L.) (= *Acer Negundo*, L., 1753); for *Catalpa bignonioides*, Walter (1788), *C. Catalpa* (L.) (= *Bignonia Catalpa*, L., 1753); for *Sassafras officinale*, Nees (1821), *S. Sassafras* (L.) (= *Laurus Sassafras*, L., 1753), to which may also be added the European Larch, *Larix Larix* (L.) (= *Pinus Larix*, L., 1753. *L. Europæa*, DC., 1805), it may be of interest, if not some comfort, to know how many names of this peculiar type are already in use among the ornithologists, mammalogists and ichthyologists.

The following examples among the birds are taken from a revised edition (1889) of the "Check-list of North American Birds," published by the American Ornithologists' Union; those of the mammals and fishes are taken from Jordan's "Manual of Vertebrates" (1888).

Birds: *Soula Soula* (Linn.), *Ajaja Ajaja* (Linn.), *Nycticorax Nycticorax Nævius* (Bodd.), *Porzana Porzana* (Linn.), *Crex Crex* (Linn.), *Gallinago Gallinago* (Linn.), *Vanellus Vanellus* (Linn.), *Lagopus Lagopus* (Linn.), *Zenaida Zenaida* (Bonap.), *Buteo Buteo* (Linn.), *Nyctea Nyctea* (Linn.), *Pica Pica Hudsonica* (Sab.), *Cyanocephalus Cyanocephalus* (Wied.), *Xanthocephalus Xanthocephalus* (Bonap.), *Icterus Icterus* (Linn.), *Carduelis Carduelis* (Linn.)

Mammals: *Vulpes vulpes* (L.), *Gulo gulo* (L.), *Bison bison* (L.), *Phocaena phocaena* (L.); less similar are: *Alce alces* (L.), *Delphinus delphis* L., *Mephitis mephitica* (Shaw), *Mus musculus* L.

Fishes: *Mola mola* (L.), *Hippoglossus hippoglossus* (L.), *Lota lota* (L.), *Sarda sarda* (Bloch.), *Anguilla anguilla* (L.)

United States Department of Agriculture.

The Western Arbor-vitæ.

To the Editor of Garden and Forest:

Sir,—In your article on this tree, published in Garden and Forest of March 11th, you say, "*Thuya gigantea*, unfortunately, is not hardy in the eastern states, and, like many of the trees of the Pacific forests, it cannot be used to beautify and enrich our plantations." Now, in British Columbia the western Arbor-vitæ grows not only along the coast, but at different places as far eastward as the western base of the Rocky Mountains proper, several hundred miles inland and northward in the region of the Interior Plateau, certainly to beyond the fifty-third and probably to beyond the fifty-fourth parallel of latitude. (See Report of Progress Geol. Surv. Can., 1879–80, p. 171 B.) In these inland stations it flourishes often at a height of several thousand feet above the sea, and is subjected, though for comparatively brief periods, to winter temperatures as low as those of any of the inhabited parts of the Province of Quebec. Arguing from these facts, and from the experience gained with

other trees tending to show that there is a wide margin of variation in hardiness within the limits of a single species, I am inclined to believe that young trees obtained from these inland localities might be successfully grown in the east. The circumstances appear to indicate that the western Arbor-vitæ is not bounded inland by low winter temperatures so much as by aridity of climate. Where the interior climate is dry, the tree is found only in deep humid valleys or ravines. It would thus appear to me to be more than probable that young trees brought, say, from the Selkirk or Gold Ranges of British Columbia, might be successfully established in most sheltered localities even in the eastern states and eastern provinces of Canada. Possibly this experiment has already been unsuccessfully tried, but, if not, it would seem to be worth trying, as the western Thuya when well grown is certainly one of the most beautiful trees on the continent.

Geological Survey of Canada, Ottawa. *George M. Dawson.*

[An attempt was made several years ago to establish the western Arbor-vitæ in the Arnold Arboretum with seedlings raised from seed collected in northern Idaho, where the climate is very severe. The plants, although carefully protected, were not able, however, to survive the Massachusetts winters. Another attempt to find a form of this tree which will prove perfectly hardy in the east should be made with seeds brought from the Selkirk Mountains and from other regions of British Columbia with extreme climates. Perhaps Professor Dawson can aid us in this matter.—Ed.]

Exhibitions.

The Boston Spring Flower Show.

THE spring exhibition of the Massachusetts Horticultural Society, which was held in Boston last week, delighted many visitors, who seemed to find their chief interest in two small natural rock-gardens which had been arranged on the floor of the lower of the two halls of the Society, and filled with forced hardy shrubs, forced bulbs and other perennial plants. The larger of these two collections was set up by Mr. C. J. Dawson, a young gardener in the employ of the horticultural department of the Bussey Institution, and did much credit to his taste and skill in selecting and arranging his material; the other, in which a smaller variety of plants appeared, was the work of the Botanic Garden at Cambridge, which institution exhibited various hardy shrubs in flower. It is always a question whether the surprises and pleasures of spring and the outdoor garden are not dulled somewhat by advancing the season by bringing into winter the plants whose flowers give to spring its peculiar charm, and whether if one sees Narcissi and Tulips, and the flowers of forced shrubs, Lilacs, Japan Apples and Spiræas all winter long, the keen delight which is felt at the north at the sudden change when winter melts into summer, and myriads of flowers open, must lose something of its delightful freshness. There is, however, one decided advantage in an exhibition of this character. It enables people who wish to make a selection of hardy plants to see them in flower just at the planting-time and to see what the best plants are for their special purposes.

It is now very much the fashion to force hardy plants to bloom out of season, and a great show can be made in this way with small outlay of money and without the skill and patience required to bring to perfection winter-blooming tropical plants which are now too much neglected, although they really belong to the winter season, and should then furnish the principal decoration of the greenhouse and conservatory.

Roses and Carnations were shown in large numbers, and, as is the case almost always in Boston, they were of excellent quality. Tea Roses were more abundant than Hybrid Perpetuals, and this, as indicating the return to popular favor of the Tea Rose for winter, is a matter of congratulation. The Tea Rose is the Rose to raise under glass, and no other Rose can equal it in delicate beauty and graceful refinement.

As examples of good cultivation, no plants in the exhibition equaled the group of Cyclamens and Cinerarias shown by Mr. Kenneth Finlayson, gardener to Dr. C. G. Weld, of Brookline. The Cinerarias were selected from a large collection of these plants which have been the horticultural sensation in the neighborhood of Boston during the past month, and which have attracted many visitors. It is not probable that a collection of better-grown or better-flowered Cinerarias has ever been seen, although, unfortunately, the plants in the exhibition were a little past their best. The collection, as seen three weeks ago in Dr. Weld's garden, was a marvel of horticultural excellence. The plants were of a remarkably good strain, bearing a large variety of enormous bright-colored flowers. It may be of interest to note that the seed from which Mr. Finlayson raised these plants was selected by himself from a strain of his own.

Indian Azaleas were shown in a number of specimens in considerable variety; they lacked, however, substance and finish, and showed the effect of having been brought forward in too much heat. Orchids were not up to the standard set in previous Boston exhibitions. Of hardy plants, the most interesting for their novelty was a small group of the beautiful Japanese *Primula Sieboldii* exhibited by Rea Brothers.

Recent Publications.

A Move for Better Roads. Essays on Road Making and Maintenance and Road Laws. Henry Carey Baird & Co., Philadelphia.

This book is one of the fruits of the wide-spread agitation for an improvement in our public highways. These essays are not solely arguments to show how great are the advantages of good roads to both town and country, but they enter into details and go carefully into the principles of road-construction as well as maintenance, and treat of the legislation which is needed to insure the best and cheapest wheelway the year through. The history of the work is this: In November, 1889, Mr. Wm. M. Rhawn offered to contribute, through the University of Pennsylvania, a prize for the best paper on the "Construction and Maintenance of Common Roads." The project received so much encouragement from the Provost of the University and Professor Haupt, the head of the Engineering Department, that the plan was enlarged through the organization of a committee and the opening of a subscription fund, until at last prizes of $400, $200 and $100 were offered by the committee, and the competition was thrown open to all. The first prize was awarded by the very competent Board of Adjudicators to Henry Irwin, Assistant Engineer of the Canadian Pacific Railway; the second prize to David H. Bergey, North Wales, Pennsylvania, and the third prize to James Bradford Olcott, of South Manchester, Connecticut. These essays are collected in this volume, together with five others which received honorable mention in the competition. To them is added a digest of the contents of the remaining essays offered in competition for the road prizes besides some contributions from other correspondents and some notes by Mr. Rhawn, making altogether a volume of more than 300 pages. The work has a good index and a still better table of contents, and, although little that is new can now be said on the subject, the book certainly presents in accessible form such general rules of road construction as non-professional readers ought to be interested in studying. The essays are prefaced by a series of resolutions by the committee to the effect: (1) That in the improvements of roads the Macadam system, consisting of small angular fragments of stone in sizes not exceeding from two to two and a half inches in the longest dimension, according to quality, should be used wherever a stone surface is practicable and justifiable. (2) That the minimum width of the metaled surface for a single track should be a demi-rod, eight and a quarter feet, and of such depth as the amount of traffic and character of the subsoil may require. (3) That the bed to receive the stone must be so prepared that it cannot be saturated with water, and, therefore, great attention should be given to the character and drainage of the subsoil. (4) That the width of the tires of wheels should be regulated by law, and that the minimum width of all heavy draught vehicles should be four inches, to be increased when the capacity of the vehicle exceeds half a ton per wheel at the rate of one inch for each 400 pounds in excess.

Stone of the proper quality for making a good road-surface is abundant in most parts of the country, and where it cannot be cheaply procured some fair substitute can be found, so that there is no reason why a few sample miles of the best possible road cannot be constructed in every township of the country which is sufficiently populous to justify this expense. This is the first step needed in road-reform. The chief reason why the people of the country do not insist upon better highways is, that they have never seen a mile of good road. When once they learn by experience what advantages are secured to them by the best roads, they will not rest until the common roads receive the same attention that is given to railroads. It is to be hoped that this book will have a wide circulation, for it will disseminate just such information as will prove of practical value in hastening forward the construction of these model bits of highway which must prove beneficial as object-lessons.

Notes.

In a portion of our edition last week the article entitled "Points in Chrysanthemum Culture" was not credited to Mr. John Thorpe, as it should have been.

In a paper on "Ferns," read before the Massachusetts Horticultural Society last week, Mr. George E. Davenport said that a single frond of *Aspidium Filix-mas* is capable of producing 18,000,000 plants, and one entire plant 1,000,000,000 seedlings.

During the census year 267,271 tons of grapes were sold for table use in the United States, and 304,868 were sold to wineries. More than 24,000,000 gallons of wine were made. Besides this 1,372,195 boxes of raisins were produced, each box holding twenty pounds.

A correspondent of the *American Florist* suggests the use of red flowering Cannas to supply the lack of scarlet flowers at Easter. Some pots of the bright blooming kinds, with good foliage, would be an admirable addition to the Palms and Lilies so generally used.

One of the largest wine casks in the world, according to the last census report, is in the Ohio vine region on the shores or islands of Lake Erie, although its exact location is not given. The cask is made of Ohio Oak, is of the finest cooperage, and contains 36,000 gallons.

The Bride continues to be the leading Tea Rose in the New York flower market. Niphetos, on account of its weak and drooping stems, does not suit the present fashion for Roses which stand up well. The Bride also has the slight pink tinge which relieves it from a dead-white and makes it much more generally serviceable.

The fourth of the "Farmers' Bulletins," so called, issued by the Department of Agriculture, relates to fungus diseases of the grape and their treatment, and has been prepared by Professor B. T. Galloway. We have in former issues given most of the information which is contained in this valuable bulletin, in which will be found the facts that have been brought out by the most recent experiments in the Department. Every grape-grower should be familiar with the new methods of treating the four diseases of the grape which are now the most destructive, namely, the downy mildew, the powdery mildew, the black rot and anthracnose. Copies of the bulletin will be sent to any one who applies to the Secretary of Agriculture at Washington.

The Verbena Mildew, so much dreaded by florists (*Oidium erysiphioides*, probably), has been very successfully combated at the Cornell Experiment Station this winter with a solution in water of potassium sulphide, at the rate of a quarter of an ounce to the gallon. A stock of plants was received in the early winter which was badly infested with the fungus. A part of the plants were occasionally sprayed with the fungicide, and, while traces of the disease still appear at times, it is rendered practically harmless. Another portion of the same lot of plants, growing under similar conditions, but without the application of this simple remedy, was soon entirely destroyed by the disease. This preparation has also been applied to Cucumbers infested with the same, or a similar fungus, with very satisfactory results.

In a census bulletin of viticultural statistics, just issued, it is stated that a grower of grapes in what is now known as the Lake Keuka district, in New York state, shipped his first crop, amounting to fifty pounds, to the New York market in 1845, by canal. The commission merchant who handled these wrote encouragingly to the shipper and advised him to send more grapes. The next year the grower was able to ship him between 200 and 300 pounds, but he overdid the matter, and the New York market for grapes broke under this tremendous pressure. Last year, from this same district, there were carried away to different cities 40,000,000 pounds of grapes, while those raised in the Hudson River district of the same state, and the Chautauqua district, where the industry has only been established for ten years, swelled the grand total to 98,000,000 pounds from New York state alone, and this does not include the grapes sold for wine, which probably amounted to 25,000,000.

A recent article in *The Grocer* says: Vanillin is the odoriferous principle of Vanilla, which, from a previous paper, our readers know to be the fruit of a plant called *Vanilla aromatica*. Vanillin exists in the Vanilla-pod to the extent of about two per cent. These pods used to be very expensive, but new sources of vanillin are being discovered, and it seems likely that the vanilla industry will soon be extinct. Vanillin, which is the only substance for which the Vanilla-pod is valuable, has been found in asparagus, raw beet-sugar, and assafœtida; it likewise results from the oxidation of Olive-wood. On a large scale it is prepared from coniferin, a compound which occurs in the sap of the cambium of Pine-trees. The latest source of vanillin has been discovered by Herr Schneegans in the seeds of *Rosa canina*. These are extracted with ether; part of the ether is separated by distillation, and the residue is agitated with sodium bisulphite solution, saturated with sulphurous anhydride. Dilute sulphuric acid is then added, and finally, after much washing and drying, a brown oil is obtained, which, in a few days, becomes a mass of crystals. Possibly the vanilla pod will find a new commercial rival in these *Rosa canina* seeds.

Although the last Congress failed to pass the law extending the boundaries of Yellowstone Park, it did enact a measure which repealed the Timber Culture Act, and in this repeal was a provision authorizing the President at discretion to withdraw from entry any public timber-lands. In the exercise of his authority, the President has made a proclamation to reserve a belt on the eastern and southern sides of the park, which practically increases its area by one-half. Of course this action is not sufficient to annex to the park permanently all this region so reserved from settlement, but it relieves it from immediate danger from lumbermen, and leaves it under Government control, so that the same provisions for protecting it from fire and other depredations can be made as those which now exist over Yellowstone Park. This new region includes the head-waters of the Madison, Snake and Yellowstone Rivers, and will thus protect the water-supply of the park, and it will also include the breeding region of the elk and other great game. It is not apparent that the railway company which has defeated the bill for eight successive years have gained any important advantage, because the President's proclamation does not give them the right of way which they have been demanding.

As it is probable that a larger and larger portion of the world's supply of sugar will come from the Beet, instead of the tropical Cane, it is not surprising that our experiment stations are beginning to investigate the possibility of making beet-sugar in this country. A bulletin from the Michigan Station, prepared by Professor Kedzie, gives two charts, one of temperature, and the other of rain-fall. In the first chart the curve for temperature at Halle, Germany, and at Cambrai, France, shows that the range of the thermometer at these places, which are great centres of beet-sugar industry in Europe, does not differ materially from that of Michigan. A similar chart shows that the rain-fall in Michigan compares favorably with that of the best sugar-beet districts of Europe. Altogether, the climatic conditions in the greater part of the lower peninsula of Michigan are very favorable for the production of good Sugar Beets. That is, there is a moist and growing spring-time, a summer filled with sunshine, and not so wet as to produce a sappy growth, and autumnal weather that will ripen up and round out the growth, which are ideal conditions for raising these Beets. Wherever, in addition to these climatic conditions, there is a sandy loam, with an open, porous subsoil, good crops of Beets can reasonably be hoped for. Many attempts have been made to manufacture sugar from Beets in this country, but most of them have been failures. The Michigan Experiment Station proposes to make a fair trial of the industry in that State, and it is desired to secure the services of fifty or sixty farmers to help them. It is suggested that the agricultural societies in various counties or townships will select two or three persons, and to such persons the seed necessary for the experiment will be sent free of expense.

Catalogues Received.

P. M. Augur & Sons, Middlefield, Conn.; Small Fruits, Fruit-trees, Shade trees, Vines and Vegetable Plants.—A. Blanc & Co., Philadelphia, Pa.; Hints on Cacti.—A. M. C. Jongkindt Coninck, Dedemsvaart, near Zwolle, Netherlands; Wholesale Trade-list of Coniferæ, Fruit-trees, Hardy Perennials and other Hardy Plants.—Gillett & Horsford, Southwick, Mass.; Wild Flowers and Hardy Ornamentals, Evergreen Ferns, Shrubs and Novelties.—Richard Nott, Burlington, Vermont; Choice Vegetable and Flower-seeds.—Rigby & Burleigh, Houlton, Maine; The Rigby Patent Potato Digger.—J. Sallier Fils, 9 Rue Delaizement, Neuilly-sur-Seine, France; New and Rare Plants.—Mrs. Theodosia B. Shepherd, Ventura, California; Plants, Shrubs, Flower-seeds and Bulbs.—Vilmorin-Andrieux & Cie., 4 Quai de la Mégisserie, Paris, France; Seeds of Shrubs, Trees and Vines for Out-door and Greenhouse Planting.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, APRIL 15, 1891.

TABLE OF CONTENTS.

A Flower-Garden for New York.

THE city of New York was startled a few weeks ago by the announcement that a bill had been passed through one House of the Legislature which authorized the covering over of the old reservoir on Fifth Avenue and the creation of a so-called air garden on the spacious floor thus provided. Fortunately this scheme was thwarted by the indignant protest of the people, but it calls attention to the question, What shall be done with this reservoir when the new system of water-supply shall render it no longer needful? In one sense this is a purely local question, but it has aspects which are of interest to all who care for the proper adornment of public grounds in cities. No single style of planning and planting is adapted to areas of all sizes and surroundings, and this space seems to offer an admirable opportunity for a special type of garden design.

Every New Yorker, and every one who has visited the city, is familiar with the appearance of the reservoir, a substantial stone structure 500 feet square. It has no remarkable features as a work of architecture, and yet there is no excuse for tearing it down for the mere purpose of getting rid it, for it is on the whole a pleasing and rather effective structure in appearance, and it gains interest and value because it is unlike everything in its neighborhood. Its simplicity in line and mass contrasts refreshingly with the elaborateness of the adjacent buildings, and its low sky-line agreeably breaks the long high perspective of the avenue and admits an unwonted amount of light and sunshine. And then, too, it is bordered by a strip of grass with well-disposed shrubbery and vines, so that it is in summer a truly welcome sight. It is better, therefore, that the reservoir should remain as it is, even if it were entirely useless, than that it should be replaced by another building of any kind.

Standing as it does between the small area known as Bryant Park and Fifth Avenue, there has been a considerable desire expressed to have it demolished for the purpose of extending this park. Of course an increase in the number and size of our urban pleasure-grounds is always worth considering, but, after all, the increase in the area of Bryant Park may be too dearly purchased. A mere extension of this park in its present character is hardly desirable. It is not as though this were in a crowded quarter of the city and far removed from Central Park. In such a case the sweeping away of any building for the creation of a park of any kind to enable the thronging population to find a green spot would be desirable. But this park is but a short distance from Central Park, and it is never crowded with the class of persons who throng Tompkins Square and the Battery Park. The only justification for the expense of removing one of the few structures of an earlier time that are worth preserving would be the assurance that the space it fills could be converted into a garden of genuine beauty that would be an appropriate ornament to our finest thoroughfare.

A mere duplication of Bryant Park would not accomplish this end. No park could be more deficient in design, dignity and charm. It is a commonplace assemblage of asphalt walks, badly shaped grass-plots and a monotonous planting of Silver Maples. It is not a formal park nor yet a bit of landscape, like Mount Morris Park in Harlem, and it is valuable only as an open and shady place and not as a delight to the eye of the passer. But if the reservoir should be removed there would be no need that its area should be treated in the same way as Bryant Park. What we should like to see here would be a great flower-garden, similar to those which ornament many foreign towns. The fact that it is slightly above the level of the street and of Bryant Park would give a better chance for good results in this direction. The space could be laid out with broad, straight main walks, and minor ones, either straight or harmoniously curved, to form grass-plots of graceful outline. Then the main walks might be planted with avenues of small trees of a single kind, and symmetrical groups of shrubs could be formed on the borders which would have a succession of flowers throughout the season. The lawns could be edged with long narrow beds of hardy flowers, which we have often described under the name of French Parterres, and in appropriate situations, such as at the intersections of the paths, could be placed pattern beds of the most brilliant hues. This would make a pleasure-ground unique in this city and admirably adapted as an ornament to the avenue and a delight to the eyes of the public. It is constantly insisted by those who wish some excuse for the intrusion of formal flower-beds into pastoral landscapes that the public like nothing so well as flowers. In one sense this is true, and such a space as this would furnish an excellent opportunity to offer flowers in profusion, and also in a most beautiful and appropriate way. Of course, other things would be needed besides the planting of flowers to make the most of this opportunity. The cheap railing on its boundary should be replaced by a handsome stone balustrade, over which the interesting panorama of the avenue could be watched from appropriate seats, and beyond the main central entrance a sculptured fountain could lift its constant streams of water, while minor fountains or beautiful statues could be placed here and there.

There is no good reason why a garden of this sort could not be made one of the most attractive and artistic spots in the city. Indeed, some surroundings of the character found here are essential to decorative gardening of the best type. The canons of good taste would exclude such rigid and geometrical planting from landscapes like those in Central Park, because it would be impossible to reconcile such an artificial work with the free and natural design of the park. The two motives would inevitably conflict with and contradict each other. A flower-garden in a stretch of greensward would interrupt its unity and rob it of the breadth and repose, which are its highest charm. And, on the other hand, an expanse of turf with an irregular border of shrubs or trees would make a peculiarly inappropriate setting for a formal flower-garden, and neutralize to a great

extent its beauty of form and color. But a geometrical design is not injured, but improved, by confinement within the straight lines of streets and blocks of buildings, and areas with such sharply defined, rectilinear boundaries furnish unequaled opportunity for the display of decorative garden art. The floral flags and banners and pictures, with which too many of our public parks have been adorned, are simply abominations. But if some artist with genuine creative faculty and a refined sense of color could be found to make a design for strictly ornamental planting, as distinguished from natural planting, adapted to the area where the reservoir now stands, he would confer a boon upon New York, and offer an object-lesson well worth study and imitation by other cities.

The Sugar Maple.

WE have already published an illustration of a New England Sugar Maple, but good tree-portraits are not so abundant that an apology is needed for offering the one which appears on page 175. This Maple, too, is a universal favorite among our native trees, and one which planters never tire of using and no one ever tires of seeing in northern fields and waysides where it is at home. When it is young the Sugar Maple, although it is always a clean and thrifty-looking tree, lacks something of dignity and individuality. It is the general habit of this tree, instead of forking into large limbs, to throw out from a central stem many comparatively slender branches, the lower tiers of which rise at a slight angle above the horizontal, while those of successive years become more and more upright. As these branches grow out to about the same length with abundant foliage at their extremities, they form a tree of perfectly symmetrical contour, usually egg-shaped, and although the foliage is bright and cheerful its smooth and regular surface presents too little variation of light and shadow. These long and slim branches are easily moved, however, so that the tree has a sprightly and almost sparkling appearance in the sunshine when its leaves are stirred by the gentlest breeze. As it grows on to greater size, and the extremities of these numerous branches are farther apart, breaks begin to appear in the masses of foliage, and here and there some one of these lateral branches will assert itself and outgrow its neighbors until the entire outline of the tree is changed. The top often becomes broad and nearly flat, the sameness of the contour vanishes, and deep shadows give it a dignity of expression which it altogether lacks when young.

In the illustration the tree on the right has passed its prime, as can be seen by its comparatively scant foliage, which opens so as to show its main stem. Dead limbs also appear at the summit and on some of the longer side branches. Trees which are standing alone in pastures often die before their time, because cattle resort so much to their shade, and trample the ground beneath their branches. Very often, too, they are struck by lightning. Sometimes a shock of this kind is apparently slight, and the stricken tree seems at first to suffer no harm, but generally, after lingering a year or two, it dies outright.

The more distant tree on the left of the picture, and apparently a larger one, is still in full vigor, and represents an admirable specimen of its kind. It is growing on lower land, and, probably, has been better supplied with moisture than the one on the little hillock.

The Sugar Maple is a beautiful tree at all seasons. In early spring, when the greenish yellow flowers suddenly burst forth with the first leaves, the tree has an appearance altogether distinct from that presented by any other. Standing in the sunshine, a tree in full flower seems enveloped with a luminous mist, and is an object of striking beauty. Later in the season, its light green and very abundant foliage give it what has been aptly termed a peculiarly sunny expression, and it stands for the very type of cheerfulness among trees. In the autumn none of our trees blaze with brighter or more varied colors, and in the winter its light, ash-colored bark is a pleasant relief from the more sombre hue of other native trees.

We have nothing to add here to what we have often said about the value of this tree for timber and for fuel, and for its sugar product, but merely wish to say, that it was a sagacious popular instinct which selected this as one of our best trees for ornamental planting, and that few trees can excel it in situations where it will thrive. In some of the old places on the Hudson River long avenues were planted with it, three-quarters of a century ago, and some of them are now worth a long journey to see.

How We Renewed an Old Place.

III.—A BABY FOREST.

WE know that mothers love best those children who give them the most trouble, and it must be on some such principle that this barren hill-side of ours wins our best affections; for, as we cultivate its seemingly thankless surface, while it disappoints and resists our loving efforts, all the more there grows in us a tender comprehension of its hidden beauty, a wider sense of its possibilities, and a greater patience with the slow processes by which it is to be restored to vigor and productiveness.

We sympathize with its struggle for self-adornment, poor, barren, ugly thing. The cold, northern slope comes slowly to life, turned away as it lies from the fostering sunlight. When the plain and swale are bright with the hues of spring, the uncut grass upon its side is still brown and withered; it seems to dread awakening from its winter sleep, but at last it begins to star itself over with blossoms of white Saxifrage, and anon it grows purple with Bird's-foot Violets, sending out in the sunshine that soft, fleeting perfume which is a hint of the riper fragrance of their English cousins.

At this season, too, the exquisite wild Columbine decks it with earrings of coral and gold, which the country children call meeting-houses from their steeple-shaped horns, and over it the all-pervading Daisy waves its white and yellow blossoms sturdily in the wind, while the wild Briers put forth their roses, and the Dog's-bane its fragrant cymes, till the Golden-rods and Asters come at last to hide its barrenness with their royal splendor. And all the while there are short, thin grasses, of tender greens and browns, clothing it humbly, while spots of vivid emerald moss indicate the presence of hidden rivulets that feed a living spring that lies at its foot.

In this spring is the possibility of a water garden, of which there is already a beginning. All summer long you can see shining there the blue eyes of great Forget-me-nots, the seeds of whose forebears were brought, long ago, from stately Fontainebleau by a gentle artist, who planted them by his own brook-side, whence they have overrun and made famous the Hingham Meadows, their bright blossoms, like scattered fragments of the sky, gleaming among the rushes, and affording a valuable industry to the small boys who sell them at the railway station as you pass. In addition to these continuously blooming flowers, there are Pussy Willows and white Violets in the spring, and in the late summer the Arrowhead lifts its sculpturesque blossom and fine outlined leaf from the water, and the Cardinal-flower uprears its scarlet spikes amid the blossoms of stately grasses. Some day we hope to see a Pond Lily asleep upon its surface, and if the Lotus-flower would but brook our rigorous winters, we should add one to the collection.

At the foot of the hill, at each end, is a clump of White Birches, ladies of the woods that have strayed from their home, and lost themselves on this waste, and rustle their thin leaves timorously, bending their slender white stems as the sea-blasts strike them. Now that we have stopped mowing and pasturing, we find clumps of Bayberry and Choke-cherry bushes coming up under the tumble-down old rail-fences between us and our neighbors, so that these last are already high enough to shade the boys when, tired and hot with play, they throw themselves upon the ground under their grateful protection. For on the summit of the hill there is level space enough, inside our line, for a tennis-court, from which you can look for a mile across the meadow to the tree-clad hills beyond, and the clustered houses and masts of the harbor, half-buried in trees, and seek for the blue line upon the high horizon that indicates the sea.

Straggling paths, worn by careless feet, lead up the hill-side in those pleasant, meandering ways that indicate the foot of man, and, in imagination, we see them shaded by the Birches

and Pines that we have hopefully planted along the borders; for, in moving our trees with the surrounding sod, we usually brought along these close companions—the Pines and Birches being so married, in most instances, that it seemed a cruelty to separate them.

Hope and faith are qualities that find splendid exercise in tree-planting, and no pursuit can be more unselfish; for, as we watch the tardy growth of our plantations, it is with the stern conviction that other eyes than ours will see the waving of tree-tops above them, and far younger feet that will tread the fragrant woodland-ways when they are at last carpeted with Pine-needles. It is by this spirit that we become one with Nature, sharing humbly in her patience, in her vast unending plans, in her bountiful provision for the future. What better boon to the race can a man leave than a wood that he has planted, in which a future generation may walk and bless his name? Or, if the name be forgotten, there shall abide the forest-blessing, ever beneficent, the mother of springs that fertilize the plain, a shelter to the weary, a delight of the eye, a source alike of profit and pleasure while it endures.

We have friends who scoff when we take them to walk in our forest, and beg them not to step on the Oaks; but, to us, these tiny seedlings, so feeble and unimportant, are personalities that we have cherished through successive seasons, feeding them when hungry, giving drink when dry, grieving when their tender leaves, scorched by too fierce a sun, withered and fell, and rejoicing when, under the cool rains of September, their little bare stems put forth fresh crowns of leaf-buds. Much comfort can be taken in the fact that an Oak once rooted will not wholly perish, but some day conquer even the most obdurate of soils. Like good seed sown in the heart of a child, the storms and sunshine of the world may seem for a time to wither the plant to the ground, but in the end the beauty and power of deep-rooted character will prevail and bear fruit.

We have in our experiments endeavored to make use of such materials as lay at hand, though well aware that nurseries and gardens could have helped us on our way more rapidly. But dealers in trees are expensive luxuries, and our object has been partly to see what can be done without much money, and with only a moderate amount of labor. Our experience has shown us, what the books on forestry told us in the beginning, that sowing seeds and nuts is far less satisfactory than transplanting small trees; but we have had the entertainment of proving their statements for ourselves, and find our compensation in such trifling results as we have achieved. The Pine-seeds, which we shook from the cones in the autumn, and planted before they had time to dry, came up profusely enough in little clusters, but so tiny and weak, that it is wonderful that they are ever discovered even in the thin grass of the hill-side, which we leave near them to afford shade. They make, under these conditions, a sturdy little growth so long as the weather is cool and moist, but are apt to disappear altogether in the month of July. Any small tree, that one can pull up by a wayside, will make better returns for a little attention than these slow-growing mites from seeds.

Such White Birch-seed as we have sown, either because we did not know when to gather it, or whether it came from the wrong tree, has failed to come up at all; but in the sandiest and most uncomfortable part of the hill we find little seedlings that have come up of themselves from the trees at the foot, so that we are fain to confess that Nature understands her business better than we do.

The very small Pines, a few inches high, of which we have set a large number on the rear of the hill, do not grow as well as the larger ones, and are more apt to die. So far our experience leads us to prefer good-sized trees of all kinds for transplanting, rather than small ones, the larger tree seeming to have more vitality to come and go upon until new roots are formed, and it has become adapted to its new conditions.

We have planted various kinds of acorns in great profusion, but the Mossy-cup and the Chestnut Oak seem to thrive best in this waterless soil. The White and Red Oaks seem to require enriching to hold their own at all, and Maple seedlings, which come up promptly, yield to the first drought, though very small transplanted trees live on. Hickory-nuts, though slow in growth, are not vanquished by the conditions, and little yearling Chestnuts, transplanted and dug about, flourish bravely.

From a friend in town whose English Walnut-tree has borne profusely after the recent warm winters, we have obtained fresh nuts, which, promptly set, have germinated and given us fine little shoots in one season. This tree is a more rapid grower than any of our native nut-trees, and so far has stood the winters, but we have had no weather below zero here since 1887, and cannot answer for the effect of an old-fashioned winter. The field mice have a great predilection for them, and gnawed our largest one down to the root a year ago, but it came up again in the spring with redoubled vigor, and made up for lost time.

Small Beeches, dug up by the road-side, and put into holes prepared for them in the side of the hill, have thriven without much attention, and make a favorable growth; but some Ailanthus-trees from a nursery, in spite of Horace Greeley, have refused to do anything at all. In the swale at the foot of the hill, where the soil is deep and moist, all trees flourish. English Oaks grow rapidly from acorns, and we have a fine group of Chestnuts, transplanted when fifteen feet high, that grow superbly after being cut back sternly when set. Though much beset by insects, they are now firmly established, having been planted in the autumn of 1888. In this same moist, rich soil we have also had very good success with that difficult tree to move, the Hemlock; and the Tulip-tree and the Mulberry also flourish, though the tender young branches of the latter suffered after the last two warm winters, dying back badly. How they will have borne this moderately cold one remains to be proved.

Hingham, Mass. *M. C. Robbins.*

The Sap and Sugar of the Maple-tree.—I.

IN October, 1890, and January, 1891, *The American Anthropologist* published two interesting papers—one on "The Indian Origin of Maple-sugar," by H. W. Henshaw, and the other on "The Maple amongst the Algonquins," by A. F. Chamberlain.

These accomplished investigators have thus opened up a new subject of Forestry which may interest some readers of Garden and Forest. They recognize the really sedentary condition of the various Indian tribes, and the fact that, while their supplies of animal food were derived from fishing and hunting for animals and men, they really depended for their daily bread more upon the fruits of agriculture carried on by the Indian squaws than on any other single source. So skilled were they in cultivating the staple grain of America, the priceless maize, that the early colonists were their willing pupils in learning the art; and to these Indian savages, in many times of famine and distress, the colonists on all the Atlantic coast were obliged to appeal for supplies of corn from stores garnered up in sacks, or baskets and boxes made from the bark or wood of forest-trees, or in holes in the ground.

However little practical interest the result of this inquiry may have, it has been thought of some importance to the student of history to know what point upward the Indian race had attained in the arts of common life and in the chemistry of nature as related to their food-supply.

From the great knowledge of the Indian as to all edible products of America, as he had often to draw a part of his subsistence from the bark and wood of trees, the *a priori* presumption of the discovery of the properties of Maple-sap by him is, as stated in these papers, entirely in his favor; yet the question of fact is to be finally decided by appeal to two classes of evidence, the historical and the linguistic, and the two corresponding lines of argument. The rarity of specific reference in the early annals of discovery to the making of sugar by the Indian is accounted for by several causes, among which is the fact that the earliest navigators and explorers were seldom chroniclers. Coming to new shores peopled by savages, they rarely went far into the interior. They generally lived on their ships, or, if on shore, drew from the ships their supplies; while the great staples of such trade as they sought and could carry on with the natives were almost wholly furs of various kinds, and fish.

The shores of the sea and the tidal streams were not the common home of the Sugar Maple. And so far as the forests were concerned, the aspirations of these bold navigators were more than satisfied by the majestic Pines for masts and spars, the other splendid timber-trees for building ships, and the rich sources of turpentine and tar which everywhere met their eyes. Besides this, their passion for conquest often led to fierce contests with one another for territorial aggrandizement, so that little heed was given to questions of plants or food-products on shores where at almost every step they were liable to meet a savage barbarian, or a but little less ferocious wild beast.

On the other hand, the missionaries, to whose habit of writing we are indebted for many of the early notices of trees and fruits, were in no respect naturalists, and their descriptions of natural products are extremely incomplete, as well as few and far between. The very early records are indeed few, but careful research has been rewarded by the statements of Lescarbot,

Le Clercq, Denys and Boucher, which are earlier than any noticed in the *Anthropologist*, with the exception of Sagard's. Yet, that readers of Garden and Forest may know the character of the evidence which exists, a résumé of the statements of the principal authorities adduced is given, mainly in chronological order, the quotations having been verified by reference to original works.

The earliest record the writer has yet found is that of Lescarbot (1606–7), a lawyer of Paris, who from love of adventure came to New France as a friend of Poutrincourt in 1606. He gives some description of the New World and its Indians, tells of their great endurance, and explains the resource they found in the sap of trees for refreshment and strength in their hunts and long journeys through the forests. He says:

"Ils aussi . . . entreprendont d'aller vingt, trente et quarante lieues par le bois sans rencontre ni sentier, ni hotellerie & sans porter aucuns vivres. S'ils sont pressez de soif ils ont l'industrie de succer les arbres, d'ou distille une douce et forte agréable liqueur, comme je l'ai experimenté quelque fois."*

That Lescarbot refers here to the sap of the Maple-tree there seems no reason to question, as in the summer of 1606 he met with Erables (*Acer rubrum*) and Sycamores (*A. barbatum*) in the forests around Port Royal.†

The declarations of Père Sagard (1623–29), when with the Hurons, as to the use of the sap of trees, are to the same effect. He says:

"Au temps que les bois estoient en sêve nous faisions parfois une fente dans l'escorce de quelques gros fouteau, et tenans au dessous une escuelle, nous recevions le jus et la liqueur qui en distillait, laquelle nous servoit pour nous fortifier le cœur lorsque nous nous en sentions incommodez."‡

Sagard also expressly confirms the statements of Lescarbot as to the use by the Indians of the sap of trees to restore their strength and relieve their thirst when on expeditions through the forests, and affirms the adoption of this custom by the French themselves when the trees were in sap.§

Monsieur Nicolas Denys, Gouverneur, Lieutenant-Général pour le Roi (1634–1671), thus writes of the Maple:

"L'Erable est encore un bon bois: . . . cet arbre-la a la sève differente de tous les autres; ou en fait un boisson tres-agreable à boire, de la couleur de vin d'Espagne, mais non si bonne; elle a une douceur qui la rend d'un fort bon goust, elle n'incommode point l'estomac, elle passe aussi promptement que les eaux de Pougues; je crois qu'elle serait bonne pour ceux qui ont la pierre. Pour en avoir au Printemps et l'Automne que l'Arbre est en sève, l'on fait une entaille profonde d'environ un demy pied, un peu enfoncée au milieu pour recevoir l'eau, cette entaille a de hauteur environ un pied, et à peu prés la mesme largeur; au dessons de l'entaille à cinq ou six doigts on fait un trou avec un vrille-brequin qui va répondre au milieu de l'entaille où tombe l'eau: on met un tuyau de plume ou deux bout à bout si un n'est assez long, dont le bout d'en bas répond en quelque vaisseau pour recevoir l'eau; en deux ou trois heures il rendra trois à quatre pots de liqueurs. C'est la boisson des sauvages et mesme des François qui en sont friands."‖

Pierre Boucher (1663), Gouverneur des "Trois-Rivieres," who dedicated his work to Monseigneur Colbert, Intendant des Finances, says, in writing of the trees which grow in New France: "Il y a une autre espèce d'arbre, qu'on appelle Herable, qui vient fort gros et haut. . . . Quand on entaille ces Herables au Printemps il en degoutte quantité d'eau, qui est plus douce que de l'eau détrempée dans du sucre; du moins plus agreeable à boire."¶

After Boucher, Père Christien Le Clercq, a Recollect Missionary (1675–91), relates the experience of the missionaries in the use of Maple-sap. He says: "Nos viandes ordinaires estoient de même que celles de nos sauvages, c'est-à-dire de la Sagamité fait à l'eau avec de la farine de bled d'Inde; des citrônilles et des pois, ou nous mellions pour y donner quelque goût, de la marjolaine, du pourpier, et d'une certaine espece de baume, avec des petits oignons sauvages que nous trouvions dans les bois, et dans la campagne. Notre boisson était l'eau de ruisseau, qui coulait au pied de nôtre maison, et si dans le temps que les arbres étoient en sève quelqu'un de nous se trouvait indiposé, ou ressentoit quelque debilité de cœur nous faisons une fente dans l'écorce d'un erable qui distilloit une eau sucrée qu'on amassoit avec un plat d'écorce, et qu'on beuvait comme un remede souverain; quoi qù á la verité, les effets n'en fussêt bien considerable."*

Père Le Clercq in another work is more explicit, and says: "Quant à l'eau d'erable qui est la sève de l'arbre même, elle est egalement délicieuse pour les Français et les Sauvages qui s'en donnent au Printemps à cœur joie. Il est vrai aussi q'elle est fort agréable et abondante dans la Gaspasie, car par une ouverture assez petite, qu'on fait avec la hache dans un érable, on en fait distiller des dix ou douze pots. Ce qui m'a paru assez remarquable dans l'eau d'érable, c'est que si à force de la faire bouillir on la reduit au tiers, elle devient un veritable syrop, qui se durcit à peu prés comme le sucre, et prend une couleur rougeâtre. On en forme des petits pains† q'on envoie en France par vareté, et qui dans l'usage sert bien souvent au defaut du sucre Français. J'en ai plusieurs fois melangé avec de l'eau de vie, des clous de girofle et de canelle; ce qui faisoit une espece de rossoli fort agreable."‡

New or Little Known Plants.

Lælia anceps, var. holochila.

AMONG the multitude of varieties of *Lælia anceps* which have at different times appeared I have never before met with one having a perfectly entire lip, as has the present one. Indeed, the aspect of the flower is so different that, apart from the plant, it is doubtful if it would be recognized by many people as belonging to *Lælia anceps* at all. Early in the present year a single flower was sent to me by the conductor of Garden and Forest, from the collection of Mr. F. L. Ames, of North Easton, Massachusetts, with the information that the plant was purchased in June, 1888, from the Liverpool Horticultural Company, with a batch of other plants, as *Lælia anceps morada*, and that, with this single exception, the lot proved true to name. It flowered for the first time in December, 1889, carrying two spikes, and again the following year with five spikes. The plant has thirty bulbs and six leads. My first knowledge of this variety dates from December 7th, 1889. On that morning two flowers arrived from two different sources. One was from the Liverpool Horticultural Company, with a note from Mr. John Cowan, the manager, that it was a very distinct variety, at first sight looking like a deformed flower, but that there were two plants with flowers exactly alike. The other flower came through Messrs. Hugh Low & Co., of Clapton Nursery, who had received it from Mr. W. Sherwin, The Gardens, Asmaston Manor, Ashbourne.

Mr. Sherwin remarks that when the first flower opened he thought it some accidental freak, but a second plant on flowering proved exactly the same. A little later a pseudobulb and leaf were sent, also a peduncle, all of which were quite normal in character. The peculiarity of this variety is almost confined to the lip, which is elliptical-lanceolate in shape, over two inches long by three-quarters of an inch wide, and more like a petal than a lip. It is, however, different from the petals, both in shape and color, being light purple, with a nearly white disc, and some yellow at the base, while the petals are almost identical with the sepals in shape, and all pale lilac in color. The column is nearly, but not quite, normal. I believe this variety represents a peloriate condition of the plant, which has become fixed or permanent, and thus bears the same relation to *Lælia anceps* that *Uropedium Lindenii* does to *Selenipedium caudatum*. That the peculiarity has become fixed seems pretty evident, but whether it could be reproduced from seed is rather doubtful. I do not know the origin of Mr. Sherwin's plants, but should not be surprised to find that the whole of the plants under mention are subdivisions of one original clump, and from the same importation. If, however, we must consider it a monster, it is only such in a botanical sense, for it is a decidedly handsome garden-

* Etablissement de La Foy. Par le Père Christien Le Clercq, Vol. i., 252-3. A Paris, 1691.
† It is brought into Quebec to-day in "petits pains" and little cornucopias of birch-bark.
‡ Nouvelle relation de la Gaspesie, Chap. vi., 124-5. A Paris, 1691.

plant, and the most distinct, if not the rarest, variety of *Lælia anceps* in existence, and a marked contrast with the ordinary form.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

London Letter.

Snowdrops.—At a late meeting of the Royal Horticultural Society these plants were the subject of three papers, prepared by Mr. F. W. Burbidge, Mr. Allen and Mr. Melville respectively. Mr. Burbidge's paper was historical and botanical, the other two dealing chiefly with the horticultural aspects of the genus. Of course, the accepted botany of the Snowdrop, as indeed of all Amaryllidaceous genera, is that of Mr. Baker, of Kew, who describes six species of Galanthus in his book, viz.: *G. nivalis*, *G. Græcus*, *G. Elwesii*, *G. latifolius*, *G. Olgæ* and *G. plicatus*. To those must be added the newly described *G. Fosteri* and *G. Alleni*. The commonest, and, taken altogether, the best of all these, is *G. nivalis*, which is wild in the meadows and copses of England, and may be established almost anywhere. It varies somewhat in the size, form and marking of its flowers, a considerable number of varieties having distinctive names, such as reflexus, lutescens, poculiformis, octobrensis, Imperati, Redouté, etc. I confess to being somewhat blind to the distinctive characters of many of these varieties. Plant them all side by side, and they present no difference to the ordinary eye.

Fig. 31.—Lælia anceps, var. holochila, Rolfe.—See page 172.

Mr. Allen, who is the first authority on garden Snowdrops, considers *G. plicatus maximus* the best of all. The type is a native of the Crimea, whence it was introduced into England at the time of the Crimean war. The variety originated, I believe, in Mr. Allen's garden. It flowers later than the common Snowdrop, and has larger flowers. Of *G. Elwesii*, Mr. Allen has not so good an opinion as other growers have. It certainly is a bad species to cultivate, dying out if planted in ordinary beds, or deteriorating so much as to be inferior in size to the common kind. At its best it is a handsome Snowdrop, the flowers being large, globose, and of the purest white. *G. latifolius* has larger leaves and smaller flowers than *G. nivalis*. The new *G. Fosteri* has disappointed many who had been led to believe that it was larger in flower, more elegant in form, and in other respects superior to all other Snowdrops. At Kew it has not even equaled some of the forms of *G. nivalis*. Its fragrance was scarcely perceptible. Possibly it may improve after it has become established, though, as a rule, Snowdrops are better the first year after importation than afterward. *G. Fosteri* is named in compliment to the eminent English physiologist, Dr. Michael Foster, who introduced this species from central Asia Minor. *G. Alleni* has been described as "the finest of all Snowdrops." Mr. Allen says it is "nearer to *G. latifolius* than to *G. Caucasicus*, but the foliage is different in color, and the whole plant is much larger. It grows very robustly and flowers very freely. It is one of the most distinct Snowdrops I have, and my friends to whom I have sent roots speak very highly of it." Mr. Allen interests himself in the crossing of the different species of Galanthus with each other, and although, as I have already said, we have nothing better than the true "Flower of our Lady," the common *G. nivalis*, better may yet be obtained. It is stated that Herr Max Leichtlin knows of a pink Snowdrop in Armenia which he will no doubt obtain, if any one can. Let us hope that it is a better pink color than the so-called yellow Snowdrop is a yellow. Rumor has it that in a certain cottage garden in England there is "a colony of Snowdrops with bright yellow flowers!" Possibly these wonders belong to the same category as the Blue Chrysanthemum and Crimson Daffodil.

Mr. Melville's paper was full of practical hints, and the photograph exhibited by him of a wood carpeted with Snowdrops at Dunrobin Castle showed how effective these plants are when planted in grass under trees. It is not every garden that suits Snowdrops, but where the soil proves suitable they ought to be planted under trees on lawns, and in all such places as would be beautiful if studded with the pretty flowers of the first herald of spring. By the way, I may note that, instead of February, March has been the Snowdrop's month in England this year.

Max Leichtlin on Hardy Plants.—The renowned horticulturist of Baden-Baden does not often express himself at any length on the cultivation of plants. The announcement of a paper by him, to be read at the last meeting of the Royal Horticultural Society, was therefore sufficient to attract many of those who take a special interest in that class of plants with which Herr Max Leichtlin has always been prominently identified, namely, hardy herbaceous and alpine plants. The paper consisted of concise practical observations on the behavior and peculiar requirements under cultivation of hardy bulbs, plants, primulas, and the choicer alpines. The writer recorded his own experiences and views derived from them. Of course he would admit that many cultivators of hardy plants meet with success by following other methods, often very different methods too, from those which prove suitable at Baden-Baden. There are fifty roads to town, and often as many to success in the cultivation of any given plant. Any one who reads the cultural directions of trustworthy practitioners will have noted this fact.

Max Leichtlin begins by stating that to imitate the natural conditions in the growth of hardy plants is the first step to success. To this the obvious reply is, that it all depends on what the natural conditions are, and the cultivator's resources. He does not believe in the possibility of acclimatization for plants, although many people still have faith in it. That many plants prove hardier when under cultivation than they appear to be in a state of nature only proves their elasticity. An example of how easily one may be deceived by the behavior of plants was seen here lately, in the effects of frost on some seedlings of *Clematis Stanleyi*. The seeds had all been obtained from south Africa. About fifty of the seedlings were planted, last summer, on a south border at Kew, where they grew well and flowered, nothwithstanding the unfavorable weather here last summer. The first severe frost killed the leaves of all the plants except three, which remained uninjured; nor were these three hurt by the cold which killed

all the others down to the ground. It is easy to see how the behavior of the three hardier seedlings might have been misinterpreted under treatment of a different kind from that which they received.

Max Leichtlin mentioned *Calandrina umbellata*, a native of Chili, which never experiences frost in nature but bears at least seven degrees at Baden-Baden. *Zephyranthes candida* is still more remarkable, for, while it is found wild only in the low, moist plains of the La Plata, the other species of Zephyranthes being always on the hills, under cultivation in England it is as hardy as a Snowdrop, and is the only one that can be grown out-of-doors.

On the question of seed-sowing, Max Leichtlin made the following suggestions: The seeds of all hardy plants germinate more quickly and give better results if sown as soon as they are ripe. It is, of course, often convenient, and even necessary, to keep many seeds until the spring before sowing. Hard-shelled seeds, he said, must be sown at once. I confess I do not see the necessity for this. As a rule, seeds with a hard shell are easily kept; they lose nothing by being kept, and they germinate freely if soaked in hot water before being sown. Seeds with oily albumen are, of course, an exception to this rule. Immediate sowing is also recommended for seeds of all bulbous plants as soon as ripe. Delay in the case of seeds of Lilies, Fritillarias, Tulips and others means the loss of about eighty per cent. of the seeds. The same rule holds good in the case of Campanulas, or the seeds will lie dormant a whole year. All bulb seeds, except those of Gladioli, should be buried an inch deep, says Herr Leichtlin.

The seeds of Himalayan Primulas take three weeks to germinate unless exposed to a shower of rain after they have been sown a few days, when they will germinate in twenty-four hours. Others entirely lose the power to germinate if allowed to get dry. I have found tropical treatment, such as one gives to the seeds of Gloxinias, expedite the germination of such seeds as *Primula imperialis*, *P. Poissoni*, *P. prolifera*, *Ranunculus Lyallii* and other sluggish hardy alpines.

It is surprising how soon a high temperature with moisture induces germination in such seeds. *Victoria regia*, which, sown in a temperature of eighty-five degrees, takes a month to push through the hard shell, may be made to germinate in about three days if sown in water at a temperature of 160 degrees Fahrenheit. The seeds must be removed to a lower temperature as soon as the plumule appears.

Max Leichtlin believes much in the influence of frost on the vegetation of seeds. Even those of such plants as Kniphofia and Tecophylœa germinate more freely by exposure to frost for a time after sowing. Soft, pulpy seeds, unless quite hardy, should not be treated in this way. All bulbous seedlings should be left in the seed-pan at least a year.

Turning to the plants, he said all those with hairy or spiny leaves require a dry sunny position. Nearly all Primulas are happiest when planted in cool, shady spots. Hellebores thrive best if exposed to full sun in winter, full shade in summer. Manure was spoken of as the curse of the alpine-garden. According to Max Leichtlin, no rock-plant should have manure, which may be true at Baden-Baden, but the reverse at Kew, as well as in many other gardens. Nor do we find that most bulbs grow equally well in light or heavy soils. Of course the terms light and heavy are vague, but there are very many hardy bulbous plants as well as tender the behavior of which in light sandy loam is much less satisfactory here than in rich buttery loam. Max Leichtlin advises that no manure should be given to newly imported bulbs. I presume he meant only those bulbs which have suffered much through exposure and drought, as this cannot apply for Lilies, Tulips, Hippeastrums, Narcissi and many other bulbs which are largely imported annually. Most of his herbaceous borders, he stated, have had no manure for ten years. This says much for the excellent quality of the soil in his borders. All sick bulbs are recommended to be lifted, washed and thoroughly cleaned, and replanted in virgin soil. *Lilium candidum* is invariably ruined if dosed with manure. Fritillarias are naturally lime-loving plants, but at Baden-Baden they thrive in a soil quite free from lime. The American and Himalayan species like a somewhat shaded position.

The plants which received special notice at the meeting were the following: *Saxifraga Boydii*, a hybrid between *S. aretioides* and *S. Burseriana*, raised by Boyd, of Kelso. The latter parent is one of the most beautiful of all cultivated Saxifragas, both as a pot plant and on the rockery. *S. Boydii* is exactly like it, except in the color of its flowers, which are soft primrose-yellow.

Chionodoxa grandiflora.—This is merely a variety of *C. Luciliæ* with fewer flowered racemes, and flowers a little larger than in the ordinary forms of the type. It was previously called *C. gigantea*. There is a tendency among dealers to overname these little hardy plants, Chionodoxas having suffered a good deal from too much attention of this kind.

Azalea mollis, vars. *Mecene* and *Norma*.—These are semi-double varieties, good in habit, free-flowering, and the flowers decidedly pretty. Mecene promises to be a really useful plant for early forcing, as the flowers are white, with the faintest tinge of yellow on the outer segments, and they would meet with favor on account of their elegance and substance. Norma is of similar character, but the flowers are orange-red.

Other exhibits which received awards were Camellia Beauty of Waltham, a perfect double flower with blush-white petals; *Arum Palestinum*, an old garden plant which is hardy in some parts of England. It has a large black purple spathe and spadix, and grows to about eighteen inches in height. This plant is frequently sent to Kew by tourists in the Holy Land, who imagine that they have discovered something new. It was offered a year or two ago under the alluring name of *A. sanctum*.

London. *W. Watson.*

Cultural Department.

Calatheas.

UNDER this head are included some of the best foliage plants for warm-house culture, as well as some that will succeed in moderate temperature. They are a moisture-loving group, and are doubtless found in the condition of undergrowth in tropical forests, the majority being natives of either Central or South America.

The few species referred to here are all well worth cultivation in the most select collection, and possibly may be more readily recognized by some readers as Marantas, since most of them were originally sent out under that name. Many of the Calatheas, or Marantas, prefer warm treatment, in order to develop their beautifully marked leaves to perfection, and during the summer they also require shading, as the foliage of most of them is quite tender. In the matter of soil, a rough open mixture is preferable, and in potting it is best not to press it down too firmly, else the roots do not easily penetrate it. The drainage of the pots should also be looked after with care.

By the term "warm treatment" is meant a temperature of sixty-five to seventy degrees at night, with plenty of moisture both in the atmosphere and at the roots of the plants, and while such treatment will be congenial to many of the Calatheas, yet there are some that can be successfully grown under very different conditions. The propagation of these plants is effected by division, and about this season of the year is a good time for this operation, though it may be performed at almost any season, if done with care. Spring or early summer is also the most satisfactory time for repotting the plants, even though the increase of stock is not desired.

C. Veitchii, a plant of strong growth and very beautiful foliage, is one of the best of the genus. It attains a height of three feet or more, the leaves being ovate in form and standing almost upright, while in color they are dark, glossy green, with several crescent-shaped blotches of yellow on each side of the midrib, which are toned down by various shades of green and white. The under side of the leaf is light purple, and this adds to the rich effect of the whole.

Another charming species is *C. Makoyana*, which is also beautifully marked, though quite dwarf in habit. The leaves of this plant are thrown up on slender foot-stalks to a height of about one foot, and are oblong, with somewhat unequal sides. The outer margin of the leaf is dark green, and the centre semi-transparent and marked with yellowish white, in which the veins show quite prominently. When well grown this is a remarkably pretty plant, and is well suited for collections where space is an object.

C. fasciata is also a good species, and of free growth. It produces broadly ovate leaves nearly one foot in length and about eight inches wide. They are bright green, with broad bands of white reaching from midrib to margin, and the under side is pale green, flushed with purple.

C. illustris, another distinct species, has ovate leaves of bright green color, marked with bands of deeper green, and also with two irregular bands of white, running from the base to near the apex. The foliage of this species is also quite large, and it is of free growth in a warm house.

C. roseo-picta is one of the most attractive small-growing kinds, with glossy dark green leaves that are nearly round. The midrib is rose color, and two bands of the same color traverse the leaves almost from end to end.

Fig. 32.—Sugar Maples in New Hampshire.—See page 170.

C. tubispatha is more rarely seen. Its leaves are of medium size, pale green, and ornamented with a row of chocolate brown blotches on each side of the midrib. This species is nearly or quite deciduous, but should be taken care of during the winter, in order to keep the tubers in good condition.

One of the best known of this genus is *C. zebrina*, and a very useful one it is too, for it will bear more hardship than any other member of the family—not only making a satisfactory house-plant, but also being useful for out-door work in summer.

C. Vanden Heckei is another easy one to manage, and has erect leaves of dark green, shaded with lighter color, the midrib being margined with white, and two bands of the same are found between the midrib and margin.

Holmesburg, Pa. *W. H. Taplin.*

The Wild Garden.

I HAVE in mind a piece of ground about three feet square which contains fourteen varieties of transplanted wild flowers. They are interesting to watch from the uncurling of the first Fern-frond in April till the Arum drops its scarlet berries in October. In most yards there is a shady corner in which wild plants might be set. The soil need not be stirred, or enriched or changed for leaf-mold. If once or twice in the summer the grass-roots are pulled out it is about all the attention required. Wild flowers are used to "short commons" and to exerting themselves to hold their own. Nature does not see fit to pet or coax them, as so many other plants are always pushing and crowding for a foot-hold. So these wildings get a certain hardy, wiry toughness, though it seems as if the winds must be somewhat tempered to the delicate Spring Beauty. This has a small tuber buried as deep as the height of its stem above ground. It is frail, but bears careful transplanting. The Hepatica or Liverwort, which has hardy leaves, may be found and moved at any time when the ground is not frozen. As early as January the mass of gray downy buds at its heart may be seen. The blossoms have quite a range of color, something unusual in a wild flower. The bright blue is perhaps prettiest, especially when wide open, in the sun, but the pink and lilac ones are of so pure and fresh a tint as never to seem faded. The Bloodroot grows best in rich garden-soil, its leaves and blossoms becoming large and showy. In lifting the plant it should be remembered that its root-stock is at right angles to the leaf-stem. It blooms before the leaves are fully developed. The seeds, of pin-head size, are abundant, and it would be an interesting experiment to plant them.

Of the twenty-two varieties of native Violets only two have been tested in the garden. The Arrow-leaved, found by a dry, hilly roadside, lived only through the summer. The Bird's-foot Violet grows in a fringy clump, as the dark leaves are finely divided even to the stem. The blossoms, in cultivation often over twenty in number, are light blue, shaded to white at the centre, and it is altogether a superior plant. My first sight of it was in a Pine-woods, which it seemed to light up as a line of poetry might a chapter of prose. I have seen it once since growing on a rocky hill-top, from which I dug it and carried it wrapped in wet Oak-leaves a number of miles to my garden, where I introduced it to the Maiden-hair Fern and other select society.

Arisæma triphyllum, or "Jack-in-the-Pulpit," grows amazingly in rich soil, but is really prettier when small. It has a corm or solid bulb, with an extremely acrid taste, and said to be poisonous. This Jack has his time of peering solemnly from under his leafy sounding-board, and then, his message delivered, there goes on all summer a transformation by which he becomes a bunch of shining, scarlet berries. The small, imperfect ones, which ripen in the woods, give no hint of the beauty of a fully developed specimen. One which grew in the garden last year ripened in September, and lasted for a month. It was fourteen inches high, and had sixty berries, each of which contained from one to five large, white seeds, and a few drops of orange-colored juice. The dull crimson receptacle, seen by removing the berries, was covered with depressed scars where the berries joined. Its interior, like the stem, was filled with white, webby pith.

I shall never forget coming upon a great circle of cardinal flowers in full bloom in a moist sunny glade. I gathered a handful, and, showing them to the one on whose farm they grew, I for the first time heard them called "Nosebleed," a name more true than beautiful, and was told of their use in dyeing. By setting a vase of them in a plate of water one may notice particles falling and dissolving a brilliant coloring matter.

Several roots from a river-bank were set in rich garden-soil, which was prepared by wetting, for a foot or more in depth, to the consistency of thick mud. Planted in August, they were well established before winter, and the next year grew on through six rainless weeks with no watering at all. By August the tall blossom-stem showed the brightest color in all the garden. Its top nodded, but it need not have been so modest. But some rushes, accidentally taken up with it, did look out of place standing stiffly by a graceful Columbine. The purplish blossoms of the Wild Bean, *Phaseolus perennis*, are due in August, as are the wild Crimson Pinks. All these, with a Cranberry-vine and varieties of ferns, complete the company of fourteen which live in one little wild garden.

Hartford, Conn. *Amy Wightman.*

The Spring Garden.

SHARP frosts still continue every night to bind the surface of the garden, and, despite the daily advancing sun, there is still much chilliness in the air. Under these conditions the spring garden makes very slow advances. However, one can note, from day to day, continued progress among the hardy plants, and bulbous ones especially are the least influenced by adverse conditions of temperature.

Iris reticulata major—blooming in March—is a noticeable addition to the early-flowering bulbous varieties, and perfectly hardy. The flowers are larger than those of the type, and of a rich deep royal purple, with a spot of yellow on the falls. The falls do not droop as much as the typical *I. reticulata*, thus increasing its apparent size. The flowers of these dwarf Irises are quite persistent, this variety lasting in good form for ten days. *Iris Bakeriana* blooms were in good condition eight days when they disappeared under the snow. In the mean time they had passed through a night when the temperature had dropped to zero without apparent harm. Aside from the beauty of the early spring flowers, there is an unfailing interest in watching, year by year, their development under the various adverse conditions, and one acquires a friendship for them which is stronger and more personal than the regard for those of other seasons. Of quite a different form of beauty is *Iris Persica*, the first flowers of which are just expanded. This is an old variety, not grown as generally as it should be. It is a bulbous variety, placed in the Juno section, and the flowers, white, with purple and yellow markings, appear before the leaves, and are apparently stemless. It seems to be hardy in not too wet locations, and, like most hardy bulbous plants, should be planted early, so as to form roots before winter. Of course the flower-buds are formed in bulbs before they go to rest, and even late-planted bulbs will flower well, but precautions should be used in planting out, and especial care will be necessary if they are grown in pots in a cold frame from which frost is not entirely excluded.

Some of my surprises last winter were losses of *Iris juncea* and *Homeria collina* in pots, while plants of the same are alive in the open. *Ornithogalum Arabicum* potted up was destroyed, while those planted out under the same sash are alive and vigorous. It would seem that in pots, with their rigid sides, frost, for some reason, takes a stronger hold, and is apt to disintegrate bulbs, which, in freer soil, would escape ruin. This fact is probably familiar to professionals, though I have never happened to see it in print, which leads me to say that these small points which every one is supposed to know are exactly the things which interest the amateur gardener and save him from losses and disappointment. Our professional friends, who are kind enough to impart to us a great deal of instruction in their catalogues and the horticultural press, do not seem to realize how little we amateurs know about cultural matters, and how helpful it is to have the simplest hints. But to return to the garden. *Anemone blanda alba*, from Herr Leichtlin, seems a different form of flower from those of the type from Asia Minor, the petals being fewer and blunter. The white is of a more creamy tint than in white forms of the latter variety. One cannot have too much of either, as a bed of these on a sunny day in February and March produces an effect which cannot be secured from any other flowers at that season.

Chionodoxa gigantea or *grandiflorum*, as it is now named, retains its character as a distinct variety. Established plants throw flowers larger than *C. Luciliæ*, and of a more slaty blue, and without the distinct white eye of that variety. A crop of Chrysanthemums were grown over my bed of small bulbs last season, and the condition of the Chionodoxes this spring is a practical example of the folly of expecting to double-crop such a bed without injury to the bulbs.

One always welcomes the Narcissi as the first of the really conspicuous spring flowers, and the first satisfactory for cutting. Trumpet Major is open on the border, and a collection in a warm corner is in all conditions from bloom to apparent dormancy, thus promising a long season. So far the flowers

have appeared in the following order: Scoticus, Henry Irving, Countess of Annesley, Ard Righ, Trumpet Minor, Obvallaris (Tenby).

My collection of Narcissi is so small that I cannot consider myself anything of a specialist in these flowers, in these days of collections with varieties numbered among the hundreds, but I may be allowed to remark that, for ordinary garden purposes, one could select a dozen varieties of Daffodils which would satisfy the wants of the average cultivator, and the cheapest are by no means the poorest. Fortunately, the rage for these bulbs has brought them largely into cultivation, and it is rapidly becoming possible to secure choice varieties at prices within reach of every one. With Daffodils about as cheap as Onions, there does not seem much excuse for not planting them in every spare corner.

Elizabeth, N. J. *J. N. Gerard.*

Lælia anceps Sanderiana.—Of the numerous white varieties of *Lælia anceps* which bloom during December and January, perhaps none is so popular as this. It has only been in cultivation about six years, and, although it comes near the beautiful variety Dawsoni, still it has the advantage over this in being much more common. The flowers are very large, and seem to improve, in size, substance and covering every year, with good cultivation. The sepals and petals are pure white, the latter being very broad in comparison, while the lip has a large white front-lobe, with a deep crimson-purple blotch on it in front of the yellow, ridge-like callus which runs from the base, and on each side of which are radiating, broken lines and spots of rich purple, which give the flower a most charming appearance. It is not uncommon to see from five to seven flowers on one spike, and when several spikes are borne on good plants, one may expect to have a display of beauty for several weeks. After the flowers are cut they will remain almost perfect for about a fortnight.

London. *J. Weathers.*

The Hydrangea Blight.—For about a year and a half the cultivated Hydrangeas, and particularly those growing under glass in the winter, have been troubled with large, rusty-brown blotches upon the leaves. So serious is this blight in some greenhouses that the tops of the plants have been entirely cut away, but even this heroic treatment failed, for the vigorous young growth afterward became as badly blighted as before. In many cases the disease has caused serious losses to those who have been growing Hydrangeas for Easter decoration. This blight is due to Fungus only recently described, and it is known as *Phyllosticta Hydrangeæ*, E. & E. The pest is spread by means of innumerable spores, which are borne in minute pimples that beset the brown areas of the leaf. As it is closely related to the black-rot of the grape, it may perhaps be controlled by the standard fungicide now used on diseased Vines, namely: carbonate of copper dissolved in ammonia water. This note is to suggest a trial of this remedy by those whose Hydrangeas are affected.

The Forest.

Prairie Forestry and the Timber Culture Law.—II.

THE requisites of successful tree Culture on the Dakota prairies are: 1, deep-plowed land, thoroughly fined before planting is begun; 2, the use of trees or seeds that are in good condition when planted, and that are set firm, with the roots in moist earth; 3, thorough culture, so that at least until midsummer a crust is not permitted to form on the surface of the soil; 4, perfect maturing of the wood, secured by cessation of culture at midsummer; 5, freedom from grass and perennial weeds. To meet the requisites prompt and careful attention is demanded at a time when the active work of the farm is most pressing. When it is remembered that most of the settlers in our state were poor, and depended on their crops for a living, it will not be wondered at that the one crop which brought no money return, the trees, was most apt to be neglected. When we recall the exacting demands of successful tree-growth, the wonder is not that so many failed, but that any succeeded.

It is not strange that ten years ago, when South Dakota began to secure its great influx of settlers, the people failed to comprehend at once the new climate. They planted as they had done in their former homes. That greater culture was necessary, in order to supplement a decreased rain-fall, was only learned at the expense of many failures, not of trees only, but of all other crops as well. It is unjust to say that the failure of artificial groves in this state was due to universal fraud; it was the result in great measure of honest ignorance. In justice to thousands of worthy citizens, who in the early days of their Dakota residence failed to understand the new conditions by which they were surrounded, the present Timber Culture Act should not be repealed, but should be amended so as to enable them, profiting by the knowledge which nothing but experience could give, to fill out their plantations and by better culture insure the growth of the requisite number of trees per acre.

Additional time will enable thousands of holders of timber claims to satisfy both the spirit and the letter of the law, who without it must relinquish their holdings, and thus lose whatever improvements they have made on the land.

The law itself contains a great element of weakness. Instead of compelling the entryman to begin planting two years after his entry is made, at least twice that time, with the methods of cultivation in vogue in this country, is necessary to properly prepare the soil for trees. By our common practice two years is not sufficient to kill the native vegetation of the western prairies. Extraordinary culture must be given if the planter would have his land ready to receive trees within the time required by law. If trees are planted in land filled with the roots and underground stems of strong prairie grasses no amount of after-culture will enable the planter to secure the growth that moderate cultivation would have insured had the soil been properly prepared before the trees were set. Thousands of tree plantations that will never enable their owners to secure a patent on their land are evidences of honest, though not the most intelligent, effort; and it is right that Government should favor such planters, and enable them to secure titles to their land in some such way as the Dunnell Bill provides, if the present law must be repealed. Every grove in South Dakota, western Iowa, Nebraska and Kansas is the outcome of the one effort of Government to encourage tree-culture. If the law has failed to meet the expectations of its promoters, it has filled for thinking men a higher purpose—it has shown that Government action can aid in checking winds from drying out the plains if it will but use its abundant means and power.

Every year vast sums are appropriated by Congress for the improvement of streams; public money is spent for the improvement of water-powers for manufacturing towns; for erecting magnificent public buildings; for sending Congressional committees to the uttermost parts of the land; and why should not the parched prairies receive a part of this vast largess?

Our representatives in Congress continue to permit, through lack of simple legislation, the wholesale spoliation of the forests of the country. The head-waters of our great rivers are rapidly being robbed of the shade that sustains them. If Congress spends money on our water-ways, why not begin at the fountain-head and reclothe the bare mountain-sides with forests?

Every year adds to the apparent necessity for overcoming the aridity of the western plains. Congress, by its appointment of committees of inquiry and investigation, is beginning to recognize the importance of the subject. Irrigation will do much toward supplying the needed moisture, but the more carefully one studies the conditions the more convincing becomes the belief that not until an adequate forest-growth is maintained on the mountain-sides and where it is possible on the level stretches between them and the great rivers, will this growing problem be satisfactorily solved.

Agricultural College, Brookings, S. D. *Charles A. Keffer.*

[Since the above was written the Timber Culture Act has been repealed, but the argument of Professor Keffer is worth preserving as it stands.—Ed.]

Correspondence.

Sap-sucking Woodpeckers and Forest-trees.

To the Editor of Garden and Forest:

Sir,—In answer to your request, I am happy to state briefly the results of certain investigations made by me into the effects upon forest-trees of the attacks of Sap-sucking Woodpeckers (*Sphyropicus varius*). In an extended article which is to appear in the next number of the *Auk* I describe, from the ornithologist's standpoint, the birds' method of attack and the way in which they use the sap which they drain from various forest-trees. My observations were made near Mount Chocorua, New Hampshire, partly in July and August, 1890, and partly in the two preceding years. The region is covered mainly by conifers, Poplars, Maples, Birches, Oaks and White Ash.

The trees selected by the birds which I watched were Red Maples, Canoe Birches and Red Oaks. In other localities they attack the Mountain Ash, the Black Alder and some other trees and shrubs. The trees chosen are comparatively young, strong, and well exposed to the sun. Beginning about twenty feet from the ground, on a tree of twice that height, the birds drill a ring of small angular holes in the bark to, and, probably in the majority of instances, through the cambium layer. The holes are so cut as to catch and hold small quantities of the descending elaborated sap. In order to maintain a steady flow of sap the birds drill several new holes each day. They also widen such of the old holes as continue moist, sometimes merging two or more holes into one. New holes, after the tree has once been encircled, are always placed above old ones. It seemed to me that some of the holes yielded much more sap than others, and that the birds observed this and placed the next new holes immediately above these prolific ones. The old holes become dry in time, and the bark cracks near them, thus making the girdling of the tree complete. This is especially true of the Canoe Birch.

A Red Maple, which I watched for many days, contained over 800 punctures. In August last it was yielding sap so freely that a steady current streamed down the trunk to the ground, while from the best holes bubbles were blown by the sap as it flowed from the bark. This tree was evidently dying. Some of its limbs were dead. Its foliage was scanty, and the leaves drooped in the sunlight. Its sap in July was as sweet as well-sugared water.

In a hundred acres of woodland which I searched with care for the traces of this bird's operations, I found four families at work in as many separate spots. They were working all day and for weeks in succession. The trees which bore their marks were newly drilled, dying, dead or long dead, and decaying. In ten years these four families had killed eighty trees —perhaps more, probably fewer. Lightning and snow combined do far more damage than these birds. As a timber-owner, I should not think of shooting these birds for any injury done by them to my forest-trees. With fruit-trees in my neighborhood they meddle little, but it is perhaps because the orchards are old and unattractive.

Summary.—The Yellow-bellied or Sap-sucking Woodpecker is the most numerous of the *Picidæ* in the White Mountain region. It attacks chiefly the Canoe Birch and Red Maple, and during a considerable part of the summer works throughout every day, draining them of sap. The birds work in family groups and use only three or four trees at a time. They return to these from year to year until the trees die, when others near by are attacked in turn. The amount of damage done by the birds is insufficient to justify killing them, at least so long as their numbers remain no greater than at present.

Recent Publications.

Third Biennial Report of the California State Board of Forestry, for the years 1889-90. Sacramento, 1890.

An account of the true Pines of California appeared in the Second Report of the Board of Forestry of that state from the pen of the botanist of the board, Mr. J. G. Lemmon, who now supplements this with a paper on the other coniferous trees of the Pacific forest, which occupies the larger part of this third report, and which is enriched with many admirable illustrations made from photographs of trees, forest-scenes, and fruiting branches of many of the species. In this paper, after some remarks upon conifers in general, their history and distribution, Mr. Lemmon describes their classification, and then proceeds to give an account of the different species (exclusive of the Pines) found in California, and in the regions of which California must be considered, from the botanical point of view, an integral part, that is, all the great territory of western America which extends north and west of the state. An account of the different species is preceded by notes on the genera to which they belong, and to this is added some information relating to species which occur entirely beyond the region. In the case of the Hemlock, for example, there is a short account of our eastern species, and of the Asiatic species of this genus; and under the Spruces, not only are the Pacific coast species described, but the White and Black Spruces of the east as well, the European Spruce, and some of the Japanese species. Changes in the generic and specific rank of a few trees are proposed. The Alpine Hemlock is here removed from Tsuga and made to compose the genus Hesperopeuce (Engelmann's sectional name), a genus characterized by Mr. Lemmon by its alpine habitat, its cones, which are longer than those of any Hemlock Spruce, oblong-cylindrical, and two to three inches long, with numerous scales, nearly all of the same size, and reflexed at maturity, broader than long, four to eight lines wide, and striate with a thin, wavy, rounded border; by the small, spathulate bracts three to four lines long, by the angular seeds with resin vescicles, and elliptical wings, three to six lines long, and linear scattered quadrangular leaves keeled above and below with a solitary and large resin duct. "The propriety," he says, in speaking of this tree, "if not the scientific necessity, of separating it from Tsuga may be justified upon the ground that the conifer family is so large, and the necessity for dividing it into groups for convenience of comparison is so apparent, that comparatively slight differences—so they are fundamental—must be taken for generic distinctions"—a view of genera, in which, we fancy, all students of conifers will hardly concur.

The large-cone Douglas Fir of the mountains of southern California, which Engelmann considered a variety of the widely distributed *Pseudotsuga taxifolia* is now restored to specific rank under the name of *Pseudotsuga macrocarpa*, because the author recognizes "in it elements that certainly point to such separation. It must be borne in mind," he remarks, "that the evidence of distinctness does not depend so much upon the number of characters as upon their permanence. Now the characters of this Spruce are always uniform—no transition trees connect it to the other species. Again, the other species is both north and south of it, particularly north. If this big-cone development is a recent variation, what has produced it? If a southern climate, why are not the Arizona and Mexican trees still larger coned? If a dwarf variety, why so prolific in fruit?" Mr. Lemmon, in a note, calls attention to the fact that when he visited the headquarters of this tree, in the San Bernardino Mountains, in 1876, "the cones of the preceding year's crop lay on the ground so abundantly that they were two or three feet deep under the trees—a degree of fecundity never observed in the Taxifolia species."

The Red Fir of the Sierras, *Abies magnifica*, is well described, and the variety of northern California, which so long puzzled botanists by its long, exserted cone-bracts, resembling those of *Abies nobilis* of Oregon, is described as the variety *Shastensis*. "The peculiarity of this variety of Fir, aside from its locality, is connected entirely with the fact of its cone-bracts becoming long and protruded, a half to a full inch between the scales, rendering the large purple cones, thus decked out with tasseled fringes, a most beautiful object." The trees of this variety, Mr. Lemmon tells us, are "very large and lofty, though not so immense and high-headed as in the typical southern form, but they become, on the southern slopes of Shasta, a dark, gloomy assemblage of massive black trunks, colored, on the north side, from base to the limbs, with bright yellow lichens or tree-moss, the lower limbs draped, here and there, with long sweeping festoons of black filmy lichen, giving a funereal aspect to the whole scene, scarce relieved by the twitter of a red squirrel, the long wailing note of a woodpecker, or the occasional cry of a bald eagle." A second variety of this species is distinguished as variety *xanthocarpa*, "a smaller, less symmetrical tree than the typical, with smaller cones averaging four to five inches long, half as thick near the base, tapering slightly to the apex, and of a yellowish color." It is found in the high Sierras around Meadow Lake, Sierra County, where, Mr. Lemmon tells us, it forms the greater part of the noble forest of that region.

Mr. Lemmon considers the White Fir of the Sierras and of the mountains of southern Oregon simply a somewhat modified form of *Abies grandis* of the north-west coast, "distinguished by having a rather rigid habit, the branches relatively shorter and stouter than those of *Abies grandis*. The young shoots are olive-green, the buds ovoid, the leaves dark green above, whitened with stomata below (also with a few rows above), the leaves relatively very long—one and a half to two inches—nearly all of the same length, obtuse at the apex, not usually two-ranked except on lower branches, yet all are twisted half around at the base, which allows the light to reach through to the branchlets past the distorted leaves. It is, in fact, midway both in locality and in characters between the green-leaved and green cylindrical-coned *grandis* of the moist northern forests and the white-leaved and light green elliptical-coned *concolor* of the southern arid interior regions." It is this tree which is called *Abies Lowiana* in English plantations, and which, from a horticultural point of view, is very distinct from the species of the north-west coast, although hardly distinguishable from the long-leaved form of the Rocky Mountains.

It is not quite clear whether our author intends to consider the California Sierra tree one variety and the Colorado tree a

second variety or not. He adopts for the California tree the name of *Abies grandis*, var. *Lowiana*. If he considers it distinct from the *Abies concolor* of Colorado, his seems to be the correct name, but if he holds that there is really but one mountain form of *A. grandis* worthy of a distinct name, then this should be known as variety *concolor*, it having been named *Abies concolor* before the name of *Abies Lowiana* was bestowed upon it.

Mr. Lemmon, in his very full and interesting description of the Big Trees, raises an interesting point as to the origin of the name Sequoia. The name was made by the Austrian botanist, Endlicher, who published the genus in 1847, but, unfortunately, did not give the etymology of his name. It has been generally supposed that it was formed from the name of the half-breed Cherokee Indian, Sequoyah, a man distinguished in having invented a syllabic alphabet for his tribe. Gordon, however, in the second edition of his "Pinetum," published in 1875, states that the name was probably formed from "sequence, separated or following in order of succession after Taxodium from which Professor Endlicher separated it." Mr. Lemmon now says that Professor Gray, at the time of his visit to the Pacific coast in 1877, informed him that "the report of its being derived from Sequoyah, the Cherokee, was doubtless an afterthought; that undoubtedly Endlicher derived his name from sequi or sequor, alluding to the well-known fact that our Redwoods are the followers or remnants of several colossal extinct species."

Further investigations do not throw much additional light on this subject, and the answers sent in reply to Mr. Lemmon's inquiries by a number of distinguished men are not very satisfactory in their conclusions. The venerable De Candolle writes: "The supposed origin of Sequoia from Sequoyah or Sequamal is entirely fanciful. By the appearance of the name it is probable that it originated from or was taken up from some native word and written more or less correctly. Historically, it is a matter of regret, of course, that any doubt rests upon the origin of the name of the two trees which surpass all others in size and in the interest attached to the history of the genus to which they belong. But, after all, as De Candolle writes, "it matters little, a name is a name, the essential things are, first, that it be the expression of a natural genus; second, that it has not been employed before; and third, that the genus has not previously received another name."

Mr. Lemmon's paper contains, in convenient and acceptable form, a great amount of useful and interesting information, botanical, historical and economic, relating to the trees which compose the larger part of the Pacific-coast forests, and which make these forests the most wonderful and important forests of conifers known to man. It will be welcomed by all serious students of American trees, and will take its place in the permanent literature of the subject.

Exhibitions.

The New York Spring Flower Show.

THE first exhibition of the New York Florists' Club, held in the Lenox Lyceum last week, was one of the most attractive displays ever seen in this city, not only because it contained so many good things, but because so few indifferent plants and flowers were admitted to fill up vacant spaces and degrade the general average of excellence. The first object presented to the eye of the visitor on entering the hall was a mass of Cytisus some twelve feet high and nearly as wide at the base. The plants at the summit and sides were of *Cytisus Canariensis*, with long, arching and pendulous branches, while the plants at the base were specimens of *C. racemosa*, of bushy and upright habit, and they gave to the whole the needed suggestion of stability. The plants were all remarkably well-flowered and the foliage was of the cleanest and freshest. Some of the plants of the type of *C. racemosa* were seedlings, and the color of the racemes of their flowers varied from nearly white to deepest yellow, and the foliage of some of them was a pleasing glaucous green. Mr. James Dean, of Bay Ridge, New York, who exhibited these plants, is said to have some seedlings of very distinct habit, which are well worth propagating as garden varieties. Mr. Dean's collection of Azaleas, too, was a noteworthy one, and he took prizes for Rhododendrons (specimens of Prince Camille de Rohan being exceptionally good) and for a remarkable group of Hydrangeas.

The centre of the hall was occupied by the prize group of Palms and decorative plants, arranged for effect, with a superb specimen of *Acanthophœnix crinita* at the summit. The mass was about fifteen feet high, and its general shape was conical. It was composed throughout of good material, and some of the plants, as, for instance, a *Dieffenbachia imperialis*, were exceptionally fine. This group was arranged with excellent taste by Mr. A. W. Bennet, gardener to William Brown, Esq., of Flatbush, Long Island. Of the three other groups which competed for this prize, that of Mr. Richard Brett, gardener to J. B. Colgate, Esq., of Yonkers, secured second prize. Besides these two prize-groups the collections of Mr. Brown and Mr. Colgate furnished many other attractive features of the exhibition. No better Calceolarias were ever seen in this city than those sent from the former, while the Palm which attracted most attention was an immense Livistona from the same place. From Mr. Colgate's collection came the first prize Cycas, the best group of Ferns, and some fine Azaleas naturally grown.

In the rear of the stage fine specimens of Areca and Pritchardia showed in pleasant relief against the light-colored paper, but this background did not help the Orchids from the same collection—that of Messrs. Pitcher & Manda, of the United States Nurseries. These Orchids were very numerous, among them being 300 Cypripediums, including many choice hybrids. The White *Lycaste Skinneri*, *Cœlogyne cristata alba*, some distinct forms of *Cattleya Trianæ*, *Odontoglossum Rookerianum* and a large specimen of *Oncidium ampliatum* were among the best. Besides the Orchids, Messrs. Pitcher & Manda's display included a tank of aquatics, some new Anthuriums, and a large general collection of greenhouse plants, and the best Tree Fern in the exhibition.

It should be added that the arrangement of the plants in the main hall was admirable throughout. Each group had abundant room, so that its best possible effect was secured, and the plants as a rule were distributed with a view to the general appearance of the exhibit, so that the collection, as a whole, looked remarkably well from the galleries and the boxes. The disposition of the plants on the floor was a great improvement on the usual plan of placing them on high stages.

In the lower room of the Lyceum there was a great display of Roses of all kinds, both in cut flowers and in pots. Taken as a whole, they were the best ever seen in New York. The wonder among them all was a group of cut flowers sent by Mr. H. Dale, of Brampton, Ontario, including Niphetos, Sunset, Bride and Catherine Mermet. They were of perfect form and good substance, while in size they were almost monstrous, being nearly as large as Pæonies. Among the potted Roses the most interesting was a large group of Baroness Rothschild and Magna Charta, shown by John Henderson & Co. The principal prizes in the Roses were taken by John N. May, F. R. Pierson, Julius Roehrs, Rudolph Asmus, Ernst Asmus and John H. Taylor. Besides the usual commercial Dutch bulbs, hardy flowers were not shown in great profusion. Some hardy shrubs forced into bloom, including Lilacs, Deutzias, Spiræas, etc., were there, but, although many of them were well flowered, it is very evident that some plants, like *Spiræa Thunbergii* and *S. prunifolia*, were never intended to be crowded out of their season. Among these shrubs were some choice hardy plants from the collection of Messrs. Pitcher & Manda, which were well flowered without overmuch forcing. Among the best of these were Tree Pæonies and Yellow Day Lilies. Hiding under the larger plants were some pots of choice Alpines, which were a very pleasant surprise to those who found them. Among them were well-flowered plants of *Frittilaria Armenna*, *Primula denticulata*, *Myosotis elegantissima*, *Aubrietia Græca* and *Arabis alpina*.

The Carnations gave renewed proof of the improvement which is steadily going on in the size and quality of these beautiful flowers. The new variety, Sea-gull, exhibited by E. G. Hill & Co., of Indianapolis, secured the silver cup offered for competition in this class. Grace Darling, another new variety, deserves special mention as an advance in good qualities over the favorite Grace Wilder. The new flower is a trifle larger, a deeper pink, and it is unusually fragrant. Flowers of the variety Mrs. Fisher, shown by Lombard, and general collections by such well-known growers as H. E. Chitty and Rudolph Asmus, were all worthy of special mention.

Notes.

More than five thousand dollars have been subscribed toward the monument to Audubon, the naturalist, which it is proposed to erect in this city.

It is said that the finest sherry wines yet produced in this country have been made in Arizona, and that this territory

promises to be to the United States what Spain is to Europe in the production of wines of this quality.

In a bulletin from the Iowa Experiment Station it is stated that since there is a concentration of albuminoids near the eyes of ripe potatoes, and since albuminoids are much more nutritious than starch, therefore potatoes should always be cooked with their skins on.

Spiræa confusa is a pretty pot-shrub which should prove of good service as a source of flowers for Easter. Messrs. Veitch exhibited a group of it in flower at a late exhibition of the Royal Horticultural Society; the plants were about two feet high, compact, yet elegant, and thickly clothed with hawthorn-like bunches of white flowers.

California truck-farmers and grape-growers are complaining about the census bulletins. They declare that a single county alone has more acres in Asparagus than is credited to the whole state, while Egg Plant, which goes eastward by the car-load, and other vegetables extensively grown, have no mention whatever. In the viticultural bulletin Californians assert that figures which were used several years ago are reproduced; that in Fresno County, for example, which is credited with less than 20,000 acres in vines, there are really more than 50,000 acres in wine and raisin grapes.

Professor Hilgard states in a late bulletin that there is little doubt that, in the valleys of the southern parts of California, Ramie can be grown, with success and with profit, as soon as satisfactory methods of marketing are devised. He reminds planters, however, that a crop that will produce, in one season, ten tons of dry stalks to the acre must be exhausting, and that the fibre sold represents a larger proportion of the plant-food in the soil than does the fibre of the Cotton-plant. This means that proper care must be taken to return the refuse of the plant to the soil, or that fertilizers must be purchased.

Mr. T. S. Gold, writing in the *American Garden*, under the heading, "Apple Orchards of My Youth," says that the first commercial orchard he ever saw "was in Dutchess County, New York, planted about 1830 by a Mr. Constock. There were some twenty or thirty acres all of one variety, the English or Poughkeepsie Russet, for the New York market." Before the year 1835, he adds, "I had never heard of an apple failure. Then there came a succession of cold springs, blasting the blossoms, and ice-storms breaking the trees, so that with the incoming of the temperance reformation, doing away with cider, many orchards were cut down and few new ones planted for twenty years."

Chrysanthemums in April are curiosities, and a few plants in flower, shown by Pitcher & Manda at the exhibition in this city last week, attracted some attention. One of them with flowers in the shape of a bird's nest, and named Ulysses, was a novelty. Mr. Manda says that these plants have had no different care from the others in their large collection, but they seem to have the peculiarity of coming into bloom soon after they are struck, without regard to the season. Suckers from the plants on exhibition, only four or five inches high, showed flower-buds at their extremities, and perhaps these plants are the forerunners of a class which will give flowers all the year round.

A very useful little book is "The Reader's Guide in Economic, Social and Political Science," edited by R. R. Bowker and George Iles. Mr. Iles, however, is credited with the great bulk of the editorial work, and, as might be expected, the work is done exceptionally well. The book is a classified bibliography with descriptive notes, which will enable any one to find out, by the help of its very complete index, where the best reading can be had on any of the subjects within its range. Readers of Garden and Forest will be particularly interested in knowing that forestry is taking its place among the subjects of economic interest, and that, in addition to a good list of writings on the subject, which cover two pages, there are allusions to the subject scattered through the "Reader's Guide" in many other places, as, for example, in the brief summary of Mr. H. C. Adams' essay on Public Debts, it is noticed that reasons are there given why state governments should take in hand the care of their forests.

We have received the first part of the *Flora Franciscana*, "an attempt to classify and describe the vascular plants of middle California," from the author, Edward L. Greene, Assistant Professor of Botany in the University of California, who has had unexcelled opportunities for studying the flora of California. The arrangement of the families, the work beginning with the *Leguminosæ*, differs essentially from that adopted by most botanists, from the majority of whom Professor Greene differs also in his limitations of some genera, like Prunus and Pyrus, the former being redivided into Amygdalus (of Theophrastus), Prunus and Cerasus, and the latter, so far as California is concerned, into Sorbus (of Theophrastus) and Malus. Several new species are proposed. While botanists may disagree with Professor Greene's views upon classification, they will find in this new book of his proof of his great industry, and much valuable information about the plants described of a character which can be acquired only by long familiarity with them in a living state, and therefore of great value and importance.

The *Kew Bulletin* for March contains a valuable list of the Orchids which flowered at Kew in 1890. It enumerates 766 species and varieties, and is published to afford data as to the time and duration of the flowering period of Orchids cultivated in England. In the Kew collection no attempt is made, by the cultivation of a large number of examples, to give prominence to the most showy-flowered. On the other hand, as the *Bulletin* explains, every effort is made to obtain and cultivate even small and unattractive kinds of scientific interest, such as the ordinary collector would consider beneath his notice. In the limited space available for Orchids as comprehensive a collection of species as possible is aimed at. Consequently, while there is never a great display of Orchid-flowers at Kew, at no time of the year is the collection wanting in flower interest. Thus, while the highest number of species flowered in any one month was 125 in May, the lowest was eighty-five in January. The average for each month was a fraction over 100. In 1811 the number of species in cultivation at Kew was only thirty-seven. There are now 1,342 species, comprised in 158 genera. These figures do not include 174 varieties, and over 100 undetermined plants. The collection is kept up by means of exchange, and a small outlay, about £20 annually, for plants which can be obtained only by purchase.

In his famous "History of Plymouth Plantation" Governor Bradford tells how the Pilgrims first made acquaintance with Indian Corn, and with the beans still so generally associated with it in New England kitchens. The discovery was made while they were searching for "a place of habitation" on Cape Cod, before the final settlement at Plymouth. On the 15th of November, 1620, an exploring party landed at a spot supposed to have been within a furlong of the end of Long Point, and the following day, after a trying experience amid "schuch thickets as were ready to tear their cloaths & armore in peeces . . . at length they found water & refreshed themselves, being ye first New-England water they drunke of, and was now, in thir great thirste, as pleasante unto them as wine or bear had been in for-times." Soon after they came upon a place where the Indians had formerly planted Corn, and upon some of their graves. "And proceeding furder they saw new-stuble wher corne had been set ye same year," and in deserted huts, among other things, found "faire Indean baskets filled with corne, and some in eares, faire and good, of diverce colours, which seemed to them a very goodly sight, (haveing never seen any schuch before)." Returning to the ship, they "tooke with them parte of ye corne, and buried up ye rest, and so, like ye men from Escholl, carried with them of ye fruits of ye land & showed their breethren; of which & their returne, they were marvelusly glad, and their harts incouraged." Going once more to the same spot they found two deserted Indian houses, and "also ther was found more of their corne, & of their beans of various collours. The corne & beans they brought away," intending to pay the Indians for them when "they should meete with any of them," as happened about six months later "to their good contente. And here is to be noted a spetiall providence of God, & a great mercie to this poore people, that hear they gott seed to plant them corne ye next year, or els they might have starved, for they had none, nor any liklyhood to get any till ye season had beene past (as ye sequell did manyfest)." In the month of April, 1621, a friendly Indian, named Squanto, helped them to plant their corn, "showing them both ye manner how to set it, and after how to dress & tend it. Also he tould them excepte they gott fish and set with it (in these old grounds) it would come to nothing, and he showed them yt in ye middle of Aprill they should have store enough come up ye brooke"; and all these things they found true "by triall & experience." Then Bradford adds, with the quaintest carefulness not to commit himself upon a doubtful point, "Some English seed they sew, as wheat and pease, but it came not to good, eather by ye badnes of ye seed, or latenes of ye season, or both, or some other defecte."

TABLE OF CONTENTS.

Recent Forest-legislation.

JUST as the last session of Congress closed, an act "to repeal the timber-culture laws and for other purposes" was passed. Hereafter, then, no settler on public lands will be able to obtain a homestead by the planting of trees, although any person who has already made entry on public lands under the timber-culture laws, and who has in good faith complied with their provisions, is entitled to make his final proof and acquire his title. There is no doubt that under this timber-culture act there was much fraud, and there was a melancholy waste of labor and energy owing to the ignorance of planters, and even when a settler did secure land by an honest effort to comply with the law it proved a most expensive way of obtaining a homestead. The repeal of this law was, no doubt, proper, although it may be questioned whether the Government should not have offered to settlers some other stimulus to plant groves and forests. Very few forests have been started on a hopeful life under this act, but every tree-covered acre on those wind-swept plains has great value in itself as an example to others.

This bill contains a great many provisions entirely distinct from the timber-culture repeal, to only one of which we can here invite attention, and of this we have before spoken. Section 24 authorizes the President of the United States from time to time to set apart and reserve any part of the public lands, wholly or in part covered with timber or undergrowth, as public reservations, and the President may by proclamation declare the establishment of such reservation and the limits thereof. The language of this act seems to imply that this proclamation of the President's means more than a mere temporary withholding of the land from entry; that it establishes such forest as a public reservation forever. The President has already under this law accomplished by proclamation the extension of the Yellowstone Park, which the friends of that reservation have been vainly attempting to gain by specific enactment during eight successive sessions of Congress. This proclamation extends the area of the park eight and a half miles to the southward, and on the east adds a strip of country between twenty-four and twenty-five miles wide and fifty miles in length. This last region includes for the most part the Absaroka range, a rough, unsurveyed and little-known country, rarely crossed except by a few hunters. Within this territory peaks rise from 10,000 to 11,000 feet above the sea-level, and its average elevation is over 8,000 feet. In these mountains many of the streams which run into the Yellowstone Lake take their rise. The country to the south is very beautiful, rough, abounding in water, full of game, the favorite breeding-place of the elk; in it is the source of the Snake River. The Secretary of the Interior will place this reservation under the jurisdiction of the superintendent of the park, so that the law and its first-fruits are a matter of universal congratulation.

As there is no restriction to the President's exercise of power in this matter, it is to be hoped that many more considerable forest-areas can now be placed in permanent forest. One place worthy of immediate consideration is the region north of Flathead Lake, within the limits which were laid down in a bill introduced some years ago by Senator Edmunds. This territory, including the crest of the Continental Divide and the wild mountain-ranges to the west of it, is altogether too rugged for prosperous agriculture, and its forests are of incalculable value at the sources of some branches of the Missouri and one fork of the Columbia River. Snow-clad peaks, scores of cascades plunging from lofty cliffs, forests which seem of limitless extent, unite to give unparalleled grandeur to the scenery. If the President of the United States could be induced to set apart this and other regions which could easily be named, and could place them under the charge of the army of the United States, a long step forward in the solution of the forest-problem on the national domain would be taken.

On the same day when this act was passed an amendment to it was made which permits timber to be cut and removed from the forest-lands of the public domain for mining, manufacturing or domestic purposes under regulations prescribed by the Secretary of the Interior. This, so far as we can see, practically opens the whole timber domain of the country to the axes of trespassers, with no restraint beyond what the Secretary of the Interior may choose to exercise. If the Secretary does this in an indirect way, as has formerly been the case, the restraint is likely to be slight. It is imperative that the Secretary should issue some strict regulations in this regard, for without energetic action on his part there will be a general devastation of the public lands. These laws have hitherto been interpreted so liberally, and the frontiersman has become so accustomed to preying upon timber of the Government as if it was his own, that any check upon this unrestricted privilege is looked upon as an infringement of his personal rights.

Class Vines and Class Trees.

IT is the custom in some of our country high-schools for the graduating class to plant a tree in the neighborhood of the school-house, and for a long period it has been the time-honored custom of universities to set out a vine in commencement week, to commemorate the class that is about to leave college.

During a visit last summer to an eastern college our attention was called to the Ampelopsis, each one labeled with the date of the class cut in one of the stones of the foundation of the chapel, by which the plants were set, and it was melancholy to see how forlorn and small many of them were, and how others had died completely for lack of attention. The same may be said of numbers of the pitiful little Maples and Elms that huddle around the unpicturesque and bare high-school buildings in some

parts of New England, which really should by this time be amply shaded, if a proper attention had been paid to the young trees when set out.

A radical change should be made in the time of planting these commemorative trees and vines. Instead of setting them out at the close of its career every class should, on entering the school or university, erect its growing monument and devote its best energies during the four years of school or college life to having its vine or its tree beat the record in growth and vigor. In this way, if one specimen died another could be planted, that the class might be sure of a memorial, while yearly a committee should be appointed to attend to the plant and a small subscription be levied on each member of the class for proper fertilizers and cultivation.

If the personal attention of the boys could be given to the subject, if they would themselves dig about and enrich and prune what they had planted and would take pride in it, the effect would be good in awakening in their minds an interest in the growth of plants and trees; and some slight knowledge might be acquired of climatic and soil conditions and a hint might be given to them of one of the best and purest pleasures which is within the grasp of man.

In this way could be instilled into the rising generation an interest in forestry that might in time bear fruit in greater care for this property of the nation. Among the books of reference in schools some should be supplied which treat of the proper management of growing things, so that the youths and maidens could study the subject for themselves. If, at the end of each year or four years, some slight reward, such as a simple medal or even an honorable mention, could be awarded to that plant or tree which had made any surprising growth, it might still further stimulate an interest among the young people in this most beautiful and useful work. Masters of schools and professors of colleges should use their influence to bring about this change as speedily as possible, for it could not fail to do good to the youths themselves, and would replace, with vigorous trees and vines, the usually melancholy specimens which many classes now leave behind them as their monument.

Notes on the Distribution of Some Kansas Trees.—II. The Cottonwood (Populus monilifera).

THE Cottonwood is rivaled only by the Elm in the extent of its distribution in the state. While most abundant on the low ground bordering the main streams, where giant trees overhang the water mile after mile, it is also found scattered along most of the smaller tributaries, but always where its roots can reach permanent moisture. Westward it extends as far as trees of any description are found, which is to the west line of the state in several valleys, scattering groves or single trees only occurring in the western tier of counties, and these on the immediate banks of the water-courses. Surprisingly large trees have grown, though now cut down, at points west of what many suppose to be the timber limit of the state. On Walnut Creek, a large tributary of the Arkansas, was the old military post of Fort Zarah, in the western part of Rush County, about two hundred and seventy miles from the eastern line of the state. The post was constructed of heavy Cottonwood logs, many of which were in good preservation ten years ago. This points to a considerable growth of the original timber along this stream, and scattering groves of fair-sized trees may be found to-day through the next county, and single trees to the head of the stream. A huge tree was cut near the Saline River, in Ellis County, a few years ago, which furnished ninety-six loads of wood; the stump measured eight feet across.

The Cottonwood is justly entitled to rank as the historical tree of Kansas. It entered largely into the construction of most of the early buildings, from the frontier stockade, which protected its group of earth-roofed log-cabins, to the wind-swept shanty of the prairie homesteader and the pretentious storehouse and hotel of the growing young town. Men who have helped to make history, both in state and national affairs, will tell of the hardships and adventures of a new country when the cottonwood shanty was the home, office and business block in one.

Park-like groves of these tall trees were abundant along the larger streams, where the first settlements were established, and their shapely trunks afforded the most available supply of logs for the saw-mills which followed the advance-guard of settlement. With Pine lumber only to be had by hauling from points on the Missouri River, we can readily see why the Cottonwood played so important a part in the development of the country.

After the building of the Union Pacific Railroad, which brought Pine lumber within much easier reach of the settlers of the Kansas valley, the greater cheapness of the native lumber caused it to be used largely for the frames of buildings, while Pine was used for covering and finish. This lumber varied greatly in quality, much of it being of a loose, spongy character, warping and twisting into the most fantastic shapes when exposed to the sun and wind. A house built entirely of it, after a few months, afforded but scanty protection against the winter winds. Certain trees furnished lumber of a firm, straight grain which made excellent frames, and even very acceptable floors and inside finish. When once firmly nailed to its place, if clapboarded and shingled with Pine lumber to exclude the weather, Cottonwood made a strong and durable building. I have examined houses that have stood for thirty years where the Cottonwood joists and sheathing boards were as straight and sound as when placed in position.

One of the institutions of the new country, which has disappeared with the steam saw-mill, was the shingle-mill, where the shingles, instead of being sawed or rived, were cut. The shingle blocks, after having soaked in a tank of hot water, were placed upon the machine at a suitable angle, when the descent of a broad, thin knife, operated by horse power, pared off the shingle much as the thin stuff for fruit packages is now cut. These shingles were of poor quality, and needed frequent renewal. A much better article was secured by the primitive process of riving and shaving them on the "horse," so common on the New England farm. These I have seen which had lasted for twenty years in fairly good condition.

A variety known as the Yellow Cottonwood was recognized by choppers and mill-men, and much prized for the superior quality of its lumber, which was unusually firm and heavy, straight-grained and of a peculiar color recognizable when the tree was cut. As seen standing, the tree was supposed to have a straighter trunk and deeper-furrowed, darker bark than the common form. Whether any well-marked, constant type can be made out is questionable, though the extra quality of lumber from certain trees cannot be doubted. Whether these characteristics can be transmitted by propagating from such specimens by cuttings is a question only to be settled by experiment.

In searching for the finest specimens of Cottonwood in this part of the state, one is constantly reminded that the trees with the finest trunks have been cut and sawed years ago. A tree upon the north bank of the Kansas (see page 187), a short distance below Manhattan, measures twenty-four feet in girth at two feet above the ground, and forks into three branches at ten feet. The spread of its top is over eighty feet. This is the type of a large number of trees which line the banks of our Kansas rivers. Their immense spreading tops have a grandeur not equaled by any other tree in the state. On the Blue River three trees, only a short distance apart, were measured which were twenty feet in circumference, with trunks of from twelve to thirty feet to the first limb. One of these has a top of 104 feet spread, and it is as many feet high. Several others of from sixteen to twenty feet in circumference were measured in the same locality.

The Cottonwood has been more extensively planted on timber claims and for shelter-belts than any other tree. This is due in part to its rapid growth while young, and quite as much to the ease with which a large proportion of trees can be procured from cuttings. That a large number of these have failed is not a matter of surprise, when we remember the moisture-loving nature of the tree. After a few years of rapid growth, trees on the upland begin to fail, and a dry season thins out a large portion of them. Where a plantation includes a little draw which obtains additional moisture the greater size and vigor of the trees are very noticeable. On bottom-lands the growth obtained from a plantation of Cottonwoods in twenty years is astonishing. There are, along many streams, acres of low, sandy land, where farm crops cannot be profitably grown, but which will develop the Cottonwood to perfection. Plantations in such places would yield in fuel enough to pay for all outlay, and the growth of body-timber in twenty or thirty years would be of great value for the many purposes to which cheap lumber is applied, such as crates, baskets and all

kinds of temporary packages, as well as the rougher lumber for buildings.

If plantations could be successfully started of the so-called yellow variety by the use of cuttings the value of the lumber would be greatly increased.

As an ornamental tree the Cottonwood is not well adapted to the fifty-foot village lot, where it is so often planted, only to be cut back into an unsightly pollard when the owner begins to need the space for his house. As an avenue tree for low lands, and where it can be offered plenty of room, no tree in the west is its equal. It is a tree planned on a large scale, and should be grown where the general landscape-effect is large and broad. The nuisance of the flying cotton at seeding time can easily be avoided by propagating only from cuttings of staminate trees, which are readily distinguished by their large red flower-buds in the spring before the leaves open.

The Sap and Sugar of the Maple-tree.—II.

NEXT comes the positive evidence of Joutel (1684–88), the companion of La Salle till his death, and the only one of his followers (as Charlevoix says) on whom La Salle could depend. He gives clearly both time and place and narrates what he found when laid up by stress of weather and lameness at Chicagou. He says:

"Nous arrivames à Chicagou le 29 du dit [Mars, 1688]. 'Le temps, qui se tint rude nous obligea à rester en ce lieu jusqu au 8 Avril, . . . nous n'avions pas beaucoup de viande mais la Providence nous fournissoit une espèce de manne pour adjouster a notre bled d'Inde, la quelle manne estoit d'un suc que les arbres jettent dans cette saison, et notamment les Érables, dont il y en a quantité dans ce canton, et qui sent fort gros. A cet effet nous faisions de grandes entailles à chaque arbre, auquel nous mettions un vaisseau et un couteau au bas de l'entaille pour conduire la liqueur qui proprement est la séve de l'arbre, laquelle etant bouillie, a force de diminuer devient du sucre.' Nous nous servions de cette eau pour fair bouillir notre bled d'Inde ou sagimité, ce qui lui donnait un assez bon goust c'est à dire un peu sucré. Il semble que la Providence fournit à tout cas comme il n'y a point de cannes à sucre dans ces cantons les arbres en fourmissent; du moins j'en ai veu qui estoient excellent; il estoit excellent; il estoit plus rouge que le notre, c'est à dire celui dont en se sert en France, mais presque aussi bon."*

Père Sebastien Rasles, of the Society of Jesus (1689–1724), says: "Ma nourriture n'est que de blé de Turquie qu'on pile, et dont je me fais chaque jour une espéce de bouillie que je cuis dans de l'eau. Le seul adoucissement que j'y apporte, c'est d'y mêler un peu de *sucre* pour en corriger la fadeur. On n'en manque point dans ces forêts."

"Au printemps, les erables renferment une liqueur assez semblable à celle que contiennent les cannes des îles. Les femmes s'occupent à la recevoir dans des vases d'écorce, lorsque ces arbres la distillent; elles la font bouillir, et elles tirent un assez bon sucre. Le premier qui se tire est toujours le plus beau."†

La Hontan (1684–92) says: "Les herables . . . n'ont aucun rapport à ceux d'Europe. Ceux dont je parle, ont une sêve admirable et telle qu'il n'y a point de limonade, ni d'eau de cerise qui ait si bouquet, ni de breuvage au monde qui soit plus salutaire."

"Pour en tirer cette liqueur on taille l'arbre deux pouces en avant dans le bois, et cette taille qui a dix ou douze pouces de longeur est faite de biais; au bas de cette coupe on enchasse un coûteau dans l'arbre aussi de biais, tellement que l'eau coulant le long de cette taille comme dans une gouttière, et rencontrant le couteau qui la traverse, elle coule le long de ce couteau sous lequel on a le soin de mettre des vases pour la contenir."

"Tel arbre en peut rendre cinq ou six boutéilles par jour, et tel habitant en Canada en pourrait ramasser vingt barriques du matin au soir, s'il voulait entailler tous les Erables de son habitation. Cette coupe ne porte aucun dommage à l'arbre. On fait de cette sêve du Sucre et du Sirop si precieux qu'on n'a jamais trouvé de reméde plus propre à fortifier la poitrine."

"Peu de gens ont la patience d'en faire, car comme on n'estime jamais les choses communes et ordinaire, il n'y a gueres que les enfans qui se donnent la peine d'entailler ces arbres."

"Au reste, les *Erables* des pais Septentrionaux ont plus de séve que ceux des parties meridiónales, mais cette séve n'a pas tant de douceur."*

Père Lafitau, of the Society of Jesus (1700–05), says: "Nos sauvagesses font le sucre, quelle expriment du suc des arbres, et en particulier des Erables."

"Au mois de Mars, lorsque le soleil a pris un peu de force, et que les arbres commencent à entrer en séve, elles font des incisions transversales avec la hache sur le tronc de ces arbres d'où il coule en abondance une eau qu'elles recoivent dans des grands vaisseaux d'écorce; elles font ensuite bouillir cette eau sur le feu, qui en consume tout le phlegme, et qui epaissit le reste en consistence de syrop, ou même de pain de sucre, selon le degré et la quantité de châleur qu'ils veulent lui donner. Il n'y a point à cela d'autre mystère."†

The "burnt taste" which he describes would naturally result from the primitive Indian method of evaporating the sap by red-hot stones in vessels of bark or wood.

James Smith (1755–60), an English youth, was taken captive by Indians in 1755 at the age of eighteen years, and carried to Fort Duquesne just before Braddock's defeat. He was adopted by the tribe, made an Indian, and kept as such with them for five years. He says:

"Some time in February (1756) we began to make sugar. As some of the Elm-bark will strip at this season, the squaws . . . took the bark off the tree, and of this bark made vessels in a curious manner that would hold about two gallons each; they made above one hundred of that kind of vessels. In the Sugar-tree they cut a notch sloping down, and at the end of the notch stuck in a tomahawk; in the place where they stuck the tomahawk they drove a long chip in order to carry the water out from the tree, and under this they set their vessels to receive it. As Sugar-trees were plenty and large here they seldom or never notched a tree that was not two or three feet over. They also made bark vessels for carrying the water that would hold about four gallons each. They had two brass kettles that held about fifteen gallons each for retaining the water; and though the Sugar-trees did not run every day, they had always a sufficient quantity of water to keep them boiling during the whole sugar season.

"The way that we commonly used our sugar while encamped was by putting it in bears' fat until the fat was almost as sweet as the sugar itself, and in this we dipped our roasted venison."‡

Again, he says: "Shortly after we came to this place—head-waters of Big Beaver Creek—in February (1757) the squaws began to make sugar. We had no large kettles with us this year, and they made the frost, in some measure, supply the place of fire in making sugar. Their large bark vessels, for holding the stock water, they made broad and shallow, and, as the weather is very cold here, it frequently freezes at night in sugar time, and the ice they break and cast out of the vessels. I asked them if they were not throwing away the sugar? They said no, it was water they were casting away, sugar did not freeze, and there was scarcely any in that ice. . . . After several times freezing, the water that remained in the vessel changed its color, and became brown and very sweet."§

Monsieur Bossu, Chevalier de l'Ordre Royal et Militaire de Saint Louis, and a captain in the French navy (1756-71), writing "aux Illinois, Nov., 1756," says: "Apres les premières civilités, [au Village des Péorias] on m'apporta une calabasse pleine du suc végétal d'un arbre qu'on appelle *érable*. Les sauvages le tirent au mois de Janvier, en'y faisant un trou au pied avec une vrille à laquelle ils adaptent une canule. Il en découle au premier dégel environ une barrique d'eau, ou de jus, qu'ils font bouillir jusqu'à ce qu'il soit réduit en sirop lequel étant rebouilli, se convertit en sucre un peu roux, et semblable à la manne de Calabre, les apoticaires le préferent justement au sucre de cannes. Lez François, établis aux Illinoiz, *ont appris des sauvages* la façon d'en faire."

"A l'entremet, on m'apporta plein une gamelle de bouillie de sagamité assaisonnée avec du sirop *d'erable*, ragout sauvage, assez bon and tres rafraîchéssant."‖

Bossu also says, writing, "Au pays des Akansas": "Ils me donnerent pour boisson une liqueur que ces sauvages nomment *Iachita*. Elle ressemble à du lait d'amande pour la blancheur; mais elle est beaucoup plus épaisse—on la fait avec du maïs. Ils le cueillent lorsqu'il est tendre, and après en avoir exprimé le suc, on y met du *sucre* de canne ou *d'erable*."

"Cette boisson est non-seulment fort nourissante mais fortifie l'estomac. . . . La plupart des femmes blanches qui veulent entretenir la fraicheur de leur teint en prennent en decoction, et s'en lave la peau du visage."*

Besides the interest of a new cosmetic, this passage indicates, at this date, a supply of maple sugar corresponding to that of the cane.

Though this record of evidence is limited, it seems clearly to show that the Indians understood and made use of the sap of the different Maples, and perhaps of the Beech, before the advent of the European; and that, before the discovery of the Mississippi, the making of maple sugar must have been an established industry among their tribes. The narrative of James Smith indicates that the making of sugar was not known by the Pennsylvanians as late as 1656.

Providence, R. I. *William D. Ely.*

Two Studies for House Plantings.

MOST American suburban houses stand naked in naked enclosures. The ugly fact has been pointed out, and the obvious remedy has been suggested in previous numbers of this paper. (See papers on "How to Mask the Foundations of a Country-house," vol. ii., pp. 350, 362, 386 and 409.) It has been shown that even in the smallest house-yards one helpful thing can be easily accomplished—the building may be connected with the ground and the appearance of nakedness removed by massing shrubs along the bases of the walls or piazzas. In almost every situation, be it among sea-side ledges or amid fertile lawns, some planting of this sort is required, the arrangement of the plants and the selection of sorts being carefully adapted to the character of the site and the style of the building.

In the suburbs of northern cities a square, stiff, high-studded and somewhat pretentious house is very common. Such houses are often surrounded by piazzas or verandas. In summer beds of gaudy Geraniums or foliage-plants border the piazzas or flaunt in scattered circles or half-moons. In winter the windows look upon bare beds of loam. This is a style of planting which costs much trouble, but its results are never permanent, and seldom tasteful. It works with herbaceous plants, and these chiefly of tender sorts.

The style of planting which uses permanently effective shrubs and hardy perennial herbs is illustrated by the diagrams and lists on page 185. Two houses of the stiff suburban type of twenty years ago are distinguished in the drawing by being numbered 1 and 2. Both houses are half-surrounded by roofed piazzas, the floors of which are several feet from the level surrounding ground. House Number 1 is inhabited the year round. Number 2 is not occupied in winter. Each house is shown twice in our drawing, for the purpose of presenting alternative planting schemes, prepared by two professional designers of plantations, one of whom submits the diagrams lettered A, and the other sends the schemes marked B.

In very briefly comparing these two schemes it must first be noted that both designers have planned continuous masses of plants, broken only at the piazza-steps. Undoubtedly the level character of the two sites and the formality of the buildings combined to compel them to this essentially stiff arrangement. Irregular buildings on broken ground would be planted in a very different manner. Here, in the schemes marked B, the formality is a little less pronounced than it is in the others, for the outline of the planted space, which is the edge of the grass, is a gently flowing line, whereas in the schemes marked A it is a line drawn strictly parallel to the edge of the surrounding drives and walks, leaving a grass strip two feet wide throughout.

As respects the massing of plants within the spaces thus outlined, the A schemes are again a little more formal than the Bs. The masses of each kind are here arranged so as in a measure to correspond to the openings between the roof-posts of the piazza, while in the B schemes this symmetry seems rather to be shunned. The writer must record his feeling that the designer of the A schemes might well have gone a step further in his chosen direction and have secured a more symmetrical balancing of masses at the sides of the several flights of entrance steps. In cases like these, where formality is almost a necessity, pronounced symmetry is generally more effective than any half-way measures.

As respects the choice of plants with which to make the masses determined upon, there is little to choose between the two schemes. This, which is commonly considered the chief problem in planting, is really subordinate to the more fundamental questions of outline, form and ultimate altitude. Plants must not be chosen simply for their prettiness; they should be selected for their fitness to produce the desired outlines and masses. Both designers have evidently been guided by this principle. Thus, in diagram 1 A, the author has set a dwarf Magnolia opposite a certain corner of the piazza, not so much because he adores Magnolias as because he wants, at that point, something distinct and forcible. Similarly, in diagram 1 B, the creeping Cranberry is freely used in the front edges, not because it is fashionable or gorgeous, for it is neither, but because it will perform a service of importance, namely, the covering of the ground in the edges near the grass.

Further comment could only emphasize the lesson that even house planting should be regarded studiously. Its problems, like those of larger planting, are real problems in design. It must be so regarded if our house-grounds are to cease to exhibit the monstrous forms of decoration which are now so common.

Notes on Some Insects and Insect Remedies.

IN the second volume of Garden and Forest, p. 461, there was given a notice and figure of a troublesome Elm pest (*Gossyparia ulmi*), an insect related to, and having many of the habits of, the scale insects. During the last two years the pest appears to have spread over a much wider territory, and to have attracted attention in various places besides the localities where it was first noted. In the Report of the Vermont State Agricultural Experiment Station for 1889 it is reported as quite common on Elms, and doing much damage to them at Burlington, where it is said to have existed for several years. While the injuries caused by this insect are slow and not immediately disastrous, the effects of large numbers on the trees prove very disagreeable and detrimental to the beauty of their appearance, and the vital sap taken from the tree eventually results in loss of vigor.

Some natural aids may ultimately be of assistance in keeping the pest in check, and meanwhile we have to depend on artificial remedies to clean the trees.

Where they are large it will be almost impossible to clear the Elms of these insects, but the nuisance may be mitigated by one or two sprayings of kerosene emulsion. Young trees recently planted out show more quickly the injurious effects caused by the insects sucking their juices. It is possible to destroy all of these pests on such small trees by giving every limb a thorough wash of whale-oil soap dissolved in the proportion of one pound of soap to a gallon and a half to two gallons of water, and applied in early spring just before the buds open.

When the insects are in an active state the spraying by kerosene emulsion may be most effectually applied against them. In this vicinity the chief active periods occur in the latter part of April and early in May, in the last of June and early July and again in August. As some inquiries have been made regarding the emulsion, the following is given as a good standard. It is the formula recommended as the best by Professor Riley.

Dissolve half a pound of common or whale-oil soap in one gallon of boiling water. While still hot add this solution to the kerosene and vigorously churn the mixture. This may be done in five minutes by means of a force-pump and spray-nozzle. The emulsion, if perfect, forms a cream which thickens on cooling, and should adhere without oiliness to the surface of glass. Before using, dilute, in the proportion of one part of the emulsion to nine parts of water, the three gallons of emulsion, thus making thirty gallons when diluted. It is best applied by means of a force-pump and fine spraying nozzle, of which there are numerous styles in the market. The Riley or Cyclone nozzle is considered one of the best, and it is not patented.

The emulsion, much less diluted, may be used as a wash, instead of whale-oil soap, on the stems and branches before the leaves expand.

Professor Fernow's notice regarding "Insect Lime for the Gypsy Moth," in Garden and Forest for March 25th, offers some valuable suggestions, and places before our notice a remedy or preventive which may prove very useful against certain destructive insects. If better, it promises to take the place of printers' ink or the expensive oil-troughs as a band around trees to keep the female Canker-worm moths from ascending to deposit their eggs in autumn and spring.

The merits of its recommended use against the Bag-worm, Fall-web worm, Tussock Moth and Gypsy Moth do not appear to be so generally understood. The female Bag-worm moth, like that of the Canker-worm, is wingless, but it undergoes all

No. 1 A.

1, Akebia quinata; 2, Lonicera Chinensis; 3, Rhododendrons; 4, Kalmia latifolia; 5, Rosa rugosa; 6, Rosa rugosa alba; 7, Rosa nitida; 8, Rosa lucida; 9, Rosa multiflora; 10, Forsythia Fortunei; 11, Magnolia stellata; 12, Exochorda grandiflora; 13, Viburnum plicatum; 14, Spiræa callosa; 15, Berberis Thunbergii; 16, Viburnum cassinoides; 17, Viburnum Opulus; 18, Thuya occidentalis; 19, Thuya occidentalis (pyramidal); 20, Cornus alba Sibirica; 21, Juniperus communis; 22, Juniperus communis aurea; 23, Pinus strobus nanus; 24, Thuya occidentalis compacta; 25, Wisteria Sinensis.

Perennials.—Among 3 and 4: Lilium superbum, Lilium Canadense. In front of 3 and 4: Crocus, yellow and purple; Daffodils, single and double. In front of 7 and 8: Daphne Cneorum, Viola, Hepatica, Myosotis. Around 11: Anemone Japonica. In front of 12 and 13: Pæony, Foxglove, Canterbury Bell. In front of 14, 15 and 16: Papaver orientale, Hibiscus Moscheutos, Hemerocallis flava.

No. 2 A.

1, Rhododendron; 2, Kalmia; 3, Spiræa van Houttei; 4, Genista tinctoria; 5, Hollyhocks; 6, Pæonies, Foxgloves, Canterbury Bells; 7, Rosa multiflora; 8, Iris Kæmpferi; 9, Anemone Japonica (white); 10, Exochorda grandiflora; 11, Hypericum aureum; 12, Hibiscus Moscheutos; 13, Delphinium perenne; 14, Viburnum cassinoides; 15, Papaver orientale vars.; 16, Viburnum plicatum; 17, Rosa rugosa alba; 18, Rosa rugosa; 19, Ligustrum Ibota; 20, Azalea in variety; 21, Spiræa Thunbergii; 22, Berberis Thunbergii; 23, Deutzia Sieboldii; 24, Rhus glabra; 25, Philadelphus grandiflorus; 26, Chionanthus Virginica; 27, Hydrangea paniculata grandiflora.

Perennials.—Among 1 and 2: Lilium superbum, L. Canadense and L. speciosum. In front of 1 and 2: Crocus, yellow and purple; Daffodils, single and double. In front of 3 to 18: Astilbe Japonica, Viola pedata, Papaver nudicaule, Lilium candidum, Hardy Pinks, Iris Germanica and aristata, Campanula Carpatica, Doronicum Caucasicum. In front of 20 and 21: Daphne Cneorum. Akebia and Lonicera as in No. 1.

No. 1 B.

1, Rhododendron album elegans; 2, Rhododendron Chas. Dickens; 3, Rhododendron Everestianum; 4, Rhododendron maximum; 5, Kalmia glauca; 6, Kalmia latifolia; 7, Vaccinium macrocarpon; 8, Berberis aquifolia; 9, Daphne Cneorum; 10, Evonymus radicans; 11, Iberis sempervirens; 12, Leucothoe Catesbæi; 13, Andromeda polifolia; 14, Andromeda speciosa; 15, Andromeda Japonica; 16, Vinca minor; 17, Rosa lucida; 18, Desmodium; 19, Clethra alnifolia; 20, Actinidia volubilis; 21, Chionanthus Virginica; 22, Xanthorrhiza apiifolia; 23, Viburnum plicatum; 24, Stuartia pentagyna; 25, Rhodotypos kerrioides; 26, Symphoricarpus vulgaris; 27, Lonicera brachypoda.

Perennials.—Gypsophila repens, Phlox subulata and amœna. Saxifraga crassifolia, Veronica rupestris, Epimedium macranthum, Epimedium alpinum, Galax aphylla, Lilium and Crocus in variety, Chionodoxa Luciliæ, Fritillaria Meleagris, Narcissus in variety, Scilla Sibirica, Galanthus nivalis.

No. 2 B.

1, Rosa rugosa; 2, Rosa lucida; 3, Rosa multiflora; 4, Pyrus Japonica; 5, Pyrus Maulei; 6, Magnolia stellata; 7, Magnolia Soulangeana; 8, Magnolia conspicua; 9, Spiræa Bumalda; 10, Spiræa Japonica alba; 11, Spiræa Van Houttei; 12, Spiræa Cantonensis; 13, Spiræa Japonica Fortunei; 14, Chionanthus Virginica; 15, Calycanthus floridus; 16, Clethra alnifolia; 17, Viburnum cassinoides; 18, Viburnum dentatum; 19, Viburnum plicatum; 20, Symphoricarpus vulgaris; 21, Forsythia suspensa; 22, Forsythia Fortunei; 23, Actinidia volubilis; 24, Diervilla rosea; 25, Rhodotypos kerrioides; 26, Xanthorrhiza apiifolia; 27, Berberis Thunbergii; 28, Akebia quinata; 29, Hypericum Kalmianum.

Perennials.—Aster Novæ Angliæ, Cassia Marilandica, Eupatoreum ageratoides, Helianthus decapetalus, Helianthus orgyalis, Lychnis Chalcedonica, Monarda didyma, Anthemis tinctoria, Asclepias verticillata, Convallaria majalis, Dicentra eximia, Epimedium in var., Euphorbia corallata, Gaillardia in var., Geranium sanguineum, Hesperis matronalis, Pæonia in var., Hydrophyllum in var., Mitella diphylla, Vinca minor.

of its transformations on the tree, and so long as there is sufficient foliage to provide food its progeny have no occasion to leave it, although many of them instinctively do go in search of new trees upon which to deposit eggs. But if trees are cleared of Bag-worms, a band of the "insect lime" will prevent migrants from ascending them from other trees and shrubs. Fortunately, this insect is rare in Massachusetts. The Tussock Moth can also, and usually does, complete the round of its existence upon the tree on which the eggs are deposited. The females being wingless, well-kept bands of the "insect lime" would prevent either the females or the caterpillars from ascending trees which were already entirely free.

In regard to the Fall-web worm, one can hardly see how the "insect lime" will prove effective. The female moth flies freely, and when the caterpillar is ready to become a chrysalis it is as likely to drop directly to the ground as to attempt to crawl down the trunks of the trees where the band of lime would prevent its passing over. A few might be destroyed in this way, but the proportion would probably be small.

The use of the "insect lime" for covering the eggs of the Gypsy Moth would, no doubt, be effectual if thoroughly applied, but it would seem to be quite as simple and expeditious, or economical, to scrape off, collect and finally burn the egg-clusters. The kerosene torches used in burning the eggs at Medford last year, must, doubtless, cause injury to tender-barked trees.

The value of the "lime" in preventing caterpillars from crawling up or down the trees can be easily understood and appreciated.

Foreign Correspondence.

Orchids at Clapton.

Saccolabium bellinum.—This is one of the prettiest of the many described species of Saccolabium. It is remarkable in being one of the smallest in habit and at the same time the largest in flower. It was introduced from Burma in 1884 by Messrs. Hugh Low & Co., Clapton, when it was named and described by Reichenbach as "one of those elegant little beauties one may delight to look at after being tired of monotonous grandeur." The plants do not exceed six inches in height; the leaves are narrow, about six inches long, dark green and herbaceous in texture. The racemes are produced at the base of the plant, and bear from three to eight flowers in a compact cluster; each flower is an inch across, fleshy, the sepals and petals yellow, with brown blotches, the lip with a large cup-shaped sac, fringed round the margin, and colored white, with red or purple blotches. I lately saw about five hundred plants of this species in the Clapton nurseries, many of them in flower, some darker than others, but every one charming in form and color. I know from experience that this Saccolabium is easy to cultivate, a plant which has been in the Kew collection since 1885, having flowered every year since. Many Saccolabiums are not nearly so well behaved in the garden as this.

Dendrobiums.—A magnificent collection of these beautiful Orchids may now be seen at the same nurseries, where the cultivation of this genus is exceptionally well done. Such species as *D. Bensonæ*, *D. Brymerianum*, *D. luteolum*, *D. crassinode*, *D. Wardianum*, *D. lituiflorum*, *D. Devonianum*, *D. thyrsiflorum* and *D. suavissimum* are grown in enormous numbers, and Mr. Low informed me that his success with these plants was the result of a radical change of treatment for them in the growing season. This consisted of exposure to almost all sunshine, a constantly saturated atmosphere, and no ventilation. The most important item is this last. Mr. Low found that closeness, with a maximum of light, was exactly what the Dendrobiums reveled in. They kept free of insect pests, and they were not attacked by "spot." The growth was rapid, and became thoroughly ripened before winter set in; consequently there was a good set of flower-buds.

Phalænopsis.—These plants have always been exceptionally well grown at Clapton, where, in a favorable winter, it is not an unusual occurrence for from five to eight hundred spikes of bloom to be expanded at one time. This winter has, however, been very destructive to the early-flowering species, such as *P. amabilis* and *P. Stuartiana*, of which scarcely a spike escaped at Clapton, although many hundreds were produced. In the case of *P. amabilis*, Mr. Low retrieves the loss of the first spikes by cutting them off to within six inches or so of the base, which induces them to develop a secondary spike, and as this matures later in the year the flowers are saved. Still it is a great strain on the plants to force them to produce two spikes instead of the normal one.

P. Schilleriana, however, is magnificently in flower at Clapton now, over 500 fine spikes of flowers being fully open at the time of my visit. The health of the plants is perfect, all, from the smallest with leaves no larger than a finger-nail, to the grand specimens with leaves a foot or more in length, being perfectly happy. The treatment for these plants at Clapton differs somewhat from that usually followed. Mr. Low thinks that a large percentage of the Phalænopsis that die in gardens are killed by too dry treatment. A light house where the winter's sunlight may be made the most of, sufficient heating power to maintain a temperature not lower than seventy degrees even in severe weather, an earthen or cinder floor and a constantly saturated atmosphere all the year round—these are the main features of the Clapton treatment for Phalænopsis. Mr. Low says the sphagnum about these plants should never be allowed to even approach dryness. Baskets are used for all the kinds, and they stand upon open wooden stages about two feet from the glass. The house is kept moist by frequent damping down. There are two large span-roofed houses devoted to these plants at Clapton, the principal species cultivated being *P. amabilis*, *P. grandiflora*, *P. Schilleriana*, *P. Stuartiana*, *P. rosea* and *P. gloriosa*.

London. *Visitor.*

New or Little Known Plants.

New Orchids.

Odontoglossum luteopurpureum, var. Amesiana, Hort., is a very handsome variety, for which Messrs. F. Sander & Co., of St. Albans, received a first-class certificate from the Royal Horticultural Society on March 10th last. It is described as having flowers of a pale yellow-green color, unlike that of any other Odontoglot.—*Gardeners' Chronicle*, March 14th, p. 334.

Cypripedium × Ceres, N. E. Br., is a handsome hybrid, derived from *C. Spicerianum* fertilized with the pollen of *C. hirsutissimum*, in the collection of D. O. Drewett, Esq., of Riding, Mill-on-Tyne. It resembles the pollen parent generally, though the dorsal sepal and staminode show characters unmistakably derived from the seed parent.—*Gardeners' Chronicle*, March 21st, p. 360.

Cypripedium × Juno, N. E. Br., is a charming little hybrid, raised in the collection of D. O. Drewett, Esq., of Riding, Mill-on-Tyne, between *C. callosum* and *C. Fairieanum*, the latter being the pollen parent. It bears a strong resemblance to *C. Farieanum* in almost all its characters, but especially in the shape and color of the flower. It appears to have arrived at the flowering stage in less than three years from the time the seed was sown.—*Gardeners' Chronicle*, March 21st, p. 360.

Cypripedium × Pallas, N. E. Br., is a hybrid, raised in the same collection as the two preceding ones, between *C.* × *calophyllum* (itself a hybrid from *C. barbatum* and *C. venustum*) and *C. callosum*, the latter being the pollen parent. The upper sepal is white, with numerous green nerves, as in the seed parent, to which in other respects it bears a considerable resemblance.—*Gardeners' Chronicle*, March 21st, p. 360.

Waluewa pulchella, Regel.—Described as a new genus of Orchids, received from the province of Minas Geraes, Brazil, by Herr Lietze, and which flowered in the Royal Botanic Garden at St. Petersburg. It is dedicated to Count P. A. Wahijew. It appears to be closely allied to *Leochilus*, but bears a strong resemblance to certain species of *Oncidium* of the *O. pulus* group. The flowers are small, the sepals greenish yellow and unicolorous, the petals yellowish, barred with purple; the lip also has some purple markings on a yellowish ground. The linear disc is minutely papillose.—*Gartenflora*, xl. (1890), p. 89, t. 1341, fig. 1.

Cultural Department.

Hardy Shrubs for Forcing.

Many of our hardy shrubs can be forced, under a moderate temperature, into early bloom in the greenhouse. In order to get the best results with the least trouble, shrubs for forcing should be selected from the early-flowering kinds. The forcing should be done moderately and gradually—that is, the plants should first be placed in a cool greenhouse or cool part of a greenhouse until growth has fairly begun; later, if desirable, they may be introduced into a warmer temperature, where growth and development of the flowers may be hastened.

When brought into a warm temperature too suddenly the buds are liable to become injured or blighted, and a dry at-

mosphere is also injurious. Plants intended to be forced may either be lifted during the previous spring and placed in tubs or pots, where they continue growth during the summer, or fibrous-rooted kinds may be lifted with an adhering ball of earth in the late autumn, and, together with the potted plants, be placed in a pit or cellar until wanted. Plants for exhibition or ornament are generally taken up and potted long before being forced, but autumn lifting usually answers where only blossoms are desired. Where the winters are not severe some of them may be taken directly from the ground in mild weather, but where the earth is liable to remain frozen it is best to have all out of reach of frost. Cuttings of some kinds may make good, compact little flowering plants in the course of a few months' growth.

Deutzia gracilis and *Rhododendron* (*Azalea*) *mollis* and others are now almost universally grown for winter forcing, and

Fig. 34—A Cottonwood Tree (*Populus monolifera*) on the banks of the Kansas.—See page 182.

the Lilac has come into quite general use among florists. The Flowering Almond, the Peaches and Cherries, and, among others, *Prunus Pseudo-cerasus*, force well, and the last is very pretty and lasts in bloom a long time, although it cannot be counted a florist's flower.

Well-grown grafted plants of varieties of the beautiful flowering Japanese and Chinese Crab Apples are easily brought into early bloom if planted the preceding year in tubs or pots, and not forced into too rank growth. The flowers of our Chokeberry (*Pyrus arbutifolia*) come out well under artificial heat, and the deep green shining leaves are attractive, although the plants have a rather straggling habit.

An interesting plant for early forcing is the very dwarf form of the Japanese Quince, which is known as *Pyrus Maulei*, and which bears a profusion of orange-scarlet flowers. It is better than many of the forms of *P. Japonica*, because of its more compact habit and its more numerous and slender branchlets.

Staphylea Colchica is now quite extensively cultivated and forced for commercial purposes, and, when well grown, its fragrant tuberose-scented flowers are among the most beautiful to be obtained from forced shrubs. This species surpasses any of the other hardy Staphyleas for forcing purposes.

Among many others of its genus *Rhododendron Vaseyi* blossoms as charmingly when hastened in the greenhouse as it does when left to bloom in the open air with the coming of warm weather.

Well-grown and full flower-budded plants of our American Laurel (*Kalmia latifolia*) may be forced into one of the most beautiful objects of winter decoration. The dark evergreen leaves are always attractive, but when the clusters of white or pinkish flowers appear, few greenhouse plants can compare with the Kalmia. Under the influence of a moderate artificial heat, the Rhodora does not take long to open its buds and display its beautiful, rosy purple flowers on its naked branches. It probably would not pay to force this for commercial purposes, but a few plants may give much pleasure to the amateur. This is also true of the Mayflower, or Epigæa, clumps of which may be moved from its native woods in the autumn, and, being transplanted into boxes or pots, the flowers may be produced, whenever desired, throughout the winter. *Andromeda floribunda* and *A. Japonica* are naturally so early-flowering that it is an easy matter to force them, and they make admirable decorative plants in winter. It takes longer to get flowers from *A. speciosa*, but they are among the loveliest of the genus, and well worth waiting for.

Among the showy-flowered hardy Daphnes the blossoms of *D. Mezereum* are very easily brought out, and *D. Genkwa*, from Japan, gives promise of being one of the most interesting plants of its kind for forcing.

Many of the Spiræas are useful for their winter bloom.

The flowers of *S. Thunbergii* are easily brought out, but a forced specimen of this shrub usually looks disheveled and unsatisfactory, but *S. Cantoniensis* (*Reevesiana*) and the plant known in nurseries as *S. Van Houttei* do better.

Grafted plants of the Japanese Red-bud (*Cercis Chinensis*) will be found much better than our native species, inasmuch as the flowers of the former are earlier, larger, and even brighter in color. Dwarfed and well-grown plants of the common Chinese Wistaria are very handsome when forced early, and it is a species which seems to do very well under these conditions. Some of the hardy species of Cytisus are well worth the trouble of bringing into early bloom.

The Forsythias are among the plants which very readily and quickly come into flower under the stimulus of gradual heat. Only those with numerous flower-buds should be selected, and *F. suspensa* and the form sold as *F. Fortunei* will be found more satisfactory for forcing purposes than *F. viridissima*, which they also excel for garden culture. The shrubby *Magnolia stellata* will easily produce its fragrant white blossoms if the buds are well developed. Among later-flowering hardy shrubs which have come into extensive use for forcing purposes is that long known as *Viburnum plicatum*, and which is in every way a much better plant than the old-fashioned Snowball-sterile or form of *V. Opulus*.

That the latest as well as the earliest of our flowering shrubs may be profitably forced is shown by the fact that *Hydrangea paniculata grandiflora* is now grown for commercial purposes in greenhouses. While almost any shrub may be forced into growth before its due season, only a limited number of kinds will be found profitable to the florist, while the amateur and enthusiast has a long and varied list from which he may select subjects for experiment. He will find that many of them never look as well at any other time as they do when blooming out-of-doors in their proper season.

Jamaica Plains, Mass. *J.*

Hardy Narcissus.

THE article on Hardy Narcissus, in Garden and Forest for March 25th, was interesting and timely, as the first of these beautiful flowers are bursting their sheaths (*N. Scoticus* being in the lead, and showing flowers on Good Friday). Mr. Orpet's advice about due care in planting late arrivals of bulbs is sound, and the same remarks would apply to all hardy bulbs, for unless some root-action takes place before freezing weather losses are almost inevitable among the hardiest of them. But there may be an exception taken to the advice to plant deeply in our climate, if this means the climate of our eastern states. That detail seems to me to depend, as with other plants, very much on the garden in which they are to be planted. In my own it is not possible to grow Narcissi deeply planted, neither have I found it necessary so to plant them to grow them successfully and produce flowering bulbs for the following season. As a matter of convenience, where there is a proper depth of suitable soil, deep planting may in some cases be desirable, but it is doubtful if it is necessary in any case. My soil is a heavy retentive one, nine to twelve inches deep, with a clay hardpan, and deep-planted bulbs simply deteriorate to the diameter of a lead-pencil. Planted from one to three inches deep, they thrive as well as one could wish. If an open fall allows the foliage to appear above ground, as it often does, little or no damage seems to be done by following frosts. In December of 1889 I bought a lot of *N. Horsfieldii* too late to plant out, and planted them in three-inch flats in light potting soil. They were lightly watered and placed in a rather open cold frame through the severe weather, and bloomed in the open. They were carefully ripened off, and, the offsets being removed, were planted at a suitable time in the border. They have been blooming freely since April 15th. This experience would seem not only to confirm Mr. Orpet's theory that late-planted bulbs, if properly grown on, would prove satisfactory, but also that very shallow planting is sufficient; in this case only enough soil being used to actually cover the bulbs.

While from necessity a second crop is always grown over my bulbs, I think it is somewhat at the expense of the bulbs; and where space is not important and bulbs are valuable, better results will be had if the beds are left exposed and without a second crop. If this is a matter of necessity, plants which require little moisture or are deep-rooting, like annual Poppies, seem most desirable for such a position. Of course, in garden matters, one only judges from his own glebe and experience. Fortunately, many plants are not as particular as the gardener, and will grow under vastly differing circumstances, so that general rules do not often seem applicable.

Elizabeth, N. J. *J. N. Gerard.*

How to Make a Wild Garden.

IF we have only a few feet of ground in some shady nook, on the north side of a building or beneath the shade of trees, we can have a constant succession of flowers from early spring until late autumn. And to all lovers of flowers this wild nook will be more enjoyable than a prim, conventional garden of florist's flowers.

The wild garden will be vastly more satisfactory if it comes by slow growth. It should never be made in haste, but as we have time now and then in any season of the year to wander amid Nature's groves and gardens and note how the wild things which we desire grow, and also notice their surroundings and the trees which overshadow them, we shall be better prepared to know with what we can best succeed.

There is but little difficulty in growing many of our earliest spring flowers. The Hepatica, the Blood-root, the Wind-flower, the Spring Beauty, the Trilliums and all of our lovely Violets will grow almost anywhere in good garden soil. But there are others which require skill and patience to make live and thrive after being removed from their native haunts.

Perhaps if I give some account of my own failures and successes with wild plants it may help those who wish to secure some of these shy woodland gems. In my wild garden I have some shady places where I concentrated my skill on some of the most difficult of our wild flowers. One of these places is an irregular spot only about fourteen feet the longest way and about ten feet in the widest part. It is situated between three trees which form a kind of triangle,—a large Oak, the body of which is covered with English Ivy, mingled with variegated Evonymus, and an old Pine (*Pinus rigida*) mingles its leaves with those of the Oak, and a Trumpet-creeper has climbed up its rugged sides to its very top, showing clusters of bright scarlet flowers among the deep green pine-needles; the other tree is a Cedar with branches nearly to the ground. This little

spot is the most attractive place in my garden, almost more to me than all the rest of the half-acre devoted to wild plants. It is wonderful how many things grow in this wild spot. From early spring until late autumn it is never without flowers.

Among the first things to greet me in spring are the lovely blossoms of the Trailing Arbutus or May-flower, not stingy little clusters of bloom, but large compact bunches of flowers. I have had many failures with this charming plant, but at last have succeeded in establishing it. I found a fine patch of the plants in the woods, under a Pine-tree, and removed quite a large section of earth with all of the other things that were growing on it, and planted all beneath the old Pine in my garden. It has now bloomed three seasons, and is spreading and growing all the time. Other evergreen trailers are also here. The little Twin-flower (*Linnæa borealis*) is among my treasures, and our little Partridge-berry (*Mitchella repens*) grows luxuriantly. Its small shining leaves, strung along in pairs, are pretty the entire year, and in June it is covered with small pink and white flowers, succeeded by the double berries, which turn scarlet as they ripen, remaining on the plant until the following season, making it as attractive in winter as in summer. Another little plant is the Dalibarda, a low, creeping perennial belonging in the Rose family. With us—in southern New Jersey—the leaves are nearly or quite evergreen, and its pretty white flowers last from June until August. The spicy, aromatic Wintergreen flourishes among the rest, and very pretty it looks in winter, with its shining leaves and bright red berries.

Scattered among these trailers are both species of Hepatica, and the Blood-root, and Spring Beauty, and Wind-flower, and the Wood-sorrel (*Oxalis violacea*), and several species of Violets. And here, too, are some of our lovely Orchids—the Lady's-slipper, the low purplish pink one (*Cypripedium acaule*), and the fragrant yellow one (*C. parviflorum*) blossom every spring.

The dwarf perennial Larkspur (*Delphinium tricorne*), with spikes of brilliant blue flowers, and the wild Hyacinth (*Scilla Fraseri*), with a long raceme of pale blue flowers, bloom here as well as in their native home on the western prairies.

These early flowers are succeeded by several species of our low-growing Ferns, which are beautiful throughout the rest of the season. On the outer edge of this spot are larger, later-blooming plants, and also some of our large Ferns—two species of Osmunda—the Cinnamon and Royal Fern, and our Chain Ferns, the Woodwardia—both species.

The Wild Lily (*Lilium Canadense*) unfolds its nodding flowers by the side of the Ferns, with Rudbeckias and low-growing Sunflowers as companions. Some of these Rudbeckias and Sunflowers are annuals from Texas, and grow readily from seed. When planted early they commence to bloom by the first week in July and continue until frost. In August the Asters and Eupatoriums and Golden-rods begin to mingle with the Sunflowers, making a brilliant display.

As the Golden-rod has become our national flower, it will naturally be more noticed and sought after than heretofore; and as we have some forty or more species growing in the northern states there will be little difficulty in securing some pretty ones in every locality. One of the most desirable and earliest-blooming of all is the sweet-scented Golden-rod (*Solidago odora*). It is widely distributed from Maine to Florida, and commences to bloom here about the middle of July. The flowers are bright yellow in a one-sided, spreading panicle, and it has smooth, shining leaves, which, when crushed, give a pleasant anise odor. This species, together with some of the later-blooming ones, will give us flowers from July until October.

Those who live near the coast should not neglect the beautiful salt-marsh Golden-rod (*S. sempervirens*). It has thick, very smooth, large shining leaves, and fine large heads of bright golden flowers. Although it is a salt-marsh plant, it has become established here, some forty miles inland, as one of our wayside flowers. The seed, no doubt, has been brought and disseminated with salt-marsh hay.

Mary Treat, in the Chautauquan.

A Raspberry Trellis.—It is rare that we find a field of Red Raspberries in which due provision has been made for sustaining the canes during the bearing season. They are cut down, as a rule, in autumn to a height of three to four feet and left to winter through as they can. The damage from snow is always serious. My own loss in winter and from broken canes in summer was so great that I have adopted the following plan: I set strong cedar-stakes at the ends of rows and at intervals of twenty-five feet. To these I staple a wire, as for a Grape trellis, about four feet from the ground. Then, bringing the canes together in bunches of three or four, they are tied with soft strong twine above the wire—not on the wire, for then the cord would soon be cut by the wire. The rows being all tied, intervening and short canes are dug out. Then, with hedge-shears, the tops are cut off at a height of six feet. This height on this plan is not too great. The Raspberry likes a moist, shaded soil; and in this way it shades its own roots. In the bearing season the sides of these trellises become a wall of berries—a wonderful sight to behold. Pickers move up and down the rows quite hidden. I have described my plan with the Cuthbert and Golden Queen in view. These, in fact, are with me the only standard first-class raspberries for market as yet. The Turner must be grown very thinly here, and in hills, to secure a reasonable crop. The Marlboro has succeeded fairly well as above, but with me is not a standard in any sense. Rancocas I must reject, as also Hansell, Lost Rubies and Crimson Cluster. Schaffer's Colossal does admirably on the wire, and is an enormous bearer on that plan. Black Raspberries, in general, had probably best be cut low and grown in stout heads.

Clinton, N. Y. *E. P. Powell.*

Mildew on Sweet Alyssum and Radish.—Among our worst mildews are the members of the genus Peronospora, and among the Peronosporas there is no species equaling the *Peronospora parasitica* in breadth of range. Usually a species of these downy mildews is confined to one or a few of the members of the same host genus, but the one named above is known to grow on forty-seven species belonging to twenty-seven genera. These genera, however, all belong to the large family of *Cruciferæ*, whose members are easily recognized by their similar flowers, pods, and even their peculiar taste. When a mildew will thrive upon a large number of hosts the presence of one host-plant will furnish the breeding-ground and produce a stock within a greenhouse for any other susceptible plant. In a greenhouse recently visited the beds of young Sweet Alyssum showed many pale and sickly plants, which were found badly infested with the downy mildew above mentioned. Radishes had been grown under glass in large quantities, and were perhaps more or less attacked by the same fungus, and while it inflicted little damage upon the short-lived Radish-plant it no doubt multiplied there and spread to the Alyssum near by, from which its destruction may become considerable. Gardeners need to know the kinships of plants, and if one crop is mildewed it is not advisable that another closely related to it should be grown by its side.

Rutgers College. *Byron D. Halsted.*

Distributing Weeds.—Novices need a warning against *Ipomœa pandurata*, "Man of the Earth," which has been rechristened by the seedsmen the "Hardy Moon Flower." Did any one ever get to the bottom of the root of an old plant? I have tried it, but always found it growing stouter as I dug, until I gave it up, and had forty plants come up in place of the one. A worse weed is now advertised as "California Rose," and with the greatest apparent sincerity the sellers give as the botanical name of this "Rose," *Calystegia pubescens*. It may perhaps be one of the California Calystegias, but the probability is that it is *Calystegia Sepium*, var. *pubescens*, the vilest weed which ever infested a garden. I have a note to-day from a lover of flowers who boasted of her new treasure, the California Rose, which she is growing from seed. I at once warned her not to plant it in her garden.

Our common "May Pop," *Passiflora incarnata* is a much prettier plant and flower than any of the *Convolvulaceæ*, but, in this latitude it has the same fault of the Bindweeds, and becomes a troublesome weed in cultivated fields. Perhaps it may not be so bad at the north, but it is well to watch all these things.

North Carolina College of Agriculture, Raleigh. *W. F. Massey.*

Primroses.—There are no more charming plants in spring-time than these, and it is little wonder that they have been garden favorites from time immemorial. For some reason there seems a quite general impression that Primroses are flowers of the shade and dampness, and that under our brazen skies there is so small a chance for success that there is no use in attempting their culture. This may be true of *Primula veris*, the native English Primrose, for there are probably very few such haunts in the United States as that in which this plant was reported by one of your correspondents to have become naturalized, and in the garden it is not long-lived. But within the last decade or two some excellent strains of hybrid Primulas have been secured by the painstaking care of a few florists, and

these prove very satisfactory garden plants in our climate. Among a number of strains Dean's seem quite the best, and leave little to be desired. The plants are vigorous and free-flowering, the flowers are large and well colored, without objectionable tints. Seeds (which may be had of leading dealers) sown now will produce blooming plants next spring. My plants of these are best in a raised border some six feet from the south wall of the dwelling. They receive the full rays of the sun all day, without the slightest shade at any time, and apparently never suffer from the heat. In the winter they remain without any covering, as this is apt to rot the crowns. During the winter many of the leaves are usually scorched by the frost, but new ones are quickly put out, and now, as they are coming into bloom, the plants look very fresh, vigorous and much more stocky and in character than any plants coddled in a frame. In three other borders facing south and west, but more exposed, and not so well drained, the lines of Primroses do not grow nearly so vigorously or bloom as early. If any of your readers have had only moderate success with these plants the location may have been at fault. With these hybrids and a good strain of *P. elatior* (Polyanthus) a long succession of beautiful flowers may be had with little care, and soon a superabundance of plants, as they increase rapidly when divided.

A Taurian Muscari, received from Asia Minor, proves on a second year's trial a valuable addition to the early spring border. This Grape Hyacinth starts into growth in early winter, putting forth leaves which are long, narrow and prostrate. The bloom slowly appears as soon as the ground loosens, and this year from early February till now a colony of a hundred or more plants has been a cheerful spot in the border. The flowers are light purple (florist's blue) on the apex of the cluster, and shade to deepest purple at the base on stems about six inches high. Each small bell-like flower is constricted at the mouth, where it is furnished with a fringe of white. The blooms are not injured by hard weather. The list of available very early blooming plants is lengthening rather rapidly, and this may be considered a desirable addition to the earliest class.

Arabis alpina.—This Rock Cress is one of the best of the hardy low-growing early-blooming plants where white flowers are desired. Its simple pure white blooms are about three-fourths of an inch in diameter, and very freely produced. In broad masses it is especially attractive. It precedes *Phlox subulata* in blooming, and like this is fond of a location not too wet. Plants of this may be had of most hardy plantsmen or it may be secured readily from seed.

Elizabeth, N. J. *J. N. G.*

Correspondence.

Colorado Conifers for Eastern Planting.

To the Editor of Garden and Forest:

Sir,—Allow me to endorse your remarks, in connection with Mr. Moon's letter, on page 153 of Garden and Forest for April 1st, 1891. An attempt to grow California trees north of the latitude of Philadelphia will be almost sure to result in disappointment. But in making this statement we must use the words "California trees" only in a geographical sense, and not forget the great difference in hardiness that exists between the same species on the Pacific slope of the Rocky Mountain range and those on the eastern slope. This difference is so great as to form separate varieties of the same species, as far as the manner of growth is concerned.

In Colorado we have *Pinus ponderosa*, *Pseudotsuga taxifolia*, *Abies concolor* and *Picea pungens*, all growing in thick forests on the mountain-sides, and enduring a climate far more severe in every way than around New York City. In winter there are sudden storms of snow and sleet, with the thermometer falling as low as thirty degrees below zero, followed by days of almost summer heat, with scorching sun and drying winds. In summer there are long seasons when no rain falls to provide their needed moisture. And these trees are no stunted, twisted trunks with a few branches, struggling for a bare existence, but grand and noble specimens of tree-life, towering in lofty grandeur to a height of nearly 200 feet. I have seen single isolated specimens of *Abies concolor*, rising like towers, full of light and shade and beautiful color, which could not be excelled anywhere as types of vegetable life. There, too, the rich deep green of the Douglas Spruce, with its soft foliage, and the bright, warm tints of the Engelmann's Spruce, give a wonderful attraction to the Colorado forests. No one need doubt the perfect hardiness of any tree that grows in Colorado, Wyoming or Montana. This has been generally recognized by nurserymen who grow forest-trees in quantity, and they will advertise the trees above named as grown from Colorado seed. Let any planter be sure his trees are derived from seed gathered in the states named, and he need have no fear of the result, but rest sure that, accidents barred, they will live to reach a magnificent maturity.

Colorado Springs, Col. *Geo. H. Parsons.*

[The conifers of Colorado, so far as it is possible to judge of them from an experience which does not extend beyond twenty-five or thirty years, are well suited to withstand the climate of the northern Atlantic states, although, as we have insisted again and again, it is not safe to pronounce upon the capacity of any tree to flourish in any locality until it has been grown in that locality in considerable numbers during a period equal to the life of an individual of the species. Of the trees mentioned by our correspondent, plants of *Pseudotsuga taxifolia*, *Abies concolor* and *Pinus ponderosa*, raised from Colorado seed, are absolutely hardy in the most exposed situations in New England, while plants of the same species raised from seed gathered on the Pacific side of the continent either fail entirely in this part of the country or are very unreliable. Judging by what we now know of these trees, the Pseudotsuga from Colorado is the most valuable exotic conifer which can be planted in the northern states; while *Abies concolor* is the hardiest and most beautiful of all the Silver Firs here. *Picea pungens* and *P. Engelmanni* are both peculiar to the dry interior part of the continent, and do not reach the humid coast-region. They are both hardy in the east. *Picea pungens*, the so-called Blue Spruce of nurseries, is already planted in large numbers, and in its young state is very beautiful. The largest plants in the east begin, however, to show indications of failure in their lower branches, and those persons who have watched these trees most closely in cultivation feel that they may not maintain their early promise—a view which is strengthened by the fact that in Colorado this tree loses its lower branches early, and is much more beautiful in its young state than it is later in life.

Picea Engelmanni, as it appears in the elevated forests of Colorado, is probably the most beautiful of all the Spruces. Transported, however, to the sea-level, it grows very slowly, like all alpine trees, and it is not probable that it will be very much esteemed as an ornamental tree in the eastern states, but as it is very promising in the extreme northern part of Europe, it will doubtless prove a valuable tree for the cold regions of Canada. It is one of the first conifers to start into growth in the spring, and for this reason is worthless in countries like England, where spring frosts prevail.—Ed.]

The Home of Certain Syringas.

To the Editor of Garden and Forest:

Sir,—Not long ago an article in Garden and Forest discussed the different species of Syringa cultivated in gardens, and in this article it was stated that the native country of *Syringa Josikæa*, Jacq., was unknown, and that all the plants in cultivation have been derived from a single specimen found in a garden in Hungary.

The statement is inexact, and the country where this species grows naturally is well known. It was discovered in 1830 by the Baroness Josika (née Craki) in Transylvania, not in a garden, but on the rocky banks of the river Sebes, in Clausenberg, and the younger Jacquin, who named the plant in honor of the discoverer, showed specimens of it at the Congress of Naturalists, held that year at Hamburg, inserting the first diagnosis of his species in the account of this meeting published in the *Bot. Zeit.* (1831, p. 67). Reichenbach, in his "Flora Germanica Excursoria," published in 1830–32, gave characters of *Syringa Josikæa*, with an indication of the region where it had been found, and the same author in his admirable "Iconographia of the German Flora" publishes a figure of it. In more recent years various Hungarian collectors have found the plant in its native country and have distributed specimens.

In order to remove any doubts which may still exist upon the occurrence of *Syringa Josikæa* growing spontaneously in north-eastern Hungary, I have written to some of my Hungarian correspondents, Professor Borbàs, at Buda Pesth, and others. They give me exact and complete information with

regard to the discovery of the plant and the localities where it grows, which can leave no possible doubt with regard to its spontaneousness in Europe. I am indebted to the kindness of Mr. Carl von Flatt, Judge at Elest, near Grosswardein, the country of *Syringa Josikæa*, for a list of the ten known localities where it is known to occur, and which extend over the four counties of north-eastern Hungary—namely, Kolos, Bihar, Ung and Màrmaros. It is in the first of these, Kolos, that the plant was discovered on the river Sebes.

S. Josikæa grows everywhere near the water at an altitude varying from three hundred to four hundred metres above the sea, between 46° and 48° of north latitude and between 40° and 42° of east longitude. Mr. Victor Janka describes (*Ostreich Bot. Zeit.*, 1885, 3, f. f.) the locality in the district of Màrmaros, where he first found it, as covered with thickets of Alder, *Rhamnus Frangula* and *Salix aurita*.

Mr. Carl von Flatt, to whom I am indebted for the bibliography * of this species, which is joined to this communication, writes: "The home of the plant growing spontaneously is in the primeval forests of the mountain-chain which separates Hungary from Siebenburgen. For miles and miles of the territory where *S. Josikæa* grows neither a house nor a hut is to be seen. The stations discovered by me are both in the Remetz mountain-forests; one, Lunka Kotuni (1885), furnished few specimens, but there are finer ones in Pareu Foeguczat (1886), where there are nearly a thousand plants growing. Probably Kitabel had heard of this plant. In his manuscripts, preserved in the National Museum at Buda Pesth, there is a drawing with the following note:

"'*Syringa prunifolia*, Kit. Ita interea pro conservanda memoria nomino quæ ad viam Munkacsino-Leopolim (Lemberg) ducentem inter Felsö-Hrabonicza et Pudpolock in cottu Beregh crescit, foliis que Pruni distincta, referente Dre Bulla.'

"Studel, in his 'Nomenclator Botanicus,' gives under *S. Josikæa* as a synonym, *S. vincetoxifolia*, Baumg. Where he found this I cannot tell, for Baumgarten did not publish such a name."

If *S. Josikæa* is to be considered an escape from cultivation, what known species can it have been derived from? Certainly there does not exist in Europe any species from which it can have been derived, a reason sufficiently important for rejecting all idea of garden origin. And, you know, Monsieur Franchet has suggested the identity of *S. Josikæa* and *S. Emodi* of the Himalayas ("Observations sur la Syringa du Nord de la Chine"), but certainly no one had ever cultivated the Indian plant in Hungary previous to the year 1830, when *S. Josikæa* was discovered, and even to-day it is very doubtful if a single specimen of *S. Emodi* can be found in all that district.

Permit me to call attention also to an error in Garden and Forest with regard to the native country of *Syringa vulgaris*. That plant does not grow wild in Piedmont, and its most western station is southern Hungary, in the neighborhood of the Danube. If more western stations are given in some Floras, it is for plants which have escaped from gardens. In this country *Syringa vulgaris* maintains itself easily, and for a long time, wherever it has been planted, and, therefore, sometimes appears spontaneous or sub-spontaneous, although it is not indigenous here. This is the case, too, with *Philadelphus coronarius*, which is often found about the ruins of buildings which have been abandoned for more than half a century, furnishing the last trace of ancient gardens.

Fungous Diseases of the Grape and other Plants, and Their Treatment. By F. Lamson-Scribner. J. T. Lovett Company, Little Silver, N. J. Small 8vo, pp. 134.

The knowledge of fungous diseases of plants has, within comparatively few years, been supplemented by so many valuable practical experiments on the relative merits of different chemicals in checking their growth, and by the invention of machines for applying them in the most efficient way, that there was need of a compact popular summary of the subject for the use of farmers and fruit-raisers. This is afforded by the little book of Professor Scribner, which gives a popular account more especially of the principal rots, mildews, blights and other diseases of the Vine, followed by shorter chapters on various diseases of Apples, Pears, Cherries, Plums, Peaches and Raspberries. The main object of the author is to show the best method of applying remedies, and the descriptions of the Fungi which cause the various diseases are designed to enable those who are not well informed with regard to Fungi to recognize with as little difficulty as possible the distinctive characters of the different diseases as a preliminary step in applying the remedies. The compass of the book prevents any extended account of the different Fungi, but those which affect the Grape are given with sufficient fullness for all practical purposes. A more extended introductory chapter on the general characters of Fungi would, however, have served a useful purpose. A considerable number of woodcuts give the gross and microscopic appearance of the Fungi and the appliances for sprinkling. It is to be regretted that the figures are not numbered consecutively, since the irregularity of the numbering makes back reference difficult. On the ground of good taste, too, the caricature which passes as a portrait of the author in the frontispiece had better have been omitted.

The work is to be recommended to the large number of persons who need a summary of this important subject with a view to making a practical application of the knowledge acquired.

The Nursery Book. A Complete Guide to the Multiplication and Pollination of Plants. By L. H. Bailey. New York: Rural Publishing Company.

This manual offers a sufficiently full account of the usual methods of propagating and crossing plants, and it will be a convenient and useful reference not only for amateurs, but for nurserymen who are familiar with only a few branches of their business. The great portion of the book is taken up with a list of plants arranged in alphabetical order, with an explanation of the methods of multiplying each one. We know of no such complete list within anything like the compass of this volume. An admirable feature of the hand-book is the ordinal index, which groups together all the references to the plants in a given family. If any plant chances to be omitted from the nursery list, or if the reader desires to learn more about the method of propagating some plant included in the list, he can consult what is said of every other plant in this natural order, and undoubtedly will find some information which will prove of value.

The explanation of the different methods of grafting, budding, layering, etc., are sufficiently clear and complete, but the cuts which were intended to illustrate these methods are not nearly as good as the text; and it seems to us that the words "graftage," "seedage," "cuttage," etc., with which Professor Bailey has attempted to enrich the English language, were hardly worth coining.

Notes.

Mr. Charles Dudley Warner's articles on Southern California, recently printed in *Harper's Magazine*, have been issued in book form under the title, "Our Italy."

The California State Board of Horticulture has published an illustrated pamphlet, written by Mr. M. B. M. Lelong, and called "The Orange from Seed to Grove," the object of which is to supply reliable guidance to those who intend to plant Orange-groves in that state.

Mr. Alfred Parsons, an English artist well known in this country by the books which he has illustrated in conjunction with his friend, Mr. Edwin Abbey, recently opened in London an exhibition of pictures called "Orchards and Gardens." Many pictures of famous English gardens were included, and, knowing Mr. Parsons' sympathetic feeling for such scenes,

and the refined, poetic quality of his talent, one can well believe that the exhibition was very interesting, as well as novel in character.

A new monthly magazine, called the *Modern Cemetery*, has been started in Chicago with the object of supplying useful information to cemetery superintendents and lot-owners, and of improving the taste of the community as regards the planning and conduct of burial grounds.

A correspondent in Massachusetts states that he has found in growing Tomatoes under glass that the old plants cut down, as recommended by Mr. Mathews in our issue of April 8th, do much better than young seedlings. We should like to hear from others who have tried this plan.

Dr. Lorenzo G. Yates calls attention, in the *Pacific Rural Press*, to the value of the Chocho Plant (*Sechium edule*) as a food-product. The plant is a native of the West Indies, and thrives satisfactorily in Florida. It is one of the Cucurbitaceæ, resembling an ordinary Squash in general appearance. Both roots and fruits are available as food.

The *Revue Horticole* states that our common water-weed, *Elodea Canadensis*, which had already spread widely in England, has more recently introduced itself into France to such an extent that many streams are now seriously obstructed by it. In the canals of Belgium it is also proving a conspicuous source of trouble, and the same bids fair to be the case with another American immigrant, the little moss-like, floating *Azolla Caroliniana*.

Last week the Cornelian Cherry, the Forsythias, the early upright Honeysuckle (*Lonicera Standishii*), with our native Spice-wood and Andromeda (*A. floribunda*), comprised about all the shrubs which were blooming in Central Park. But two or three hot days in a northern spring work wondrous transformations, and no doubt the thickets will be all ablaze with the flowers of the Japan Quince and a dozen other shrubs before this paper is read.

Three of the Strawberries which were specially commended by Mr. T. T. Lyon, who tested them at the South Haven Substation of the Michigan Agricultural College, were Parker Earle, Pearl and Cloud. The first of these originated in northern Texas, the second came from southern New Jersey, and the third is a Louisiana seedling. That these plants are all promising in places so far from their origin would seem to indicate that they have great strength and adaptability of constitution.

According to *L'Art dans les Deux Mondes*, "a splendid collection of wood specimens" will be sent to the World's Fair at Chicago from Jamaica and the other West Indian islands. "These specimens . . . will have the appearance of bound books, one cover of which will be polished, while the other will show the natural aspect of the wood, and the back will retain the bark and will bear a tablet giving, in gold letters, the name of the species. This 'botanical library' will be accompanied by notices explaining the localities where the tree is found, and the qualities and uses of its wood."

In an address, delivered at a recent meeting of the Massachusetts Horticultural Society, Colonel Henry W. Wilson said that the Cocoanut Palm thrives in the Bahamas as well as in any part of the world, and this is the only district near to the United States where it certainly will. These Palms will bear in four years from planting the seed, and then fruit perennially, a leaf expanding every month, with a cluster of flowers at the base which produces from forty to sixty nuts. They keep growing the whole year, and show, at all times, the whole gamut, from flower to ripe fruit; every day the owner can pick fruit, which sell there for three cents apiece.

Colonel J. B. Clark, editor of the *Mirror and Farmer*, of Manchester, New Hampshire, offered $100 in prizes for the best essay on maple-sugar making. Forty-one essays were received, and all of them are published in the *Mirror and Farmer* for April 2d. They would make together a duodecimo volume of 250 pages, and contain a body of doctrine comprising about all that is known of practical sugar making in northern New England. The first prize was taken by E. W. Bisbee, of Moretown, Vermont; the second by H. I. Collins, of the Experiment Station, Burlington, Vermont; the third by A. S. Moody, of Moscow, Vermont, and the fourth by Timothy Wheeler, of Waterbury, Vermont.

A correspondent, writing from Kansas Experiment Station at Manhattan, under date of April 15th, says that the Forsythia was in full bloom there for the first time in a number of years. The mercury reached zero but twice during the last winter, and then remained there but for a short time. Usually this shrub shows only a few blossoms on the lower and more sheltered branches. *Lonicera fragrantissima* was also in full bloom, and seems perfectly hardy in severe winters in stiff, clayey, upland soil, but is often killed back on bottom-lands. Nearly all the *Arbor-vitæs* on the station grounds have suffered unaccountably, notwithstanding the mild winter. Trees which have endured, in former years, a temperature of twenty degrees below zero without harm now appear disfigured and dead on the north side.

A "Biographical Index to British and Irish Botanists," compiled by Messrs. James Britten and G. S. Boulger, has recently been issued in serial form in the Journal of Botany. It is now proposed to publish it in book form, and subscriptions will be received by the editors of the *Bulletin of the Torrey Botanical Club* in this city. The price will be one dollar, payable on the delivery of the volume. The list includes "all persons residing in the British Islands who have been at all prominent in the science, including collectors and patrons of botany," and gives the date and place of birth and death, the place of burial, dates of election to the Linnæan and Royal Societies, and references to sources where fuller information may be obtained.

In his proclamation, setting apart April 25 as Arbor day, Governor Russell, of Massachusetts, gives this wise counsel as to the higher uses of the celebration: "And I recommend that it be observed in ways which may serve to increase the love and respect in which we all hold the dignity and beauty of this noble land which God has given to our keeping. Let us devote the day to the establishment and adornment of public grounds, to the restoration of our wasted forests, to the repair of every defacement which makes this commonwealth less beautiful than it should be, so that we may not only have it appear the nobler in our own time, but that we may hand it down to our children the statelier and more fruitful for our care."

A circular has been prepared by Professor B. T. Galloway, and issued by the Department of Agriculture, on the treatment of nursery stock for leaf-blight and powdery mildew. The Bordeaux mixture and the ammoniacal solution, both of which preparations have been often described in this paper, are alone commended for use. The circular gives directions for applying these remedies to the various kinds of trees for the different diseases and gives illustrations of the most effective pumps and nozzles which have been devised for spraying. Apple-seedlings, it is stated, can be treated with the ammonia solution five times at a cost of eight cents a thousand, while the Plum, Pear, Cherry and Quince can be treated six times the first season with the Bordeaux mixture for fifty-five cents a thousand. These are certainly inexpensive remedies, and they are reported to be very effective. This little circular of eight pages will be forwarded by the Department to any nurseryman or fruit-grower on application.

It is now possible to add a few facts relating to the lamented Maximowicz to the short note which appeared a few weeks ago in these columns at the time of his death. The information is gathered principally from a notice published in *Nature* on the 12th of March, from the pen of Dr. Otto Stapf. Maximowicz was born at Jula in 1827, and was educated in St. Petersburg. At the age of seventeen he entered the University of Dorpat, where, after completing his studies, he was appointed assistant to the director of the botanical gardens, a post which he continued to fill until 1852, when he was made conservator of the Botanic Garden at St. Petersburg. A year later he started on a voyage round the world on the frigate Diana, being entrusted with the duty of gathering living plants for the St. Petersburg garden. On this journey he visited Rio, Valparaiso and the Hawaiian Islands. The Crimean war compelled the Diana to seek a Russian port, and the nearest was De Castris on the coast of Manchuria. Maximowicz was obliged to leave the ship, and decided to explore the basin of the Amour and the adjacent region, then little known. This task he carried out under great difficulties and with severe privations, and returned to St. Petersburg through Siberia in 1857. He traveled in Manchuria again in 1859 and 1860, visited Jesso in 1861, Nepon in 1862, Kiu-siu in 1863, and returned to Europe by sea in 1864. In 1869 he was appointed Botanicus Primarius of the Imperial Botanic Garden at St. Petersburg, and was entrusted with the care of the herbarium of the Academy. Those who had the advantage of Maximowicz's acquaintance and friendship will feel, with Dr. Stapf, "that he was a noble, high-minded nature, a highly cultivated scholar in almost every branch of learning, and a gentleman in the truest sense of the word."

TABLE OF CONTENTS.

A National Reservation at the Head-waters of the Mississippi.

In the eighteenth annual report of Professor N. H. Winchell, State Geologist of Minnesota, it is suggested that a state park should be established, and the location especially favored is the region about the Itascan source of the Mississippi River. Here are the prime attractions of many lakes, rivers and streams of pure water which are found where the tumuli of the glacial epoch formed depressions and reservoirs such as mark its moraines. Besides this, it has much historic interest as a region of adventure since the days of Lieutenant Allen, of Schoolcraft and of Jean Nicollet.

This recommendation of a great forest-reserve, which might include the head-waters of the Mississippi, the St. Lawrence and the Red River of the North, has more than a mere local importance. In the first place, a dense forest on the north-western highlands of Minnesota, or, as it is known, the Height-of-Land region, which constitutes the divide between the Red River and the Mississippi, would be of great value in preserving the water-supply of these great rivers. The land here consists of rolling, gravelly drift-hills, with many small lakes which have neither inlet nor outlet, while at a lower level there are springs and lakes, with under-ground supply, which constitute the remotest sources of the three great drainage-systems of the continent. No doubt, if all these lakes and streams and reservoirs could be protected from sun and wind by dense coniferous forests, which would also protect the ground from deep freezing and the snow from melting rapidly, this would help to make a more uniform distribution of water. It is well known that, in the woods, ground which was frozen in the fall will thaw out under deep snow, and the snow will gradually settle, thawing underneath, though the temperature above it may be below freezing. While these conditions prevail in the deep woods, on the prairie, but a few miles away, where the winds have full sweep, and the ground is blown bare, the frost is often from five to fifteen feet deep, and may remain in the ground until June or July. Meanwhile, the melted snows with the spring rains have run off from the surface, instead of settling into the soil. The great floods in the Red River valley, which is practically treeless except near the heads of its eastern tributaries, follow cold winters with deep snow, and occur in April and May as the snow melts.

For the purpose, therefore, of protecting our water-supply there are few regions in the United States where a forest-reservation could serve a better purpose. It should be remembered, too, that fires started by Indians and settlers run over this drift-region, through the forests of Norway Pine, Jack Pine and Poplar in front of the lumbermen. It is probable that, west of the Mississippi, as much log-timber has been destroyed by fire during the past thirty years as has been cut. If a reservation could be held here, while some of this timber remains, an experiment in systematic forestry might be made, with a reasonable chance of proving that it could be conducted with profit. If this is delayed for a few years, instead of having timber and young growth to start with, nothing will be left but worthless barrens throughout all this elevated region, and, indeed, these barrens cover a considerable portion of it already.

This proposed reservation, which should include Itasca Lake and the tributaries above its outlet, is a basin of unusual beauty, abounding in mineral springs as well as in typical moraines, drift-hills and lakelets. It is from 1,200 to 2,000 feet above the sea-level, and is, substantially, a non-agricultural region, although not too cold for farming. The hills are covered with the growth of the trees named above, where they have not been destroyed by fire, and there are forests of Tamarack, Spruce and Fir in the low-land. It is mostly unsettled yet, but it may be impossible in Minnesota to secure an unbroken reserve that would cover all the land which should be held in timber, for, scattered among the forests, there is land here and there which could be profitably tilled. But there is little doubt that it would be wise to withhold all the timber-land and brush-land of the state from settlement until it should be examined and the question of its adaptability settled. The present practice is to enter the land, strip it of its timber, and then, if it is not good agricultural land, to abandon it to annual fires. In this way millions of acres are made non-productive. There are at least 9,000,000 acres in northern Minnesota, at a rough estimate, which could be always more profitably kept in wood-land than in farm-land, while the entire 30,000 or more square miles which are in timber and brush should be protected from fire and held for producing timber until it was actually entered for farm-cultivation.

The senate of Minnesota has already passed a series of resolutions, which were prepared at the suggestion of the Minnesota State Forestry Association, petitioning President Harrison to set apart a vast tract of unoccupied and non-arable lands which lie contiguous to the Lake of the Woods, to Rainy Lake and to Rainy River, for a great national park. There are 3,000,000 acres in a compact body in that section, and the Forestry Association urges that at least one-third of this be reserved. Recent law, as we have explained, empowers the President to set apart such reservations. No doubt, the friends of forestry in various parts of the country will be prompt to point out places where it may be wise to exercise this power. It seems to us that this high region of Minnesota is one which is certainly worthy of attention for this purpose.

The Boston papers announce that the Forester of that city is prepared to give shade trees to citizens who will agree to set them on the streets before their property, the recipients to supply at their own expense the labor and soil necessary to plant the trees. Theoretically, this sounds attractive; practically, if the offer is accepted by many people, the appearance of the city will be seriously injured, and the taste of the inhabitants for trees and tree-

planting will be checked rather than developed. It is a difficult matter to make trees thrive in cities; they must be carefully selected for the purpose, and special attention must be given to planting them if they are to struggle successfully against the hardships of a city life. Uniformity is essential in a street plantation, and uniformity can only be obtained by planting in one street trees of one kind, and by planting them all in the same way—that is, with the same amount of soil about their roots and equal chances for obtaining moisture. If each of a dozen men, living in the same street, should exercise his individual taste in selecting the tree to be planted before his door—one planting an Ash, another an Elm, another a Maple, the next a Spruce, a Pine, a Catalpa or a Sycamore—and if the trees are furnished with soil according to the intelligence or liberality of the individual planter, it will not require any very great expenditure of imaginative force to picture to the mind what this row of trees will look like at the end of ten years. A line of lamp-posts, each selected according to the fancy of the citizen in front of whose house it was placed, would be less grotesque and objectionable.

The decoration of city streets with trees is a proper and excellent thing; its importance is recognized in most of the great cities of the world, and in some of them it has been carried out in an admirable manner. It is a part of street construction, however, just as much as paving or the setting of curb-stones, and unless it can be done well under an intelligently studied system by the municipal authorities themselves, it had much better not be done at all. If the citizens of Boston feel any doubts with regard to the advantage of good street-planting over bad street-planting, they have only to compare their delightful Beacon Street mall with the older plantations at the eastern end of Commonwealth Avenue.

The Gardens at Monte Carlo.

MANY are the sins that have been committed in the laying out and building of American towns, but the greatest of all, perhaps, has been the neglect or defacement of their water-fronts. Whether the adjacent water is ocean or great river, lake or little stream, we seldom see its shores turned to the best advantage, and often they present a more deplorable aspect than any other part of the town. In New York tumble-down, malodorous, muddy wharfs, flanked by streets which are frequently pools of water, line a shore that ought to be encircled by well-built, well-kept piers, and even the precious little expanse of Battery Park is daily threatened with curtailment; in Boston the back yards of Beacon Street houses lie along the wide estuary where a stately, tree-bordered esplanade should have stretched; and the river or brook which intersects a country town is most often edged by rickety sheds or fringed with ragged weeds, and is spanned by bridges as perishable as they are ugly. Of late years public attention has, indeed, been directed to the subject of water-fronts, and much has been done to secure them, in the outskirts of great cities, against the disfigurement that has overtaken them in portions already built. The parks at Chicago have been laid out with a wise sense of the value of the lake-frontage. Boston has claimed for similar purposes certain stretches of the Back Bay Shore, and New York has constructed Riverside Drive and bought the water-front near Pelham. But there is need that more should be done in this direction and that we should learn from older countries the art of beautifying the water-fronts we are beginning at least to reserve. All foreign countries are full of examples of this art, whether it has been employed merely to dignify reaches of shore that must be put to commercial use or to create ornamental promenades and gardens. The quays at Antwerp are as good in their more prosaic way as the Thames Embankment in London. The Elbe at Dresden is not defaced by the structures that line its banks, though they are not all terraced promenades, but include steamboat-landings, private grounds, hotels and restaurants. At Rouen the chief hotels look out on a river crowded with shipping, yet look on a scene devoid of squalor or architectural meanness. At Lyons the great stream rushes between close-pressed ranks of tall buildings, yet a fine drive runs by it in many places, and everywhere the shore is agreeable to look upon. At Prague there is a truly magnificent series of wide esplanades upon which some of the finest buildings in the city have been placed, and a succession of bridges where the newest wrought-iron span does not seem out of artistic keeping with the famous great stone bridge which, until some of its arches were swept away last summer, had stood intact since medieval times. And so one might pass from land to land and town to town, only to find that everywhere the water-front is valued and everywhere is intelligently treated, with parks or avenues if possible, and if not, at least with respectable buildings and cleanly shores.

The picture we give on p. 200 shows a peculiarly charming treatment of a water-front. As possessing the only public gaming-house still open in Europe, Monaco would in any case attract a multitude of visitors. But its development would never have been so great, and it would never have drawn thousands of tourists who do not come for the sake of gaming, had its situation not been so marvelously beautiful. The town itself, and the promontory of Monte Carlo where the Casino stands, overlook from their rocky heights the vast blue expanse of the Mediterranean, and the gift of nature has been sedulously enhanced by the intelligence of man. The drives along the cliff-edge are admirably planned, and, like the Casino gardens, show what may be achieved when architecture and horticulture are combined by an artistic hand. Monsieur Edouard André, the famous French landscape-gardener, never did a better piece of work than here, and the effect of his planting has been increased by the skill of gardeners who have caused Palms and other exotic plants to grow with extraordinary luxuriance. The treatment is somewhat formal, as befits the neighborhood of stately buildings and the presence of perpetual crowds of visitors. But there is no monotonous regularity in the arrangement either of the terraces and balustrades or of the sub-tropical plants which give such a singular charm to the spot in the eyes of travelers fresh from the wintry north. We can imagine what such a shore would be were this an American watering-place. It would doubtless not be given up to utter neglect and dishevelment, but a wooden paling would probably replace the marble balustrade, board walks the gravel slopes and marble steps, badly chosen trees in inharmonious variety the orderly avenue, and a stretch of Coleus-beds the beautifully grouped shrubbery. Of course, the exact treatment appropriate at Monaco would not be appropriate in a northern American watering-place; but something of the same orderliness, dignity and beauty ought to be secured far more often than it is. And while, in American country places, picturesqueness, rather than symmetrical stateliness, is usually appropriate, there are cases where it would be best to try for the more formal architectural charm which distinguishes the Casino gardens at Monte Carlo.

How We Renewed an Old Place.

IV.—CLEARING UP.

THE forlornness of an old, neglected farm is largely owing to the condition of its trees and shrubs, which, being left to themselves, take on a tumble-down, half-dead look that often belies their real condition. A few decayed trees bring all the others into disrepute, like a grog-shop in an otherwise respectable neighborhood, and untrimmed shrubs are as unbecoming as unkempt hair.

When we came to examine matters at Overlea, as we named our acquisition from its command of the meadow, we found that a good sweeping and dusting would do wonders for it, and with that enthusiasm for setting to rights inborn in the New England breast, we prepared for a grand redding up.

While the grading of the knoll was going on preparatory to building the house, our factotum, appropriately named Blossom, since his function was to adorn the place, was busily employed in removing all the unsightly dead limbs from among the live ones, and in hewing down such old Pear and Apple-trunks as proved hopeless.

The logs and branches were dragged away to the wettest place in the meadow at the back of the knoll, and transformed into a corduroy road, by which one could pass dry-shod out into the rear street. This floating rubbish, supported by the tangled grass on the marsh, formed a foundation upon which, after inserting a plank water-way at the bottom, for the ebb and flow of the tide, we subsequently built a substantial carriage-road of stones and gravel, which now affords a back entrance to the stable and kitchens.

The palings of the fence were removed for kindlings, but the posts and rails were left to form a slight boundary until the hedges and tree-rows should be fairly established; the straggling shrubs were trimmed into better shape, the Box-arbor clipped and cleared of weeds, trailing vines were taught

once more the use of a trellis, and the grass was mown and raked clean of the last year's rowan.

Fierce war was made upon the Burdocks and Mint and Horse-radish that had squatted everywhere on the land; load after load of the accumulated rubbish of years was buried under the corduroy road, and hidden from view with gravel; the Pear-trees we carefully pruned and tied up, and the old Grape-trellis stiffened with new posts and lattices.

When all this was done, and it was no brief job, the place took on a civilized air truly surprising, but, like the boy's washing his face, which cost his father a thousand dollars, the felling of the first ragged old tree was an entering wedge of improvements that find no end.

The clearing up revealed unsuspected beauties and possibilities in the old place, and at the end of it we had taken an account of stock, and were aware that we had become owners of a treasure-house of enjoyments. But the charms and wealth of that old garden are "another story" which remains to be told later.

While all this spring and fall cleaning was going on, the heavy labor of grading was in progress. Teams and men were coming and going, heavy scrapers were plowing part of the little knoll down into the valley, and loads of gravel were being dumped to bring the slopes into proper form, the surface soil having been first removed to cover the future lawn. Week by week the work went on, till the very landscape changed its contours, as the removal of the crown of the knoll threw open to view, from the sidewalk, the fine sketch of green meadow and blue stream, once hidden from view by its cone.

When our much-interested critics found that we had chosen the site for our dwelling in an unexpected part of the grounds, their murmurs again reached our ears.

"Why in the world don't the doctor build up on top of the hill, where he can see everything, and be among neighbors?" sang half the chorus.

"If I had a lot of big trees like those Elms I'd get the good of 'em, and put my new house on the old cellar," echoed the antiphonal.

"Never can make anything better 'n a Shumack-bush grow in that gravel-pit," shouted they all together.

"Well, perhaps he knows what he's about," would interpose some friendly voice; "but it wouldn't be my way, anyhow. He'll find out, come to plantin', that he's got to have soil, even for a door-yard."

When it came to building the foundations, their distance from the highway seemed inordinate to most of these critics, but now and then we were reproached by the more ambitious for not leaving front enough. In fine, we came to be in full sympathy with the Old Man and His Ass of the fable; but being luckier than he in having a mind of our own, we did not end by pitching house and all into the water, as we might have been tempted to do from the multitude of counselors, in which, in spite of Solomon, there is not always wisdom.

Our firm conviction was that the hill, in spite of the commanding view toward the north, was too bleak and exposed a position to be pleasant for an all-the-year-round home; it was also too near the neighbors' lines, and too remote from orchard and garden.

On the other hand, tempting as the great Elms certainly were on a hot summer day, the lot at that end of the farm was quite too narrow for a house and stable such as we required. The knoll, though limited in area, gave us plenty of elbow-room, and from its elevation we overlooked the grassy swale on one side, with the hill for a background, and northward could view the ever-changing tints of the meadow, behind the gardens and the fruit-trees. Experience has confirmed the wisdom of our choice, and, in justice to our advisers, I will say that they now handsomely admit that, though they "didn't think much of the doctor's ch'ice, to begin with," they are now convinced that "he has got about the likeliest lot on the street."

Since publishing the first of these papers I have received various inquiries with regard to some of our experiments, which, perhaps, it would be well to begin to answer here, before going farther. One of the questions, which concerns the Willows, asks whether we are to make a hedge of them or allow them to grow up into trees. "If you allow the Willow-trees to grow up," asks my correspondent, "won't they shut off all your views; and if you don't allow them to, won't the labor and trouble of cutting them back every year be serious?"

In reply to this I would say that we do mean to let them grow into trees at their own sweet will, at least for the present. The knoll is so high, and the slope of the ground, from the foot of it to the edge of the place, so decided, that our veranda-floor is some twenty-five feet above the level where the Willows are set, so that they can grow for some years to come without becoming an annoyance. They are also quite a long distance away, as the line runs diagonally between us and the meadow. Should they ever become a serious obstruction, polling once in five years, we think, will keep them where we want them, as from our elevation we can look directly over the top of a very tall old Apple-tree which stands at the foot of the slope near the house, and a Willow in the distance will have to be quite a tree to be really troublesome. A vista cut here and there in the line will really enhance the charm of the prospect, but at present they are not more than fifteen feet high.

Another inquiry comes with regard to the preparation of the soil on the hill for the Pines.

Unfortunately, we did nothing in the way of making a bed for them beyond the process I have described. No doubt, they would have fared much better for a little feeding and more of them would have lived, but the hill was very steep and hard to get at, even with a wheelbarrow; and, besides, we had no soil to spare, for we needed everything we could get for the lawn and did not care to buy any for so doubtful an enterprise. We, therefore, tried our experiment under the sternest conditions. However, those tiny Pilgrim Fathers of the future forest stood the trial like little men. Some of them, it is true, died of consumption, and some of fever; but the survivors are growing tall and stout on their poor pickings and will do us credit yet.

There is one of them, nicknamed Episcopus, from its birthplace in the church lot, which is a beautiful illustration of that fable called Nature and Education, in "Evenings at Home," a book which was the delight of the childhood of a previous generation and an infinite bore to the present advanced infant.

I spied the poor thing one day hanging by one root to the side of a sand-hill, which was being graded to a smooth slope, and asked the men who were working there to let me have it. Though much ridiculed for its shapeless and unpromising aspect, it was given a comfortable shelf pretty well down on the slope and coaxed to hold its head up by various devices. Unused to kind treatment, this wayside waif, which had got used to growing nearly upside down, hung its head and sidled up against the hill, and seemed to find its branches as much in its way as the legs and arms of a guttersnipe in a parlor; but time and training and the neighborhood of Boston have their influence even on a Pine, and that clerical tree is now a very Bishop in erectness and dignity, having been lopped and pruned and tied to stakes till it puts the most symmetrical of the other Pines to shame by the vigor of its development, proving that if anything can "beat Nature" it is Education.

The consolation of a limited number of trees is that each one acquires an individuality, and their owner gets to know them as a shepherd does his flock. I wish every one could learn the way in which these little growing things take hold of one's interest, and people life in the country.

The forester of ever so minute a wood has a fund of enjoyment on his plantation that no unlimited order to the best of landscape-gardeners can ever give him. It is a fine spiritual exercise to bring the mind into sympathy with inferior organisms, and when one has fairly learned to love anything so stubborn and irresponsive as a tree, he has gained a step in mental development, even beyond that point won by a sympathetic understanding of his brother man.

However fond one may be of a flower-garden, I doubt if it ever yields quite so sturdy a satisfaction as the culture of trees. It is the difference between bringing up a girl and a boy—one all light, color, sweetness, a thing to be cherished and tenderly sheltered and nurtured; the other less outwardly winning, more obstinate in development, more independent and manly in habit, but more worth while; of positive pecuniary value when well grown; and formed, when symmetry and breadth are fully attained, to be of service in sheltering the weak and weary who seek protection in what Mrs. Gamp would call "this wale."

Hingham, Mass. *M. C. Robbins.*

Winter Studies of the Pine Barren Flora of Lake Michigan.—II.

IN some of the sphagnous bogs, or in the shallow water of sloughs on which the Peat Mosses encroach, we shall come on another shrub of the Heath family, *Cassandra calyculata*. Wherever found it grows in the greatest profusion. It is not quite an evergreen, but its oblong leaves are very persistent, and of a thick texture, giving it its common name, Leather-leaf. They fade to a yellowish or straw-colored hue in the winter, though some are purple or purple-tinged. The numerous ascending leaves are closely appressed to the stem at this season. This exposes their scurfy lower surfaces, cov-

ered with brown scales, an interesting feature of epidermal structure when examined by a magnifier, and a pretty object for an opaque mount. The stems of the Leather-leaf are about two feet high, and end in slender tips clothed with small leaves. These bear the flowers in the early spring, for it is one of the earliest to bloom. They are also peculiar in bending away from the axial line of the stem with a moderate curve, giving a graceful turn to the extremity. The Cranberry nearly always accompanies the Leather-leaf, but is not so restricted in range or habitat. It is seen in other localities, sometimes in the wet sands, where it seems to do well, showing a natural basis for the different conditions to which it has been subjected in cultivation. The species is *Vaccinium macrocarpon*, and the berries of all the vines I have seen here are spherical. They are scarce in winter, having been picked for market, or more often for domestic use, since the areas covered are too small to make their gathering of much profit. But when seen, there are few handsomer fruits than these large red or flesh-colored berries hanging from a slender stem, and made prominent by the pale sphagnous Moss among which the delicate vines creep. They are darker-colored in the winter, and the frost takes away some of their acidity. The small glossy leaves are changed to a light purple, and, as in Cassandra, are frequently turned so as to expose their lower surface, in this case smooth and glaucous.

There are other humble evergreens, almost herbaceous in character, but with leaves capable of enduring the cold of winter. They are mostly *Ericaceæ*, and are visible when the ground is bare. One of these is the Prince's Pine (*Chimaphila umbellata*). Its thick and glossy leaves, clustered on the short stems so as to form a kind of rosette, are as green and shining as in the summer. Very rarely I have found the other member of the genus, *C. maculata*, in the shade of Pines and Cedars. Its leaves, mottled with white blotches, do not shine like those of the other kind, but furnish it with one of its chief characteristics. The Checkerberry, or, as it is better known with us, the Wintergreen (*Gaultheria procumbens*), is abundant in suitable locations, generally in the shade or where the sand is damp. The leaves on some of the stems are green and glossy, but on many they have changed to a dark or vinous purple, so that a patch of these plants is quite variegated, but not as much so as in the case of the Bearberry. They are often furnished with scarlet berries, only partially hidden by the leaves, which adds to their variety and gives them prominence for fruit as well as leaves. This remains upon the plants till spring, and is frequently gathered for market, rather for its bright color and pleasant, spicy taste and aromatic flavor than as an article of food. Similar to the Wintergreen as to its scarlet berries, but quite different otherwise, is the Partridge-berry (*Mitchella repens*). This small trailing or prostrate vine, but a few inches long, is rare in the Pine-woods, growing sparingly on the richer shaded knolls, or creeping beneath the evergreens, where the soil is most productive. I find it oftener in this vicinity in the hard-wood forests, with a soil of clay or loam, in which it commonly takes the drier knolls as a place of growth. The leaves are green and shining, small, roundish and opposite. Its curious double drupes, of a sweet and pleasant taste, stay upon the vines a long time if they escape the notice of birds, and when in flower in June the fruit of the preceding year may be obtained.

Several kinds of Pyrola will be found when the ground is free from snow. As in Chimaphila the leaves are clustered near the ground, from the midst of which they send up a flower-stem in summer. The leaves are mostly oval or roundish, and often large for the size of the plant. *P. rotundifolia* has shining, coriaceous leaves, round or broadly oval; *P. elliptica* thinner and more delicate leaves, more elliptical in outline. But the two species are very closely allied, and appear to run together in their leaf-characteristics, both as to shape and texture, so that it is sometimes difficult to identify the species, the specific names not being diagnostic in this respect. Both species are common. *P. chlorantha* is much rarer, its small round leaves, rather thick and dull, so well characterizing it as to make it easy to determine in the winter-time. So of *P. secunda*, well marked by its thin, ovate, finely serrate leaves, more scattered on the low stems, and but little shining. Though met with more frequently than the last, it is somewhat rare. Both of these are more delicate plants, and with smaller leaves, than the two first mentioned. The conditions of growth of all are essentially alike, though *P. secunda* may affect drier situations, and *P. rotundifolia* those more damp than are habitual to the rest.

Another small plant with very bright fruit is seen now and then, the Dwarf Cornel, or Bunchberry (*Cornus Canadensis*). Its compact bunch of red berries, at the top of the low stems, is very prominent, and, since there are no leaves to hide it, the ground is fairly red where they grow in beds. It falls an easy prey to birds, which are very fond of the sweet and palatable berries. One more pretty evergreen vine sometimes delights the eye when a spot thickly covered with the slender, trailing stems of *Linnæa borealis*, the Twin-flower, is found. It grows in the dense shade of evergreens, and the tangled and matted stems, with small, roundish leaves, almost carpet the ground, and afford the botanist in themselves and their associations one of his choicest plants. This and the Dwarf Cornel, together with the stemless Lady's-slipper (*Cypripedium acaule*), when all are found in the cool, damp woods in blossom about the same time in early summer, bring to mind more vividly than any other plants in the barrens scenes from woods farther north. The places where they grow with the surrounding Cedars and Pines seem like spots taken from the foot of Lake Michigan and transferred to its head.

Englewood, Ill. *E. J. Hill.*

New or Little Known Plants.

Aster Tartaricus.

THERE is more pleasure to be had in the open air in North America in the autumn than at any other season of the year. It is the time of all others here to enjoy the garden and the woods, and we should lose no opportunity to increase the number of plants which are at their best at that season, and which can be successfully grown in our climate. There are many plants which are more beautiful in the autumn than at other times on account of the colors their leaves assume toward the end of the year, but there are not a great many which bloom in the autumn in comparison with the number which expand their flowers in spring or in early summer. Thanks, however, to Asters and Golden-rods the list is a fairly long one, and the flowers with which these plants enliven the autumn landscape are not without variety of form and of color.

It is desirable that they should be better known and their value for the garden appreciated more fully than it is now, in this country at least; and with this end in view we have already published figures of some of the handsomest and most distinct American species. The illustration in the present issue (p. 197) represents the end of a branch of one of the few Old World Asters known in gardens. It is an Asiatic species, and excels all the American Asters in the height to which it grows, in robustness and in the great size of the lower leaves, sometimes more than two feet long, and like the leaves of some great Silphium or Inula. The leafy stems, which are not developed until the end of summer or the beginning of autumn, shoot up rapidly sometimes, if the plant is well fed, to a height of six or seven feet, and then branching produce at the ends of the branches, which form immense, long, rather loose panicles, large, bright-colored, blue or purplish blue flowers. These do not open until the end of October or early November, or not until the flowers of all but two or three of our American Asters have passed; and if the season is favorable they continue to open until almost the end of November. A sheltered position must be selected, however, if flowers from the open ground are expected anywhere in the north after the middle of November, except in years when the coming of winter is exceptionally delayed.

Aster Tartaricus is blessed with a good constitution and a rapacious appetite; and it needs strong feeding and a deep soil into which to send down its long, stout roots; and, like most perennial plants, it gives the best results when the great clumps it soon spreads into are occasionally lifted, divided and reset in fresh soil. Treated in this way, this really noble plant will not fail to do justice to itself and to delight the owner of the garden who is fortunate to possess it, and his friends.

Aster Tartaricus is one of the best hardy herbaceous plants for supplying cut flowers for large decorations at the time of the year cut flowers are most difficult to obtain.

Foreign Correspondence.

London Letter.

Iris Robinsoniana.—The flowering of this plant at Kew is an event of considerable interest to English horticulturists, to whom its exceptional size and beauty were long since made known by botanists, but its flowers have never before been produced in England. It is larger in leaf and inflorescence than any other known Iris, the plant at Kew being seven feet high and six feet through, the leaves eight feet long by four inches in width, gracefully curved near the top and of a healthy glaucous green; they remain fresh on the plant several years. This specimen is growing in a sunny, airy position in the house where Agaves, Aloes, Dasylirions, etc., are grown, and it is planted on a raised mound which is kept fairly saturated by drip from a water-tap close by. It is about six years old.

The flower-spike is from five to six feet high, branched above and producing from 120 to 200 blooms which expand in slow succession, remaining open only a few hours. This species is a native of Lord Howe's Island, where it was found by Mr. Charles Moore, Director of the Botanic Gardens at Sydney, when on a visit to that island in 1869. In his report he stated: "A large Iridaceous plant, called the Wedding Flower, was found sparingly in two or three situations. Of this seed vessels only were obtained, but the flowers are described as very beautiful. . . . In appearance it resembles a large Morœa, but will probably prove a new genus." Bentham described it under the name of *Morœa Robinsoniana* in the "Flora of Australia." The expanded flower is about four inches across, pure white, except at the base of the larger segments, where there are some lines of golden yellow.

It is remarkable that a solitary species of Iris should occur in a small island off the east coast of Australia, thousands of

Fig. 35.—Aster Tartaricus.—See page 196.

miles away from any other member of the genus; for there is no species of Iris in the Australian continent, nor anywhere nearer than China. The South African *I. bicolor* (Dietes) and the North African *I. stylosa* are the most nearly related to this giant from Lord Howe's Island.

The Kew specimen is as ornamental without the flowers as the New Zealand Flax, *Phormium tenax*, and in countries where severe frost is not experienced the Iris would, no doubt, prove equally serviceable as a specimen for lawns, etc., as the Phormium is here.

According to an account of this Iris, published in the *Gardeners' Chronicle* in 1872, by Dr. Bennett, it appears to have first flowered under cultivation in the Sydney Botanic Gardens in 1871. It also bloomed in the hill gardens at Hakgala in Ceylon in 1885, and in the gardens of Mr. Dorien Smith, at Tresco Abbey, Scilly, in 1886.

Phajus Cooksoni ×.—The stock of this beautiful hybrid has been secured by the Messrs. Sander & Co., of St. Albans, where some of the plants are now finely in flower, some of the spikes being over two feet in height, and as stout both in stalk and flower as *P. Wallichii*. Evidently, Mr. Cookson's latest fine production is a first-rate garden Orchid, as it has consistently grown and flowered from the first as freely as one need wish, in this respect partaking largely of the nature of *P. Wallichii*. Of the other parent, namely, *P. tuberculosus*, the hybrid appears to have inherited only a large share of its beauty without any of its "miffiness." As Mr. Sander says, we need no longer bother about *P. tuberculosus* now we possess *P. Cooksoni*. Unluckily, however, the "we" in this case is only Messrs. Sander & Co.

Dendrobium Venus ×.—This beautiful hybrid was raised by Mr. N. Cookson from *D. nobile* and *D. Falconeri*, and flowered for the first time in May, last year. It is now again in flower at St. Albans. The habit of the plant is intermediate between the two parents, and it appears to be as free in growth as *D. nobile*. The flowers are as large as the largest *D. Falconeri*, and similar in color, but minus the yellow disc of the lip. Altogether, *D. Venus* is a distinct gain, and is certain to take a foremost place among the best hybrid Orchids of artificial origin. Mr. Cookson, evidently, does not waste his time and skill in operating upon Orchids that cannot produce anything worth having. He has raised two of the finest hybrids yet seen, namely, *Phajus Cooksoni* and this Dendrobium, besides many other beautiful things.

High-priced Orchids.—A portion of the collection of Orchids formed by Mr. Pollett, the well-known horticultural printer, was disposed of by auction in London this week, and some of the plants realized exceptionally high prices. Among them were *Odontoglossum crispum*, var. *Leopardinum*, a small and not very healthy plant, which sold for 100 guineas; *O. crispum*, var. *lilacinum*, fetched eighty guineas; *O. elegans*, thirty-eight guineas; *O. excellens*, thirty-six guineas, and *O. Hallii*, var. *magnificum*, thirty-four guineas. Several other varieties of *O. crispum* sold well; for instance, one called Bonnyanum, for nineteen guineas, Bickleyense for sixteen guineas, Pollettianum thirty-seven guineas. *Cypripedium Morganiæ* realized thirty guineas, *C. Schroederæ* seventeen guineas, *C. leucorrhodum* eighteen guineas, and so on. The unusual success of this sale is attributed largely to the colored illustrations of the best Odontoglossums printed and circulated along with the sale catalogue. Of course, Mr. Pollett's excellent judgment as an Orchid connoisseur, which led to his collecting only what is best among Orchids, gave buyers confidence. Scarcely any of the plants were what would be termed large specimens.

As a set-off against the high prices paid for choice cool Orchids I may mention the miserable prices realized by a large sale of East Indian Orchids from the collection of the Duke of Marlborough at Blenheim, which were disposed of by Messrs. Protheroe & Morris a few days ago. Big specimen Vandas, Ærides, Saccolabiums, Angræcums, Cypripediums and other tropical Orchids were sold for less than the pots containing them had cost, and they were good healthy plants, too. A democratic acquaintance remarked that buyers were justly boycotting a nobleman who had entered into competition with the struggling dealer, an allusion to the well-known trading character of the Blenheim collection.

Hippeastrums.—The collection of these plants in the Chelsea nurseries of Messrs. J. Veitch & Sons is now one of the great horticultural attractions in London. A large span-roofed house is entirely filled with the plants, and they now carry over three thousand scapes of flowers. The effect of these when expanded is magnificent. Every year brings new and improved varieties, the successes of last year being eclipsed by the successes of this. New crosses are made, seeds sown, and the bulbs grown on year after year, so that the thousands of plants sold are replaced by a successional lot, and there is never a gap. The brilliant results obtained in this field by Messrs. Veitch place them a long way ahead of all other breeders and growers of Hippeastrums. I have heard it whispered that the profits of Hippeastrum culture have proved exceptionally satisfactory at Chelsea. Apart from their commercial value, these plants, when well managed—and, according to Messrs. Veitch, few bulbs give less trouble—are almost without a rival among in-door bulbous plants. I am told that enterprising planters in the West Indies are buying some of the best of these plants for extensive cultivation under the favorable conditions afforded in some of those islands, with a view to supplying the European and American markets with Hippeastrums by the thousand.

London. *W. Watson.*

Cultural Department.

The Reticulated or Sponge-bearing Cucumber.

UNDER the name of "Luffa," or "Cucumber Sponge," we now import in compressed bales, from Japan and Egypt, the reticulated skeletons of two varieties of what Ebn Baitar, the Arabian botanist, twelve hundred years ago described as the "Luffah," taking his title from the Egyptian name of "Luff." Dr. John Veslingius, of Holland, in 1638, in writing a work upon the plants of Egypt, as a sequel to that of Prospero Alpini, describes, with two engravings, the Cucumber-plant that now furnishes the commercial Luffa of Egypt, under the title of *Luffa Arabum*, or *Cucumis reticulatus Ægyptius*. The Japanese and Egyptian commercial varieties so closely resemble each other that the pictures of Veslingius, which were taken from plants grown by himself, are excellent representations of the Japanese *Luffa macrocarpa*. Had he cultivated the Japanese variety, which comes to maturity much earlier, he would not have fallen into the error of describing the seeds as white instead of black. From a very early period the reticulated skeletons of *Luffa Arabum* were used by the Egyptians in their bath-rooms, and it is probable that the Japanese did the same with that of the *L. macrocarpa*.

Sponge-bearing Cucumbers may be found in a large number of hot countries, and vary in size from that of a plum to three feet in length. In some the skeleton is very thick and strong, and capable of being made of use in the household, but in the majority the netting is thin and delicate, and can only be regarded as a curiosity. Like ordinary Cucumbers, some are edible, and are grown for the table, while others are more or less medicinal, and are used as domestic remedies. As the reticulation forms at a late period, the Luffa, when of an edible sort, can readily be cooked as a vegetable when young; the rank odor of the fruit would be an objection to its use with us, but this has not availed much against the tomato.

But little attention has been paid by botanists, either ancient or modern, toward collecting, arranging and describing the class of cucumbers which is distinguished by bearing a subcutaneous or a complete internal skeleton. Under the name of Momordica, Cucumis, Pepo and Luffa we may find several varieties described in old botanical works, chiefly in Latin, Dutch and French; and may also discover that several, as the *Luffa Petola*, *L. acutangula*, *L. Ægyptica*, etc., have been very correctly represented by large plates.

The Luffa is fully entitled to membership in the Cucumber family, and is in no sense a Gourd, as it has sometimes been called. It is monœcious, having separate staminate and pistillate flowers, of which the former are much the larger, or more conspicuous; and the leaves much more closely resemble in form those of our common cucumber than do many in Egypt, Palestine and India, upon plants producing the best table varieties, some of which are much more like Cantaloupe-vines than Cucumbers, as we know them.

My first trial in growing Luffa-seeds was a failure, because I made the attempt with a variety that required so long a season in which to perfect its net-work, that frost came, even before it had begun to form. The fruits grew half a yard in length, and the vine was vigorous, but the season required was too long for this latitude. My second venture was with the *L. macrocarpa* of Japan, which produced fully matured fruits in five months from the day of planting. This is the best sort to grow in a temperate climate, and bears the most symmetrical of all the sponge cucumbers; the fibre of the netting is coarser than that found in the Egyptian variety, and not so well adapted for use as a scrubber in bathing. *L. macrocarpa* bears cucumbers from thirteen to fifteen inches long, and some of them are very nearly straight. The vine is a vigorous

grower, and, in favorable seasons, bears a fair crop of cucumbers. In very dry weather there will be a scarcity of pistillate flowers until after a supply of rain, when they will appear in almost every joint. The cucumbers develop rapidly, and, but for the slow growth of the vine in the early season, would come to maturity in large proportion ; as it is, however, there will be many fruits that will only be partly grown when frost arrests their development. Much time may be saved by having the plants grown a yard or two in height in a greenhouse, and then setting them out on the 10th of June ; as the plant is tropical, it will stand the full heat of the sun all day without drooping, and grow all the better for it. My best success came from planting against a trellis on the south side of a wooden building, with an all-day exposure to the sun.

Next to *L. macrocarpa*, the wild Cuban does the best in Philadelphia, as it comes to maturity early, and grows much larger than in its native island. The Egyptian variety grows well and sets many fruits; but these are late in maturing, so that as yet I have not produced any with black seeds. The Petola I have not tested yet ; it looks promising in its picture, and is one of the few that produce a good reticulation. A hybrid between the Japanese and Egyptian varieties might readily be produced with a brush, and, theoretically, should be finer than the Japanese in its netting, and shorter-seasoned than the Egyptian. Hybridization should be produced each way between the two parents, and plantings tested with seeds from several experiments, as this way of producing new varieties has much uncertainty in its final results.

The first Luffa sponges sold in this city were grown from Cuban seed ; the second came from Japan, and the third from Cairo, in Egypt. Japanese seed were grown in Louisiana before there were any sponges of *L. macrocarpa* for sale here, and my first stock came from that state. Under the name of the Bonnet Gourd and Dishcloth Gourd, this and the Cuban Luffa are now well known in several of the southern states, although, as I have stated, the name of Gourd is a misnomer. Bonnets are sometimes made from the opened sponges, shaped out with some woven fabric, but the entire head-covering was not produced of the net-work until the large white Luffas of Egypt furnished the material for cutting and fitting.

The *Cucumis reticulatus* of Egypt is grown in large quantities, and has become quite an article of commerce, being exported mainly to England and Germany, the packages containing 1,000 to 1,500 each ; but a small proportion of these are sponges of the whiteness and quality that indicate a proper care in preparation. When a sponge cucumber is dried whole the netting is easily separated ; but its fibre will have a brownish color and will have lost much of its tensile strength. Naturally, the reticulation is of silvery whiteness, and this can only be preserved by a proper method of cleaning it from rind, seeds and pulp when the cucumber is matured, but still green ; and the whole must be done at one operation or the sponge will change in color. When a luffa has reached its maturity of growth it will be known by its green rind lightening in color and becoming more dry ; it should then be cut off and hung up in the house for a week or more until the juice in large measure dries out of the rind. The cucumber should then be pared and the cap at the lower end removed, which will open the seed channels ; it should then be kneaded and squeezed under a large pan of hot water until the seeds and pulp are washed out. When fully ripe the seeds are jet black, and will number from 400 to 600 in very large fruits. When the reticulated skeleton has been well cleaned, hang it up on a pin-hook and string to dry in-doors, when it should become of silvery whiteness and weigh three-quarters of an ounce to an ounce.

By exposure to the air, even when kept in darkness, the whitest luffa-sponges gradually change to a light orange-yellow. This color is largely soluble in hot water with soap, and much of it may be washed out, leaving the fluid of a decidedly yellow tint and the sponge much lighter in color. Sponges in frequent use become of a light grayish white tint and slowly weaken in fibre, particularly in the outer or circular layer, which is not so tough as the internal longitudinal one. The sponges are quite durable when compared with those obtained from the sea, and are odorless when well washed ; no fabric when wet has as decided an effect as a rubefacient upon the skin, and care must be taken that it does not take too deep a hold where the surface is young and tender. For delicate skins and children the immature skeletons should be selected, or the small end of the mature ones, which is much finer in fibre than the base.

My record of varieties in the *Cucumis reticulatus* amounts to twenty, and these belong to Japan, Moluccas, China, India, Africa, Spain, Cuba, Brazil and Mexico. The tests thus far made go to show that but very few of the varieties will perfect fruit in this latitude, and that it is useless to grow the others, except for ornament or curiosity. The Macrocarpa stands at the head of the list, as it has been repeatedly grown ; the Acutangula, as a curiosity, grows equally well ; the Cuban comes to perfection ; and by starting under glass, the Egyptian may likewise ; the Petola and Mexicana are yet to be tested in a favorable season. Some others have grown well, but the character of the cucumbers does not make their propagation desirable.

The plants designated are quite ornamental and interesting, with their beautiful leaves, large staminate flowers and hanging fruits, borne sometimes as high as a second-story veranda. The Egyptian flower is about four inches in diameter, and others are nearly as large. The staminate-buds grow in bunches and bloom singly, so that the vines are constantly in flower ; all of the blossoms are a bright yellow. The pistil of the productive flower develops into the point of the cucumber, and the long ovary into the fruit, the sepals of the blossom long remaining attached.—*Dr. R. P. Harris before the Pennsylvania Horticultural Society.*

Some Early Native Flowers.

AMONG the first of our wild flowers to bloom are two which are somewhat similar. One the Wind Flower (*Anemone nemorosa*), the other the little Rue Anemone (*Anemonella thalictroides*). So far as their individual attractiveness is concerned it would be hard to choose between them. Both are charming little plants, with white or pinkish flowers about an inch wide, the former ranging rather further to the north than the latter. In transplanting, the latter is much the easier to manage, and, if taken up at almost any season, it will thrive in any ordinary soil. The Wind Flower demands more care, preparation of soil, and is most safely moved in late summer or early autumn. It needs more time to become established than the Rue Anemone. The best soil for such a plant is the one as nearly as possible like that which it naturally selects, namely, a dry loam. When this is not at command a compound of sand, leaf-mold and clay, in about equal parts, well placed under and around its roots, is a good substitute.

Our two Hepaticas (the one with round, and the other with sharp-lobed leaves) have long been appreciated abroad. The first has a variety of tints, from a blue or purple to almost pure white. The other has about the same variety of color, with the addition of pink. Well-established clumps of them in a thinly shaded situation make a display of early bloom which can hardly be excelled by any plants of their season. They like a clay loam with a moderate amount of well-decayed barn-yard manure mixed with it. The flowers will be much more satisfactory in thin shade than in the open sun or in a dense shade, though the plant will do fairly well in either. They may be transplanted at almost any season, yet it takes time for them to become well-rooted, and fairly at home.

The Dog's-tooth Violets, or Adders' Tongues, as they are often called—a term which, I believe, is more common in New England than in the west—are all early bloomers, and, with the several species and varieties from the Pacific coast, one or two from the south, our eastern yellow *Erythronium Americanum* and the white one (*E. albidum*), we have a fine representation of natives in this genus. They are always welcome harbingers of spring, not only because they are early, but because they have attractive flowers and foliage. *E. Hendersoni*, with its purple and yellow flowers, is probably the most showy of them all, but others from our west coast, such as *E. Smithii*, *E. citrinum* and *E. giganteum*, are also very attractive when in flower. From Texas we have a near relative to the white Dog's-tooth Violet, *E. albidum*, var. *coloratum*, which is quite hardy in New England, and is a much better bloomer that the typical plant. Its flowers have a purplish tinge. The proportion of flower-bearing bulbs of *E. Americanum* and *E. albidum*, even in their native haunts, is often very small, and in cultivation it usually grows more so, especially with the latter. In taking up the bulbs of these species I have noticed that the largest, which are usually the flowering bulbs, are generally at the greatest depth, often ten inches below the surface, and I believe that this is why, in cultivation, they are so inclined to divide up into offsets, one large flowering bulb making several smaller ones which do not bloom the second year. I have, in one or two instances, noticed that deeply planted bulbs were less inclined to divide up in this way than shallower set ones, and I think this habit may be partially overcome by deep planting. The best season for transplanting Dog's-tooth Violets is after their leaves begin to turn yellow.

Twelve species and five varieties of Trilliums are native to North America, all early bloomers, and each having special merits to give it interest in any collection. Some of the more showy, such as one would select for an early bed, if the entire list were not used, are *T. nivale*, *T. grandiflorum*, *T. sessile*, var. *Californicum*, all with white flowers; *T. sessile*, with dull purple flowers, but having very large, handsome and durable foliage, and *T. stylosum*, with pinkish white flowers. The white-flowered variety of the purple Trillium is also handsome. These are all easy of culture. The Painted Trillium (*T. erythrocarpum*) should be added as one of the finest, but it is the most difficult to grow, requiring deep planting, excellent drainage, and a light soil rich in leaf-mold.

The Spreading Globe Flower (*Trollius laxus*), with its abundance of creamy or greenish yellow flowers, should not be forgotten among the early bloomers. It gives variety of color, and the large flowers continue for a long time. It is quite desirable for a thinly shaded situation.

The Virginia Cowslip (*Mertensia Virginica*), with its handsome panicle of pale blue flowers and its rich dark green foliage, and the so-called American Cowslip, or Giant Cyclamen (*Dodecatheon Meadia*), with rose-colored or nearly white flowers, are both early and attractive species, requiring no special treatment beyond a rich soil and ordinary culture.

Botanical Garden, St. Louis, Mo. *F. H. Horsford.*

Fig. 36.—The Gardens at Monte Carlo.—See page 194.

The Snowflakes.

THESE plants belong to the genus Leucoium of the *Amaryllidaceæ*, a name derived from two Greek words signifying white Violet; and their fragrance is almost as strong and sweet, while the common name indicates their general resemblance to the Snowdrop.

The genus comprises some eight or nine species of bulbous plants, including those formerly known under the genera, Acis and Erinosma, only two or three of which, however, are worthy of general attention. The Summer Snowflake (*L. æstivum*) is one of the best. It is a native of southern and central Europe, and has been found as far north as the south of England. This plant is perfectly hardy in Massachusetts. It attains a height of from eighteen inches to twenty-four inches. The bulb is comparatively small and roundish; the leaves narrow and bluntly pointed. The fragrant, drooping, campanulate flowers are three-fourths of an inch wide, and appear in early summer, six to nine in a cluster, at the top of a spathaceous scape which equals the leaves in length. The perianth differs from that of a large Snowdrop in having all the white, green-tipped segments of equal length.

L. autumnale, the Autumnal Snowflake, is an elegant little plant, which, unfortunately, requires the protection of a slightly heated greenhouse or frame during the winters of this region, but it will doubtless prove quite hardy in more favored parts of the country. The oblong bulb supports three or four linear-acuminate leaves, about three inches in length, which usually appear, when the reddish scape has already attained its full dimensions, early in autumn. The flowers, usually borne two on each scape, are nearly half an inch in diameter, of similar form to those of *L. æstivum* and white in color, with a profuse display of deep rose around the base. The beauty of its tiny blossoms, combined with its free-flowering propensity, would render *L. autumnale* a very desirable addition to any garden in which it could be safely trusted. It is native on the sand-hills of Algiers, Spain and Portugal, and was introduced to cultivation from the latter country in 1629.

Still more attractive than either of the above species is *L. vernum*, the Spring Snowflake; it is the best of the genus, though hardly of such vigorous constitution as *L. æstivum*. The flowering season opens from two to four weeks later than that of the earliest Snowdrops; but it is much larger, and is, among spring-flowering plants, the gem of all the garden. It is from nine to twelve inches high; bulb oval; leaves six inches long by half an inch wide, obtuse; scape bearing one or two flowers an inch wide, but otherwise like those of *L. æstivum*. It is a native of moist, shady localities in many parts of central Europe, and was cultivated as early as 1596. A variety of this plant, generally named *L. Carpathicum* or *L. biflorum* in gardens, is distinguishable from the species in the very frequent occurrence of two-flowered scapes, and in the divisions of the flowers being tipped with yellow. It was introduced into England from the Carpathian Mountains in 1816. The plant is quite as pleasing as *L. vernum*, and it blooms somewhat later.

The Spring and Summer Snowflakes like good soil, partial shade, and a moist rather than dry situation. They are most effective when planted in large masses. Once planted, the latter may be left to shift for itself, but the less sturdy character of *L. vernum* and variety renders an occasional inspection of their bulbs a necessity. *L. autumnale* should be planted in pots, using sandy loam, where the winters are too severe to

permit of its exposure, and placed under cover until spring, when the pots may be plunged in a dry sunny position, such as is found in the elevated portions of a rock garden. Remove it to the greenhouse, or other place of security, again before frost, and propagate by separating the bulbs after the completion of growth.

Cambridge, Mass. *M. Barker.*

Palms.

THIS is a good time for repotting most Palms, except where a shift was given late in the fall, and even in such case the plants would be benefited by the removal of some of the surface soil and the application of a top-dressing of fresh compost. Some judgment is required even in the simple operation of potting. For instance, if the rapid growth of young plants is desired, the compost should be made rather light and rich by the liberal use of peat and old manure, a very satisfactory fertilizer, and one in good condition for potting, being the spent manure from an old hot-bed. When such manure is used it may be added to the potting-soil in the proportion of one-fourth of the whole mass. For plants almost large enough for their quarters the soil may be heavier and poorer, the deficiency of plant-food being made up with an occasional dose of liquid manure, which will serve to keep up the color of the foliage.

Light-rooting Palms, such as *Cocos Weddeliana*, *Latania aurea*, *L. glaucophylla* and some others, grow best in a soil largely composed of peat and sand, but, for a majority of the strong-growing kinds, a good loam, well enriched, will be sufficient. The drainage of the pots should always allow the free escape of surplus water, but, to secure this, a few crocks, properly placed, concave side down, will do more good than a handful that are thrown into the pot indiscriminately. The question whether firm or light potting is better for plants of this class can hardly be answered directly, for much depends on the character of the soil used, but moderately firm potting is usually good practice, although it must be borne in mind that the coarser the roots the more loose should be the soil, within a reasonable degree.

Some attention should now be paid to shading the houses, else some of the tender species will suffer, and as the growing season for most of the vegetable world comes on, new vigor seems to possess the various insect pests to which Palms are subject. The worst among these are the numerous varieties of scale, all of which are troublesome and are best dealt with by careful washing. Red Spider may be eradicated by thorough syringing, and Thrips by sponging with tobacco solution or by fumigation. Mealy Bug may be more easily disposed of than some of the varieties of scale, and in the same manner.

Most Palms enjoy thorough watering, and as more active growth takes place, a copious supply will be required by all well-rooted specimens. In case some particular specimen does not make satisfactory progress, owing to an unhealthy condition of the roots, it may be improved by washing out the roots and then repotting in as small a pot as possible. This treatment is, however, only recommended for plants of especial value, as the various species that are in common use are so readily and cheaply obtained that it does not pay to nurse unhealthy ones.

The species to which reference has been made above are notably handsome ones, *Cocos Weddeliana* being the most useful dwarf Palm that has been introduced to our gardens.

Holmesburg, Pa. *W. H. Taplin.*

Orchid Notes.

ARPOPHYLLUM GIGANTEUM.—Flowers are the attraction of most Orchids, but in the subject of this note these are supplemented by foliage of pleasing form and color. The massive spikes develop flowers profusely, and they keep in good condition about two weeks if the plant is kept in a cool, shaded house during the flowering period. It is a native of Guatemala and Mexico, and has been grown in England as an exhibition plant for many years past. The slender pseudo-bulbs, from eight to twelve inches high, bear at the top a single coriaceous leaf, from eighteen to twenty-four inches long by two inches wide, pointed, dark green, and elegantly arched. The spike is boldly erect, and emerges from a brown sheath, from four to six inches long, and beyond it the spike is some twelve inches long. The flowers are half an inch long by one-fourth of an inch wide, and closely packed on the portion of the scape above the sheath, as many as 150 having been counted on a space measuring five inches. They are not particularly interesting individually, but in the aggregate they form an attractive cluster, in which a reddish purple color, deepest in the lip, prevails. This plant is found growing on trees at a considerable elevation, and on this account it will not require a great amount of heat, a maximum temperature of eighty degrees during the growing season, with one of sixty degrees when the plant is at rest, proving sufficiently high. It requires plenty of light, a position close to the glass, and when in an active state a plentiful supply of water. The new growths appear simultaneously with the spikes any time between March and May, and they are often seriously injured by keeping the plants dry at that time in order to accelerate the development of flowers. The plant succeeds well in a basket, and it should not be allowed to shrivel with dryness, even after the completion of growth.

CATTLEYA AMETHYSTOGLOSSA.—The last flowers of this gorgeous Cattleya faded with the month of March, after having preserved their richness of color about four weeks. The plant is of striking appearance, and attains a height of some three feet. The erect scape protrudes from a greenish white sheath at the summit of the pseudo-bulb; it is scarcely more than twelve inches high, and two-thirds of its length is enveloped in the sheath, the flowers—twelve to fourteen in number, and each from three to five inches across—being arranged around the exposed portion. The oblong and pointed sepals are lilac-tinged, white, profusely spotted with rose; the petals are broader, rounded at the tip, and, with larger blotches of rose, similar to the sepals in color. The lip is deep purple, with numerous lines of a still darker shade. A number of these dense clusters give the plant a grand appearance, and they develop freely under easy treatment. The heavy head of the plant, as compared with its base, at once suggests a pot as the most convenient receptacle for its roots. Its side and bottom should be well perforated. The plant might also be grown in a basket, but unless this were exceptionally deep, and affording much surface for the clinging roots, the gain would be more than counterbalanced by the plant's liability to topple unless supported. A mixture consisting of fibrous peat, charcoal and crocks, with a good coating of sphagnum, suits this plant very well. A stove temperature and a moist condition about the roots and in the atmosphere are needed during growth; heat and moisture should be somewhat reduced when growth has been completed. The plant should be kept as near the light as possible at all seasons, but sunshine should be excluded during the growing period.

Cambridge, Mass. *M. Barker.*

Transplanting Hardy Ferns.—Spring is, no doubt, the best season for transplanting hardy Ferns, especially when the work is done in early spring. It too often happens that the transplanting is put off until the young and tender fronds have well started or are half-grown, and then it is next to impossible to handle them without injury. After this stage of growth has been reached the transplanting had better be deferred until the fronds mature, and then cut them back one-half or one-third before removal. Some species, like the Climbing Fern (*Lygodium palmatum*), do not transplant well in autumn, and seem to require spring planting. The growing points or buds of the Maiden-hair Fern (*Adiantum pedatum*) are extremely tender and brittle at any time in spring, and when they are packed for shipping great care is needed, or the plants will fail. Few plants pay more richly for the labor spent on them than the hardy Ferns, for, unlike most flowering plants which are attractive only in their flowering season, Ferns are a delight the whole season through. And then they can be put away in the shade, where other plants would not live. Many a dark, not to say an untidy, corner about American homes might be made attractive, and even beautiful, if planted with hardy Ferns and other shade-loving plants.

St. Louis. *H.*

Decay Spots upon Leaves.—Plants with large leaves are often much disfigured by blotches that appear at any place upon the foliage. The cause of these spots is sometimes not easy to determine. An otherwise perfectly healthy Calla-leaf may have a brown spot an inch long and a half-inch wide near its centre, and with no apparent reason for its existence. The probabilities are, however, that some days before a withered blossom of a plant above it fell upon the leaf, and, remaining there for a time, began to decay. Soon after, the force of the water from the hose drove the blossom off, but not until it had left the seeds of decay in the leaf. In other words, the fungus, usually a species of Botrytis, while flourishing upon the rich succulent substance of the blossom, sent its threads into the leaf below and began the decay that finally ruined the leaf. The Botrytis fungus is not usually accused of making

its attacks in a direct manner upon living tissue, but it does not hesitate to pass from the dead to the living when conditions favor it. In other words, the Calla-leaf is safe against the attack of the spores of the Botrytis, but when the vigorous filaments of well-established plants present themselves the resisting power is not sufficient to overcome them. If we had found the remains of the blossom in the centre of the dead blotch it would have been natural to ascribe the cause to the flower or the fungus it harbored, but in many instances the leaf blackens without any apparent cause. Nevertheless the cause remains the same, for the source of contamination had been removed before the decay in the leaf had become perceptible. The practical conclusion is, that no opportunity be given these half-way parasitic fungi to gain an entrance to healthy plants. The gardener knows how important it is to keep all dead leaves and decaying blossoms from contact with the healthy parts. Neatness as well as health demands that the living be kept apart from the dead.

Correspondence.

Notes from Passaic.

To the Editor of Garden and Forest:

Sir,—"American trees for American gardens," enthusiastically exclaimed a friend while making a tour through the ranges of the Blue Ridge, where is to be found such a variety of handsome trees and shrubs, only partly appreciated by our planters. Very much the same enthusiasm for American flowers moved me a few days since as I strolled through the hill-side garden of Messrs. H. Meyer & Co.'s Passaic Nursery and found many of our native plants well established and in bloom. *Shortia galacifolia*, in flower there, needs no introduction to the readers of Garden and Forest, but it cannot be too often told that this plant is one of the choicest of our native flora. Entirely hardy in this latitude, with beautifully colored firm, persistent foliage and dwarf habit, add to these charming fair-sized flowers, bell-shaped, with graceful curves, petals white, with the most dainty rosy flush borne on pink peduncles, you have a plant to excite enthusiasm. A mass of this gives distinction to the choicest border, and it will flourish, which is a merit not possessed by all Alpines. *Trillium grandiflorum*, *T. stylosum* and *T. pusillum* were well in bloom and happy in the not too dense shade. Erythroniums are now at their very best, with their beautiful maculated leaves and graceful flowers—among them the yellow "Dog's-tooth Violet" (*E. Americanum*), *E. grandiflorum* and *E. giganteum*. The white flowers of *Dicentra cucullaria* were just showing above the daintily cut leaves, while *D. eximia* showed racemes of red above its attractive foliage. If Hepaticas and Sanguinarias were rare flowers perhaps they would be appreciated by us as their beauty deserves, but looking through this hill-side garden and noting the dainty beauties in bloom, and Cypripediums, Sarracenians and others just pushing, and thinking of the succession of native flowers unmatched in their various seasons, the thought was forced on me that we do not appreciate our own treasures. Our hardy plantsmen, however, are finding a larger demand for native plants, and they are a feature in most nurseries. It is curious, though, that if seeds of any but the most common native plants are desired they must be ordered from abroad.

In the more open part of the nursery I noticed good breadths of Aubrietias in full bloom—*A. Græca*, *A. deltoidea* and *A. macrostyla*, the last distinctly the best of the purple varieties, and making a fine mat. *A. Leichtlini* may be a break toward the red, but its dull red flowers are of a color which can be spared from the garden.

Mertensia Virginica (Lungwort) was showing its gracefully drooping flowers; a most valuable plant in not too conspicuous a position. Hellebores are still in full bloom, *H. niger* in varieties and *H. orientalis*, both untouched by the severe winter. *Saxifraga cordifolia* is opening its rose-colored flowers, and is one of the best of the section, but its broad leaves sometimes suffer in hard winters. It will well repay protection. I think it has before been noted that Doronicums are the best early-flowering, large yellow composites. Here *D. Clusii*, *D. plantigeneum excelsum* and the variety Harpur Crewe were in bloom. The latter seems a good form of *D. plantigeneum excelsum* (and the name is much easier). *D. Clusii* is very similar in form, but its finely cut petals are slightly recurved. But space forbids my mentioning all the blooming plants, and I can only note *Arabis alpina variegata*, with flowers like the type, but with white variegated foliage. Great breadths of Narcissi, such as Pallidus Præcox, Golden Spur, Henry Irving and Sir Watkin, give the principal effect of color at this early season.

I noted *Heuchera sanguinea* in the open, strong and vigorous, and only the lower leaves scorched. Evidently this plant may be considered reliably hardy.

Elizabeth, N. J. *G.*

Botanical Nomenclature.

To the Editor of Garden and Forest:

Sir,—In No. 162 of Garden and Forest (vol. iv., pp. 165, 166), Mr. George B. Sudworth, of the Forestry Division, United States Department of Agriculture, discusses the use of binomials composed of specific names identical with generic, brought about by the rigid adherence to the rule of maintaining the oldest specific name, and records himself as in favor of the practice. He alludes to its non-acceptance in my "Catalogue of the Plants of New Jersey," but expresses the supposition that I had good reasons for not using it there. He is in error. I had no good reasons. I was deterred from accepting the well-known practice of zoölogists from simple conservatism.

When, in 1887, the committee of the Torrey Botanical Club which was appointed to issue the "Catalogue of Anthophyta and Pteridophyta growing within one hundred miles of New York," decided on taking the stand of maintaining original specific or varietal names, it was well aware of the revolution which such a measure would suggest, and had no idea as to the measure of support which such a suggestion would receive. Up to that time Professor Greene and myself were the only American botanists, I believe, who had recorded themselves in favor of the practice, and the committee deemed it wisest to await the result of its work before going further, deciding to throw out generic names identical with specific, and not to take up a considerable number of genera whose claim to priority was perfectly well known. In my New Jersey catalogue the nomenclature of the Hundred-mile Catalogue was closely followed, from my being governed by the same considerations of conservatism. However, now that the desired change of opinion, which we have ever since attempted to influence through the *Bulletin of the Torrey Botanical Club*, has been brought about, and, as Mr. Sudworth remarks, "nearly all botanists are thoroughly in unison with the present vigorous movement to place botanical nomenclature on a firm footing," I am heartily in favor of the practice he approves. But I would now favor going considerably further toward the methods of the ornithologists, so far, indeed, as to practically accept most of their "Code of Nomenclature." I would write *Magnolia fœtida* (L.), not *Magnolia fœtida*, Sargent; *Hicoria minima* (Marsh), not *Hicoria minima* (Marsh), Britton; *Catalpa Catalpa* (L.), not *Catalpa Catalpa* (L.), Sudworth. In other words, I would quote the original author of the name, and leave the author of the binomial to be brought out in the synonymy of the species, by means of a check-list or other compilation. This has the advantage of doing away with the double citation and eliminating all personal considerations in the publication of new binomials.

And there is another exceedingly good rule of the ornithologists which I may remark on here. It is to the effect that a generic name or binomial once used in description is unavailable for use for any other genus or species, even if it be shown to be a synonym. "Once a synonym, always a synonym," is a terse and very useful motto, which prevents many troublesome complications.

Insect Lime, Nevertheless.

To the Editor of Garden and Forest:

Sir,—Allow me to make a rejoinder to both Mr. Smith's and Mr. Jack's exceptions to the application of insect lime.

I appreciate Mr. Smith's warning not to turn a good remedy into a quack medicine, to be used "against all ills," but I must warn him in turn not to diagnose too hastily. There are two points he overlooks—first, that we do not expect our police to catch all the thieves, that a reduction only, and not extirpation, is attainable by all our remedies; and, secondly, that besides the biotic phases of insect life, accidental conditions must also be considered in devising means of protection. Now, while there may not be any voluntary wandering observed in the Tussock moth and Bag worm, as there is with the Gypsy moth, and, to some extent at least, with the Web worm, Mr. Smith, in my opinion, does not appreciate sufficiently the services of wind and rain in downing the larvæ. By these agencies they are thrown to the ground, probably

more than once during the season, and they return, of course, to their food-supply.

During the past few years the trees in the parks and streets of Washington have suffered severely from the ravages of the Fall-web worm, Tussock moth and Maple worm, and any one who has observed the countless numbers of caterpillars thrown down by rain-storms and winds, besides those which migrate voluntarily, re-ascending the trees, will not doubt that preventing this ascent would have a marked effect. Total defoliation would, no doubt, be prevented in many instances, and partial disfiguration at least retarded. The "lime-band" furnishes a cheap, simple, effective barrier. It is in preventing the ascent, Mr. Jack will notice, not the descent, that the "lime-band" becomes valuable, since the Fall-web worms, "both old and young, drop themselves to the ground without spinning when disturbed or sorely pressed for food."

Mr. Smith says that this remedy "does not begin to compare in effectiveness with winter collecting and destruction of egg-masses." This assertion could only be made after proper comparative experiment. Not only has the winter collecting of the pupa—as I know from personal unpleasant recollections—and the destruction of egg-masses by crushing been practiced against the European congener of the Tussock moth by the forest-administrations of Germany, and that on a large scale, but the latter method has been improved by using oils, tar, and, still better, "insect lime," to cover the egg-masses, which is a more radical measure, as it is not liable to miss or throw to the ground as many eggs as is done in crushing.

The only experiment with "lime-bands" against this pest, which was made in a Prussian forest-district (because the above methods have not yet proved satisfactory), under the direction of the well-known entomologist, Dr. Altum, has remained incomplete. It showed, however, that a considerably larger number of larvæ was captured by the bands than the previous counting of the eggs would have led to expect, and that the defoliation on the treated Beech-growth took place at least five weeks later than in the neighboring unprotected growth, an effect which may be considered highly satisfactory. This was during a widespread attack of *Orgyia pudibunda*, when the remedies must be applied over large areas to be effective.

My contention, however, was, in the main, for the application of this remedy, in case of the Gypsy moth, in the same manner in which it has been found effective in its native home.

I would also take occasion again to point out to our economic entomologists, that insect fighting is done on a very large scale by the forest-administrations of Europe, and that it would be worth their while to study the methods practiced there more closely, and profit from experience dearly bought by others.

Forestry Division, Department of Agriculture, Washington. *B. E. Fernow.*

The Sugar Maple in Flower.

To the Editor of Garden and Forest:

Sir,—In speaking of the Sugar Maple in your issue of April 15th you say that "a tree in full flower when standing in the sunshine seems to be enveloped with a luminous mist, and is an object of striking beauty." This peculiar appearance of the Sugar Maple does not occur in this region every year, but just now this tree is unusually conspicuous. This is perhaps due to the fact that the flowers pushed out very rapidly during three very warm days, while the leaves are as yet hardly to be seen. These flowers hang in clusters from every bud, sometimes as many as twenty in an umbel, and on slender pedicels three inches long. The stems as well as the flowers are almost straw-color, and owing to their great abundance the tree is completely enveloped with these swaying tassels. No other trees are in leaf except an occasional Willow or Aspen, so that the Maples stand out from the bare forests and the fields, which scarcely begin to show the grass, in very striking relief. Individual trees can be distinguished at a distance of two or three miles, and are certainly much more conspicuous than usual. I only remember to have witnessed such a display but once before in a dozen years.

I should like to hear some satisfactory explanation of this noteworthy difference in the aspect of the Sugar Maple at this season in different years. Is it simply that the flowers are more abundant, or do they come out more slowly some years, so as to be partially hidden by the foliage, or do they open much earlier in certain years and make so striking a display because there are no other trees in flower or leaf to attract attention?

Periodical Literature.

Lindenia. Iconography of Orchids, conducted by J. Linden, Lucien Linden, Em. Rodigas and R. A. Rolfe. American edition, Brussels, 1891.

We have received the first two numbers of the American edition of this sumptuous Belgian publication which has now been appearing during the last six years under the editorship of Mr. Lucius Linden, the son of the well-known botanical collector who is honored in the title. The literature of Orchids is singular in the considerable number of handsomely illustrated and therefore expensive works specially devoted to them, published by commercial firms engaged in the propagation and sale of these plants. At the present time *Reichenbachia* and Williams' *Orchid Album* in England, and *Lindenia* in Belgium, all with magnificently colored plates, strive to lay before the Orchid lovers of Europe and of America all that is new, rare and interesting in these plants. *Lindenia* is a worthy rival of its English competitors.

The American edition has been undertaken, the editor tells us in his introduction, "at the request of numerous amateurs of Orchids, who regret that they are not able to profit completely by a work written in the French language." The American edition is to be "carried on in exactly the same way as has the French edition during the last six years, in which 264 species or varieties have already been figured; appearing regularly every month, seeking the accomplishment of the same programme, with the co-operation of the same contributors, and the same artists who have hitherto received the favorable sympathies of the public."

The first figure (No. 265 of the French edition) is devoted to the beautiful new *Cattleya Rex*, a plant which is just now exciting in the highest degree the imagination of the lovers of Orchids, and as an example of the character of the information *Lindenia* is intended to convey, we shall quote at some length what it says of this plant:

"The Cattleya of which we give to-day the representation has been known to M. J. Linden for fifty years, but it was only at the end of last year that it was sent to Europe.

"Originally discovered by M. J. Linden during his travels in South America, it was met with again, thirty years later, by Wallis, who proclaimed it the most beautiful of Cattleyas, but he did not succeed in sending living plants to Europe. Twenty years after this second discovery, one of the collectors whom M. Linden had sent to search for it diligently, succeeded at last in obtaining it, and sent some plants in good condition to Brussels.

"The great difficulty of this search arose especially from the fact that the plant has not, as have Orchids in general, a central district, a place where it may be found in quantity. Also, one of the collectors of Messrs. Linden spent a whole year in the same locality (which it is not yet possible for us to divulge) without seeing or collecting more than thirty plants of this Cattleya during this long period.

"The country in which it grows is, moreover, one of the least accessible in South America, and the journey across the mountains, among rugged rocks, sometimes cut naturally in nearly vertical steps, without even an indicated path, without any base of operations, in the midst of difficulties without number, entail the loss of considerable time, and frequently the life of the plants collected with so much trouble. One can form an idea of the difficulties encountered when it is stated that not only the plants but also the collectors themselves have to be carried for several days on the backs of the Indians.

"These persistent efforts were amply compensated for when one of the plants imported produced in December last a raceme of its splendid flowers, of which we now publish a representation. Seldom has the appearance of a new Orchid made an equally striking impression on the beholder, and yet the flowers were produced on an unmatured growth, and had not attained their natural dimensions. We may affirm that those which will appear this year will be sensibly larger than those represented on our plate. As to color, we do not think it possible to surpass them in beauty. Throughout the whole Orchid family there exist but few gems comparable to the labellum of this species, in which the purple combined with gold is modified into a crimson of the hue of Spanish wine, and the marblings and the veins are of an exquisite elegance."

Cultivators of Orchids will certainly have good reason to complain that the information with regard to the practical details of cultivation, which they have a right to expect in a work of this character, is either omitted entirely or is so very meagre as to be of little practical value. The plates are generally well drawn and very beautifully printed, but the appear-

ance of the book, from the artistic point of view, is sadly marred by the bright red line which surrounds the page of text.

It may be a convenience to our readers to know that Monsieur Linden's address is 100 Rue Belliard, Brussels, and that *Lindenia* can also be procured from all the principal booksellers of the United States.

Notes.

In a report on Forage Grasses, just issued by the Mississippi Experiment Station, Japan Clover is said to yield on rich land from two to three tons of hay to the acre of as good quality as the best Clover hay.

According to the Census Bulletin on Truck Farming, the season at which a given vegetable reaches a marketable size advances northward along the Atlantic coast at the rate of about thirteen miles a day.

The second annual banquet given by the trustees of the Missouri Botanic Garden in honor of Henry Shaw, the founder of the Missouri Botanic Garden and the Shaw School of Botany in St. Louis, will be held in that city on Thursday, the 21st of May.

The census returns show that the average melon-fields of the southern Atlantic states yield 400 salable melons to the acre. Twelve hundred of these will load a car, which will sell in the north for from $150 to $275, which leaves a net return of from nothing up to $150 an acre.

The Third Report of the California State Board of Forestry, which has been noticed in these columns, can be secured from Mr. J. C. Lemmon, of Oakland, California, by remitting ten cents a copy to cover expenses. The previous report, which relates principally to the Pines of the Pacific slope, can be obtained in the same way of Mr. Lemmon.

The *Illustrirte Gartenzeitung*, of Vienna, under the title of "New Roses for 1891," publishes a list of eighty-seven varieties, produced by thirty horticulturists. Five varieties are of American origin: Golden Gate, Henry M. Stanley, Maud Little, Mrs. Jessie Fremont and Pearl River, all announced by Messrs. Dingee and Conard, of West Grove, Pennsylvania.

One of the most curious plants in Europe was a Birch-tree which for about eighty years grew vigorously on top of the unfinished tower of St. Stephen's Church, in Vienna. When, in recent years, the work of completing this tower was begun, the tree was transplanted into the Rath-haus Park, but, in spite of the most careful tending, it died about three years ago.

The office of Commissioner of Forests has been abolished in Colorado. Since this state has been hitherto supposed to take a more enlightened view of the value of her forests than some others, the determination to dispense with any officer whose duty it was to give special attention to this interest is a surprise, and, at this distance, seems like a step backward.

It is about forty years since the Weigelia was first introduced into European gardens from China. German catalogues now note between thirty and forty varieties, most of which have pink or pale crimson flowers, although, in one or two, the flowers are darker crimson, and in about half a dozen are pure white. A few varieties have also been grown with leaves streaked with yellow or white.

From the interesting address on the Sponge-bearing Cucumber, of which we have quoted the greater portion in another column, we learn that Herr E. Dammann, of San Giovanni-a-Teduccio, near Naples, has for years been hunting the world for seeds of the Luffa, which he has cultivated as a seedsman, and that he has secured varieties which are of great interest to botanical collectors. By exchanging with Herr Dammann, Dr. Harris has added materially to his own list of varieties for testing here, and has sent several of the most valuable sorts to Japan, Egypt, Cuba, Mexico and Florida, with a view to improving the varieties there.

A bill has been passed by the legislature of Ohio which creates a park board for the thriving city of Youngstown, and gives it the authority to establish the boundaries of a park, to accept lands for park purposes, and to make necessary regulations for its government and maintenance. The Commission was authorized to make a preliminary survey, with an estimate of the cost of the probable improvement, and submit the same to the vote of the people. The project was sustained by a majority of three to one. We understand that suitable grounds near the city have been secured, and the descendants of the men who inaugurated this movement will bless them for taking steps in this matter before the opportunity was lost of securing the land at a reasonable price.

From Mr. H. B. Ayres, of the Forestry Department, Washington, comes the following note of observations which he made in the forests of northern Minnesota last winter. In slightly timbered regions the "pot-holes" along the hills of drift have a border which is frequently covered by standing water, and upon which trees do not grow. Where the timber has been lately cut away it is a common thing to see a belt of thrifty timber on the moist land encircling the pond-hole, and again inside of this belt of living timber another belt of dead trees and grass above an old shore-line. The inference seems irresistible that denudation causes a more rapid accumulation of water, which means a higher rise of water in the basin, thus killing the trees which had grown up where water had not previously injured them.

A German horticultural journal says that one of the latest inventions in medicine is the use of cold greenhouses in tropical countries as a means of combating yellow fever. This disease, it states, can be conquered if one removes to those elevated regions in which Oaks will grow. This fact recently inspired a celebrated Cuban physician with the idea of reducing the temperature of sick-rooms by artificial means, and wonderful cures resulted. Now it is proposed that, in districts liable to the epidemic, each town shall erect a great glass-house in which plants of cold and temperate regions may be grown, the temperature being artificially cooled instead of heated, as in our greenhouses; and that they shall be devoted to the treatment of patients suffering from the fever.

The California Board of Forestry has memorialized the Congress of the United States on the subject of the water-supply which so profoundly affects the material welfare of that state. Environed as they are on the south and south-east by an arid district almost uninhabitable by reason of its torrid heat, the people of California look upon the enlargement of this inhospitable region with profound apprehension. Their immunity from invasion by this hostile climate depends upon the benign influence of great forests, and the diminution and extinction of these forests must be inimical and fatal to their prosperity. The forest-commissioners, therefore, urge the absolute withdrawal from sale of all the timber-lands in California until future surveys have determined what tracts should be held in permanent forest. And, again, they ask that the timber of such lands, when fit to harvest, should be sold, and not the lands. The lumberman, as a rule, cares little for anything beyond the number of feet of timber to an acre, and, therefore, there will be no loss of revenue in selling the logs only, while, if the fee remains in the United States, the Government can impose such reasonable regulations for preserving the young growth and preventing fire as will insure the perpetual forest-character of these lands and yield future returns of revenue.

A series of field meetings will be held in the Arnold Arboretum during May and June for the purpose of supplying popular instruction about the trees and shrubs which grow in New England. They will be held on Saturday mornings at ten o'clock, and on Wednesday afternoons at three o'clock, beginning on Saturday, May 9th, and will be conducted by Mr. J. G. Jack. The class will assemble in the lecture-room of the building of the Bussey Institution, where a brief review will be given of the plants to be especially observed during the meeting of the day. It will then adjourn to the plantations and the nurseries of the Arboretum for an informal study of the plants themselves. It is not proposed that the instruction given in these meetings shall be technical, and a knowledge of descriptive botany is not essential for persons who desire to follow them. The intention is to indicate, by comparison, the easiest means of distinguishing the common native trees and shrubs as they appear in this part of the country, and of recognizing the foreign species which have been introduced into our gardens. The ornamental and useful properties of trees and shrubs, their habits of growth, their peculiarities and common diseases, will be considered, the different plants being taken up, as far as possible, in course as they become conspicuous by flowering. An hour and a half to two hours will be devoted to each meeting. During the season it is expected that the class will be conducted to at least two well-known gardens in the vicinity of Boston. Applications or further inquiries may be addressed to Mr. J. G. Jack, Jamaica Plain, Massachusetts.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MAY 6, 1891.

TABLE OF CONTENTS.

The Douglas Fir.

THE Douglas Fir, from many points of view, is one of the most interesting trees of the American forest. Its monotypic character, its probably recent development in its distinct existing form, for the record of the ages has not divulged the secrets of its ancestry, the vastness of the region it occupies, its size and value to man, its beauty and capacity of adapting itself to new surroundings, all make the Douglas Fir an important inhabitant of the forests of western America—forests remarkable for the variety, size and value of the cone-bearing trees of which they are principally composed.

The Douglas Fir is distinguished from the true Firs or Abies by its petioled leaves, which, in falling, leave oval scars, by its pendulous cones with persistent scales, and by its seeds, which are not furnished with resin vesicles. It looks, moreover, in general appearance, more like a Hemlock than a Fir; it differs from the Hemlock, however, in the absence of the permanent, persistent bases of the fallen leaves which roughen the branchlets of all Hemlock-trees, and in its much larger cones, which may be always recognized by the large acutely two-lobed and long-pointed bracts extended beyond the scales. It can be readily known, too, by the flat, distinctly stalked leaves which are somewhat two-ranked by a slight twist at their base.

Where climatic conditions favor the growth of large trees, as they do in the humid region of western Washington and Oregon, or on the middle western slopes of the northern Sierra Nevada, the Douglas Fir often rises, in the course of five or six hundred years, to the height of three hundred feet, and forms a trunk ten or twelve feet in diameter above its enlarged base. The bark, which, like that of the Hemlocks, contains a considerable amount of tannin, is thick, deeply furrowed, and dark brown or red, or sometimes gray, in certain situations. Young trees, like young Spruces and Firs, are pyramidal in form, and retain their lower branches for a considerable time, sometimes even for two or three hundred years, when the individual finds sufficient space for their lateral growth, as it does occasionally when it has stood on the margin of the forest or on the steep slopes of some mountain cañon. Usually, however, the trees stand close together, especially in those parts of the country in which, under the favoring influences of a heavy rain-fall, they grow to the largest size, and then their great trunks tower upward, for a hundred feet or more, without a branch. The leaves are linear and generally obtuse, an inch or an inch and a quarter long, dark green and very abundant, covering the long, slender, graceful branchlets. The flowers of the Douglas Fir are produced from the axils of the leaves of the previous year, the males surrounded by conspicuous bud-scales, the females much shorter than their narrow bracts. The cones, which are subcylindrical, ripen the first year, and vary in length from two to four inches. The seeds are triangular, convex, and red on the upper side, flat and nearly white on the lower side, with short wings, broad at the base and acute at the apex.

The Douglas Fir extends from latitude fifty-five north, where it is found in the coast ranges and on the interior plateau of British Columbia, southward through all the region west of the Cascade and the Sierra Nevada Mountains to southern California. It is abundant in the Rocky Mountains from British Columbia far into Mexico, extending eastward to their eastern slopes in Montana, Wyoming, Colorado and Texas; it is common on the Wahsatch and Uintah Mountains in Utah, but is unknown on the ranges of the great basin and on the eastern slopes of the Sierra Nevada. It is most abundant and reaches its greatest size on the low glacial plain which surrounds the shores of Puget Sound. Here the Douglas Fir can be seen in all its majesty. It is the most common tree in a forest in which trees stand so close together that the traveler can barely push his way between their mighty trunks which support far above his head a canopy so dense that the rays of the sun never pierce it. Through these dark and awful shades the most thoughtless man cannot pass without experiencing that sense of solemnity and awe with which the human mind is impressed when confronted by Nature in her grandest manifestations.

The Douglas Fir grows almost as large on some of the California mountain-slopes as on the shores of Puget Sound, and it is one of the remarkable things about this tree that it flourishes at the sea-level and on high mountains. In California it often grows to a great size at elevations varying from 6,000 to 8,000 feet above the sea, and sometimes ascends on the Rocky Mountains of Colorado to even higher altitudes, although it is always smaller and less valuable as a timber-tree in the dry interior portions of the continent than in the moist coast region.

Other trees of the Pacific forest produce more valuable wood than the Douglas Fir—the Port Orford Cedar, the Sugar Pine and the Redwood. These trees are confined to a comparatively small region, however, and the Douglas Fir, in view of the great territory over which it has spread, must be considered the most important timber-tree of western America, and of no other tree is there now standing such a body of valuable and available timber. The wood of the Douglas Fir is hard, strong and durable; it may be recognized by the numerous spirally marked wood cells which distinguish it from the wood of allied conifers. The small cells which are developed in the wood of conifers at the end of the growing season are very numerous, and form broad bands which often occupy half the width of the layers of annual growth. These bands of small cells are dark colored and conspicuous, and become hard and flinty with exposure, making the wood of this tree difficult to work except when it is freshly cut. Some trees produce light red and some yellow wood, and individuals vary to a much greater degree than those of most other trees in the time required for their sap-wood to turn into heart-wood. The yellow wood is closer-grained and is considered much more valuable than the red wood. Lumbermen recognize

these two varieties and pretend to be able to distinguish the trees which produce them, an assumption which still needs demonstration. The conditions which lead to the formation by the same species of such different wood are not well understood; in the case of the Douglas Fir they are probably due to soil and elevation, and, in part at least, to the age of the individual. The wood of the Douglas Fir is known in commerce as red fir, yellow fir and Oregon pine, the last name belonging, however, more properly to the wood of the Yellow Pine (*Pinus ponderosa*) of western America. It furnishes the principal product of the immense saw-mills situated on Puget Sound, and is manufactured, besides, wherever forests of this tree exist; it is used for all sorts of building purposes and for construction, railway ties and fuel.

The Douglas Fir was discovered late in the last century by Archibald Menzies, Vancouver's surgeon and naturalist on his voyage of discovery; and a few years later Lewis and Clark found it in Montana during their transcontinental journey. David Douglas rediscovered it on the Columbia River in 1825 and introduced it into England; and it is the name of this bold and enterprising botanist which has become associated with this tree, although, unhappily, it cannot bear it in the language of science. No tree is more unfortunate in its name; and there are few instances where the application of the rules which govern botanical nomenclature has produced a more unsatisfactory result. Lambert, who first named the tree, called it *Pinus taxifolia*, from the fancied resemblance of the leaves to those of the Yew-tree; then Lindley, disregarding Lambert's specific name, named it *Abies Douglasii* in honor of its rediscoverer. Carrière, recognizing the characters which separate this tree from the true Firs, coined for his genus a bastard word, half Greek and half Japanese, and called it Pseudotseuga, a perfectly improper name, as it has little in common with Tsuga, the Japanese name for the Hemlock. Carrière retained, however, Lindley's Douglasii, calling the tree *Pseudotsuda Douglasii*, but as Lambert's specific name is the oldest, the Douglas Fir must be known as *Pseudotsuga taxifolia*, a name bad in every way, and especially bad in its failure to recognize the name of Douglas, which, more than that of any other man, should be associated with it.

The Douglas Fir has proved itself in cultivation to be an ornamental tree of great value. The largest specimen in England is already more than 110 feet high, with a stout trunk furnished with branches from ground to tip, and showing no signs of diminishing vigor or beauty. The earliest attempts at cultivating the Douglas Fir in the eastern states were not successful; the trees raised from seed, gathered in the mild and humid climate of the north-west or in England, first planted here were unable, except in exceptional positions, to support our climate for any length of time. The late Dr. Parry, however, in 1862 discovered the Douglas Fir growing on the eastern slopes of the Rocky Mountains of Colorado in a climate distinguished by the severity of the cold of winter and by the drought of summer; he sent seed to the Botanic Garden at Cambridge, and the plants raised from this seed have proved hardy in the most trying situations in New England. Some of these trees are now more than twenty feet high, and although it is too soon to speak with anything like certainty in the matter, there is reason to hope that they will grow to a large size and retain their beauty for many years.

Much attention has been given to the Douglas Fir of late years as a subject for forest-planting in Europe, although the best authorities on such matters do not yet agree as to its value for this purpose. Large experimental forest-plantations are made every year, especially in some parts of Germany, where some forest-experts believe that the Douglas Fir is to rival and finally replace the Larch in Europe as a timber-tree. It has the merit of growing with surprising rapidity and of producing a large amount of timber in a comparatively short time. Few coniferous trees grow as rapidly as the Douglas Fir, and it is not uncommon to see self-sown seedlings in Washington and Oregon producing, when they stand very close together in good soil, annual shoots twelve feet long.

A remarkable form of the Douglas Fir, distinguished by its large cones, occurs on the San Bernardino Mountains, in California. It has been considered a variety of the typical tree, and by some botanists a second species—a view supported by the fact that no intermediate forms connecting it with the type have been found, while in the region north and south of that occupied by this large fruited tree the typical Douglas Fir abounds.

The beauty of the trunk of the Douglas Fir and the spread of its great buttress-like roots are shown in the illustration on page 211. It is from a photograph by Notman, of this city, and represents a tree of medium size standing in the park at Vancouver, in British Columbia.

A California Cemetery.

THE most beautiful cemetery in California, the one that is more nearly what a cemetery should be than any other in the state, is Mountain View, near Oakland. It is a nest in the foot-hills, shut out from harsh winds, and so varied in surface that when Mr. Frederick Law Olmsted drew the plans, about 1865, he is said to have expressed the greatest pleasure in the "opportunities for landscape-gardening" that the tract afforded. Owing to unfortunate complications, Mr. Olmsted's plans for the University grounds were neglected, but the Mountain View Cemetery is his sufficient memorial on the Pacific coast.

For twenty-five years a group of prominent Oakland men have worked together developing a beautiful garden of the dead. In some portions there is too much expensive and grandiose monumental glitter, but for the most part good sense and modesty prevail, and trees, vines, flowers and running water unite to make a quiet loveliness. This very March morning as I sat in a perfect tangle of trees, Roses and wild Blackberry-vines in the winding valley that crosses the grounds from hill to hill, I heard the shrill piping of California quail in the copse, and presently saw a very gentle-minded "cotton-tail" rabbit a few yards away meditating on the phenomenon of a reporter's pencil and pad. Looking up I saw three humming-birds poised above the Cherry-blossoms of some old trees in a half-acre orchard planted by some pioneer, and left by the landscape-gardener to give a pleasant homely effect to this part of the grounds. All the while birds kept singing everywhere—golden orioles, brown robins, meadow larks, hosts of blackbirds in the tree-tops. Such places as this are in all the ravines; the rounded hills are planted with flowers and shrubs, but most of the trees are set in the richer soil below.

The late superintendent, Mr. William Collins, was a man of much executive ability, a Scotsman of the Scots, and absolutely devoted to the enterprise. He made every square rod of the land produce growth and beauty. Many flowers bloom even in midwinter at Mountain View, and miles of Rose borders, in which all the newest sorts are represented, extend along the drives. Masses of Iris, Lilies and Daffodils, and the simple old-fashioned flowers that appeal to every heart, remain to illustrate the late superintendent's methods. In the way of trees he planted great numbers of Magnolias, English Laurels, Oranges and the finer broad-leaved evergreens, with Acacias and the rarer conifers, but the latter have been but sparingly used, except in a few bold masses. An almost continuous belt of Eucalypti, Monterey Cypresses and Pines sweeps around the western and southern sides of Mountain View and shuts out the city beyond. Higher hills lie to the east, and over these the cemetery can be extended whenever it is necessary to have more room. In this wilder region there are many ledges of rock that stand out of the hill-side like Cyclopean walls. A few similar ledges are within the present limit of the cemetery, and are covered with vines and rock-plants, sach as Cacti, Cistuses and the low succulents. Several large boulders of trap-rock have been used as monuments, and the possibilities in this direction of the castle-like ledges of the adjacent tract are certainly very striking. One of the rock-piles stands at the head of a ravine overlooking the whole valley, and covers a parallelogram of fifty by a hundred feet in extent, and rises forty feet above the slope. Five or six good specimens of *Quercus agrifolia* grow upon the top of the splintered ledge, and it would be easy to hew out a vault beneath their roots, if one chose, and to cover the whole pile with vines. Such a "memorial mound" would be far more in keeping with Mountain View, as it was planned, than the stateliest mausoleum of polished Rocklin granite or Amador

marble. The late superintendent chose for his own monument an isolated moss-grown boulder, upon which an inscription will be placed, but nothing else will be changed about it.

I spent an hour in the more cultivated parts of the cemetery a few days ago, and was particularly interested in studying the blooming plants there. Mountain View, as I have already said, is one of the most sheltered nooks in the region of San Francisco Bay, and the climate is surprisingly mild. The Orange and Lemon grow and fruit there, and Roses bloom earlier there than anywhere else in the district. On the 20th of March there were Apple, Peach, Plum, Almond and Cherry in the old orchard; long rows of English Laurel; about thirty kinds of Roses, with Japan Quinces, Spireas, Acacias, with immense clumps of Irises, and white and rose-colored Peonies on the hill-side. Nasturtiums, self-sown last autumn, and seedling French Marigolds mingled with wild Poppies and early Lupines, and in many a nook the native flowers of the coast range still hold their own, while the slopes beyond are splendid with spring annuals in full bloom. This is the cemetery of which the lamented E. R. Sill wrote in his poem entitled "Home":

> There lies a little city in the hills;
> White are its roofs, dim is each dwelling's door,
> And peace with perfect rest its bosom fills.
>
> There the June mist, the pity of the sea,
> Comes as a white, soft hand and reaches o'er
> And touches its still face most tenderly.
>
> Unstirred and calm, amid our shifting years,
> Lo! where it lies, far from the clash and roar,
> With quiet distance blurred as if thro' tears.

Such is the spirit of the place, and, as time goes by, that spirit will ripen as its trees grow old and all its bare rocks become more weather-stained and moss-grown.

Niles, Cal. *Charles Howard Shinn.*

The Sap and Sugar of the Maple-tree.—III.

THE linguistic evidence of the *Anthropologist*, introduced by Mr. Henshaw and continued by Mr. Chamberlain, is interesting as well as comprehensive, and not only valid, but perhaps as convincing as the narrations of history.

It reaches back far beyond the advent of that class of European travelers who are said to tell stories by inclination and truth by accident. It is independent of the romances of discoverers and of the neglect of historians. It draws out the history of the Sugar Maple and its products from the very elements of the Indian language. It also takes account, as it should, of their myths and legends, and especially of their solemn rites and celebrations as illustrating past events in ceremonies and figures as by a sign language, through which preceding ages are yet telling events which transpired in their times. This argument from language, in its simplest form, as stated by Mr. Henshaw, is essentially this—namely, "That if investigation shows that the Indian name for European sugar is the same as, or a derivative from, the Indian name for maple-sugar, and especially if the name of maple-sugar is derived from the Maple-tree, we can hardly expect to find better evidence of the fact that maple-sugar was truly an aboriginal production."

For if sugar had been introduced to the Indians by Europeans, the Indians would naturally have adopted the name or sounds under which the new article came to them, as nearly as their word sounds would allow, as is found to have been quite a constant result in respect to various new objects introduced to them under foreign names, of which many illustrations might be given. The exceptions to this rule seem to be in the case of novel animate objects, impressive at first sight, to which they sometimes give a name of their own coining, compounded from the name of a familiar object with a new and characteristic affix.

A few of the facts brought out in the articles referred to, as to the legends and sacred rites of the Indians and the signification of the names relating to the Maple-tree, have been selected for notice here as illustrating more clearly the way in which the investigation has been commenced, and the method in which it will be carried on.

We are told that among the Algonquian tribes there were many myths and legends relating to the Maple-tree.

For the Chippewas, an "Ovid"-like "metamorphosis" of Nishosha, the magician, took place, and in a few seconds he stood a tall and stiff Maple-tree.

Then, too, a certain month of the year was called by some Indians the "Sugar Month," or "Sugar Moon," which could hardly have been unless sugar-making were aboriginal.

Others believed that the snow which melted in the spring furnished the trees with sap—the snow being only "the dripping oil" of the celestial bear slain by the hunters in the winter-time.

Another evidence of the antiquity of their sugar-making is in their ancient religious festivals instituted to the Maple, as the Maple Dance, and the sugar festival in the spring, when the old sugar and the new are mingled by the medicine-man and the aid of the Great Spirit is invoked. Such a conclusion is fully sanctioned by A. de Candolle, who says: "Rien ne montre mieux l'antiquité et la généralité, que cette fusion intime avec les usages religieux d'anciens habitants."*

By way of word illustration, it is stated that the Ojibwa word for maple-sugar is "*Zeence-zee-bah-quod*," which is pronounced *Sen-se-pah-qwot*. Derivation: *Zeence-zee*, drawn from; *bah-quod*, wood or stick, referring to the sap drawn from the tree.

Enin-ah-tig weesh-ko-bun is also employed. Derivation: *Enin*, man; *ah-tig*, wood or stick [tree]; *weesh-ko-bun*, sugar—hence, man-stick-sugar.

"The etymology here," Mr. Henshaw states, "contains a metaphorical reference to the manner in which the sap flows from the tree, as curious as suggestive."

The name so well accords with the natural growth and polysynthetical character of Indian words, and is so paralleled by names of water-falls in foreign countries and languages that it carries in itself the evidence of its origin.

The far-extended Algonquians have corresponding names whose origin seems to have been similarly derived, as Hard Maple, *An-in-a-tik;* Sugar, *Si-si-pak-wat;* Maple-sugar, *An-in-a-tik si-si-pak-wat.*

The Ojibwa form for Sugar Maple, *Nin-au-tik*, seems without doubt to be the same as *Enin-ah-tig*, "*e*" being dropped for easy pronunciation, and to mean not, as Tanner suggests, "*our* tree," but simply, *Enin*, man; *ah-tig*, tree, stick; hence *Nin-au-tik*, man-tree, again.

No doubt, as Mr. Henshaw suggests is probable, "Tanner's etymology is faulty" in this case. The only other etymology which Mr. Chamberlain considers of any weight here is that of Cuoq, who explains *in-in-a-tik* as meaning "*the tree*" par excellence. Yet in this he defers quite too much to Cuoq's authority, and has to regret that the doing so "seems to cast little light on the real question."

If Mr. Chamberlain, to use his own language, "would make the word in question signify 'man-tree,' either from a conception of the tree as man-like (with respect to the sap probably) or from some myth such as that noted above," it seems as if his path here would be full of light. With all respect for the lexicography of Cuoq, the question here is one in which considerations of anthropology are paramount to those of a doubtful etymology.

But whatever may be obscure or uncertain in minor details of the various words of the many divisions of the Indian race, still, as a rule, in the long list of names for the Maple-tree, Sugar-tree, maple-sugar and for sugar *per se*, not a name (with a single exception) as yet is found which resembles, or has relation to, any European name for sugar. The single exception in the case of the Cree language establishes the general rule, from the fact that it is to white (French) sugar only that they give a special name—*So-kaw*—evidently their adoption into their own tongue of the French word *Su-cre* by its nearest kindred sound.

To place the subject more clearly before the eye of the reader, a few of the names in question taken from the *Anthropologist*, and as used by different families or tribes, are here annexed:

Indians.	Hard Maple.	Sugar.	Maple-Sugar.
Ontarios	*An-in-a-tik.* Man-tree.	*Si-si-pak-wat.*	*An-in-a-tik Si-si-pak-wat.* Man—tree—sugar.
Two Mountains	*In-in-a-tik.* Man-tree.	*Sin zi-pak-wat.*	*Sin-zi-pak-wat.*
Another settlement	*Nin-a-tik.* Man-tree.	*Sinz-hab-ak-wat.*	*Nin-a-tik Sinz-hab ak-wat* Man—tree—sugar.
In Cree	*Sisi-bask-wat-at-tik.* Maple-tree.	*Sis-i-bask-wat.*	*Sis-i-bask-wat.*
Ojibwa	.....	.....	*Zeence-zee-bah-quod,* pronounced *Sen-se-pah-qwot.* Expressed from tree.
Omaha and Ponka	*Ja-ni-hi.* Wood—sap—tree.	*Jan-ni.* Wood—sap.	
Winnebago	.....	*Ta-ni-ju ra* Tree-water, or rain.	
Tuscarora	.....	*U-ren na-kri.* Tree—sap.	

* L'Origine des Plantes cultivées, p. 315. Paris, 1883.

A mere inspection of these names seems to make clear what has been stated, that not only were they not derived from any European name or description of sugar, but that, whatever may be the difference in the dialects or language of different tribes, they all agree in referring sugar to the Maple-tree, and to the flow or rain of sap which runs from it so freely in the spring. And when we estimate the natural force and internal pressure of the sap when most active in trees, the suggestion that the idea of pressure exerted to express the sap applies better to the Sugar-cane than to the Maple, loses all its force. It is true that more extended information as to Indian names for the Maple and for sugar is desirable, and it is to be hoped that the investigation of them will be pursued through all the languages of the tribes within the habitat of the Sugar Maple. But whether it takes place sooner or later only one result can be anticipated.

The historical facts adduced show maple-sugar to be a product we owe either to the Indian or to the French. But the French, whether clergy or laity, always in their writings treat the sap and the sugar as novelties to be explained to their correspondents; and no claim on the part of the French to its introduction by them has yet been found. On the contrary, both the cleric Lafitau and Bossu the chevalier explicitly agree, though writing at different periods, in ascribing its origin to the Indians themselves—a conclusion which it is difficult, if not impossible, to avoid.

The linguistic evidence, so far as brought out, is remarkably consistent, and points with equal directness and force to the same conclusion.

As the evidence of history and of language thus combine to support the same proposition, it seems only reasonable to accept their decision, that it is, after all, to the Indian that we are indebted for the important and national product of maple-sugar.

Providence, R. I. *William D. Ely.*

Winter Studies of the Pine Barren Flora of Lake Michigan.—III.

THE Huckleberry and the Blueberries are objects of interest in their winter appearance. Four species, representing two genera, are found here. All have reddish or purple branches, whatever may be the color of the bark in summer. The Black Huckleberry (*Gaylussacia resinosa*) often looks rusty, even to the smaller twigs, imparting to the shrub, as a whole, a sombre look. It branches freely, with an irregular, straggling spray. Many of the twigs are red or reddish, and the small buds on them of a brighter red. It averages about two feet in height, but attains three or four feet in damper and richer soils, equaling smaller stems of *Vaccinium corymbosum*, near which it may be growing. It is very abundant on the sand-ridges, especially where they are open, and the Pines have given way to the Oaks. The Low Blueberry (*Vaccinium vacillans*) grows along with it, and is about as common. It is not quite as tall, averaging a foot and a half, and is a prettier plant in its winter garb. The main stem has a smooth, light-gray bark, frequently greenish above, crossed and checked with fine cracks, forming a mesh of dark lines. The branches are short and spur-like, somewhat regularly arranged around the stems. They start out horizontally, but soon curve upward. The fresh-grown twigs and smaller parts of the branches are usually pale red or pink, and contrast very clearly in color with the body of the plant. Such branches, as well as those of Gaylussacia, look as if they had been dipped to a certain depth in a red dye, the line of division between the red and the gray bark being abrupt and sharply drawn. The bud-scales are of a darker red than the twigs, and the buds near their ends prominent. In the Dwarf Blueberry (*V. Pennsylvanicum*) the whole plant is reddish purple, or the lower part of the stem may be green and the top colored. Its height is about a foot; the branches are irregular and ascending, making an acute angle with the stem, and the buds are quite large, with scales bright-colored like the bark. The Dwarf Blueberry generally grows in damper places than the two just mentioned, fringing the open places occupied by sloughs or wet ground, taking the border-land between the wet and the dry, where it thrives best. But the three grow together in many localities, and, though no close lines of habitat can be drawn, they prefer those mentioned, and are about equally abundant. The largest of the Vacciniums, *V. corymbosum*, the Swamp Blueberry, is of limited range, being found on the borders of a few of the ponds and Cranberry-marshes. The canes are from three to seven or eight feet high, the thickest of them barely an inch in diameter, the shrub being considerably smaller than those found in the Tamarack swamps, which are its more usual habitat. The grayish, flaky, outer bark of the older stems is easily detached, coming off in spots and exposing the brown inner bark, giving them a mottled look when this occurs. The new shoots and twigs are red, the longest of them straight and brier-like, though with a bark more shining than that of the Dogwoods, in this respect resembling some of the Willows. The bark of this fresh growth is slightly roughened by countless specks of a lighter color, appearing like minute blisters, and contributing a pretty feature to the comely shoots.

With the Dwarf Blueberry, but oftener in wetter ground, will be seen the purple stems of the Running Blackberry (*Rubus hispidus*). They are very slender, and clothed with an abundance of weak, reflexed prickles. The leaves are quite persistent, becoming dark purple in autumn, and clinging to the vines in winter. Sometimes, when the winter is mild, the leaves of the Strawberry persist, turning purple like those of the Running Blackberry, and appear quite fresh when in sheltered spots where they are partly covered by fallen leaves, or protected by the branches of some low-growing Pine.

Englewood, Ill. *E. J. Hill.*

New or Little Known Plants.

Encephalartos Frederici Guilielmi.

THIS remarkable and extremely ornamental Cycad was introduced into England in 1877, when stems of it were forwarded from Grahamstown to Kew as "a new species of Encephalartos, with fronds like those of *Cycas revoluta*, the crown of the stem clothed with wool to the thickness of about an inch." The specimen represented in the illustration on page 209 was one of these. Soon after its arrival it developed a whorl of female cones, each about nine inches long, which, however, had to be removed to save the life of the plant. So far as I know, it has not attempted to flower since. It is now a handsome specimen, the stem being five feet in circumference, nearly three feet high, crowned with one hundred and seven leaves, each three feet long, rigid and spineless. The pinnæ are narrow, set closely together, conduplicate, gray-green and spine-tipped. A whorl of new leaves is produced every year, the last whorl consisting of no less than thirty-four full-sized leaves. The diameter of the head is seven and a half feet.

There are about a dozen species of Encephalartos, all natives of tropical and southern Africa. They are all represented by living examples at Kew, where many of the specimens are of very large size. *E. caffer*, *E. Altensteinii* and *E. horridus* are veritable giants in the Palm house, the conditions in which appear to be peculiarly suitable to this genus. *E. brachyphyllus* and *E. Ghillinckii*, both natives of the same region as *E. Frederici Guilielmi*, namely, Kaffraria, and both near allies of that species, may be grown in an ordinary greenhouse if kept a little dry in winter. All the other kinds are happiest in a sunny stove.

The cones of some of them are very ornamental, the female cones of *E. villosus*, another south African species, being, when ripe, at least twice as large as the largest pine-apple, the color of the large, fleshy scales being rich, orange-yellow, that of the nut, like fruits half-hidden beneath them, a brilliant scarlet. In the woods along Buffalo River, near King William's Town, this species is as plentiful, and produces a somewhat similar effect to that of the male fern in the woods of England. The fruits, if allowed to remain till they ripen, are destroyed or greedily eaten by the monkeys and large birds, but in the vicinity of towns they are favorite ornaments with the colonists, who cut the cones in their green state and take them home to ripen.

Some of the species produce very large cones, as, for instance, *E. Altensteinii*, recently figured in the *Botanical Magazine* (t. 7162). This has a female cone eighteen inches long by thirty inches in circumference, the fleshy scales packed closely together, and orange-yellow in color. A male plant at Kew developed two cones last year. Sir Joseph Hooker mentions a huge specimen of this species which was seen by a Mr. Sanderson "in a secluded valley in Natal, about thirty miles from the sea, the trunk of which measured sixteen feet before branching, and twenty-five to the crown, which was formed of five branches."

For large conservatories these plants have a special value, being bold and handsome, the fronds exceedingly durable and not easily injured, whilst they are so robust in constitution that it takes a considerable amount of bad treatment to affect their health. In the southern states of America most of them

would probably flourish if planted in the open. Any one who has seen these plants at their best must admit that, whether among large Palms in conservatories, or planted in masses or as single specimens out-of-doors, they produce a particularly grand effect. Some of the specimens at Kew must be something like a century old. That here figured, for instance, had a stem as much in diameter, and only a few inches shorter, thirteen years ago than it has now, although it has been in vigorous health almost from the first. The photograph from which this illustration has been prepared was taken in 1883.

Kew. *W. Watson.*

Foreign Correspondence.

London Letter.

LACHENALIAS.—Mr. Moore, of the Glasnevin Botanical Gardens, Dublin, read a valuable paper on these plants and their cultivation in London last week. So far as I am aware, nowhere are Lachenalias grown so successfully as at Glasnevin, the spikes of flowers produced there being almost as strong as Hyacinths and the substance of the flowers almost as great. Such kinds as *L. tricolor*, *L. Nelsoni*, *L. quadricolor*, *L. aurea*, *L. pallida*, *L. orthopetala* and *L. pendula* Mr. Moore can produce with spikes a foot long, the stalks as thick as a man's little finger, and the flowers correspondingly large. As commonly seen, Lachenalias are not good garden plants, but no one who saw the fine examples with which Mr. Moore's lecture was illustrated would deny to them a place among the very best of early spring-flowering bulbous plants for the greenhouse. A considerable number of hybrids have been raised, some of them by Mr. Moore himself, the best of them being *L. Nelsoni*, which was obtained by crossing *L. aurea* with *L. tricolor* about ten years ago. There appears to me to be in Lachenalias material which in capable hands would soon produce a race of most valuable garden plants. The splendid and varied children of the comparatively poor *Hyacinthus orientalis* may be pointed to as examples of what has been done by selection, etc., with a plant very closely related to Lachenalias.

HÆMANTHUS MULTIFLORUS.—This is one of the most beautiful of the thirty-eight species of Hæmanthus now known, its large umbel of rich crimson flowers with golden anthers being very handsome. In one of the stoves at Kew there is a plant of it now bearing an umbel eight inches through composed of about sixty flowers, each an inch and a half long, with linear reflexed segments, and stellately arranged stamens one and a half inches long. The scape is scarcely a foot in length, and it precedes the leaves, springing from the centre of a globose bulb three inches in diameter. This and *H. Kalbeyeri*, *H. Abyssinicus*, *H. tenuiflorus* and *H. filiflorus* are all alike or very nearly so. It is quite tropical, and should not be kept dry at any time. *H. multiflorus* was introduced many years ago, but it has never found much favor, because of its bad behavior, as a rule, under cultivation. In this respect it is inferior to *H. Catherinæ*, *H. cinnabarinus* and *H. magnificus*, which are equally beautiful and at the same time easily kept in health.

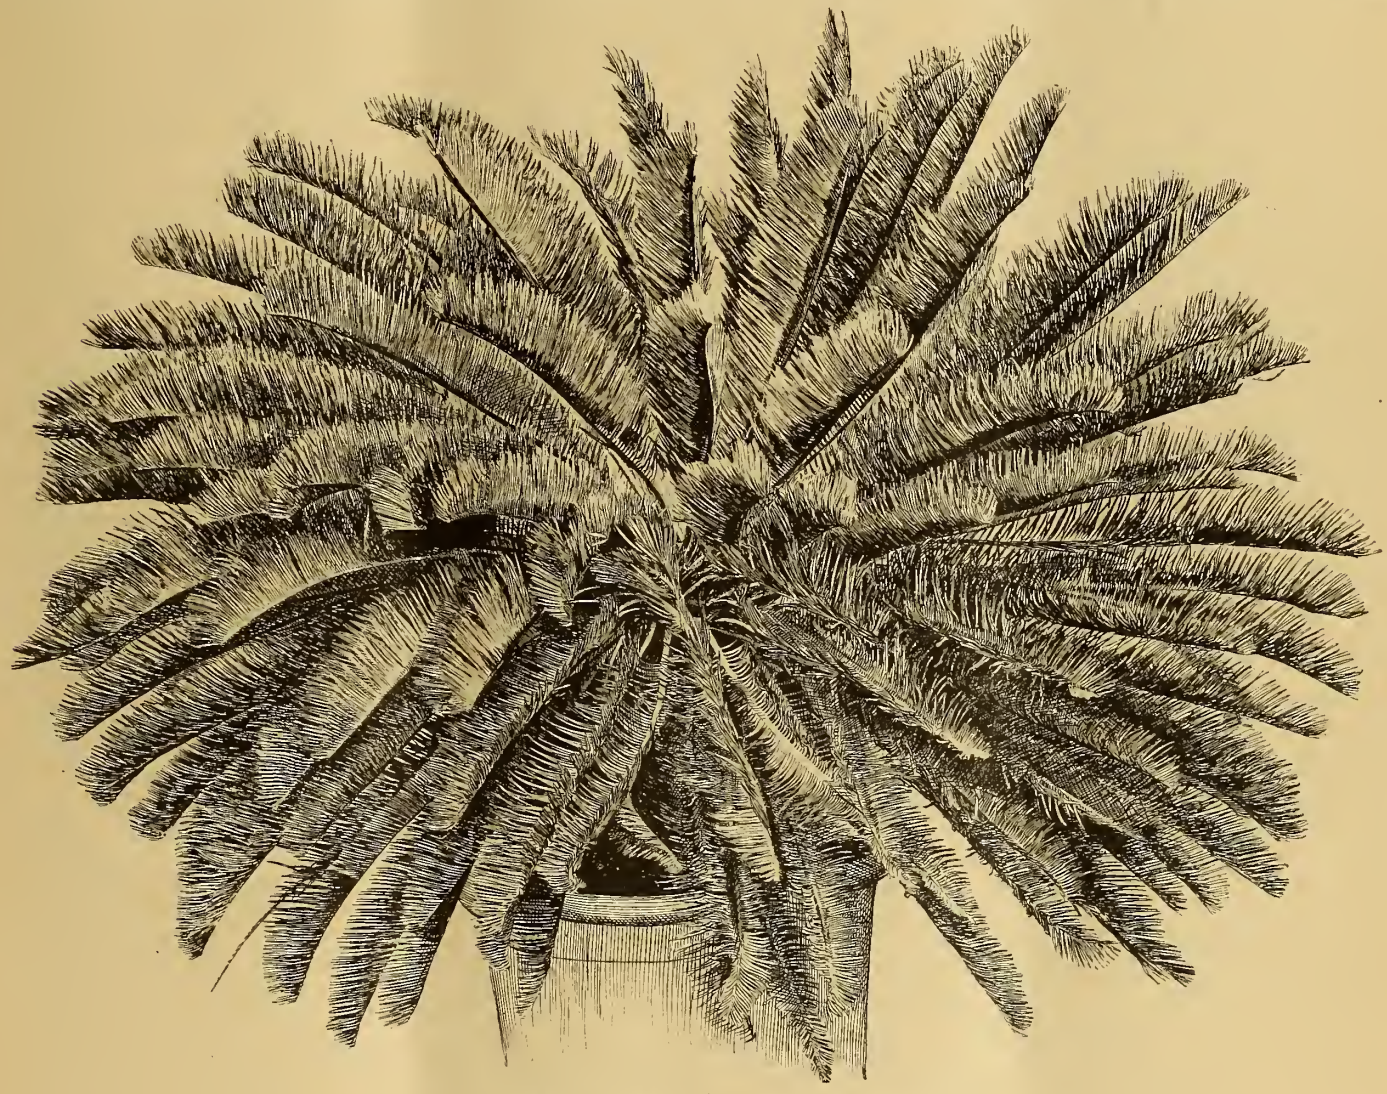

Fig. 37.—Encephalartos Frederici Guilielmi.—See page 203.

GREENHOUSE RHODODENDRONS are represented at Kew this month by a considerable number of Himalayan species, about half a dozen of the Javanese hybrids, and as many forms of *R. formosum*. The queen of the lot, in regard to size, elegance and purity, is *R. Rucklandii*, of which there are two large plants in full flower in the temperate house, their loose umbels of enormous saucer-shaped, pure white flowers being very handsome, fragrant and durable. A hybrid raised at Kew between this and *R. Hookeri*, and flowered several years ago, is noteworthy on account of its having stood the severe weather of the past winter much better than either parent, and as well as the hardiest of the Himalayan species of this genus. The Javanese kinds are flowering well in the temperate house, where, apparently, they are as much at home as the Camellias,

Acacias and hard-wooded plants generally. The "Andean Rhododendron" (*Befaria glauca*) is also flowering now, and is much more attractive in color and number of flowers in a raceme than it has been before. This dwarf and evidently free-flowering plant ought to become a favorite for the greenhouse. Seedlings take a long time, about ten years, to grow to flowering age, but cuttings or grafts from flowering plants would no doubt bloom when only a year or two old. A hybrid raised many years ago from *R. Dalhousiæ* and *R. formosum* is a very beautiful and free-flowering greenhouse plant. It is not unlike R. Countess of Haddington and *R. Gibsoni* in habit and flower, and it closely resembles the true *R. Dalhousiæ*, a Himalayan species scarcely known in cultivation. The flowers are deeply campanulate, over three inches in diameter, and white tinged with rose. They remain on the plant several weeks.

Epiphyllum Gærtneri.—This plant was introduced into notice by the Belgian nurserymen three years ago under the names of *E. Russellianum*, var. *Gærtneri*, and *E. Makoyanum*. It was at first thought to be a cross between an Epiphyllum and a Phyllocactus, but it has since been shown to be an introduction from Brazil, and is looked upon at Kew as a third species of Epiphyllum, the other two being *E. truncatum*, of which numerous varieties are known in gardens, and *E. Russellianum*. The new one differs from these in having flowers of about twenty lanceolate petals varying in length from half an inch to two inches, and arranged regularly round the cluster of short stamens, so that when fully expanded each flower is in form like a Phyllocactus; the color is a brilliant orange-scarlet. The leaf-like branches are similar in form and arrangement to those of *E. truncatum*, each joint being about two inches long by an inch in width, the margins dentate and the upper end clothed with a brush-like tuft of stiff brown hairs half an inch long. Grafted upon a thin-stemmed Cereus this species forms in a year or so a sturdy standard, with a head a foot through, and it produces two or three flowers on the end of every branch. The plant at Kew has a dozen flowers fully open, and is a beautiful object.

Shortia galacifolia has been exhibited in flower several times this year at plant shows in London. It has proved quite hardy in England, growing freely and retaining its foliage all the winter, in spite of severe frost and poisonous fogs; in spring it sends up numerous flowers, and when at its best it is a really pretty rock plant. The leaves assume a deep, glossy, chocolate color in spring.

The Blue Himalayan Poppy, *Meconopsis Wallichii*, has succumbed to the severe weather of the past winter, although previous winters of the last eight years have not been too much for it. Luckily, we have a batch of young plants which had been placed in a cold frame for the winter, and these are quite safe. At Kew this splendid plant is one of the annual attractions of the rock garden, where it is grown in a damp, somewhat sheltered and shaded position, in a bed of peat. Here it grows well and produces, in July, its tall spikes, a yard or more high, of rich, purplish blue, poppy-like flowers. Seeds are sown every year, and the young plants grown on in pots to take the place of those which die after flowering. This plant is one of the many beautiful garden subjects which come from the high Himalayan Alps, where, in Sikkim, Sir Joseph Hooker found it at an elevation of 10,000 feet. Six other species are found in the same region, three of which are in cultivation at Kew. They are, however, not nearly so useful in the garden as *M. Wallichii*.

Orchids.—The meeting of the Royal Horticultural Society this week was remarkable for the number of rare and beautiful Orchids exhibited, chiefly by Sir Trevor Lawrence, the president of the society, Baron Schrœder and Messrs. F. Sander & Co. The collection of Masdevallias from Burford Lodge was most beautiful, and comprised some very fine varieties of *M. Harryana* and *M. Lindeni* and others. In Baron Schrœder's group there were the following: *Lælia Digbyana Mossiæ*, with two large flowers on a raceme. It will be remembered that when this grand Veitchian hybrid flowered for the first time, two years ago, it bore only one flower. *Cypripedium Morganiæ*, a fine specimen of this most beautiful hybrid, bearing twenty-two fine flowers. Three varieties of *Odontoglossum crispum*, named, respectively, *Stevensii*, *Wolstomholmiæ* and *Veitchianum*, and bearing each a strong raceme of flowers. These are three of the very finest varieties known. *O. hybridum dellense*, *O. Ruckerianum*, *O. Cervantesii moralla*; *Cattleya Laurenciana* and two varieties with a lilac shade in the segments, named *Vinckii* and *concolor*; *Lælia Jonghiana*, *Cymbidium Devonianum* and the hybrid *C. eburneo-Lowianum*. *Masdevallia Lindeni* was represented by a splendid specimen bearing over a hundred flowers. So fine a collection of Orchids has rarely been seen anywhere. Messrs. Sander & Co. sent their new *Dendrobium Venus*, described by me last week; *Maxillaria Sanderiana*, *Scuticaria Hadweni*, *Zygopetalum graminifolium*, with some beautiful Odontoglossums and Cypripediums, several of the latter being new hybrids. These fortnightly meetings in London have grown very much in interest and importance recently. Every plant of anything like special horticultural interest, and which happens to be in flower at the time of the meeting, is sent for exhibition, contributions coming from even the most distant parts of the country. In time the progress in English horticulture will be focused at these meetings of the old Society.

Cultural Department.

Earliness in Vegetables.

WHATEVER criticism we may make on the eagerness of buyers for the earliest vegetables, and however philosophically we may ourselves be disposed to wait for the better things that come later, it is of prime importance for the commercial grower to be first in the market with each of his specialties. The best exposure and the warmest soil—often much too warm for later crops—that can be obtained are seized upon, and the competition between gardeners often has the excitement of a game, and success gives an exhilaration out of proportion to the mere money-value of the result.

Usually, the gardener depends upon the seedsman in this matter; but nearly all gardeners of experience and skill have some specialties of which they grow the seeds themselves, and do not let them out of their hands without a liberal *quid pro quo*. In this way originate many of the new sorts put forward in our seedsmen's spring catalogues, and so severely commented upon later by purchasers of little experience. The older heads do not expect many real bonanzas, though they make many tests. It seems to me worth while to ask ourselves what we really have a right to expect of such offerings. Nothing can be more unwise than to condemn them all untested, unless it be to expect a large gain in testing them.

Every old gardener must be aware that our existing varieties of garden vegetables are not only better grown, but better in themselves—in some lines far better, and offer a much wider choice than they did, say thirty or even twenty years ago. Now, how has this advancement been realized? It is safe to say that, while some of it is due to care in cultivation, and a close study of the requirements of each variety, as much or more is due to a quick eye to note valuable variations, and a quick mind to make the most of them. Every crop which we grow exhibits many variations from the designated type, and the best opportunity for success lies in noting those which indicate special value.

Though variation is constantly showing itself, it appears more frequently as the distance widens between the locality where a variety originated and that where its cultivation is attempted. It often happens that such variation may seem to make a variety utterly worthless in its new location. This was the case in an attempt made, not long ago, to grow a northern variety of Sweet Corn in the south. There was an almost entire failure; but, by successive replanting from the southern-grown seed, not only was the type re-established by spontaneous adaptation, but it was absolutely improved.

In my own experience, extending over twenty-five years in northern Vermont, I have reached the conclusion that a variety of early peas, or beans, or corn, can be made to order in a longer or shorter time, according to the complexity of the requirements imposed. When a variety begins to sport—and they all do it—by successive plantings they may be made to fly, so to speak, in all directions, and then we have only to select and fix the form that suits us. From a single bean sport I have grown hundreds of varieties, which could have been increased to thousands before a tendency toward fixity again showed itself. In these varieties were seen almost every form of plant, of seed, and of markings; but it was not until the fourth generation that the original type reappeared, even approximately. In peas, I have actually produced, by crossing and selection, a predetermined variety with a special characteristic previously unknown. In the same way I have, by crossing, produced a sweet corn having all the characters of the Black Mexican (but much earlier), without the least aid from the latter.

It is easy to see from this how easy it may be, in a proper location, to obtain and measurably fix a habit of early maturity

in any garden vegetable capable of being successfully grown there at all. But when the desired thing is produced, it is to a great extent the child of its environment, capable, with care, of perpetuation in that specific locality, but with no sure promise that it will live up to its home character when removed to a considerable distance. I believe that no variety of corn will continue the same if moved in latitude more than fifty miles; and where it is a question of altitude as well as latitude, it will prove itself quite unstable under changes of a very few hundred feet.

This subject is one that seems to be worthy of careful attention. If properly studied, I am confident that very surprising results will be reached, and certain principles established, which will not only remove all mystery, but will give us mastery where before we trusted to chance.

Newport, Vt. *T. H. Hoskins.*

Fig. 38.—The Douglas Fir.—See page 205.

The Egg-plant and its Cultivation.

A LATE bulletin from the Cornell Experiment Station gives some interesting experiences with the Egg-plant, and from it we make the following extracts :

The chief difficulty in growing the Egg-plant in the north is the shortness of the seasons. It is only by starting plants early and maintaining a vigorous growth that we can succeed in fruiting the large sorts satisfactorily. The plants should be started under glass from the middle of March to the middle of April in a warm house. In the cold and small house used in our early tests the plants grew slowly, and when set out-of-doors they were not of sufficient size and vigor to begin bearing at once. We sow in "flats" or boxes, and when the first true leaves are about a half inch in diameter—which is about a month after the seed is sown—the plants are pricked off into two-inch pots. As soon as the pots are filled with roots the plants are shifted into four-inch pots. We have had indifferent success in transplanting into other flats, as the plant is more severely checked when placed in the field from the greater injury to the roots. It is imperative that the plants should not become "drawn." The plants are transferred from the four-inch pots to the garden from the first to the middle of June. The early sorts, as Early Dwarf Purple, are not so seriously injured by a check in growth as the large and late sorts, and they can therefore be handled with less care. These sorts can be started two weeks later than the others and receive but one transplanting. The effects of early and late setting are shown in the following experiment :

Seeds of several varieties were sown March 27th and May 15th. On the 7th of September they presented the following differences : Long Purple, Giant Round Purple and Long White from early sowing were productive, but few or no fruits had formed on the plants from late sowing. Early Long Purple and Round White from the late sowing were fully as productive as those from the early sowing. Early Dwarf Purple gave best results from plants started April 15th. This shows that there is little or no gain in productiveness in the small early sorts from very early sowing, while the large sorts profit by it. The Black Pekin, which is one of the large varieties, proved an apparent exception, however. Plants started May 1st gave better results than those started earlier, but neither lot was satisfactory. The unsatisfactory results from the early sowing may have been due to the loss of the first flowers because of the transplanting. Transplanting usually has the effect of keeping plants growing to the detriment of the flowers ; and Egg-plants which are in bloom when removed to the field are apt to drop the flowers. It is important in the large sorts to induce the first flowers to set.

The best soil for Egg-plants is a rich sandy loam—not too light—which contains an abundance of humus and retains moisture. Manure heavily. Large kinds should be set three feet apart each way. The ground should be thoroughly cultivated throughout the season. We run lightly through the land with the cultivator twice a week. The worst enemy of the Egg-plant is the Potato-beetle, which prefers Egg-plants to Potatoes. The Egg-plant grows slowly, and any injury to the young plant is with difficulty overcome. If the plants are seriously injured when first set there will be little use in attempting to fruit the large kinds. Paris green, at the rate of one pound to one hundred gallons of water, is destructive to the beetle. Very rarely do plants in a large plantation of the late varieties all mature fruit, and such kinds as Black Pekin, New York and Giant Round Purple rarely mature more than two large fruits to the plant in this latitude, and often only one. Some of the early and medium varieties mature from four to eight fruits. The value of any late variety depends largely on the uniformity with which all the plants set and mature fruit. The New York Improved possess this advantage over the old New York Purple. The value of long and careful selection to this end was illustrated in our large plantation of crosses last year. A large percentage of the plants were entirely unfruitful, showing that a promiscuous lot of seedlings is likely to be unproductive, and in this case these seedlings were crosses between productive parents. Breeding plants of uniform productiveness is the most important field in experiments with the Egg-plant now.

The varieties are not numerous, and vary widely in habit, pubescence, spininess, color of plant and fruit, size, shape and season of fruit. The larger varieties are most popular in market, but some of the earlier and smaller kinds are better. The white varieties find little demand in the market, and there is an impression that they are unwholesome, but they possess no other fault than a hardness of flesh and rind in the case of the smaller varieties. The White Chinese is as good as any for table use.

Besides a record of experiments in crossing different varieties, the bulletin contains an interesting study of the botany of the plant, by Professor Bailey. A summary of the bulletin is given as follows :

1. Egg-plants are adapted to cultivation in the north. The requisites of success in growing them are these : early starting ; warm quarters ; vigorous plants ; rather late transplanting to the field ; warm, rich and rather moist soil ; constant attention to Potato-beetles ; frequent cultivation.

2. The best varieties for private use are Early Dwarf Purple, Early Long Purple, White Chinese, with perhaps Black Pekin for late.

3. The best market varieties are New York Improved and Black Pekin, with perhaps Early Long Purple for the first demands.

4. In crossing different races of Egg-plants, the purple-fruited types appear to be stronger in their power to transmit color to offspring than do the white-fruited types ; and this appears to hold whether the purple type is used as the staminate or the pistillate parent.

5. The white-fruited types appear stronger in the power to transmit form and productiveness.

6. Fewer seeds are produced by flowers artificially pollinated than by those left to mature, even though an excess of pollen is used.

7. It is probable that the Egg-plant may be included among those plants which are capable of producing fruit without the aid of pollen.

Garden Annuals.

HOWEVER valuable perennial plants may be, some, like the Oriental Poppy, die down early and leave a gap, while others do not make much show until late in the season, and it is just here that the annual plants help out and contribute their share toward the summer display. A garden planted with perennials will still have room for patches of Mignonette, a group of China Asters, various in color or all alike, as the fancy is, or some Helichrysums, which, if cut when fully open and before they are discolored by the rain, will keep bright until more may be cut next season. One who tries to grow all the good perennials will still have room for all the good annuals ; and a model flower-border is one that combines the best of both classes with hardy bulbous plants.

. Our Narcissus are of necessity planted in a wide border in rows eighteen inches apart, and between the rows will be planted later on a quantity of Asters of various kinds for cutting ; this will save despoiling the flower-garden proper, for although Asters make a brave show while they are in flower, a heavy rain gives them a sorry and bedraggled look, and they should never be employed except in a secondary place, where they will aid in forming a display. Zinnias are entirely different, and may be used alone or dotted about in groups among other plants, because they blossom continually until frost, are not hurt by rain, and are excellent for cutting. In these three respects they excel the old bedding Geranium. In a wide border, or in any place where it is customary to plant the Geranium, Zinnias will answer the purpose admirably, and one has not to provide room for them all winter. In sowing Zinnias it is best to get separate colors, as in the mixed seed there are so many displeasing shades. Good colors and true to name can now be obtained, and if you want the "finest mixed" buy the colors you like and make your own. The same remark applies to Stocks.

Another annual plant, not half so well known as it should be, is the "Yellow Corn Flower," *Centaurea suaveolens*. In shape it is similar to the blue one, differing only in color, which is bright yellow. As the flowers are borne on long stems they have already attracted the attention of florists for winter cutting. The plant succeeds well when sowed in the open ground in May.

The Marguerite Carnation is one of the most valuable of recent introductions for those who cannot grow the ordinary florist Pinks, for, in a comparatively short time, good strong plants can be raised from seed and flowered, and it is surprising how really good the flowers are. The percentage of single flowers is very small. A florist of my acquaintance planted a lot of these on his benches last fall, with other pinks, and they gave an immense crop, many of them being beautiful in color, and all were fragrant. After a little more careful selection this Carnation will be an indispensable garden plant.

Sweet Peas should be sown by this time, and wherever they may be planted provision should be made for watering in dry weather, or failure is certain. Last summer six weeks of dry weather deprived us of these flowers, and this season we took

the precaution to dig a trench eighteen inches deep and place plenty of manure at the bottom, filling in the soil and sowing the seeds. In hot dry weather the rows will also be mulched and watered, and in this way a constant supply will be maintained. Do not buy mixed seed.

Mignonette is so much liked, and there are so many sorts offered, that one does not know which to sow out in the open ground. While all may be good in-doors, few will stand our hot sun and dry weather. We have found Machet the best; it produces good stout spikes of fragrant flowers until the fall.

Nasturtiums are often planted in rich soil. This is a mistake, for very few flowers are then produced; but when sown in poor soil they will flower abundantly. The same rule holds with *Salvia splendens*, now often treated as an annual. The Poppies, of which there are so many kinds, are very showy. They do not last long, but if cut when about to open they will last several days, and are useful for large vases for room decoration.

South Lancaster, Mass. *E. O. Orpet.*

Odontoglossum Œrstedii.

THIS small compact species is nearly always sure to be found in flower during the early months of spring, and although its blooms do not equal in size those of many other Odontoglossums, nor are they borne in such profusion, nevertheless they possess a charm peculiarly their own. The pseudo-bulbs are small—about the size of a pigeon's egg when fully developed—ovoid, more or less compressed, and furnished at the summit with a solitary oblong-elliptic leaf from three to five inches long, the lower portion being narrowed somewhat abruptly into a petiole. About two or three flowers are generally borne on the scapes, which spring from the base of the ripened pseudo-bulbs. Each flower is from one to one and a half inches across, and pure white with the exception of the bright yellow callus, which is more or less densely covered with deep orange spots. The sepals are rather broader than the petals, and are bluntly oblong with apiculate tips; the spreading petals are somewhat similar in shape, but are contracted at the base, while the roundish or wedge-shaped lip is more or less cut in the centre.

Messrs. Veitch & Sons, of Chelsea, were the first to flower *O. Œrstedii* in England in 1873, a year after its actual introduction to cultivation through the collector Endres. The knowledge of this species, however, dates as far back as 1848, when it was discovered by Warscewicz in moist situations in Costa Rica at the height of 7,000 to 9,000 feet above the sea-level. It was afterward found by Dr. Œrsted (whose name it bears), Endres and Wendland, the latter, it might be remarked, being now the sole survivor and director of the gardens at Herrenhausen, Germany. It is possible that the first plants introduced were somewhat sickly or did not produce flowers of much merit, for, although shown on several occasions since the time of its first flowering, it was not until March, 1884, that this plant received a first-class certificate from the Royal Horticultural Society, the specimen on this occasion having been grown in the then famous, but now obsolete, collection of Mr. William Lee, of Downside, Letherhead.

Growing at a high altitude in its native country, *O. Œrstedii*, naturally requires only a moderate amount of heat under cultivation. It is found to thrive best in well-drained shallow pans in a light compost of peat and sphagnum. The pans should be suspended near the glass, so that the plants may obtain the greatest possible amount of light, without, however, subjecting them to the very hot rays of the sun. Watering is regulated according to the condition of growth, more frequent supplies being given when the young bulbs are rapidly increasing in vigor, and a gradual diminution, with plenty of air, as they are becoming mature and ready to produce their flower-scapes. The temperature may be fifty to fifty-five degrees Fahrenheit in winter, gradually rising to sixty or sixty-five degrees during the summer.

Isleworth, London, W. *J. Weathers.*

Iris Caucasica came into bloom about the middle of April. This is one of the hardy bulbous (*Xiphion*) Irises of the Juno section, and should probably be grown in rather stiff soil. The habit is very peculiar and distinct. The plant is dwarf, leaves short, pointed, shiny above, with a slight, thin, white line on margin. The leaves are distichous, *i. e.*, arranged in two perpendicular rows. The flowers are small, and appear in succession from the axils of the upper leaves. They have a very quiet beauty, being of a translucent greenish yellow, with a distinct crest on the claw and blade.

Scilla trifolia is a distinct but not very showy Squill, which was in flower in April. The three leaves are lance-shaped, slightly glaucous, and rather thinner in texture than is usual in the family. The flowers are individually small and borne in pyramidal raceme on short scapes. In color they are light blue, of a pleasing shade. They are natives of Asia Minor, and excellent subjects for the rockery.

Phlox subulata Sadie.—This is a plant to be made a note of now that it is in bloom. It is apparently a cross between *P. subulata* and *P. stellaria*, showing many of the characteristics of the latter, with the compact growth of the former. The flowers are large and white, with a very slight lavender tint. As grown in a large mass at Myer's nursery, where I saw it coming into bloom a few days since, it was very effective, and seemed a valuable variety for an early spring border.

Begonia Triomphe de Lemoine, the flowers of which have been illustrated in Garden and Forest (vol. ii., p. 557), proves to be a very distinct variety of this interesting family. The plant has not proved of very attractive habit in the greenhouse, but this may be a fault of cultivation, as the stock was secured too late to cultivate out-of-doors in summer, as advised by the raiser. The leaves are round and peltate, the stems herbaceous. The influence of the Socotrana parentage is quite pronounced in these, as well as in the flowers, which are the most persistent of any Begonia yet introduced. I am not prepared to say exactly how long they remain on the plants, but some clusters of flowers which appeared in the winter still seem to be undiminished. The flowers individually are not specially attractive or large, but they are of a good pure dark red and very abundant. Plants of this variety should be secured now and grown in the open air during summer, so that they will be strong for their winter work. *Begonia Socotrana* seems to be the missing link between the fibrous and tuberous-rooted sections, making crosses with either. None of the fibrous-rooted hybrids as yet have the large showy flowers of the tuberous crosses, but in some respects they are more desirable for general cultivation, as they do not have such a distinct period of rest and are always in evidence. The deciduous section are easily lost if care is not taken of the bulbs, and there is always more or less care required to dry them off properly and start again at proper season.

Begonia Louis Closson.—Among the Rex Begonias, Louis Chrétian has long held first place as the brightest and most effective, but it is very probable that this new variety will at least equal the older one, if not surpass it, in popular favor. The leaves of Louis Closson are broadly margined and centred with a lustrous pure black, and the zone is a rich satiny deep wine-red, a very quiet, rich and effective combination.

Botanical Nomenclature.

To the Editor of Garden and Forest:

Sir,—The discussion in regard to the establishment of a stable botanical nomenclature has a special interest to me from the fact that, in a short time, I propose to have published from this division a check list of the arborescent flora of the United States, containing both botanical and vulgar names; and, while Mr. Sudworth is working out the botanical synonymy, it will fall to me to decide muted points.

I should like, therefore, to see all such points discussed fully, in order to arrive at what the consensus of opinion is, and to render our work of revision as stable as possible.

Dr. Britton suggests that we follow the practice of the ornithologists in not citing the author of a new combination of specific and generic names. I think this would be a mistake, and, while we may admire the modesty and the deference to artistic sense on the part of the ornithologists (inasmuch as the names of one or two authors who made the revision would appear endlessly repeated), we have no such reasons in the botanical nomenclature for abandoning historical accuracy.

The practice of adding the author's name to the plant name serves, first of all, the valuable purpose of identifying the plant to which the name is given; it is the mark of identity. Thus, by writing *Tilia Americana*, L., we want to insure that we call up the plant which Linnæus described and named, and not, perhaps, the plant which Walter described under the same name.

Next comes the historical relation which the citation of an author at once brings before the student. We are informed that Linnæus knew the genus Tilia and the species Ameri-

cana as such, and can find in his writings a description under that name. Last, though in the minds of many this seems the foremost use of the citation, the personal consideration comes in of giving credit to the discoverer, the describer, the namer of the plant.

Making priority of name the criterion for its use, I take it, is not to glorify the namer and give him due credit, but to find some basis upon which to establish order out of chaos.

The notation, by which we write *Hicoria minima* (Marsh.), Britton, answers admirably all the requirements of ready reference, historical accuracy and personal responsibility. None other will suffice; none better, I think, can be proposed. Leaving out "Britton" at once introduces a factor of error or doubt as to what plant really is meant, for Marshall never described any plant under that name, and we could not identify it by reference to his publications unless we guessed that his Carya corresponded to Hicoria; furthermore, it would be misleading historically, for in his time, or by him, Hicoria was not known as equivalent to Carya, and even personal responsibility would be misplaced, for he was not the author of the name as it stands, but only of a part of it.

On the other hand, if we write Catalpa Catalpa (L.), Sudworth, we know at once this is a plant which bears its name by virtue of a revision made by Sudworth, and somewhere I may find the history of that revision and the relation of this name to other names. It shortens the road, moreover, by giving me the historical information that Linnæus used the specific name Catalpa, but did not place it in the genus Catalpa; hence, if I know that the genus Catalpa and Bignonia have been differentiated, I can at once identify Bignonia Catalpa of Linnaeus as the plant here meant, and identification, historical truth and proper reference, the three objects of citation, have been attained.

Let us for once agree as to what thing we mean to call by a given name, and it will be possible by and by to drop the author of the name entirely, just as in common life, when we speak of a billiard-table it is not necessary to add, "I mean that which So and So first called billiard-table." This time, however, is not near at hand, except perhaps with some well-established, unmistakable species, and, therefore, we shall have need, for the sake of accuracy, to continue citing authors. But by all means let us have them cited fully and accurately, or else the value of the citation is illusionary.

Forestry Division, Department of Agriculture, Washington. *B. E. Fernow.*

April Flowers in Northern California.

To the Editor of Garden and Forest:

Sir,—The middle of April, in California, north of San Francisco Bay, finds the wild flowers, in hundreds of species, and often in vast quantities, covering acres on acres of ground. As yet the height of the season is not reached. The San Joaquin Valley and Monterey are fully three weeks earlier, and southern California earlier still. A month ago our common Buttercups, *Ranunculus macranthus*, were few in numbers; now the roadsides are yellow with them, and pastures are covered with them by the acre. In wet places *R. Bloomeri* takes its place with equal profusion. Yellow seems a favorite color here, for it is always seen in masses. In places a low-growing Œnothera, in profuse flower, shows the richest of yellows for a long period. Then the Eschscholtzia fairly monopolizes some vacant lots in this town where there is a deep gravelly soil. These beautiful Poppies appear, not in dozens or thousands, but turn whole acres into billowy masses of splendid orange; other acres glow with the darker orange of Amsinckia or the purple-blue of Lupines. The Eschscholtzia foliage is especially rich this season in scarlets and bronzes, which, if they could be relied upon as permanent, would make it an interesting foliage plant.

Nemophilas are largely used by nature as bedding plants here. *N. insignis*, Blue Eyes we call it, is everywhere in single plants or in beds, a few yards in extent, and occasionally by the solid acre. *Gilia tricolor* is another plant which now covers entire hillsides. *Platystemon Californica*, another member of the Poppy family, is also a favorite with nature. The flowers are a creamy yellow, borne separately on long stalks. In dry fields it covers large areas. White is the rarest color in these natural parks. Several species of Eritrichium are here, with delicate, white flowers. *Limnanthes Douglasii*, long in cultivation, forms large, white masses in moist places. Scarlet does not yet appear in abundance, although *Calandrinia Menziesii*, another cultivated species, is everywhere.

Mendocino County and the region around the base of Mount Shasta have the richest flora in California. The Sierra Nevada range is largely volcanic. In the coast range clays prevail, with here and there volcanic projections. At Shasta these two ranges meet, giving in a small space great variations in soil, altitude, exposure and moisture. The rainiest spot in California is closely adjacent to a lava desert, so at Mount Shasta the conifers have a wonderful development in species, and the flora as a whole is very rich. In Mendocino County the Redwood-forest furnishes shade and moisture. The dry Chemisal region is close at hand, giving the prevalent flora of the coast range. Elevations of 5,000 to 6,000 feet give alpine conditions, while isolated volcanic points add variety to soil. Add to this narrow valleys and deep cañons, and the variety of vegetation is not to be wondered at.

Among shrubs the various Ceanothus are common, going far to make up the unbroken growth, from six to fifteen feet high, which, in an almost impenetrable thicket, clothes many of the mountain-sides of the coast range, and gives them a smooth, Heath-like appearance. The local name for this low growth is chemisal when the shrub *Adenostoma fasciculatis* predominates; chapparal, if the growth is largely mixed. In the aggregate vast areas are so covered. One continuous belt is sixty miles long by eight or ten wide, with very small breaks in timber or grazing-land. *Ceanothus divaricatus* is one of the commonest elements of chapparal, and is now in bloom. In the open Redwood *C. thyrsiflorus*, a fine shrub, often fifteen feet high, with flowers much like a lilac, and fully as beautiful, covers large areas in an almost impenetrable thicket.

In my garden *Erythronium grandiflorum* is beginning to fade. It gave fine satisfaction this season, planted in chip mold, and rather shallow. *E. giganteum*, from Oregon, bloomed for the first time this year. The bulbs were strong and produced large blossoms, four to six to each, and several three inches across. Close observation shows some difference between this and *E. grandiflorum*, but the distinction is not well enough defined to be satisfactory. The yellow of the flowers of *E. giganteum* has a slight greenish shade, while those of *E. grandiflorum* shade from light straw at tips to rich yellow near the centre, and occasionally with markings from light brown to very dark. *E. Smithii* lacks the elegance of form of the two former, and is one-flowered. Its color, at first, is white, with a pink tinge, and becomes pink-purple. *E. Howellii* has a straw-colored flower with a peculiar pinkish orange centre. With me it was quite small, but the bulbs may not have been strong.

Brodiæa multiflora and *B. congesta* blossomed together, and very beautiful they were. They were planted in shallow boxes, the top soil mold and clay with a light dressing of sand. The first Calochortus to flower was the dainty little *C. cæruleus*. It was closely followed by *C. lilacinus*. The first is doing well in a common clay loam. *Fritillaria lanceolata* seems to run to many forms, which, to the gardener, would be good varieties. The prettiest I had this year was a light yellow one. They were in shallow boxes about three inches deep, in clay loam, and shaded in the afternoon. Considering the quality of the bulb the flowers were as good as I have seen in the very best natural wild growth. There is a variety of *F. recurva* which is unusually fine. Some racemes were sent to me with five to nine blossoms, and I have heard of one with eighteen.

Ukiah, Cal. *Carl Purdy.*

Washington in April.

To the Editor of Garden and Forest:

Sir,—No city can be more beautiful than Washington is in the latter part of April, with mile upon mile of flourishing trees of all varieties in their fresh young foliage. These border the streets and avenues and stand guard over the wide parking of emerald turf spread out before each residence. The fronts of many houses are at present one mass of long violet clusters of Wistaria, or almost covered with the brilliant green of Honeysuckle or the half-open leaves of the Virginia Creeper, or its next of kin, the Japan Ampelopsis.

The public parks have burst into bloom and beauty in the most marvelous manner within a few days. Great clumps of white and purple Lilacs, pink sprays of Flowering Almond and Tamarix, snowy blooms of many sorts of Spirea (although the latter are not doing their best this year), Snowballs just ready to "turn white in a single night," occasional small groups of Blood Maples, Purple Plums and Golden Barberries, with the silver bells of the Halesia and the flame of Japan Quince blossoms against the rich satiny turf, make a wealth

of bright color even under the soft sunshine and the opal haze of spring.

The attractive features of this locality are not confined to the city limits, however. Yesterday a drive of a few miles up the Potomac brought me to Glen Echo, where, on the river's bank, the new and permanent home of the Chautauquans has been selected.

The woods abound with Dogwoods and Redbuds, and they are now in their glory. The bright blossoms among the sombre Cedars and Pines, and the rapidly bursting foliage of the Chestnuts, Elms, Oaks, Poplars, Beeches, with their varying tints and shades, make the prospect one dream of beauty.

The carpeting of these groves, which has long been flecked with the Trailing Arbutus, the milky Bloodroots and pale pink and blue Liverworts, is now ornamented with clumps of Saxifrage, Spring Beauties and graceful Wind-flowers, with here and there a patch of Bluets, Buttercups and Violets. Besides these are Adders'-tongues or Dog's-tooth Violets, some bunches of the early Daisy, with its broad golden eye and fine lavender lashes, sometimes, I think, called Robin's Plantain, and graceful stems of Solomon's Seal almost in bloom. Farther down the slopes are snowy stretches of the great starry Chickweed, and near the water the stiff Jack-in-the-pulpit, the odd umbrella-leaved May Apples and uncurling fronds of many Ferns are running riot. Around the base of the rocks, many of the crevices of which are adorned with clumps of wild Columbine, are tufts of Everlasting, wild Pinks (*Silene Pennsylvanica*) and the pretty-leaved Lousewort. There is an occasional breath from the Swamp Magnolia, and the warm pink Azaleas are just beginning to bloom among the Huckleberries on the hill-side. Near the river grows the purple Lady's-slipper, with its rosette of light green leaves, amid a great wealth of the Lungwort, with its smooth, tender foliage, graceful stems and loosely flowered racemes of dainty purplish pink buds the size of a pin-head, with the full, open trumpets of the developed flower, a delicate clear blue. Surely, Glen Echo is worth a visit.

Washington, D. C. *M. Fuller.*

Orchids at Whitinsville.

To the Editor of Garden and Forest:

Sir,—In the conservatories of Mrs. J. W. Lasell, at Whitinsville, Massachusetts, I recently saw a plant of *Cymbidium Lowianum* with eleven spikes, and nineteen flowers on some of the spikes. The flowers of this plant had more of the golden yellow tinge than is generally seen, while the lip was a rich dark brown.

A superb specimen of *Cattleya amethystoglossa* had a spike with twenty-three flowers. Fortunately, this remarkable plant has been photographed. In other Cattleyas this collection is remarkably rich, having good specimens of all the choice species and varieties.

Among Cypripediums are many fine plants of Spicerianum, Lawrencianum, Sanderianum and others, some forty varieties in all. Mr. McWilliam, under whose care those fine plants flourish, has a great many seedling hybrids which are yet too small to flower. Notable among the large collection of Dendrobiums here, is a specimen of *D. formosum giganteum*, which made a twenty-nine-inch growth last season, producing twelve large well-developed flowers. The English horticultural journals complain that this plant does not succeed well there. Mr. McWilliam grows it in a much lower temperature than it is said to have in England, and gives it a three months' rest after flowering at a temperature of forty-five degrees. *Cœlogyne cristata* was almost past, but had been a mass of flowers for three months. Twenty-six ten-inch pans produced from thirty to fifty-four spikes each.

Disa grandiflora flowers here every summer, with Lælias in variety, and many Lycastes, Masdevallias, Oncidiums, Phalænopses, Saccolabiums, Vandas and Zygopetalums. Of Odontoglossums there are more than two hundred plants of choice varieties, *O. vexillarium* being particularly well done. One plant last season had thirteen spikes.

Calanthes were a show of themselves for about three months, a hundred plants being in flower at once last year.

Peristeria elata, the Holy Ghost Plant, is well grown here, as those will testify who saw the remarkable plant at the exhibition in Boston last August. This plant had twelve spikes, and one of them bore seventeen expanded flowers, with as many more to open.

Apart from Orchids, there is much here to interest intelligent lovers of plants, not only in the way of rare and choice specimens, but in the admirable growth of all kinds of plants, which is the test of a good gardener.

Whitinsville, Mass. *W. S.*

Recent Publications.

Floriculture as an industry has never been made the subject of census investigation until now, and, therefore, the preliminary report which has just come to this office has exceptional interest. The business has been carried on, of course, for more than a hundred years in the country, and yet the statistics show that it has only assumed large proportions during the last quarter of a century. Out of nearly 5,000 establishments, three-fifths have been started since 1870 and one-third of them since 1880. At the beginning of the century there was but one commercial florist in the country, and only three establishments were started between 1810 and 1820. Eighty per cent. of the entire business has been developed during the past twenty-five years. During the census year every state and territory, except Idaho, Nevada, the Indian Territory and Oklahama, reported some business in floriculture, and, perhaps, in these states small establishments would have been discovered if sufficiently thorough investigation could have been made.

The report makes record of 4,659 establishments, of which 312 were owned and conducted by women. These establishments had in use 38,823,247 square feet of glass, covering a space of more than 891 acres. Their value, including fixtures and heating apparatus, was $38,355,722, and the tools used were valued at $1,587,690 more. Wages amounting to $8,483,600 were paid to 16,847 men and 1,958 women. The fuel cost more than $1,000,000, and the postage on the 20,000,000 catalogues amounted to $767,438. In addition to this, more than $1,000,000 were paid for advertising, and another $1,000,000 for freight and express bills. The receipts from cut flowers amounted to more than $14,000,000, and from plants and shrubs more than $12,000,000. The largest area in glass in a single establishment was found in the District of Columbia, and the smallest in a New England farm-house, from which the lady of the house sells annually from $35 to $50 worth of plants and flowers, raised under sixty square feet of glass. Besides the Society of American Florists there are 965 state and local societies and clubs, and 358 horticultural societies, and these, aided by the agricultural and horticultural press, have helped to put the industry in its present healthy and prosperous condition, giving employment to thousands of people, and furnishing a fair reward for capital invested, besides doing much to adorn the homes and elevate the taste of people of all classes.

It is difficult to estimate the rate of wages paid, because many of the greenhouses are small—that is, having a glass area of from 300 to 1,500 square feet—and in them there is no outside labor employed, since the owner or some member of his family does all the work, often in connection with market gardening or a small nursery-trade, and some of the smaller establishments are conducted by women or persons who are invalids and who are not able or do not care to work all the time. In many of the larger establishments during the busy seasons numbers of extra men are employed, and this makes an additional difficulty in the estimate. The figures seem to show, however, that the wages paid in what is called the North Atlantic division of the United States are rather more than $1.50 a day to men, and rather less than a dollar a day to women, although in every establishment of any size there are men acting as experts, or as foremen, who receive from $15 to $20 a week. In the southern states lower wages are paid, and higher pay is commanded in the Pacific states.

Of the plants sold the demand in the northern and eastern states is greatest for the following in nearly the order named: Geraniums, Coleus, Roses, Pansies, Verbenas, Heliotropes, Carnations, Chrysanthemums, Palms, Ferns and Fuchsias. In the south the demand is for Roses first, and then for Chrysanthemums, Geraniums, Coleus, Palms and Ferns, while California shows the demand to be largest for Roses, Carnations, Chrysanthemums, Geraniums, Palms and Pansies. There is also a very general and growing demand for aquatic plants, and specialists are giving marked attention to this branch of the business. Regarding cut-flower sales, reports show that, while there is a slight variation in the demands of the different markets, the greatest demand everywhere is for Roses, followed closely by Carnations. These two furnish about sixty-five per cent. in value of all cut flowers sold. Violets, Chrysanthemums, Lilies, Hyacinths, Smilax, Bouvardias, Heliotrope, Pansies and Tulips, in the order named, supply twenty-five per cent. more, while the other ten per cent. is made up of Orchids, Tuberoses, Mignonette, Primroses, Camellias, Daffodils, and many others cultivated in a small way to supply a special or local demand. As to the profits in the business from the different classes of plants, eighty per cent. of the re-

ports mention Roses as most profitable, Carnations second and Violets third, while twenty per cent. rank Carnations first, Roses second and Violets third.

Notes.

Mr. Jacob Austin, of Fergus Falls, Minnesota, who has done much to encourage tree-planting on the borders of the prairie, has been exhibiting a fine lot of maple-sugar made from trees of his own planting.

"Reader," who wishes to know whether the Rose Baroness Rothschild is correctly described in a leading trade catalogue as "delightfully perfumed," is informed that the Rose in question has no fragrance.

Lilies-of-the-valley have recently been grown in England in large pyramids formed of a light, wooden, lattice-work filled with moss, the bulbs being set about an inch apart, and the plants, when fully developed, forming a solid mass of leaves and flowers.

For the past week the Weeping Japanese Cherry has been an object of striking beauty. These trees grow very rapidly, and soon become twelve or fifteen feet high, with branches which droop to the ground in a circle of as many feet in diameter, and covered completely with light pink blossoms.

Rarely do we see Peach-trees, Cherry-trees, Plum-trees and Apple-trees all in bloom at once, but this is what has happened this year in this neighborhood owing to the sudden coming of warm sunshine. Singularly enough, hereabouts, the blossoms of the Cherry-trees opened before those of the Peach-trees. What was the occasion of this change in the order of the floral procession ?

In a paper on cultivating Carnations, read before the Philadelphia Florist Club, Mr. A. M. Herr gave the following list of varieties as the best market sorts with him, on sandy loam that does not readily become water-clogged: For white, Lizzie McGowan, Mrs. Fisher, L. L. Lamborn and Silver Spray; for pink, Grace Wilder, Christmas, Fred Creighton and Day Break; for scarlet, Hector only; for crimson, Anna Webb; for carmine there is nothing to compare with Tidal Wave. Buttercup is the best of its color, but it cannot be grown successfully by Mr. Herr, and therefore he substitutes for it Golden Gate. For fancy, J. J. Harrison, Nellie Lewis and Chester Pride have proved the best.

It is asserted in a German horticultural journal that two valuable novelties, *Iris Danfordiæ* and *Heuchera sanguinea*, have proved entirely hardy in Silesia during two severe winters. The former, which was procured by Herr Max Leichtlin from the banks of the Euphrates, perished the first winter that the writer attempted to grow it, when it was protected with planks and leaves. But this year, when it was left entirely unprotected, it survived and came bravely into bloom with the Snowdrops. An old plant of *Heuchera sanguinea*, which is a native of Arizona and northern Mexico, was also left uncovered and likewise survived, while seedlings of 1889 did as well under a slight covering.

A Hyacinth exhibition was recently held at Charlottenburg, near Berlin, for the purpose of proving that German horticulturists and amateurs need not feel dependent upon Holland for their supply of these plants. Twenty thousand blooming plants were exhibited by eleven growers of the immediate vicinity, and the display is said to have been very fine despite the unfavorable weather of the winter just past. A writer in *Gartenflora* declares that, although much greater areas are devoted to Hyacinth culture in Holland than in Prussia, and although the varieties there produced are more numerous, the Berlin flowers now equal the Dutch as regards purity of strain, good general development, prolific blooming, and the beauty of individual flowers.

In response to a request for a list of varieties to restore a run-down fruit-garden, Mr. J. J. Thomas names the following, which are hardy and productive, and as they are for home use good quality has been considered of the first importance. Apples, for succession: Early Harvest, Yellow Transparent, Sweet Bough, Primate, Autumn Strawberry, Gravenstein, Fameuse, Hubbardston, Wagener, R. I. Greening, Jonathan, Red Canada. Pears: Summer Doyenné, Giffard, Tyson, Bartlett, Howell, Anjou, Lawrence, Malines. Peaches: Early Rivers, Mountain Rose, Large Early York, Crawford, Nivette, Richmond, Stump, Salway and many others. Plums: Bradshaw, Imperial Gage, McLaughlin, Jefferson, Lawrence Gage, Bavay. Cherries: Coe's Transparent, Rockport, Black Tartarian, Windsor, Early Richmond, Large Morello. These are only a few; there are other sorts nearly as good, and which may be substituted when a change in locality requires, or where personal preferences would make additions.

In an article on "The Republic of Uruguay," by Mr. Theodore Child, published in the May number of *Harper's Magazine*, there is a description of the Central Cemetery of Montevideo which shows that the Campo Santo of the south of Europe has perpetuated itself in South America. This cemetery, we are told, "is considered one of the sights of the capital. It has a monumental entrance and an elaborate chapel, and is reputed to be the most luxuriously and best-arranged cemetery in South America. It is situated on the sea-shore and divided into three sections, surrounded by high walls, in which are arranged, on the inside, innumerable niches, each with its marble tablet recording the names of those whose remains are deposited inside. The coffins are wound up to the mouth of these mural cellules by means of a portable lift and ladder combined, and the whole surface of the walls is hung with wreaths of fresh flowers or of beads, which stand out in strong relief against the marble facings. Each section of the cemetery is carefully laid out, fenced in with iron railings, and full of tombs and monuments of great price and pretensions, due to the chisels of the sculptors of Rome and Milan. The vegetation in the cemetery is most varied, and, besides the funereal Cypresses, there are flowering shrubs of many kinds, and on almost every grave wreaths of fresh flowers, constantly renewed, that fill the air with their perfume. The pious luxury displayed in this Campo Santo is remarkable."

The name of Baron Haussmann, who recently died in Paris at the age of eighty-two years, is probably better known than that of any of his contemporaries whose public services were of a purely pacific kind. Appointed Prefect of the Seine in 1853, soon after Napoleon III. placed himself on the throne, he was busied until the fall of the Empire in improving the city of Paris. Not unnaturally, he was severely criticised for many of the changes he wrought in sweeping away the old narrow filthy streets and opening wide, straight thoroughfares in their stead, for the historic interest of Paris was thus greatly decreased and many buildings of architectural as well as historic importance were swept away. But those who believe that the first purpose of cities is to afford comfortable and wholesome places of habitation rather than to be museums for the delectation of travelers, cannot but look with admiration on the results of his work, which have made of Paris the most stately and splendid of modern towns. Nor were his services confined to the cutting of new boulevards and the transforming of whole regions like the Batignolles Quarter from tangles of dirty alleys, inhabited by the most wretched poor, into spacious, airy and healthful districts. He carefully arranged for the planting of avenues and small squares, was the first to propose the improvement of the Bois de Boulogne and the Parc Monceau, and established the Parc des Buttes Chaumont, which, on account of the peculiarly broken character of its site, is now one of the most interesting pleasure-grounds in Europe.

The court-gardener at Carlsruhe recently wrote to a German horticultural journal that many of the trees under his care had suffered terribly during the exceptionally cold season just past. Cherry-Laurels and Aucubas had frozen, and likewise Cedars of Lebanon, Deodars, *Sequoia sempervirens*, *Libocedrus decurrens*, *Cryptomeria japonica*, *Abies concolor* and its variety *lasiocarpa*, *Abies Webbiana*, *Picea Morinda*, *Pseudotsuga taxifolia*, and many other conifers had seriously suffered, and dead wood was already to be seen on many deciduous trees, while the whole damage could not be estimated until later in the season. But, says the writer, as was the case eleven years ago, when even native trees perished, no specimen of the Tulip-tree had suffered, neither an old tree, a sapling in the nursery, or a seedling. Even further north in Germany, he believes, this tree will prove itself hardy, at least in somewhat sheltered situations, if a slight protection be given to its roots while young. The beauty of the tree receives high praise at his hands, particular mention being made of an avenue in Carlsruhe, composed of eighty-one specimens measuring from one metre to nearly two metres in the circumference of their trunks. He deplores the fact that Tulip-trees are not more generally planted in Germany, and says that, in the avenue just mentioned, many naturally produced seedlings are found each year, all of which, when transplanted, prove perfectly hardy. He insistently recommends the end of April or the beginning of May as the best season for planting.

TABLE OF CONTENTS.

The Decline of the Country Gentleman.

WHEN the first census of the United States was taken in 1790, about one-thirtieth of the population lived in towns of more than 8,000 inhabitants. The last census shows that nearly one-third of the people of the United States now live in towns of that size or larger, while, in the north Atlantic States, more than half the population is urban. In Maine, Vermont, Massachusetts and New York the increase of the city element is numerically greater than the total increase; that is, the rural population has actually decreased. This disproportion in the growth of city and country would appear more striking if towns of 4,000 or 5,000 inhabitants and upward were transferred from the country to the city class, as they should be, since their inhabitants live under conditions which are distinctly urban.

The growth of smaller towns and villages, as compared with the strictly rural population, has been quite as well marked. Taking an agricultural community like Sussex County, New Jersey, which is less than fifty miles from New York, it appears that the population has been practically at a standstill for sixty years, while the towns and villages in the county have increased many-fold. This means that the farms have lost a great proportion of what the towns have gained. In addition to the relatively slow growth, and, in some cases, to the actual decline of the rural population, it is to be observed that the lands have decreased in value. Taking this county of Sussex in New Jersey, as an example, it is a fact worth considering that forty years ago, before the inflated prices of war times, farm-land there, which was fifteen or twenty miles distant from a railroad, was worth fifty per cent. more than it is to-day, although it has convenient and direct railroad connection with this city. Nothing is plainer than the fact that the towns and cities are increasing in wealth, in population, and in influence at the expense of the rural communities.

Professor Rodney Welch contributed to the February number of *The Forum* a striking article on the changed condition of the American farmer. He drew a graphic picture of the life on a New England farm fifty years ago, where the inhabitants seemed perfectly independent because they were engaged in a husbandry which was domestic, and in which nearly everything in the way of food and clothing for the family was produced at home. There was no labor-saving machinery and little ready money then in rural communities, but there was much local pride and a society which considered itself a trifle superior in refinement and influence to that of the towns. The love of land and forests, of orchards and gardens, was inherited from English ancestors, and in the early years of the Republic, rural life was more highly esteemed than city life, and it afforded greater facilities for enjoyment and for physical as well as intellectual development. Country physicians and country divines took rank with the great preachers and surgeons of the capitals. Nearly all the students in colleges and professional schools came from rural districts, and the graduates returned to the neighborhoods where they had spent their youth. Most of the early Presidents and Governors of states were farmers, and in one early congressional directory a majority of the senators and representatives were farmers. A large proportion of the trustees of the colleges were farmers, and even professional men gave some attention to agriculture. In short, men who lived on their own farms and secured a competency and independence by the produce of their land were the most influential class of the country. As Professor Welch points out, there was quite as radical a difference between this agricultural class and the shifting population of commercial and manufacturing towns as there was between real and personal property. The country gentlemen were on their farms to stay there, no matter how prices or wages might vary at the factories or in the seaports. They felt a sense of dignity and responsibility as leaders in society and politics, and while they were the last men in the world to insist upon anything like different ranks in society they constituted as truly a controlling class in the nation as if they had been titled.

But the country has been losing its relative importance, and the migration to the towns has been rapidly accelerated during the last ten or twenty years. In many of the western states farmers obtained land for little or nothing, and improved it with the intention of remaining there, but as they became independent they divided up their farms into small tracts, erected cheap buildings on them, and leased them to persons generally of foreign birth. In this way it is said that in the states of Illinois, Wisconsin and Iowa more farms have been deserted by their owners, although for a different reason, than there have been in New Hampshire, Vermont and Massachusetts. In these New England states farms have been abandoned because it no longer pays to cultivate them as they have been cultivated. But, whatever the motive, the best blood of the country, and the very worst blood, too, finds its way to the cities. The tenant-farmers who are left in temporary charge of the land have little interest in sustaining schools of good character, or in improving the farms by erecting substantial buildings or by planting orchards and vineyards, or by setting out ornamental trees and shrubs. They lease the land from year to year, and have no permanent interest in it. When a stately residence, surrounded by lawns and pleasure-grounds, is now seen in the country, with evidences that it has recently been erected, it is probably not the home of a farmer. It is more likely to belong to some raiser of fine stock or to some man of wealth who has removed from the city for his health's sake or in order to manage a farm as a pastime. Wealthy farmers, like other people of means, desire the advantages of society, schools and amusements of one kind or another, and the town furnishes what the country fails to furnish for them. On the other hand, where a farm does not support its owner he turns to the town for a more attractive open-

ing for earning a livelihood. Thus it happens that the farms in many parts of the country are passing out of the hands of proprietors and into the hands of a tenant class. Most persons past fifty years of age can recall some rural community the character of whose population has entirely changed within their memory. The country gentleman, a term which we use for want of a better one to designate the man who earned an easy competence by tilling his own acres and who expected that his land would be the home of his descendants for generations, has been supplanted by a class of men who seem to lack not only his love for the land and his pride in it, but his stability of character, his public spirit, and his influence.

Now, it is a narrow view which looks upon this rapid growth and increasing importance of urban communities as an unmixed evil. Sanitary science has made life in the town more healthful than it was in the early decades of the century, and more complete organization has multiplied its comforts. If there has been an apparent decline in the social and political importance of some rural communities, the towns have gained what the country has lost. And yet the tendency we speak of cannot be altogether wholesome. The comparative prosperity and luxury of our cities are evidences that the men who transport and traffic in the products of the soil are receiving a larger proportion of the value of these products, while the farmer's share is growing less. With no peasant class, with the land tilled by men who own it and who govern it, agriculture, here if anywhere, should be a profitable and honorable calling. It is degraded from its proper rank among industries when the farmer's boy is eager to abandon his birthplace and sees, without a pang, the homestead pass into alien hands. The farmer of the old style had local attachment and local pride, and these sentiments formed the basis of a broad public spirit and an intense patriotism. From the homes of contented farmers has come the best blood of the Republic, and any decline in agricultural prosperity should be a matter of public concern. Men lose their love for land which cannot support them, and if the land bears any unequal burdens in the way of taxation or restriction, these should be removed. The men who carry the products of the farm and the men who stand between the farmer and the consumer form compact, well-organized bodies, able to command their full share of the profits of agriculture. Farmers are numerous and so widely separated that co-operation is impossible. That farmers suffer in this unequal competition is undeniable.

It is hardly to be wondered at that the discontented farmer listens to the specious arguments of professional agitators and is willing to waste effort upon sham reform. The questions involved are worthy of study by the most thoughtful men. How can the conservative practices of Agriculture and Horticulture be adjusted to the swiftly changing conditions of this growing country? How is the farmer to command his fair share of the value of the products of the soil? What can be done to make country life more attractive, wholesome and satisfying? Is it possible to restore the tiller of the soil to the position of consequence he once held in the social and political life of the Republic?

Early Spring in Central Park.

AN unusually long succession of hot days coming suddenly before the middle of April brought our vegetation forward this year with almost miraculous rapidity, so that by the first of May the parks wore an aspect rarely seen so early.

The Tulip-beds had been at their finest a week before, and the Forsythias were in full bloom by the 22d of April, when, too, the frequent plantations of Moss-pinks and blue Aubrietias were beginning to show their equally vivid colors. A week later these plantations were vivid indeed. In some places, especially where the Moss-pinks occupied rocky ledges or broken, scantily turfed slopes, their great masses of crimson-pink were extremely beautiful. But these essentially woodland flowers look less well when they spread in more uniform masses on smooth grassy inclines, where the edges of their carpets do not blend naturally with the herbage, but form a disagreeably sharp, artificial-looking line. And in one or two such spots where their crimson contrasted with the yellow of Forsythias growing just above them as well as with the uniform bright green of the lawn, the effect was striking enough, but distinctly inharmonious. The white form of the Phlox is, of course, better adapted than the pink for association with other strong tints, and is largely used in the park.

But still more beautiful, because more delicate and more natural-looking in most portions of the park-landscape, is the white *Stellaria Holostea*, which was also at its best on May-day, beautifying shady reaches and slopes of wide extent, especially along the West Drive. The loveliness of its snowy stars, sprinkled through the grass, but not forming thick clumps of unrelieved color like the Moss-pinks and the blue Aubrietias, could not be surpassed by that of any early spring flower.

At this same time the Judas-trees were in full bloom, and the Lilacs and Wistarias were beginning to pass from bud into flower; the Japanese Quinces and Forsythias had not yet dropped their petals; the various blossoming Plums and Cherries spread like snowy clouds; and, while the Dogwood clusters were not yet fully developed or entirely white, they were almost as charming in their immature shapes and creamy hue. Many very beautiful effects of contrasted color met the eye in traversing different parts of the park; but the most striking and harmonious we chanced to note was displayed by a large bed of shrubs on the West Drive near the turn which leads to the terrace at the lake end of the Mall. The foreground of this bed was filled with rather low groups of the Japanese Quince in both the red and the pale pink-flowered forms, the two varieties not being intermingled, but massed in considerable quantities. Above this array of scarlet and delicate rose color stood masses of Lilacs, much more crimson in the color of their flower-panicles than they would be when the flowers were all unfolded. And back of their ruddy purple stood, sharply defined against the vividly blue sky, the splendid rose-colored, flowery, leafless branches of small Judas-trees. There was just enough green in the foliage of the Quinces and the Lilacs to give relief and tone to the brilliant hues thus happily contrasted; and the picture they made proved that, whatever may be the case with a painter, Nature can easily succeed in associating pink and scarlet, purple and crimson.

Other flowers and blossoming shrubs will adorn the park with new garments of loveliness as the weeks go by, but at no future time will its general effect be so enchanting as during these first days of May. For then the wealth of low-lying color was not more attractive than the varied character of the canopies of higher foliage. Here we saw, as in some Horse-chestnut tree, a mass of green, already strong and deep and solid. There the Maple-leaves were half-unfolded, the leaves of the Liquidambar defined themselves as separate tiny stars, and each leaf of the Tulip-tree showed, still in miniature, its singular individuality of outline. Now the green was but a diaphanous garment, and again, only a faint cloud or a thinnest mist. On one tree it was not green at all but yellow, and on another a pale, soft gray. Where the Oaks stretched their infinitesimal but many-pointed leaves a careful eye could discover every tint of green, brown, gray, yellow and pink. And here and there were still, quite leafless trees, the delicate tracery of their branches exquisitely defined against their more enterprising neighbors. Of course there is a charm in mere priority. Early spring has a peculiar attraction of its own simply because it is early spring. But, quite apart from this, May is the most beautiful of months. Such variety, such endless kinds and shades of beauty, such subtile contrasts and unexpected harmonies, no other time can offer. Fortunate were those who, if unable to enjoy its tender yet swiftly passing phases in the actual country, could spend an hour or two each day in Central Park. Indeed, owing to the greater variety of its vegetation, a fine park is perhaps a better place than any but an exceptionally favored countryside in which to study the fullest beauty of early May.

As a rule, in laying out parks, the principal roads and walks should be so disposed as to leave the central parts unbroken, so that broad, quiet landscape effects may be had in looking across them; at the same time, they should be kept far enough from the boundaries to allow exterior objects, which may not be consistent with the designed scenes, to be screened from view by border plantations, and to admit of such a free and natural treatment of the intervening space as to avoid the suggestion of limit and confinement.—*Frederic Law Olmsted.*

Recent Botanical Discoveries in China and Eastern Burma.—VI.

Cyrtandreæ.—A group or sub-order of the *Gesneraceæ*, comprising about 500 described species, belonging to forty-two genera, all exclusively confined to the Old World. When Mr. C. B. Clarke monographed the *Cyrtandreæ* in 1883 only nineteen species were known to him from eastern Asia—that is to say, from China, Japan and Cochin China. Now about fifty species have been collected in China proper, and doubtless many yet remain undiscovered. Many of the Chinese species are exceedingly pretty, but they are by no means so brilliantly colored as the sub-tropical Gesnerads of the mountains of Mexico and South America, to say nothing of the gorgeous tropical members of this family in both hemispheres. Nevertheless, several of them are specially worthy of cultivation. *Primulina Tabacum*, though not one of Dr. Henry's plants, is of comparatively recent discovery. It is a native of the province of Kwangtung, and was figured in the *Botanical Magazine* last year (t. 7117) from plants raised at Kew two years previously; but it is a delicate kind of plant not likely to find favor with gardeners. Its strong resemblance in habit and flowers to some of the Primulas suggested the generic name, and the specific name was given in allusion to the strong smell of Tobacco which the living plant exhales. Indeed, the Chinese call it Rock Tobacco. The flowers are violet and white; and this is the only species of the genus hitherto discovered.

Turning to some of the more ornamental recent discoveries I may name *Oreschariş Auricula* (De Candolle's "Monographia Phanerogamarum," v., t. 6), *Didissandra speciosa*, *Didymocarpus rotundifolius*, *Didissandra sanatilis*, *Chirita eburnea* and *Bœa crassifolia*. All of these must be very pretty, and some of them, if easily cultivated, might equal the Chinese Primrose, of which they have the habit, as winter-flowering greenhouse plants. Of course so much depends upon the amount of care and time required to rear them. The prettiest, perhaps, of all these is *Didissandra speciosa*. It has thick, oblong, stalked, toothed leaves from three to five inches long, and very slender scapes rising well above them, and bearing usually one or two, though sometimes as many as five, pendulous flowers, much resembling in shape and coloring those of the pendulous Gloxinias; but they are narrower and perhaps of less substance. The largest of the dried flowers are about two inches long; and different gatherings are described as pink, purplish and bright blue, spotted with another color inside along the lower half. Dr. Henry states that it inhabits the face of vertical cliffs. This reads a little difficult for cultivation, at least for general cultivation, but when we know that our old favorite, *Primula Sinensis*, inhabits similar localities, we may rest assured that there is a possible future in our greenhouses for some of these beautiful Chinese Gesnerads.

I may so far digress here as to give Dr. Henry's note on the habitat of *Primula Sinensis*, the Rock or Winter Primrose of the Chinese. He says: "It grows on the ledges of rocky cliffs, where there is no soil and practically no moisture." He further adds that the rocks are limestone, that the flowers are produced in December and January, and that the flowers are pink, with a yellow ring round the mouth of the corolla-tube.

Didymocarpus rotundifolius has a cluster of radical leaves similar to those of *Saxifraga sarmentosa*, and relatively tall, slender scapes bearing an umbel of long-stalked, medium-sized blue flowers. *Didissandra saxatilis* has foliage very similar to that of *Primula Sinensis*, and bears a profusion of narrow tubular flowers, about an inch long and yellow in color—a color very rare in this family of plants. *Bœa crassifolia* has very thick fleshy leaves, like the Auricula, and slender umbels of "very pretty blue flowers," like those of a small Didymocarpus.

Before leaving this group I may say a word or two respecting two of the older members. First, there is the grand *Chirita Sinensis*, sent home by Fortune in 1844, and figured in the *Botanical Magazine* for 1847 (t. 4284), and previously in the *Botanical Register*, 1844 (t. 59). The figure in the *Botanical Magazine* gave evidence of what high cultivation would do, "the largest plants having borne a succession of twenty large trusses of flowers," and these nearly double the size of those represented in the *Register*. But even these are far surpassed by cultivated specimens sent to Kew from Hong-Kong by Mr. Ford, the superintendent of the botanic garden there. The flowers on these specimens are almost as large as the largest of the pendent Gloxinias; but, as Mr. Ford notes on the label accompanying them, they do not otherwise differ from ordinary *Chirita Sinensis*.

Lysionotus pauciflorus, which does not deserve the depreciative specific name, is the last I have to mention. It is a small under shrub, with small lanceolate leaves clustered at the ends of the branches, and white or pink flowers on slender stalks from the axils of the leaves. This apparently very pretty plant is found on the Ningpo Mountains and westward in the same latitude to west Szechuen; and it is also found in Japan; yet it has never, so far as I can ascertain, been in cultivation, and there is no figure of it. Fortune found it growing on old walls in the eastern province of Chekiang, but does not appear to have introduced it. Dr. Henry found it growing in clefts of rocks in the central province of Hupeh; and the Rev. E. Faber collected it on Mount Omei, in Szechuen, at altitudes of 3,000 to 4,000 feet. Finally, the lamented Maximowicz discovered it growing on trees in old woods in Nagayama Island, Japan.

Kew. *W. Botting Hemsley.*

How We Renewed an Old Place.

V.—On the Perversity of Certain Trees.

A FAITHFUL student of Garden and Forest takes exception to my calling trees stubborn and irresponsive, and says, "They are only stubborn and irresponsive when they are misunderstood and made to struggle against unnatural conditions; only give them a chance, and you will find that they will respond fast enough."

I feel that I ought to make an apology to my nurslings, many of whom have given me so much satisfaction, for this slur upon their character. I am not sure that it is not almost as bad as betraying a domestic secret; but the editor of these records has enjoined upon me in his kind introduction of them to be as honest about mistakes as about successes, in order to render them truly valuable, so that, lest you may be led away into thinking a tree-nursery freer from failings than a child-nursery, I must tell you the painful as well as the charming facts about them.

No one knows better than I how much some of the more satisfactory among them will do for one under kind treatment, but, all the same, I must reluctantly maintain that many of of them are freakish and disappointing; not, perhaps, so much from their inherent wickedness, as from the baneful influences of the world outside, the flirtations with insects of which they are capable, their predilection for ornamenting themselves with white-colored fungous growths which check their development, a perverseness about living, even when given the very best advantages, only paralleled by those Chinese servants who go and kill themselves if their master speaks sharply to them, and, above all, a stubbornness about adapting themselves to new conditions as great as that of a true-born Briton.

Your tree is the true conservative, and will insist upon its own way quite as unreasonably as a human being, even when you are sure you know what is better for it than it does itself. It is as hard to bring it to a new way of living as it is to bring about a constitutional amendment. If there is a spot where you do not want a tree to grow, notably a garden bed or your potato patch, there it will insist on coming up and making itself at home; but, take up this interloper and put it in a proper place, where you want it, and, ten to one, it will sulk and defy you.

One's favorites show in extreme youth a propensity to come in contact with cows' horns and the jack-knives of mischievous boys; that is another proof of ill-regulated character. They let their top-buds perish in the most careless way, and put out two leaders instead of one before you know it; they grow unevenly, they make themselves untidy with absurd little leaves up and down their stems, with a vague idea of keeping the sun off their trunks. One has a constant struggle with evergreens to keep their lower limbs in condition, they always prefer to go barefooted; indeed, I call one Norway Spruce I know of Sockless Jerry, on account of this very failing.

A crying instance of depravity I will give you in a moderate-sized White Ash on our lawn, which ought to be a stately tree by this time, for a neighbor tells us it has been growing there for forty years. Every spring it puts out a magnificent crop of new shoots, and we congratulate ourselves that at last it has really made up its mind to go ahead and reward us for all the digging around and high feeding we have given it; but in late June ominous yellow spots appear upon the leaves, great orange-colored excrescences disfigure the young shoots, and the first thing we know they are all shriveled and dying, and the ground underneath it is strewn with blackened leaves. Later it pulls itself together and gets out a feeble crop of young sprouts, just enough to enable it to hold its own from year to year, but which seem to add almost nothing to its girth, and very little to its height.

Now, can my correspondent tell me what is the proper punishment for that?

Of the perversity of Hemlocks I could write a volume. I knew something of their waywardness in the state of Maine, but even in Massachusetts, where everything is regulated by law, they show no higher sense of duty.

In vain do you coax along a beautiful little tree, carefully raised in a nursery till it has a fine ball of roots, to live and thrive for several seasons; at the end of that time you find it in the spring yellow and brown and bare, with every sign of premature decay about it. In a clump they may condescend to grow, or in a swamp, but if you don't want a clump, or a swamp on the lawn, what then?

Any one who has ever set his affections on a Peach-orchard knows something of the shameless coquetry of its behavior; and in the course of these papers I shall be compelled to record instances of misconduct even in the most innocent and carefully brought up trees, as well as in the wild and unsophisticated ones. Even the common White Birch, which will live anywhere and everywhere, and thrive on a sand-bank, goes and gets itself eaten up with Hessians the minute we try to utilize it on a lawn. Lombardy Poplars, too, in spite of much specious promising, behave shamefully; and I have known a Catalpa to grow undaunted in an enclosure for twenty years, and then succumb in a cowardly way to one cold winter. The fact is, though I am loath to say it, as a class you cannot absolutely depend upon trees, and when you say that—why, you say everything!

I have also a question to answer concerning our grove of Chestnut-trees, an inquirer wishing to know how we came to move such tall ones, and whether they came from the woods or from a nursery?

They were taken from a plantation of trees in our neighborhood, which had been made some years ago, on one of the neglected places hereabout. They had been set out when small, and left to take their chances without cultivation for certainly ten years. How much they had received when very young I cannot say, for their gardener has long since moved away. When we got them they were some three inches in diameter one foot from the ground, and slim and stately, with fairly good roots, but not like those of frequently moved nursery trees. We topped them when they were set in the autumn, and as they did not seem very vigorous, the next year we cut them back very severely, of different lengths, as an experiment. Some of them we left ten feet high, and one of them which had poor roots and looked sickly we cut down to within two feet of the ground.

Last summer they all put out vigorous tops with enormous leaves, but they are much beset by the aphis, which makes havoc with the first growth, and later by the insatiable rose-bug; yet, in spite of these drawbacks, they thrive in the rich deep soil of the swale, sheltered by the hill from the sun and the burning south-west winds. They are planted about fifteen feet apart, as we thought they would do better in close company, and they can be trimmed out when they are larger if it seems desirable. Smaller ones are set on the hill-side, where they seem to flourish, and some future generation may see our hill-side, like those noble slopes of the Connecticut valley, waving with their splendid foliage.

Since I have given up so much of this letter to answers to correspondents, I may as well also reply to the gentleman who inquires what books we found useful in planting our trees.

The public library of our small town, though it is full of excellent works on fruit-trees and horticulture, only afforded one book, "Elements of Forestry," by Franklin B. Hough, which treated solely of that subject in a large way; but it had also a late edition of Downing's "Landscape Gardening," in the appendix to which is a valuable paper by Mr. Henry Winthorp Sargent, in which he gives an interesting account of the way in which his own country-seat at Fishkill, New York, and that of Mr. Hunnewell, at Wellesley, Massachusetts, had been laid out, by two precisely opposite methods: Mr. Sargent having started in the midst of a forest, which he gradually cut away and adapted to his uses in the landscape; and Mr. Hunnewell having laid out his grounds in a region barren of trees, which he gradually developed into its present exquisite fertility. Some of Donald B. Mitchell's books—"Out-of-Town Places," "My Farm at Edgewood" and "Rural Studies"—also afforded valuable suggestions. The Massachusetts Agricultural Reports had many interesting statistics about the planting of Pines on a large scale in Plymouth County, and the books of the National Department of Agriculture have given additional details as we went along. Garden and Forest held up our fainting hands, and also made us suffer by publishing articles the day after the fair, which showed us how much better we might have done had we had the information a year or two earlier. In fact, we had reason to think ourselves among those

> Mountainous minds that were awake too soon,
> Or else their brethren slept too late,

for no sooner had we evolved an idea and put it in practice than at every turn the public press was crammed with views on this very subject which it had never seen fit to express previously.

Overlea labored under the enormous disadvantage of being born the year before Garden and Forest.

> Hinc illæ lacrimæ.

Had the periodical only been the elder, how much easier everything would have been! But, also, how afraid we should have been to undertake anything, having learned from it that we ought never to build without a landscape-architect, never to plant without the advice of an experienced landscape-gardener, never to suffer from mistakes that could so easily be avoided by proper appeals to a professional! But all this wisdom might as well have come in the next century as just a year too late, and so here we are, with all our blood upon our own heads, because we chanced to dig our cellar and make our contract in 1887.

As it was, we went to some scientific neighbors, who had done the same thing we were doing thirty years before with very distinguished success; and some of them gave us advice, and others gave us trees, which were even more to the purpose, and they kindly encouraged our efforts and took an interest in what we were doing, that sustained and cheered us on our way.

No one's experience, either in books or in real life, proved to be exactly like our own, so that we feel that we have had the benefit of an original experiment. Only time can fully reveal where our mistakes lie, for it alone can show whether we have planted not wisely or too well.

Hingham, Mass. *M. C. Robbins.*

New or Little Known Plants.

Ilex lævigata.

THE smooth Winter-berry, *Ilex lævigata*, of which a figure appears on page 221, although one of the most beautiful shrubs of the eastern United States, is one of the least-known and least-appreciated plants in all our eastern flora. It is nowhere very common, although it may be found from Maine to the mountains of Virginia, growing in low, wet, sphagnum-covered bogs, where it associates with the Cassandra, the Nemopanthes, and other water-loving plants. It is little known to people whose powers of botanical observation have not been trained, and is usually confounded by them with the much more common Black Alder (*Ilex verticillata*), which it resembles in many of its general features. It grows, however, in wetter situations than that plant. The fruit, which is bright red and not scarlet, ripens early, and falls in the autumn, while the fruit of the Black Alder remains on the branches during the winter months. But the two species can be most easily distinguished in the autumn by the foliage; that of the smooth Winter-berry turns, rather early, bright yellow, while the leaves of the Black Alder remain green until they are blackened and destroyed by severe freezing. Another character which separates the two plants is found in the pedicels of the sterile flowers, which are long in *Ilex lævigata* and very short in *Ilex verticillata*. The leaves of the former are lanceolate or oblong-lanceolate, pointed at the two ends with small appressed teeth on the slightly revolute margins; they are two or three inches long, and are bright and lustrous on the upper surface, rather paler and usually quite glabrous on the lower surface, with the exception of a slight pubescence along the midrib and principal veins. The sterile flowers are produced on slender stems, varying from a third of an inch to an inch in length. The fertile flowers are sessile or short-stalked. The flowers are pearly white, a quarter of an inch across when expanded, and appear about the middle of June. The fruit ripens in September, and is from a quarter to a third of an inch in diameter.

Ilex lævigata is a graceful shrub, eight or ten feet high, with pale branchlets covered with minute lenticular dots and smooth, brownish green stems. It flourishes when transferred to the garden, and grows apparently as vigorously and rapidly in garden soil as in the deep, undrained swamps which it has selected as its home. In the autumn it is one of the most brilliantly fruited plants in the Arboretum; and it is one of the best of our native shrubs to cultivate when effects of autumn colors of fruit and foliage are desired. *C. S. S.*

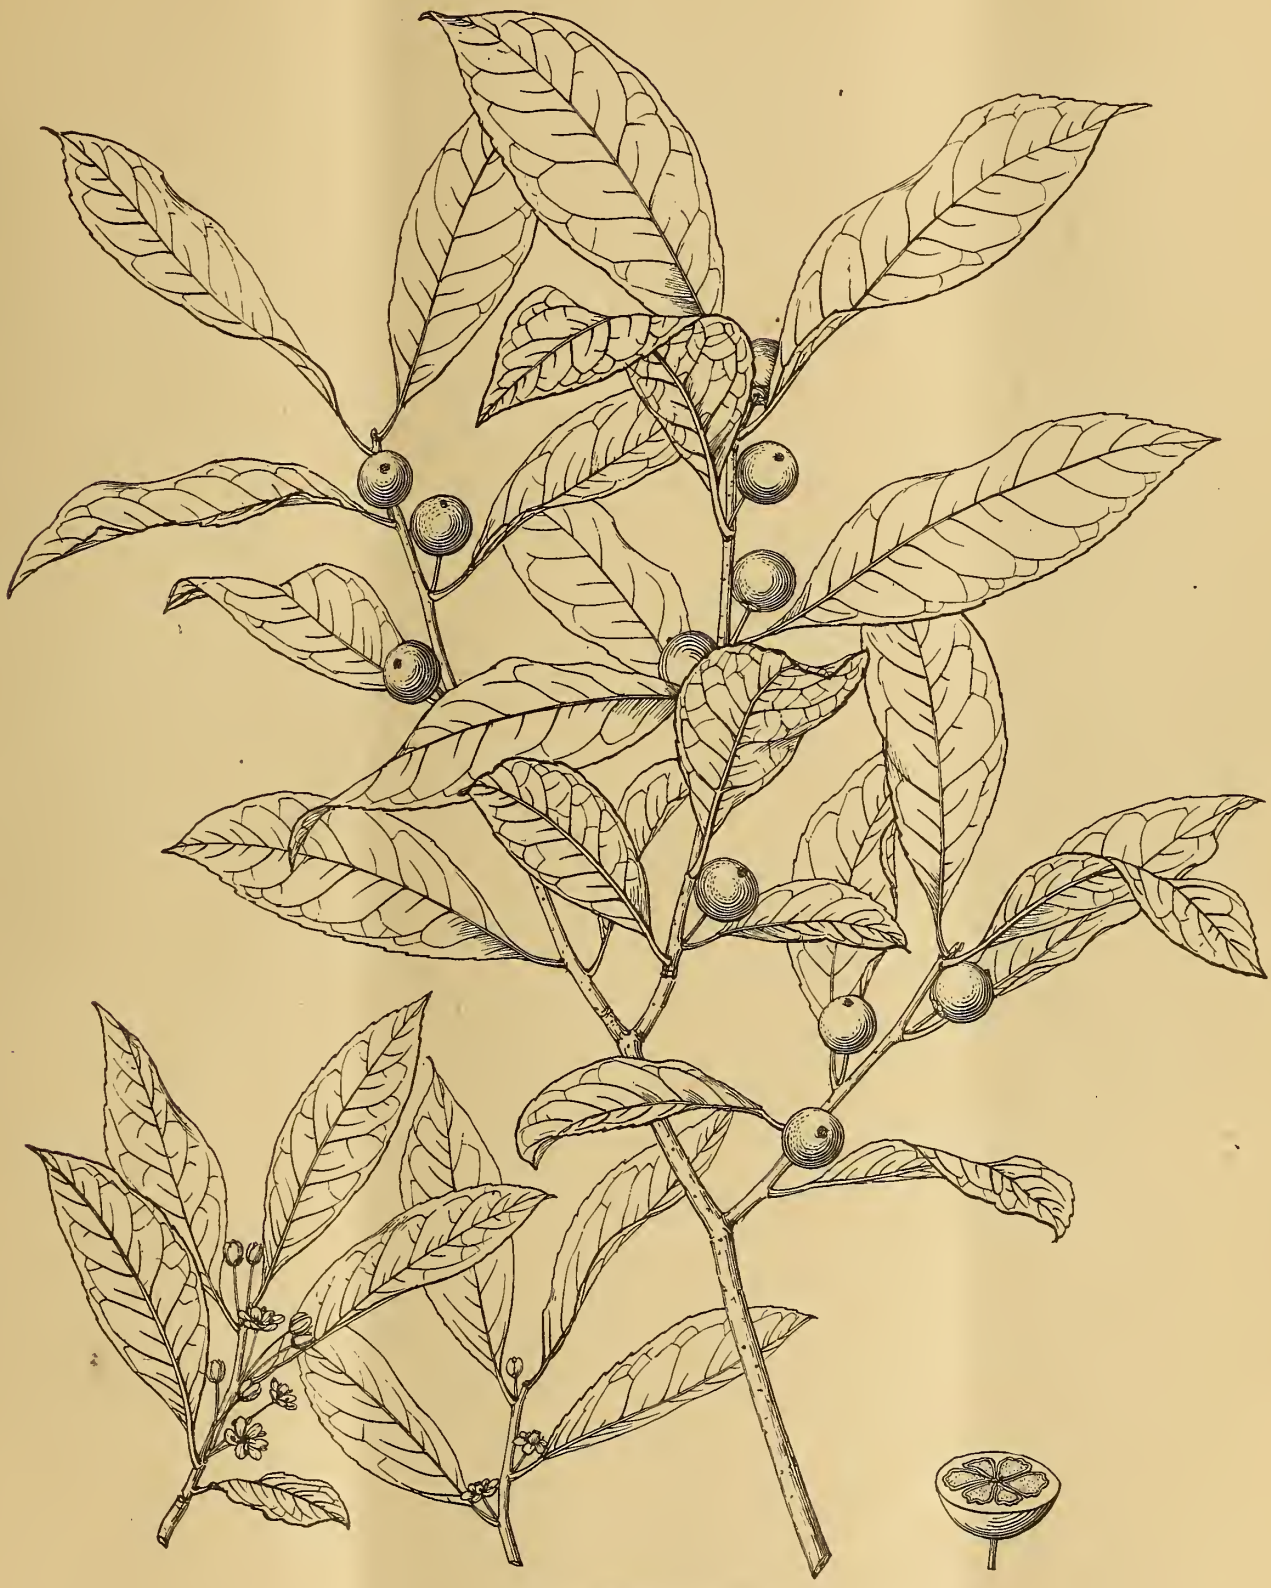

Fig. 39.—Ilex lævigata.—See page 220.

Crinum giganteum.

THIS appears to be as common in the moist tropics of Africa as *C. Asiaticum* is in Asia. It occurs in the collections of almost all African travelers, and, although an old garden plant in England, it has been introduced several times recently as a new species of exceptional beauty. It is gigantic only in the size of its flowers, the stature of the plant being considerably less than many of the evergreen Crinums. It has a short-necked bulb, thin gray-green

channeled leaves about two feet long, the base narrowed almost to a petiole, the widest part being about four inches across. The erect scapes are produced several times a year at varying seasons, and they are from eighteen inches to two feet long, with a loose umbel of from four to twelve pure white flowers, which have a curved tube and broad spreading segments, so that the flower when fully open is five or six inches across.

The flowers are powerfully and deliciously fragrant, and they last about a week. This species requires plenty of moisture all the year round, and it is happiest when planted in a large pot of rich soil, or, better still, in a bed. In the Palm-house at Kew it is perfectly at home, and the illustration on page 223 is taken from a specimen growing there. The plants thrive in the beds under the shade of the large Palms, treatment which also suits *Eucharis amazonica* and some of the tropical Pancratiums. There does not appear to be much, if any, difference between *C. giganteum* and *C. Careyanum*, while *C. podophyllum* is only a dwarf form of the first-named. *C. nobile* is another synonym of *C. giganteum*. In 1806 a figure of this Crinum was published in the *Botanical Magazine* as *Amaryllis ornata*, or "Cape Coast Lily." I recommend this plant as a really first-rate stove-bulb.

Kew. *W. Watson.*

New Orchids.

Odontoglossum × Andersonianum imperiale, O'Brien, is a handsome variety which appeared in the collection of W. J. Thomson, Esq., of St. Helens, Lancashire. It is described as having segments of the size of *O. crispum*, blotched with chestnut-red on a pale yellow ground.—*Gardeners' Chronicle*, March 14th, p. 330.

Masdevallia biflora, Regel.—A species which was imported by Roezl from the province of Santa Martha, in New Granada, and was received at the Royal Botanic Garden of St. Petersburg in 1871. It belongs to the *Amanda* group, and is allied to *M. polysticta*, Rchb. f. It is compared with *M. caloptera*, Rchb. f., but is nearer *M. pachyura*, Rchb. f.; indeed, it appears to me to be synonymous with it. It has a white perianth, with two or three purple stripes, at the base, and short yellow tails.—*Gartenflora*, xl. (1890), p. 90, t. 1341, fig. 2.

Odontoglossum × Clacsianum, L. Linden, is a very handsome natural hybrid, evidently derived from *O. crispum* and *O. luteopurpureum*. It was imported with a batch of *O. crispum*, collected by M. F. Claes for L'Horticulture Internationale, Parc Leopold, Brussels, and flowered in that establishment about the end of last year. At a meeting of L'Orchidéenne of Brussels, it was awarded a certificate of merit of the first class. It is now in the collection of M. G. Warocque, of Mariemont. The segments are broad, white and heavily blotched with bright red-brown.—*Lindenia*, t. 271.

Kew. *R. A. Rolfe.*

Recent Plant Portraits.

The most interesting plant for the general reader figured in the April issue of the *Botanical Magazine* is doubtless the Vanilla (*Vanilla planifolia*, t. 7167), the plant which furnishes the vanilla of commerce. It is a Mexican Orchid, with long climbing stems and thick fleshy leaves. The earliest European travelers in Mexico found the vanilla used as a condiment with chocolate. The Spaniards introduced it into Europe, and the first account of it appeared as long ago as 1605, and was published by Clusius in his "Exoticorum Libri," who received a specimen from Morgan, the apothecary of Queen Elizabeth. Plumier called the plant Vanilla, adopting the name used in Mexico by the Spaniards (the diminutive of the Spanish *vaina*, a pod). Toward the end of the seventeenth century the Vanilla reached France by the way of Spain, and was used to flavor chocolate, and to perfume tobacco. In England it was first valued as a drug, and it was not until after the idea of its medical value was exploded that it came into general use in cooking. The supply of vanilla, which is obtained from the fruit or seed-pod, was originally derived from Mexico, but of late years much attention has been given to cultivating this plant in other parts of the tropics, and it is now produced in Bourbon, Java, Mauritius and Central America in large quantities.

An excellent account of the Vanilla-plant, and of its properties and uses, will be found in Fluckiger & Hanbury's "Pharmacographia, or A History of Drugs," where the cultivation of the Vanilla is described as very simple. Shoots, about three feet long, having been fastened to trees, and scarcely touching the ground, soon strike root on to the bark and form plants, which commence to produce fruit in three years, and remain productive thirty or forty. The fertilization of the flower is naturally brought about by insect agency. Morren, the director of the Botanical Garden of Liége, showed, in 1837, that it might be efficiently performed by man, since which the production of the pods has been successfully carried on in all tropical countries without the aid of insects. Even in European forcing-houses the plant produces fruits of full size which, for aroma, bear comparison with those of Mexico. In Vanilla-plantations the pods are not allowed to arrive at complete maturity, and are gathered when their green color begins to change. According to the statements of De Vriese they are dried by a rather circuitous process, namely, by exposing them to heat alternately uncovered and wrapped in woolen cloths, whereby they are artificially ripened, and acquire their ultimate aroma and dark hue.

Interesting, too, is the figure (t. 7171) of the single-flowered form of the Banksian Rose. The double-flowered white and the double-flowered yellow Banksian Roses are well-known plants, especially in our southern states, where they grow to a large size and flower abundantly year after year, but the single-flowered type from which these plants were derived by the Chinese has only recently come to light. It was first sent to Kew by Mr. Hanbury, from his garden near Mentone, and also by Paul & Son, the well-known nurserymen. Judged by the figure, it is a more beautiful plant than either of the double-flowered forms, and will prove a decided acquisition in our southern gardens as well as for cool conservatories at the north, where the Banksian Rose is one of the most desirable of climbing plants.

There are also figures in this issue of *Asarum geophilum* (t. 7168), a species of southern China; and of *Epidendrum Sceptrum* (t. 7169), a striking species found on the coast regions of the Caribbean Sea, from Cumana to Santa Martha and New Granada, and to Ocana. It belongs to a section of the genus in which the lip is more or less adnate to the whole length of the column, with a few leaves arranged at the top of the pseudobulb and a terminal erect inflorescence. There is a figure also of *Furcræa Bedinghausii* (t. 7170), a native of Mexico.

The cone of a beautiful Mexican Pine which is met with in many gardens of northern Italy under the name of "Del Doctor" is published in the issue of the *Gardeners' Chronicle* of April 4, and is referred by Dr. Masters to the *Pinus patula*, var. *macrocarpa* of Schiede.

Cultural Department.

Out-of-door Roses.

Hardy Roses should now be progressing nicely in growth, but will need some attention from time to time in order to discourage the various insects to which they are subject. One of the best applications for this purpose is powdered Hellebore, if of good quality, for unless it is fresh and pure it is valueless as an insecticide. Another preparation that I have used with success on out-of-door Roses is "Slug-Shot," which may be dusted over the plants in the early morning, just as Hellebore is applied. In the absence of either of these, some slaked lime may be dusted on the plants to act as a check on some insects, though not necessarily on all.

As the buds appear on the Roses a good top-dressing of manure will be a benefit to the blooms, unless the plants have been heavily manured before.

For general decorative effect the claims of the Prairie Roses should not be forgotten, for when such varieties as Baltimore Belle and Queen of the Prairies are allowed to ramble carelessly over an otherwise unsightly fence they make it a thing of beauty. The two well-known varieties mentioned above are among the best of this section, though Gem of the Prairies is also a good one, and the single *R. setigera* is for many purposes the best of all.

In the treatment of these Roses it will, of course, be remembered that, in common with other climbing Roses, they do not like hard pruning.

Many persons enjoy a dark Rose, and to such Charles Lefebvre is suggested as a good old variety; it is a better Rose for out-door work than for forcing. It is dark crimson in color, rich and velvety in appearance and of good form and substance. Another good one is Fisher Holmes, of somewhat similar character. Its color is much like that of General Jacqueminot, but the flower is more full.

Fig. 40.—Crinum giganteum.—See page 221.

Among the many pink Roses John Hopper retains a place in the foremost rank for outside use; its firm, large flowers being of excellent color, while for free-blooming it has few equals.

It has been suggested that the white La France, so-called, Augustine Guinnoiseau, one of the much-praised novelties of the present season, may prove a valuable white variety for summer cut flowers, but this, of course, has not yet been tested. If it should prove as free in blooming as La France, and have the same charming form, it would certainly be a particularly beautiful white Rose. For bedding purposes the Polyantha Roses are gaining in favor each season. Clothilde Soupert, especially, has the good opinion of many last year, while the sales of the older sorts of this class do not fall off much, if at all.

One of the very best Teas for out-door planting is Marie Van Houtte, a strong grower and free-bloomer, with flowers of good size and very firm and double. The outer petals of this Rose being tinted with pink does not seem to be an objection to it when planted outside; in fact, the contrast with the pale yellow of the interior is quite pleasing.

André Schwartz also produces some fine buds at times out-doors, and of deep red color, but this is not a satisfactory Rose in all localities, and therefore should not have a general recommendation.

As a forcing Rose the lamentable failure of this variety is fresh in the minds of many cultivators, some of whom, doubtless, found their experience rather costly.

Holmesburg, Pa. *W. H. Taplin.*

Tulips.

THE skill of the cultivator with one division of this family, that is, the Garden Tulip, is well known. At this season these plants are in bloom in the open ground, and we shall see them in flower again in the stores of florists, painfully out of season, in November, with short stems and scant foliage. When Garden Tulips are properly planted in the fall, with a sprinkling of clean, sharp sand around the bulbs, there is no reason why these should be renewed annually, if one does not object to seeing the foliage ripen off naturally in the beds. The summer occupants should be planted without disturbing the bulbs of the Tulips. When frost kills the tender summer plants, such as Coleus, Geraniums or China Asters, these should be cleared off and a good top-dressing given to the bed, and the second year's flowers, from the same bulbs, will be better than the first. The only objection to this system is, that Tulips are usually planted in the most conspicuous place in the garden, and the foliage, when ripening off, would look somewhat out of keeping with its surroundings.

And now, a few words in favor of some of the natural forms of the Tulip which are, to many, even more interesting than the highly developed products of garden art. *T. Greigi* has bright, flaming-red flowers, with a yellow bordered black centre and leaves with distinct brown blotches, not unlike those of a Dog's-tooth Violet in the markings. This plant is hardy, easy to grow, and, with proper care, will flower every year.

For several years past I have had a great deal of satisfaction from the cultivation of that charming species, *T. Turkestanica*. The pretty, though not showy, flowers of this little Tulip may be found on the first bright day after the frost is out of the soil. It is peculiar in bearing several flowers on a branched stem—I have seen as many as five. The leaves of this species are developed above ground in fall and are never injured by cold. It deserves to be more widely known. Another attractive species is *T. cornuta*, the horned Tulip. This is a robust species which flowers every year without assistance. The petals, instead of overlapping each other and forming a cup-shaped flower, are narrow and taper to a point; they are about four inches long and usually yellow, striped with red. This Tulip is seldom grown, though cheap and easily obtained, and is worthy a place in every garden. The bulb of *T. Oculus-solis*, the Sun's Eye Tulip, is of itself remarkable. Between the bulb and its outer covering is a beautiful lining of cotton-like hairs, so interwoven as to be a complete protection. The flower is bright red, with a red and yellow centre, and, although very beautiful and perfectly hardy, it is too rarely met with in cultivation.

T. Gesneriana is interesting as one of the recognized parents of the Garden Tulip. This species has a very good flower, though not as showy as its progeny. *T. Gesneriana Dracontia* is the parent of the varieties known as Parrott Tulips, which are difficult to succeed with in pots, although their flowers are pretty, curious, and in some varieties, as Monstre Rouge, really showy. They should be staked, as they are weak-stemmed, and fall down on the ground unless supported. They will not force at any season; as I write, pans that have been brought on slowly in cold frames have a number of flowerless bulbs. We shall try them in the open ground next season in poor soil.

There should be no difficulty with the culture of the species of Tulips any more than with the garden varieties. They are natives of Algeria, central Asia and the south of France, and this suggests the need of a somewhat dry soil. This is especially true during their resting season—our summer months. Very seldom does a summer pass when there is not enough dry weather to ripen them thoroughly and enable them to make a vigorous start again in the fall. If the species now in commerce were more generally grown, many others now known in European gardens would soon be obtainable here, and our Tulip-beds in spring would not all be of one invariable pattern in regulation bedding colors or made up of the still worse "mixed Tulips in fine variety."

South Lancaster, Mass. *E. O. O.*

The Hardy Flower Garden.

THE blooming of the Narcissi, Hyacinths and Tulips marks the second phase of the spring-garden. The small bulbous plants are generally past, and the garden, with the advancing season, the more showy flowers, and the rapidly increasing foliage of hardy plants, is showing new, but not greater, attractions. "When you wish to drive a nail home keep hitting it" is a good homely adage which will explain my insistence on the charm of the spring-garden. The flowers of spring seem of such special beauty, and so enjoyable, that it is difficult to refrain from advocating their culture. The constantly increasing nomadic habits of our people, who now almost invariably spend their summers away from home, is having a serious result on many gardens, as in such cases, of course, little attention is given to flowers. In such cases the spring-garden is the only one to be enjoyed. Of course, those who will not give the matter forethought can never have a spring-garden, for this, unlike summer bedding effects, can never be ordered ready-made of the florist. But with notes taken now, as the plants are in bloom, and a little forethought in the fall, a spring-garden is quite within the management and means of any one. This first week in May the majority of the Narcissi are past, though there will be a succession for several weeks still. There were so many varieties of these it seems the part of prudence to refrain from commending particular kinds, for they all have some merits, and certainly most remarkable contrasts; from the mammoth Sir Watkin to the minute Triandeus Albus is a long range of size and form, while between the white Cernuus and the deep yellow of Obvallaris may be found all shades of those colors. The Polyanthus Narcissus are usually recommended for in-door planting, for which their penetrating odor quite unfits them. With a good covering they can be grown out-doors in this latitude, and looking them over the other day, it seemed to me that a good bed of these would be very effective, as they bloom profusely, and their flowers are small and borne gracefully. Spring Snowflakes (Leucoium), now at their best, are worthy successors of Snowdrops. Triteleias are useful front-border bulbs with pretty but malodorous flowers—flowers which will not be plucked are not without their uses. Hyacinths are waning, their lumpiness always making one long for a hardy strain with the habit of the Roman varieties. Tulips, if properly selected, should be in good form till the end of the month. A bed of Tulips all blooming on the same day, of the same height and the same color, does not seem worth planting.

Of the small hardy plants, *Papaver nudicaule* is the showiest thing in the garden; strong plants are exhausting themselves in bloom, and will last till the great Oriental Poppies flaunt their banners of orange and scarlet. Seeds of the Iceland Poppy sown now will give a few blooms in early fall, and make strong plants for another season, and are perfectly hardy without protection. The alpine Forget-me-nots make neat mats of blue; while stray blooms of Aquilegias are heralds of a new season of these ever-charming flowers. *Androsace sarmentosa* proves hardy in my garden, and from each rosette is now displayed a cluster of the dainty pink flowers. Anemones follow Anemones, *A. sulphurea* being one of the most charming at this season. The Irises are gradually unfolding their beauties, *I. Sibirica*, *I. Chamæiris* and *I. pumila*, with its variety, Alba, being the Irises of the week.

Trouble, of course, it is to arrange for all such flowers, and perhaps many of them do not impress a casual observer—the

casual observer at present being mostly engaged in stealing accessible Lilacs—but there is a great enjoyment with it all, and one gathers in such a garden in a fine spring morning delightful impressions to help him during the cares of busy days.

Elizabeth, N. J. *J. N. G.*

Notes from the Missouri Botanical Garden.

THERE are few more attractive plants that bloom in early spring than *Epimedium violaceum*, a native of Japan, and first imported into Great Britain about the year 1839. It is said to be only a variety, a smaller form, of *E. macranthum*, and the handsomest of the genus. It grows about a foot high in a compact mass. Not only are the light violet flowers very numerous, large and showy, though not very durable, but the foliage of the plant is worthy of admiration after the flowers are gone. It is perfectly hardy in St. Louis, where the weather is often very severe. It seems not at all difficult to grow, and is perfectly healthy in a heavy clay soil and in full sunlight.

The largest of the wild Bellworts (*Uvularia grandiflora*) is now in bloom here. A fine clump is growing in full sunlight and in a heavy soil, and is quite as beautiful as it will average in its natural soil in the woods. Near it in similar soil and in the sun is a tuft of *Viola striata*, a low-growing form. Its very numerous creamy white flowers and dark thick foliage look fresh and attractive at this season.

Ranunculus septentrionalis and *R. fascicularis* are both in bloom. The former is a trifle the later in flowering, grows about eight inches high, and somewhat spreading, with numerous bright yellow flowers half an inch wide. The latter is the best plant on account of its earliness, its brighter yellow flowers and dwarfer habit. Neither of them is very showy, but they give variety to a large collection, and *R. fascicularis* makes a pretty addition to the early border.

Helonias bullata, now in bloom, is a rare and local species, usually about fifteen inches high. Its dense head of light purple flowers is borne at the terminus of its naked scape, and is quite showy. Its leaves lie close to the ground in a cluster near the tuberous root. It is a natural bog-plant, though it does fairly well on an upland loamy soil if in the shade.

Phlox divaricata is quite common around St. Louis, and finds its way into the shaded portions of the parks when allowed to, without being planted there. It is a pretty plant as seen in its natural home, and one of the easiest to cultivate.

Claytonia Virginica (Spring Beauty) is the most abundant of the early wild flowers here, coming in almost everywhere in moist shaded situations. In Forest Park there are acres that are white with it, and the children take great delight in gathering it, in spite of the rigid rules forbidding any one to pluck a flower.

Dicentra eximia seems as much at home here in the sun and in a heavy soil as could be desired, and the fine clump now in flower in the herbaceous grounds is one of the most conspicuous there.

Trillium grandiflorum and *T. erectum*, var. *album*, are both in bloom; also *Trillium sessile* and *T. recurvatum*. The latter is quite common here in favored situations.

Among the most striking of the trees and shrubs are the Magnolias, first of which to bloom was *M. conspicua*, with its large fragrant white flowers, closely followed by *M. Soulangeana*, *M. purpurea* and the *M. Lenné*, which is the most showy of the four, and is at its best stage about the time *M. conspicua* is past.

The Japan Quince and the Redbud, or Judas-tree, are both in full flower; the latter the more conspicuous, being entirely covered with bloom.

Botanical Garden, St. Louis, Mo. *F. H. H.*

Orchid Notes.

CHYSIS LÆVIS.—Good authorities have called this the best species of its genus, and yet it has fallen into unaccountable neglect. It is found in Guatemala and Mexico, and was introduced in 1829. A year afterward it flowered in England for the first time. The pendulous, pseudo-bulbous stems are from twelve to fifteen inches in length, wrapped almost completely with whitish, sheath-like scales, and terminating with several lanceolate leaves of nearly their own length, deciduous, light of texture, with prominent veins on the lower side, and of a pale green color. The drooping racemes, equaling a full-grown stem in length, appear with the new growth in late winter or early spring, and the scapes carry from five to eight half-spread flowers of heavy substance and enduring quality, and about two inches in diameter. The oblong sepals are pale yellow, with a free diffusion of orange on the inside, tipped green on the exterior; and the linear petals resemble them in color, but without the green; the trilobed lip is yellow, profusely marked with orange-crimson, and the stout column resembles it in color. The cultural demands of *C. lævis* are easily satisfied. It thrives in a basket, and from its drooping habit it looks better there than in a pot. Rough peat, with abundant drainage material, is best for the roots, and the whole should be lightly surfaced with sphagnum. A night temperature, ranging from sixty to seventy degrees, Fahrenheit, and copious supplies of water are required during the season of growth; but very little water, and a temperature of from fifty to sixty degrees will suffice during the long resting period which ensues.

EPIDENDRUM AURANTIACUM.—Only a small proportion of the large number of known Epidendrums are worthy of general culture, and these are decidedly whimsical and unsatisfactory in conduct. Sometimes they grow and bloom perfectly for years together; then, for no apparent reason, they become unhealthy and die, or they preserve their full vigor of growth and refuse to bloom. *E. aurantiacum* is no exception to the rule. It cannot be depended upon to produce its splendid flowers in anything like profusion; they appear regularly, however, and when one happens to secure a good crop of blossoms it makes full amends for a score of bad ones. This species is a native of Guatemala, whence it was sent to England by Mr. Skinner in 1835. The entire plant rarely exceeds fifteen inches in height. The flowers measure an inch and a half in diameter, and are borne in dense racemose clusters—the number in each cluster varying from five ten—which proceed from pale brownish sheaths at the apex of the pseudo-bulbs; the column yellow, the other parts of the flower being of a brilliant orange color, with occasional small patches of dark crimson on the lip. The blooming stage is reached in spring, and the flowers retain their vivid hue about a month. The most reliable way of getting this plant to flower freely is to grow it in a basket near the light, using a compost of rough peat and chopped sphagnum in mixture, and providing ample drainage of crocks and charcoal. The growth should not be hastened in any way, but rather allowed to proceed naturally in a temperature ranging from sixty to seventy degrees, admitting abundance of fresh air, and a free supply of water given as long as the process continues. A temperature from ten to fifteen degrees below sixty will not injure the plant when in bloom, the lower temperature, on the contrary, tending to preserve the flowers for a longer period than would otherwise be possible.

Cambridge, Mass. *M. Barker.*

The Wardian Case.

FOR a long time I used a modification of the Wardian case, which I found to be very valuable for a large class of house-plants, especially those which cannot endure the dust or air of an ordinary room. The Wardian case proper made its first public appearance about 1842, and was exhibited in this country at the World's Fair in 1851. It consisted of a zinc pan on a stand, over which was placed a glass case, making it nearly air-tight, and was used for the propagation of delicate tropical plants and for their transportation. By confining air and moisture the case constituted a little world by itself, and there was no need of adding water or of ventilating it. My own case was so far modified as to require occasional supplies of water. The tray was built as wide as could be passed through an ordinary door; it was seven feet long, and was mounted on a strong frame on castors; over this was built a stout frame set with the best plate-glass, two panes to each side and one for each end. The roof sloped up to a small top pane. Each end was hung on hinges, and served as a door. The depth of the tray was six inches. Instead of filling this with soil for the plants to grow in, I grew all plants in pots, which could be lifted out for rearrangement. The case was capable of any degree of ventilation, and was, therefore, adapted to a much larger range of plants than an ordinary Wardian case. Begonias, Ferns and Lycopodiums were often removed and the case given over to Fuchsias and other plants not suited to the Wardian case proper. I found it easily adaptable to Camellias, Azaleas and dwarf Oranges.

The charm of such a case for a lover of plants is very great. The frame should be built quite strong, especially if it is desired to suspend baskets from the roof. The cost of the one I had built was about $40; a very good one could be built for $25. The plants are always clean, and are free from red spider. There are, however, other insects that must be guarded against in a close, moist atmosphere, and it is possible to ruin

everything by letting the stand remain closed in the full blaze of a noonday sun. Such a case has also all the advantages of the propagating box, and most cuttings will root in it with astonishing promptness.

As a fernery, the Wardian case is always exceedingly beautiful. I found my own case equally well suited for this purpose. The tray was water-tight, and I once readjusted it to serve as an aquarium. These possible adaptations are suggested for the advantage of persons who may be inclined to try a case of this description.

Points of Merit in Tomatoes.

THIS is the queen of vegetables, and one in which there is as wide a difference between the good and the bad as between a "frost" pear of the hedge-row and a well-grown Seckel. The ideal tomato may vary somewhat in shape, but, whatever that may be, there should be no deep corrugations or seams, the fruit being nearly smooth, although a slight depression along the line of natural division is not objectionable. The stem should always be relatively small and set in a very shallow basin. When it is large and set deeply into the fruit it is accompanied by a large pithy core extending into the fruit, and ruining it for slicing or for canning. The stem end of the fruit should be nearly flat or slightly rounded. When there are any marked projections here they will be sure to be imperfectly ripened at the time the rest of the fruit is in the best condition. As to color, tastes differ; but I have never yet found a tomato of the purple tint of the old Fiji, which was not of a sharp, hard, metallic-like acid, very much less pleasant than the mild, fruit-like acid of the true red or scarlet tomato; and I am quite certain that, were we to select ten of the best varieties, quality to rule, eight at least—and, I believe, more likely nine or all of them—would be found to be clear, bright red, with little trace of purple.

Of the interior of the fruit, the general opinion as to what constitutes merit is certainly at fault. Most people only ask for a solid, seedless, pulpless flesh. Fortunately, the fruit is too good to develop any such worthless variety as is thus called for. If you will carefully examine a tomato you will find that the greatest amount, and by far the finest flavor, is found in the pulp surrounding the seed, and that the flesh surrounding the fruit next to the skin is quite different, and greatly superior, to that in the interior divisions, which many people value as making a solid fruit. Often these interior divisions are made up of perfectly flavorless, hard, but corky, tissue. This is the case in an exceedingly large-fruited sort which I have grown several years for comparison, but have not considered worthy of a name or of general cultivation, although I am certain that this variety can be made to produce the largest fruit having the smallest proportionate weight of seed and the largest proportion of dry matter of any of the hundreds of sorts I have tried; and yet I have seen the Mikado recommended as the best variety because it stood first of any the writer had tested in these respects. My ideal tomato, as far as interior is concerned, is one in which the outer circle of flesh next to the skin is very thick, the thicker the better; the interior divisions few, and, consequently, comparatively large, and each completely filled with pulp. Seeds are of themselves a disadvantage, but as we never have pulp except surrounding seeds, we shall have to have a fair quantity of them in order to get the desired pulp. This pulp should be as thick as possible. We sometimes find fruit in which it is very thin, and in such cases it is usually quite acid. The pulp should be as thick or solid as may be, while the flesh, both of the outer circle and of the inner division, should be as soft and juicy as possible, thus making the fruit as nearly uniform in consistency as it can be made to grow. I would be as critical as to the flavor of the fruit as of that of a pear or apple, and insist that, to be good, a tomato must have a distinct fruit-like, sub-acid flavor. Lastly, the entire interior, except the seeds, should be in color as nearly like the deep, rich red of the outside as possible, making a fruit which is a delight both in color and flavor.—*Professor W. W. Tracy, before the Michigan Horticultural Society.*

Support for Garden Plants.—I am using this year 1,000 lineal feet of galvanized wire netting four feet wide. This cost, delivered, a little more than one half cent per square foot, and will last indefinitely if cared for. It is the cheapest of all material for Peas, Beans and Tomatoes. Last year I made a comparison between this and brush for Peas. The only expense of the brush was the cutting, hauling and setting. Allowing for the time of two men and a pair of mules and wagon getting the brush, the cost of the brush, good only for one year, exceeded the first cost of the wire, good for ten. This wire throws no appreciable shade, and for training Tomatoes is admirable, since there is always a place to tie to. In fact, but little tying is needed after the plants get well up, as a little attention to directing the shoots to and fro in the meshes supports them perfectly. Climbing Beans fairly riot over it, and there will be no bother about Limas failing to catch to poles. Light stakes, well set about ten or twelve feet apart, are all that are needed to support it, and short pieces of wire are better than the more permanent attachment of staples.—*Professor Massey in Orchard and Garden.*

Neviusia Alabamensis.—This shrub, which is interesting botanically from the fact that it is known wild in only one locality in the United States, deserves more attention than it has received for its ornamental value. In an earlier number of Garden and Forest (vol. i., page 212) it is reported as hardy in Boston, and here it shows perfect health. A plant in Meehan's nurseries is some six years old, and it is rather more than four feet high and as many in diameter, making a compact bush, and it is now covered completely with the tufted, feathery clusters of flowers, whose long white stamens make them very showy. It blooms every season, and becomes more and more beautiful as it gets older. It can be propagated by cuttings as readily as any of the Spiræas, and it is related to the Kerria and Rhodotypus, two of our very best shrubs from eastern Asia, which are also now flowering very finely.

Germantown, Pa. *J. M.*

Correspondence.

The Owl and the Sparrow.

To the Editor of Garden and Forest:

Sir,—I read with much interest in the columns of your journal the discussion upon the owl and the sparrow. I will only observe now, in continuation of what I have already said, that we have in France two chevêches—the large one, which is a little larger than a blackbird, although rather stouter, and the special enemy of sparrows; and the small one, called also chevêchette, rather smaller than a blackbird. This is a very rare animal, frequenting principally the mountainous regions of the east of France (Savoy, Dauphiny and Switzerland). It is known to very few people. The large chevêche, the bird which I have always considered the true *Stryx passerina*, is common in all parts of France, and is often sold in the bird market of Paris. It is more common in the south than in other parts of the country, and here the people use it as a means of capturing other birds. The method is amusing and original. It is carried on by the aid of a big basket, upon the top of which a chevêche is fastened. The hunter, or perhaps trapper would be more appropriate, seats himself inside the basket, and by means of a little hole in the side he protrudes a long piece of wood branched at the extremity, the two branches being so far apart that a bird attracted by the owl can seat himself upon one of the two branches. Once the victim has seated himself upon the branch the man within the basket pulls a cord which brings the two branches of the fork together and catches the bird by his feet. The bird is then drawn into the basket, and, being made to cry, serves to attract other birds, which are captured in the same way. A considerable number are sometimes caught by one man in this way in a morning, and when any one locality is exhausted the hunter picks up his basket and locates himself in another position.

One thing is certain, and that is, that sparrows are not common, and do no damage in towns or villages where the chevêche has become established, either in old walls, or in churches, or in the hollow trunks of Olive and other trees. They become more or less diurnal in habit, and hunt in the evening before sunset. They do not fly high, and often skim along the surface of the ground in pursuit of field-mice, which, with the sparrows, constitute their ordinary diet. It is not known that the chevêche pursues other game. It appears to me probable that it would support the winters of the United States at least as well as the European sparrow, for it occurs in the north as well as in the south of France.

Antibes, France. *Charles Naudin.*

An Old Orchard.

To the Editor of Garden and Forest:

Sir,—I own at present the oldest orchard planted by a white man west of Albany. In the year 1791 or 1792, Dominie Kirkland, missionary to the Oneidas, planted a small nursery of

Apple-seeds at the foot of what is now College Hill, in the town at present called Kirkland, a part of what was then the town of Paris. This nursery was on a grant of land made to the dominie by the tribe to which he preached the Christian doctrine. They were much attached to him, and the chief, Sconondoa, aided him in his horticultural as well as religious enterprises. Out of this nursery three or four orchards were planted. The dominie's own was on a slope of the hills overlooking the valley of the Oriskany, one of the most beautiful valleys in New York state. I remember the trees fifty years ago, as they stood in their prime, and all of them were giants, compared with modern Apple-trees. Now there are standing but a dozen out of one hundred. As the loss is clearly traceable to neglect for a few years, I feel confident that an orchard of seedling Apples might be kept in good health for one hundred and fifty years. I hope to preserve a few of those now standing for at least ten years more.

The fruit is perceptibly of the old English and French families of Pippins, Bellefleurs and Swanro. One sort only proved to be so very good as to deserve careful preservation. This is named Kirkland, after its planter. It is every way a Bellefleur, pure white when picked, but rich yellow in the spring. The shape is like the yellow Bellefleur, but rounder, core open, and less acid than most of the family. It keeps well into April, or even June, in a cool moist cellar. I have had samples keep entirely through a year into the next spring. It is, in fact, the best keeping apple I have ever grown that had good value. A curious feature of this seedling is that another tree from the same nursery bears an apple so nearly identical as to be distinguished only by close examination. The original Kirkland tree stood until 1889, when I was obliged to cut it, but have carefully preserved a sucker from the roots that is capable of replacing the old tree.

The Broad-leaved Maple.

To the Editor of Garden and Forest:

Sir,—Since your correspondents have shown so much interest of late in relation to the hardiness in the east of trees from the Pacific coast, I send you some sprays of *Acer macrophyllum*, gathered from one of our trees here. We have three of them and they are all some twenty-five feet high. While young they suffered in severe winters, but for several years past they do not seem to have been injured in the slightest degree. The flowers of this Maple come out slightly in advance of those of the ordinary Sycamore Maple.

Germantown, Pa. *Joseph Meehan.*

The Rattlesnake Plantain as a Window Plant.

To the Editor of Garden and Forest:

Sir,—Some of your correspondents have recently shown that many wild flowers, even of shy-seeming sorts, lend themselves well to careful transplanting; and I should like to add a mite of evidence with regard to one which I have found a bo d and brave little bloomer even under conditions when nothing that could be called care was bestowed upon it. In my summer home on the shore of Buzzard's Bay I have fortunately made friends with two ladies who, living there all the year round, are examples of the incorrectness of the oft-repeated statement that country people neither know nor care much about wild flowers. Their kindly hands have brought me rarities for which, despite all Asa Gray's directions, I had searched with small success, and great bunches of other flowers which, while not exactly rare, I had rejoiced to find as mere isolated specimens. In a basketful of such treasures I discovered last July a Rattlesnake Plantain with white-striped leaves (*Goodyera pubescens*), the tall spike of which was in bud, and which, apparently by accident, had been taken up, roots and all. This I planted in the woods near my house in a shady moist spot close to a big rock, watering it at the time, but giving it no further attention save an occasional glance to see what it was doing. For many days it apparently did nothing, for though its flowers did not open, neither did they wither. Then, after a fortnight or more, they came into bloom as prettily and completely as though the plant had never been disturbed.

At Christmas-time, again, I received from these same friends through the post a box of greens and berries, and among them was another of these little Orchids with the root, embedded in moss and earth, still attached to the cluster of evergreen leaves. I gave it to a friend whose care is surer than mine and whose window is sunnier, and she set it in a saucer of water. The second week in April it was more than merely alive. It was putting forth new little leaves and bore a promising spike of flower-buds, although not so large a one as though the time were July and the spot a Plymouth County wood. Of course it was but a wee and modest plant compared with those usually seen in-doors in early spring. But its very unlikeness to such plants and the flavor of deep summer woods that hung about it seemed for the moment to put their showier claims to admiration out of court.

New York. *M. G. Van Rensselaer.*

Recent Publications.

Chrysanthemum Culture for America. James Morton, 1891. The Rural Publishing Company, New York.

This little volume is the first treatise on the Chrysanthemum which has as yet appeared in the United States in book form, and is an interesting compendium of the foreign and domestic history of the flower, with cultural details which the author considers best adapted to this country. The book also contains an extended list of synonyms and a good calendar of garden operations. Any writer on the Chrysanthemum at this time is hampered by the exhaustive manner in which both the history and culture of the flower have already been recorded abroad. Mr. C. Harman Payne, a London amateur, has made the history of the subject his own by searching out and recording the slightest facts connected with the flower in all countries where it is grown. Mr. Morton has summarized these annals, and has supplemented them with some points as to the American history of the flower. As for all details of culture, Mr. Edward Molyneaux has fairly illuminated this subject with such minuteness and clearness as to leave little to be said, except in the way of modification to suit climatic conditions. His writings, not only in his book but in his very extended monographs in the horticultural press, may be fairly considered among the curiosities of literature, for he has recorded not only notes on general culture, but special points on the different families and varieties, showing powers of observation which would be remarkable if applied to any subject. Mr. Morton's cultural details seem, in the main, sound and helpful, although there are points in practice upon which experts differ. The book would have been improved, perhaps, by more explicit directions as to some of the finer points of cultivation, such as the treatment of weak-growing varieties and the details of disbudding, both of which are important matters to novices. The list of synonyms is very full, and Mr. Morton has done a service in collecting such an extended catalogue. Curiously enough, one of the best-known examples is omitted, that of Domination, also called Mrs. G. Bullock and Milkmaid. Mr. Morton's lists of varieties are more open to criticism. We are at a loss to know at what exhibition blooms of Cullingfordii and Mrs. John Wanamaker would be allowed to be staged with Empress of India, etc., among the "best twelve Chinese."

Great care should be taken to secure correctness in the matter of nomenclature in hand-books of this sort, and the hasty proof-reading which has permitted some errors in this department is to be regretted.

Mushrooms: How to Grow Them. By William Falconer. New York: Orange Judd Co.

This is a compact treatise of 165 pages which has been prepared for the purpose of giving complete and accurate details of all the processes of Mushroom-culture both for home use and for market. In addition to his long personal experience as a gardener, Mr. Falconer has taken pains to visit many of the principal establishments where Mushrooms are successfully grown in this country, not only to examine the various methods employed, but to secure from the growers careful explanations of the methods employed by each. There are also chapters on the growing of Mushrooms by the gardeners who supply the London market, and a very interesting account of the productive beds in the caves underneath the city of Paris and its suburbs. One would think, on reading this little treatise, that such a delicious and nutritious article of food as the Mushroom should be abundant on every American table, for it seems so easy to raise them, not only by those who have a greenhouse or can afford a house especially prepared for them, but by every farmer or householder who can command a shed or an ordinary cellar. Every one knows that in certain old pastures Mushrooms abound in a wild state, and the directions for growing them in the fields are so simple that there appears to be little excuse for their scarcity. And yet, although their cultivation seems so easy to a reader who has never tried

to grow them, the fact is that a great many men who have attempted it seriously have failed, and it is probable that the Mushroom crop will prove more uncertain than the Bean crop to the average cultivator for many years.

To grow Mushrooms well needs some experience and needs constant care in the details of cultivation from the beginning to the end, and just here is the prime value of this little manual. The directions are full and minute, covering the smallest particulars, so that one who had never seen a single Mushroom growing could take up this volume, and by following the directions explicitly have a reasonable hope of some success. The first fifty pages of the book are in the main devoted to the proper construction of caves and houses for Mushroom-beds or for the proper adaptation of the beds to ordinary cellars and sheds. Then there are directions for selecting and preparing the manure, the making of the beds, the use of the spawn, the loaming, earthing, top-dressing, etc., even to the final work of gathering and marketing the crop. After this come some directions for invigorating old beds, and for the discouragement of insect enemies, together with a selection of receipts for various methods of cooking. The book has an excellent index and some illustrations which serve fairly well to explain the text; but it would have been more attractive if the publishers had taken greater pains in preparing the cuts and had printed them on better paper.

Notes.

The late Mr. Shirley Hibberd had formed in his garden a collection of ninety different varieties of Ivy.

The Flowering Dogwood, the Black Haw (*Viburnum prunifolium*) and the Sassafras are all blooming abundantly in the woods and hedge-rows near this city, and very beautiful they are.

The Messrs. Putnam are about to publish a book called "Practical Landscape-Gardening," by Mr. Samuel Parsons, Jr., whose long experience as Superintendent of Parks in this city has qualified him to write an interesting and instructive treatise.

Le Nôtre, the great seventeenth-century gardener, lies buried in the Church of St. Roch in Paris. His tomb was designed by Coysevox, one of the most prominent sculptors of the time, and one of those who had assisted him in decorating the royal gardens at Versailles.

A Philadelphia correspondent writes that a fine tree of *Magnolia Fraseri*, still standing in the old Bartram Garden, now Bartram Park, is covered with bloom and is a beautiful object. This is really one of the most beautiful of the native Magnolias, its large flowers having a tint of canary yellow which is very delicate, and their fragrance, too, is almost equal to that of our *Magnolia glauca*.

The leading article in the *Illustrirte Gartenzeitung* of Vienna for the month of April is devoted to *Begonia bicolor*, Wats. The history of its discovery in Mexico by Dr. Palmer, in 1886, is quoted from Mr. Sereno Watson's account in vol. xxii. of the "Proceedings of the American Academy of Arts and Sciences," and the article is accompanied by a fine colored plate, prepared from a specimen which bloomed last autumn in the Royal Belvidere Gardens at Vienna.

It is a matter of concern to some people that the blossoms have come, hereabout, and many of them have gone, without any heavy rain. There is a popular superstition that the so-called blossom-storm is in some way connected with a fruitful year. On the other hand, there has been a theory that a cold rain while the trees are in flower may prevent fertilization, and therefore injure the fruit-crop. Recent investigation seems to show there is no real basis for this belief. The blossom-storm, like the equinoctial, is an uncertain quantity, and, whether it comes or not, has little effect on the fruit.

William M'Corquodale, a Scotch forester of reputation and the forest manager on the estates of the Earl of Mansfield, died last month in his eighty-first year. He is spoken of as the acknowledged father of forestry in Britain. During the long period he was connected with the Mansfield estates he planted and raised thousands of acres of woodlands, and has done much to encourage the taste for planting in north Britain. David Douglas was a townsman of his, and in this way M'Corquodale early became interested in the conifers of the north-west coast, especially in the Douglas Fir, which he was one of the first to plant in large quantities as a forest-crop. Many contributions from his pen are found in the *Transactions of the Scottish Arboricultural Society*. He was ardently devoted to the interests of this society, and was a constant attendant at its meetings.

A particularly fine specimen of *Licuala grandis* is included in the small, but choice, collection of Palms and other foliage plants in the conservatories attached to the city residence of Mr. A. J. Drexel, in Philadelphia. The plant referred to is about five feet in height, and carries over twenty fine leaves, doubtless being one of the best examples of this handsome Palm to be found in the country. In the same collection are some nicely grown Gleichenias, among them being *G. flabellata*, *G. Speluncæ*, *G. dicarpa longipinnata* and *G. dichotoma*, the last-named being well represented by a specimen between five and six feet in diameter.

One of the most charming descriptions of English rural scenery which we have recently read may be found in *Harper's Magazine* for May, being the first instalment of Mr. Quiller Couch's account of a boat journey down the Warwickshire Avon. It is delightfully illustrated by Mr. Alfred Parsons, and one of his most effective pictures shows us "Guy's Cliffe Mill," with regard to which the author writes: "The beauties of this spot have been bepraised for centuries. Leland speaks of them; Drayton sings them. 'There,' says Camden, 'have yee a shady little wood, cleere and cristal springs, mossie bottoms and caves, medowes alwaies fresh and greene, the river rumbling heere and there among the stones with his streame making a milde noise and gentle whispering, and, besides all this, solitary and still quietness, things most grateful to the muses.' Fuller, who knew it well, calls it 'a most delicious place, so that a man in many miles' riding cannot meet so much variety as there one furlong doth afford.' The water-mill is mentioned in Doomsday-book and has been sketched constantly ever since—a low quaint pile fronted by a recessed open gallery, under which the water is forever sparkling and frothing, fresh from its spin over the mill-wheels or tumble down the ledges of the weir."

The death is announced, in his ninety-first year, of William Barron, a Scotch gardener, distinguished in his day, and at one time considered the highest authority in England on cultivated conifers. His greatest achievement was the formation of the gardens at Elverston Castle, the seat of the Earl of Harrington, in Derbyshire, famous for their topiary work and the great collections of coniferous plants which they contain. Barron made a specialty of moving large trees, and scoured the country round for old Yews and other large specimens with which to embellish the pleasure-grounds at Elverston. His greatest feat of this sort is said to have been the removal from the Buckland churchyard of the so-called Buckland Yew, a huge tree supposed to be more than a thousand years old, and mentioned in the Doomsday-book. Barron left the immediate control of Elverston some forty years ago, and established himself in the neighborhood as a nurseryman and landscape-gardener. For many years he was one of the most active figures in English horticulture, and was employed in all parts of the kingdom in executing works of landscape-gardening and in moving large trees. He was a man highly respected by every one, and his influence and example did much to elevate the profession of gardening in England. His portrait and a detailed account of his career, with views taken in the gardens at Elverston, appear in the *Gardeners' Chronicle* for the 25th of April.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MAY 20, 1891.

TABLE OF CONTENTS.

The Report of the Secretary of Agriculture.

IF the agricultural industries of the country are to yield a greater profit in the future, it will be mainly because the work in our farms and gardens, orchards and vineyards, is conducted with greater skill and intelligence. If, then, Government is to give any assistance to agriculture, the best aid it can render is to give information which will help farmers and gardeners to decide correctly the questions which confront them in their daily practice. Of course, Government may give direct aid in other directions, as, for example, it may introduce new varieties of economic plants, or it may help in the battle with destructive insects, as it did recently by importing from Australia the parasite which has done so much to save the Orange-groves of southern California from the devastation of the pernicious scale insect. But, after all, the most effective work of the Government for agriculture must be educational. In the first place, then, the Government must gather knowledge in order to disseminate it. Either under the direct supervision of the department or under the various experiment stations which are now vitally connected with it, a corps of skilled workers must be employed to make such tests in various directions as farmers are unable to make for themselves. Many of these experiments are necessarily expensive, and can hardly be undertaken by private persons. Many more of them require such habits of investigation and comparison as only men of long scientific training are able to accomplish. Others, again, require a long series of years before any satisfactory results are arrived at, and such tests can only be entrusted to institutions with a continued life and a well-directed purpose. It is worth while, therefore, to examine the report of the Secretary of Agriculture, which has just been published, in order to form some judgment of the extent and quality of the work of his department.

It will be observed at once that this publication is far in advance of the reports of a generation ago, over which the newspapers used to make merry. Even in that early day these volumes contained much that was of profound and permanent value, although this matter was usually smothered under a mass of crude and ill-digested facts and fancies. In the main, however, these public documents deserved much of the contempt with which they were treated, and the current report certainly shows in a very marked way an improvement in scope and method. In the first place it should be remarked that this report is a very small part of the publications of the department during the year. A very interesting chapter of the book contains a summary of the publications of the department, and the list for the year covers five pages. These publications vary in size from bulletins of a few pages to bulky volumes. Many of these are monographs by men who are recognized as authorities in various fields of scientific study. We have just received, for example, a Report of the Entomological Commission on Insects Injurious to Forest and Shade Trees, which has been prepared by Dr. A. S. Packard. Our students of entomology have naturally been led to concentrate their studies upon garden and field-insects rather than upon forest-insects. This treatise, however, a revised and enlarged edition of an earlier bulletin, makes up a volume of nearly a thousand amply illustrated pages, and not only gives a careful account, so far as is possible, of the insects which attack various forest and ornamental trees, but describes the diseases which they cause, and gives directions for using the remedies and the various means of applying these remedies to shade and forest-trees. Among other publications of merit may be named Dr. Vasey's Catalogue of Agricultural Grasses and Forage Plants; Professor Wiley's treatise on the Beet Sugar Industry; Mr. Tratman's Forestry Bulletin on the Substitution of Metal for Wood in Railroad Ties; Dr. Merriam's contributions to the Study of the North American Fauna. In fact, all the divisions of the department have issued books or bulletins which have scientific and practical value.

One of the most interesting of the reports of the divisions, which are published in connection with the Secretary's report, is that of Professor Atwater, the Director of the Office of Experiment Stations, an office which has been established now for a little more than two years. This is interesting, not because it records any marked discoveries in science or improvement in practice, but because it promises in time to be very efficient among the agencies of the department. The experiment stations as yet have not given any adequate return for the large amount of money they cost. In the first place, it is difficult to find trained experimenters to conduct the station work, and, again, their work is not sufficiently specialized, but is spread over too much ground. Besides this, the Boards of Control are under constant pressure to show results, so that abstract research is neglected for superficial work, which makes some immediate show of practical use. However, it seems probable that these and the other causes of failure will be gradually eliminated under intelligent discussion. Ambitious and able young men graduating from the schools of this country and of Europe are ready to take occupation in the stations, so that, with a central bureau, which, in some measure, may unify and collate the work in the various states, we are justified in hoping for such efficient aid in the practice of the arts of agriculture and horticulture as can be furnished by a more thorough understanding of the sciences upon which these arts rest. The bulletins from this office have so far been judiciously compiled and edited, and their distribution must in time make a sensible increase in the popular knowledge.

Of some of the other special reports, like that from the Division of Forestry, we shall take occasion to speak hereafter; but the work in the Divisions of Chemistry, of Botany, of Vegetable Pathology and Statistics is shown to be worthy of respect, and the chiefs of these departments hold an honorable position in the republic of science. The Secretary's summary of the year's work is in the main judicious,

and altogether it would seem that even in fields which require specific training, popular opinion can be trusted at last to pronounce judgment upon the efficiency of our public servants and upon the quality of their work. The abuses in the matter of seed-distribution are being gradually cured, and we may hope that this bureau will finally be restricted to its only legitimate purpose; that is, of making a careful trial by means of skilled agents in various parts of the country, of new seeds and plants which promise to be of economic value.

We can see no reason why there should be a Secretary of Agriculture, with a seat in the Cabinet, whose position is essentially political, and who must of necessity be changed with every changing administration. The practical control of the educational machinery of the department, at least, ought to be invested in some officer whose standing as a man of science is universally recognized. The position of this man should be certainly as permanent as that of the Director of the Coast Survey. He should be able to make plans for work that will extend through more than one administration. But, after all, when we consider how much time and experience is necessary to organize a force of skilled workers in various branches of scientific inquiry, and how difficult it is in Washington to select men on any other principle than that of political availability, we ought not to complain of the progress that has been made, but rather to feel encouraged to hope that the work of the department will improve in quality as the years roll on.

It is now ten years since a bulletin of the Tenth Census set forth the fact that fires had swept over more than 10,000,000 acres of forest in the United States, and destroyed more than $25,000,000 worth of property in a single year. The publication of these startling figures caused wide discussion. The people of the country were generally informed through the press that even this enormous destruction was only a portion of the actual loss, for, in addition to the annihilation of so much forest wealth, the ruin of millions of seedling trees should be counted, besides the actual burning up of the soil or its deterioration in those qualities which make forests possible—that is, these annual fires not only destroy the standing timber, but they destroy the hope of timber in the future. Since the publication of this bulletin, forestry associations in various states and scientific societies have been passing resolutions on this subject and presenting their views to various legislative bodies, state and national, and yet in the first half of this month forest-fires were raging unchecked in half a dozen states, and the devastation has been unusually widespread. In most cases they have burned themselves out, or have been stopped by timely rains; very rarely has any human agency prevailed to arrest their progress. The fact is, that after a drought in the early spring, especially in a forest where loggers have been at work and have left the ground covered with dry branches, a fire once under good headway is practically uncontrollable. In Europe there is no longer any serious danger from these fires, because every one hastens to smother them as soon as they are started, and in this country the only way to prevent this wholesale devastation by flame is by an organized effort to arrest the fire as soon as it is kindled.

Of course, every state needs a special law relating to these fires, but even where it is made a crime to set fire to any woods or underbrush, either through malice or negligence, conviction is rare. For the same reason a forest-police can hardly be trusted as a protective agency until the whole community has an intelligent interest in forests. No law can be effectively enforced unless it has behind it a strong public opinion, and the fact that thousands of acres of Pine-lands have been recently on fire within a few miles of cities like New York and Philadelphia is a proof that there is no genuine popular appreciation of their value. Men who live on clearings in the forest, or on lands adjoining forests, will fire brush-heaps in the spring, especially when it is dry, although they know the flames will sweep over miles of wood-land. To them and to the public generally a forest has no value—it is waste-land, the prey of every trespasser. So long as forest-property is held in so little esteem our existing forests will have no adequate protection, and there will be small encouragement to plant new ones.

Do Americans Love Flowers?

The *Illustrated American*, as quoted by *Science*, maintains that Americans do not love flowers, because they are used, among the rich and fashionable, in reckless profusion for display rather than enjoyment. It is also claimed in *Science* that we are not a flower-loving people, because we accept botanical appellations for our indigenous plants, instead of giving them simple, homely names like the charming ones with which familiar flowers have been christened in older countries.

To this it may be answered, that what ostentatious dwellers in towns are guilty of is by no means to be accepted as a national trait. The place to study the characteristics of a people is not among the very rich, but among those in moderate circumstances, who make up the bulk of the inhabitants.

Any one who has driven through New England or the older middle states cannot doubt that there, at least, the people truly love their gardens, and the house plants, with which their windows, in winter, are stocked. Even the humblest dwelling has its row of flower pots, or tin cans, well filled with slips of Geranium or other bright flowers; and the hours spent over their gardens, by gentlewomen who cannot afford a gardener, are the best proof that the affection they have for them is a real and ardent one. We have known many a house mother, burdened with domestic cares, to rise before day to snatch an hour for weeding or watering her little border, that its fragrant contents might be of avail for a friendly gift, or an adornment for her own table. It is the rarest thing, in a New England village, to enter a room in summer and find no flowers disposed about it; and in the winter the eager question, "How are your plants prospering?" often comes before the conventional inquiries after the health of the members of the household. Their new varieties are discussed and exchanged; there are rare Chrysanthemums to talk about in autumn, and choice tulips and hyacinths to be complimented in the spring, and each one knows what her neighbor's garden is most famous for, and who is the most successful in her general management of her pets.

Many women are experienced botanists in their own locality, and can tell where every wild flower of the region is to be found. They rejoice, too, in the discovery of a new weed with as much enthusiasm as an astronomer shows over a fresh comet. Most of the men who live in the country are too busy to give much time to flower-gardens, but they show great interest and pride in those so carefully tended by their wives and daughters, and are ready enough to lend a helping hand, even though they may pretend to begrudge the space taken from grass or vegetables for what they think it their duty to call an idle diversion. But given a retired merchant, with not much to occupy his mind, and the chances are that he will soon be wearing himself out in loving labor among his Rhododendrons and Roses, taking pride in having the earliest and largest blossoms in his parterre, and conferring in a friendly way over the fence with his neighbors, who stop to consult with him on the best way of dealing with insect pests. Of course, in the remoter west, life is too strenuous to leave much space for flower-gardening. But we have seen flowers growing in a little enclosure on a frontier sheep-ranch, which had cost not only labor but self-denial, and yet they were hardly seen once a year by any save their owner. The care which it cost the mothers and daughters among the early emigrants to transport seeds and slips and roots of the old home flowers from New England to brighten new homes in the west has often been described, and the love with which these flowers are cherished by their descendants is well known.

It is to these people we must look to discover whether the love of flowers and gardening is implanted in a people, not to the wasteful and luxurious dweller in the town, who only uses flowers as a pretext for wanton expense. And it should not be forgotten that aside from this extravagance, which may show itself in the purchase of flowers, as in the purchase of other luxuries, simply because they may be rare and costly, the great body of common-sense people in the city buy flowers habitually because they love their beauty and fragrance.

As to the nomenclature there is this to be said: In older countries the people and the flowers lived together long before the botanist appeared, while here the botanists came with the early settlers to an unexplored field, found the new flowers, and named them before the people had become familiarly acquainted with them. The state flower of California has been introduced to the children of that commonwealth as the Eschscholtzia before they could spell it, but this does not prove any lack of love or admiration for it on their part. They have a pet name for the flower, too; and in all the older settled parts of the country wherever a plant or flower is so abundant or useful or obtrusive that there is need to speak of it a name is found at once. The children of New England call the wild Columbine, Meeting-houses, from their shape, no doubt, and with them *Viola pedata* is the Horse Violet, perhaps from its long face. The Houstonia, which is Bluets in some places, is Innocence in others. In northern New Jersey, the Marsh Marigold of other regions (*Caltha palustris*) is invariably a Cowslip. Last week children were gathering Dog-tooth Violets by the handful within sight of Trinity Church spire, and when asked the name of the flowers they expressed much surprise that the inquirer had never heard of Yellow-bells. Even Shortia, which hid away from botanists for a hundred years, had a name which was common enough to answer every purpose, and the man who first discovered it in any quantity was told by the dwellers in the mountain hamlet, where it was spreading over acres, that it was nothing but Little Colt's-foot. Even where botanical names have not been adopted outright as common ones, they have often been changed, just as Pyxidanthera has become Pyxie to all the dwellers among the New Jersey Pines. There are plenty of common names in every locality which have never found their way into the botanies.

American women wear flowers for adornment more generally than the women of any other country. This of itself is proof of the genuineness of their love for flowers. It is absurd to imagine that a custom so universal is based on any sham or passing fashion. The desire for display is prevalent enough, beyond question, but if any one doubts whether the admiration for flowers is an acquired taste—because it is fashionable to wear them—let him carry a handful of them through a city street among groups of children, where unsophisticated nature will find expression. The keen delight of these little ones, who will always accept such a gift, shows that the affection for flowers is an original instinct, which is as strong in this country as it is anywhere. Fashionable freaks and follies pass away, and flowers would have their brief day like any other craze if the regard for them was artificial or fictitious. The flower-dealers of the country need have no apprehension as to the future of their industry. It is based on one of the elementary wants of our nature. Flowers will be loved until the constitution of the human mind is radically changed.

A California Rose-bush.

THE illustration which appears on page 233 will convey to those of our readers who are unfamiliar with southern California a better idea of the possibilities of horticulture in that favored region than any description of a California garden could give. It is made from a photograph of the cottage occupied by Mrs. S. C. Barclay, in Los Angeles. The Rose-bush, which covers the front of the cottage, is only twelve years old, and its size and vigor show what rose-growing may become in California in the hands of an intelligent and careful cultivator. This particular plant is the old-fashioned Noisette Rose, Lamarque, a variety which thirty or forty years ago was the most popular greenhouse climbing plant in our northern states, and which is still occasionally found in old-fashioned gardens, both at the north and in the south.

The Lamarque is a rampant grower, with abundant handsome foliage, and in early spring produces a great crop of large clusters of double, white or slightly yellow, fragrant flowers. There are not many double Roses that are more beautiful, and not many plants that are more prolific, and the Lamarque, like several other old-fashioned and now neglected Roses, might be well restored to popular favor. The fact that it produces only one full crop of flowers in the year is one reason, no doubt, why it has had to give way to plants which flower with more or less regularity every month. None of the newer Roses, however, grow so vigorously or are more reliable, and to cover the rafters of a large conservatory at the north or to climb through the trees or over the verandas of a southern garden, no Rose which has yet been produced surpasses or quite equals this old-fashioned favorite.

How We Renewed an Old Place.

VI.—THE WRECK OF AN ANCIENT GARDEN.

WHEN the Swiss Family Robinson went ashore on their desert island they found all they needed to make them comfortable, on the wreck, from which, luckily, they were able to help themselves before the old hulk went to pieces. After that, every little thing which was quite indispensable came out of a wonderful bag that belonged to the worthy mother.

Since we landed upon the barren waste of this abandoned farm we have often had reason to compare the old house-lot with the ship, and the front yard with the mother's bag, for a number of trees and shrubs have been forthcoming from the one, while the other has proved an inexhaustible resource, not only for our own, but other people's gardens.

For, once upon a time, in the old house which is now no more, there dwelt two dear old ladies who took great pride in their garden, and stocked it well with all the best flowers of their day, and from it came bulbs and cuttings of roses, and roots of perennials, that still help to make beautiful the ancient gardens of this fine old town. They were women of refinement and learning, much respected and beloved, and the older people still warmly recall Miss Peggy and Miss Betsy, and the days when the old house was always a sunny and cheerful resort. After the place was abandoned and unoccupied for many years, people felt at liberty to come and help themselves to slips of the shrubs and to roots of the old plants, so that one might hardly hope to find anything of value still existing there; but when we came to clear away the rubbish, we were surprised to find what a tenacious hold the occupants had of the soil, so that, as the spring and summer months sped by, we were constantly surprised and charmed to find, in unexpected places, some shrub or flower that clung to its old haunts, and, half-hidden from the eye, bloomed away its sweet life heedless of observers.

Along an uneven old wall that had supported the terrace of the house, I had a bed dug, into which I transplanted such bulbs and roots as would consent to be torn from their original homes. This bed I call Miss Betsy's Garden, for I am quite sure that in old times that gentle soul must have watched and tended her favorites by this same sunny wall. There is one prim little Columbine which wears a minutely fluted lavender cap that I associate with her, and always call by her name. The flowers that come up in Miss Betsy's Garden are all simple and homely, but to me their quaint familiar faces are more appealing than the far showier and splendid blooms of to-day.

They must have family records of interest, these lady-like old blossoms. Those yellow Daffodils, with their long green ribbons, have nestled up against that wall till, no doubt, they regard it as an ancient castle, of which they are the chatelaines; and I am sure that dignified Narcissus must have a history. There is a sweet June Honeysuckle straggling there which breathes an old-time fragrance, and the tiny petals of the pale pink Bridal Rose which flutters beside it have the very tint of soft color one sees in the cheek of an ancient maiden. A wild Clematis seems to grow out of the wall itself. I have never been able to find its root, and every fall a Prince's Feather waves its tall plume where once it danced with a Lady's-slipper. The Pansies have all degenerated into Lady's Delights, and the Hollyhocks come up single, but here they grow and blossom beside a pendulous Forsythia, the seed of which was, no doubt, sown by some passing bird, for it is not, I think, one of the older shrubs in this village.

The rest of the garden is perfectly formless and wild. Nothing has been done to the old part of the farm, except to clean away the weeds and sticks that encumbered it, and the old plants have grown lank and tall along the fence and under the heavy shade of the trees. But here in the spring the ground is blue and fragrant with hardy English Violets that fill the air with perfume and blossom long before even the native White Violet, which leads the way among our New England flowers; and wherever you walk you come upon a Tulip, or a Star of Bethlehem, or a feeble Crocus choked by the strong grasses, and other Daffys are wagging their golden heads in sheltered spots, and later there are to be seen more sculpturesque Narcissus shining whitely under the shrubbery, "like good deeds in a naughty world." The Flowering Almond sends up spikes of bloom; the Periwinkle, white and blue, hides among its shining leaves, while the Moneywort has strayed away from the garden and made of itself a nuisance in the orchard, where it threatens to root out everything else. There also are great clumps of the giant Solomon's Seal in shady nooks, where they grow to wondrous size.

There are Lilacs, purple, white and Persian, in profusion, and the Mock Orange and Spiræas, all have their turn as the seasons go round. One White Lilac has shot up to the height of a two-story house, and now that the windows are no longer there to help one to gather them, it shows, when in bloom, a crown of inaccessible blossoms; others yield their wealth of flowers nearer at hand, and by the well, a Persian Lilac drops like a fountain with rosy jets.

No longer supported by the fallen house, a Trumpet Creeper, which trailed along the ground, has been clipped into a compact bush. A venerable Althæa, which we did our best to save, blossomed feebly for a season or two and then perished, deprived of the accustomed shelter of the porch, but great bushes of the old-fashioned White Rose abound, and there, too, is the sweet Blush Rose, beloved of the bee and the sturdy Hessian. A large Damask Rose still flourishes under the Lilacs, and a luxuriant Baltimore Belle climbs in reckless profusion over its confining wires. Where the fence stood is a low cluster of bushes covered in summer with a bold Red Rose, single and splendid, the remote parent, perhaps, of the Jacqueminot; they call it here the Russian Rose, but I do not know what its real name may be; and down in the orchard I found a bush of the dear, thorny, little Scotch Rose, the smell of which is laden, as is no other, with the memories of childhood.

There are clumps of Tiger Lilies and old-fashioned small Bluebells and Sweet Williams, and a Barberry-bush swings its yellow blossoms and red berries over the rear wall, and under the Box-arbor I found Spiderwort growing in great clusters.

One day, while strolling down along the orchard fence, a familiar odor, heavy and sweet, led me on to where a wild Azalea was hanging out its fragrant blossoms. I do not see why a hedge of these might not do well in this moist soil. I hailed this one with delight as a fine ornament to the place.

But what we like best is the fine old Box arbor, which has grown up from a garden border until its stout trees are now six inches in diameter, and nearly ten feet high, which shows their great age. They were fair-sized bushes when old men of this town were boys, and to make even a bush of a Box-plant is slow work. Here, shaded by a young Elm which has sprung up in the kindly shelter of these twisted old trunks, we sit and look out upon the meadow and the growing plants, and feel linked with the past by this memento of those who loved this garden spot, and toiled to make it fair and fruitful, even as we, too, toil to restore its beauty and productiveness.

Hingham, Mass. *M. C. Robbins.*

Winter Studies of the Pine Barren Flora of Lake Michigan.—IV.

In peat swamps, and also in wet sands, the Pitcher Plant (*Sarracenia purpurea*) may be studied. The leaves are mostly purple or wine-colored, striped sometimes with brighter lines. A nest of these leaves, resting on the Sphagnum, or among Cranberry-vines, is an attractive sight, aside from the interest which their singular form excites. Every curve and swelling of the vasiform leaf and of the hood is perfect, in harmony with the flowing lines of beauty, and the eye lingers on a beautiful shape. In winter they are mostly filled to the brim with water or with ice. When the latter is the case, by removing the integument a complete model of the cavity is obtained in ice. The water is limpid and the ice clear, except at the bottom of the cavity where objects that have fallen in have settled. The repeated freezing and thawing to which the pitchers are subjected by change of temperature does not harm them, for the tissues are not torn, and they are ready to resume their function of catching insects in the spring, and continue till the plant is supplied with a new growth of leaves.

The nest-like clumps of the Prickly Pears (*Opuntia Rafinesquii*) are very different in appearance and habitat, finding a congenial soil in the dry sands where they grow abundantly. The mixed character of our flora is well displayed by this and the Pitcher Plant, for the latter may be seen in the wet sand, and a few feet away the Prickly Pears and the Bearberry may be found growing. As the only representative of the Cactus family it is an object of special interest to the student of this flora. The winter aspect of the plants will at once be noticed. During the warm weather the joints of the stem are green and plump, and the skin quite smooth, except on some of the oldest, and the stems are somewhat ascending, and some of the joints upright; in the cold season, though retaining their green color, they are much wrinkled, the skin wavy, and the joints are limp, lying flat upon the ground as if to expose as little of their surface as possible. The stiff tissues have become very pliable, and the stems, if lifted up, fall back like a weak or lifeless body. When partly buried in sand, or covered with dead leaves, which their irregular shape and spines well adapt them to catch and hold, they retain more of their summer habits and position. Their spines are sometimes rather formidable, though not present on all plants, or so greatly developed, except upon a few, where they become an inch to an inch and a half long, and stout in proportion.

Several of the herbaceous plants have not lost all their seeds, though the stems are dead. The cottony heads of Anemones, especially those of *Anemone cylindrica*, attract attention. They are swollen to an oblong bunch by reason of the loosened akenes, and the down is rusty-looking. The faded stems abide stiffly in their places, and contribute their part in giving variety to the scene. The pale pappus of the Golden-rods and Asters, and the hairy spikes of the Beard-grass (Ardropogon), still remain in quantities sufficient to remind one of the spots where they were common in summer; and when the ground is mantled with snow, and flocks of snow-birds and snow-buntings appear, such plants as these, rising above it, are a welcome source of food to these birds, lighting on the stalks to gather the seeds or skipping over the surface of the snow to pick up those which have been scattered by the wind.

Those interested in Mosses and Lichens will find many of these forms of plant-life in as good a state to investigate as in the summer. Dr. Henry Muehlenberg, a careful and diligent botanist in the days of firesides and back-logs, resorted to his wood pile for material of this kind in the winter-time, and considered it the best season for their study. Under date of January 18, 1811, he writes to his friend, Dr. Baldwin: "For Mosses, the present season is best. They are best distinguished when the operculum is ready to fall and the peristoma beginning to show itself. The Lichens we can often find at the fireside, and I have gathered a good number just before I put the wood in the stove or on the fire" (Darlington's "Reliquiæ Baldwinianæ," p. 26). But to enjoy such plants and discern their beauties, to learn some of the lessons they may teach, it is not necessary to be a bryologist or lichenologist, or be called by any such hard names, or even be skilled in the use of the compound microscope, though this instrument is indispensable if one would go very far.

The Reindeer Mosses (*Cladonia rangiferina* and allied species) here take to the sand as readily as in rocky regions they do to the rocks. The shapely clumps, usually circular in outline and with a rounded surface, resting on the bare ground, the dichotomous branching of the stems, their varied colors, pale, ashy-gray, greenish-gray, yellowish, pink and flesh-color, all please by their variety. The trunks and limbs of many of the Pines are spotted or nearly covered with the flat expansion of other Lichens, varying in shades of color, but mostly those of gray. These colors are too subdued for brightness, but harmonize well with the dark-colored bark of the Gray Pine, there being enough of contrast for good definition, and the boll of the tree, however small, when provided with the Lichens, takes on the appearance of age. Species of Usnea, with long, glaucescent stems depending from the limbs of trees, are not common as they are farther north, where they hang from the limbs in such quantities as to make the bearded trees, look venerable.

Several of the common mosses are quite noticeable in winter. In patches on the sand are the light green, or the yellowish green tufts of one of the most abundant kinds, *Ceratodon purpureus*. The cushiony tufts vary in size and shape, being as small as a coin to a foot or more across, and round, oval or irregular in shape. The fruiting-stems have already started, and in early spring the bunches will be bright with purple stems and capsules. Much like them are the tufts of Bryum, but with stems less condensed. In marked contrast with these, both for stoutness and color, are the stems of the White Moss (Leucobryum). The compact tussocks are almost white, or white tinged with green, and are very pale, spread out at the base of some sheltering tree, the soft cushions are very inviting as a place of rest in summer, but, if tried, may be found as fully saturated with water as the stems of the better-known Sphagnum, able to absorb seven or eight times their weight of water. Wherever they are, these cellular Mosses aid the trees under whose shade they grow, by helping to retain the moisture near their roots, and enriching the soil with humus when the stems decay, and thus find their rôle in the economy of nature. Large reaches in the damper grounds are carpeted with the Hair-cap Moss (*Polytrichum commune*). Its sharp, slender leaves, resembling those of the Juniper, have an evergreen look. The stems are tall for a Moss, sometimes nearly a foot in height, and in walking through the soft beds one sinks into them ankle-deep. Another pretty moss growing in loose patches of considerable extent in the partial shade

Fig. 41.—A California Rose-bush.—See page 231.

of trees is worthy of notice for the effect its peculiar coloration has on the sandy ground. It is the *Thelia Leseurii*, of Sullivant. The round and closely leaved stems are barely an inch high, and of a glaucous-green hue, contrasting well with the surrounding sands. The leaves are beautiful objects when examined under a low power of the microscope, being thickly studded with lobed or star-shaped papillæ, which seem to affect the light they reflect, and contribute to the charm they have when seen in masses. I find this Moss nowhere except in the dry sands. It is assigned a range in our literature on Mosses from New Jersey south along the Atlantic, and in the southern states, but is not uncommon in the Pine Barrens here.

Englewood, Chicago. *E. J. Hill.*

New or Little Known Plants.

Clematis connata.

NO figure has yet appeared apparently of this handsome Indian Clematis, which produced flowers at the Arnold Arboretum at the end of October of last year, from a plant sent here three years before from the Royal Gardens at Kew under the name of *Clematis Japonica.*

Clematis connata * (see p. 235) is a stout woody climber, with ample long-petioled leaves composed of three to five remote leaflets, which are three or four inches long, broadly ovate, cordate by a broad deep sinus, coarsely and irregularly serrate, or sometimes slightly three-lobed and borne on stout petiolules one and a half to two inches long ; they are dark green on the two surfaces, with five principal veins and prominent reticulated veinlets. The flowers are produced in many-flowered panicles, and are campanulate, an inch long, and clear light yellow in color. The sepals are oblong, acute at the apex, pubescent on the outer and tomentose on the inner surface, and reflexed above the middle when the flower is expanded. The filaments are linear, and are coated with long silky light hairs. The fruit, which has not been produced here, is described as "silky pubescent."

Clematis connata is a native of the temperate Himalayas from Hazara to Sikkim, at elevations varying from 4,000 to 10,000 feet above the sea-level. The stems suffer here in winter, and are generally killed back to the ground. This, perhaps, accounts for its flowering so late in the season (October 27th), a peculiarity which deprives this species of much value as a garden plant in New England. It is, however, a rampant-growing plant with high-climbing stems, large bold foliage and beautiful flowers ; and in regions of longer summers and warmer autumns it will doubtless prove a desirable addition to the plants of its class, certainly well worth experimenting with in some parts of the middle and southern states. *C. S. S.*

Cultural Department.

Cinerarias.

THE Cinerarias at the gardens of Dr. C. E. Weld, Brookline, Massachusetts, this spring, were probably the best, taken altogether, which have ever been seen in this country. In a late number of the *American Florist* Dr. Weld's gardener, Mr. Kenneth Finlayson, describes his method of cultivating these plants, the main portion of which we herewith reproduce :

My experience with Cinerarias, especially with those sown early, say any time in June, and for early-flowering purposes, is that they require more care than most kinds of plants to pull them through the hot months of summer. It is a well-known fact that Cinerarias are very impatient of strong sunlight, such as we get here in the months of June, July and most of August, and the prime difficulty is in providing a temperature which suits them. My method is simply to shade the glass with a thin coating of white paint, and over this, on hot, bright days, I put a lattice shading. These lattice shades are made to fit over our sash (ordinary cold frame, or six by three feet). The bars run horizontally instead of crossing each other ; they are one inch wide and a quarter of an inch thick, the space between each bar being a trifle over half an inch ; the frames on which the bars are nailed are one inch square.

These shades I consider the best of all when shade is necessary, for the reason that they are movable, in the first place, and put on when really needed, and secondly, because they keep the glass cooler than any paint or canvas shading will do, thereby giving, as near as possible, the conditions most favorable to plants needing a shade.

I further lower the temperature by raising the sash at both ends by wooden blocks, cut longer than they are wide, and wider than they are thick, so that one block will raise the sash to three different heights, as necessary.

Syringing overhead in the morning and afternoon of hot, dry days is very beneficial to the plants under consideration.

Greenfly attacks these plants at all stages of their existence, but are easily kept under by fumigation. When in frames outside I strew tobacco-stems all round the pots in which the plants are growing, and find no difficulty in keeping them clean in that way. In the greenhouse I seldom have to resort to any remedy for these pests, as they do not attack them much. To some this may seem strange, but the reason is quite plain, and nothing more or less, in my opinion, than that the Cinerarias are kept in a temperature admirably suited to them, but less congenial to the greenfly, namely, forty and forty-two degrees Fahrenheit at night.

The soil I use for the Cineraria in the early stages consists of one-half leaf-mold and one-half good turfy loam, with a liberal dash of sharp clean sand added. At each successive potting the leaf-mold is withheld partly and the loam increased proportionately. The final potting soil consists of one-fifth leaf-mold, one-fifth good rotten cow-manure, the remaining three-fifths turfy loam, very little sand, a liberal dash of fine crushed bones.

The stimulating begins when the pots in which they are to flower are well filled with roots ; cow-manure, liquid, I use frequently, but chiefly guano and soot in equal parts mixed. I put a large handful of the latter in a six-gallon can of water and stir well with a stick, to incorporate the stimulating ingredients in the water before using. I apply this dose once or twice a week, as the weather demands—that is, if the weather should be bright there is more demand on the water-pot than there would be on cloudy days, therefore the stimulating must be regulated accordingly.

I use guano alone on almost every kind of plants, and on gross feeders, like Cinerarias, Calceolarias and Chrysanthemums, I use it in stronger solutions than do most cultivators.

Odontoglossum coronarium and O. brevifolium.

GREAT confusion has always prevailed among Orchid growers in respect to these two species of Odontoglossum. From the descriptions which have from time to time appeared in horticultural journals, it is evident that but one is referred to under both names—sometimes *O. brevifolium*, sometimes *O. coronarium.* This being the season of flowering, it will not be inappropriate to point out the differences between the two species, and to show that the plant, carelessly designated under both names, is in reality the true *O. coronarium*, as described by Lindley in his "Folia Orchidacea." How the confusion arose it is difficult to say. *O. brevifolium* was discovered about ten years before *O. coronarium*, but does not seem to have been successfully grown in Europe, and it is possible that the latter species, when introduced, was, in the first place, thought to be the true *O. brevifolium*, and was launched into commerce as such.

To afford some means of distinguishing the two species, which certainly appear to be closely related, it may be as well to state that *O. brevifolium*, according to Lindley's description in "Plantæ Hartwegianæ" (1839, p. 152), has ovate oblong compressed pseudo-bulbs, surmounted by a single leaf; the leaves are two inches broad, and sometimes not much longer ; the individual flowers are an inch and a half or more in diameter, and eleven or twelve are borne on a drooping raceme, being apparently purple in color. This species was collected for the first time, with many other Orchids, by Theodor Hartweg, who was dispatched to South America, in 1836, by the Royal Horticultural Society of England, in search of new and rare plants. Dried specimens and plants were sent to England, but, beyond the botanical description recorded in "Plantæ Hartwegianæ," nothing has ever since been heard of them, except when the name has been misapplied to *O. coronarium*, which has flowered several times, and has been

figured in the *Illustration Horticole* (1874, t. 170) and the *Orchid Album* (t. 27) unfortunately under the name of *O. brevifolium* in both works.

The distinguishing features of *O. coronarium* may be described as follows. The plant has a creeping rhizome, about as thick again as an ordinary lead-pencil, emitting thick, fleshy roots from the lower surface. Numerous pale brown scales are on the rhizome, and these gradually become larger and more foliaceous in character as they approach the base of the pseudo-bulbs, which are encased by some of them, and

are produced, one year after another, at intervals of two or three inches. The pseudo-bulbs are ovoid, compressed, with edges more or less acute, and are terminated by a single leathery, elliptic, oblong leaf, which varies from six to twelve inches in length, and is about two or three inches wide. The stout, erect scapes are produced from the base of the pseudo-bulb, and are from twelve to fourteen inches high, often carrying as many as eighteen or twenty large flowers on the upper portion. The lower portion of the scape is clothed with large, pale-brown, leafy bracts, the outer surface of which is spotted with purplish red, as is also the epidermis of the scape itself. The flowers appear in March and April, and each individual, borne on a pedicel about two inches long, would occupy as much space as a circle with a diameter of two inches and a half. The roundish petals and oblong-clawed petals are of a deep glossy brown—as if the surface were varnished—with a narrow undulated margin of clear yellow, which is very attractive. The base of the petals is creamy yellow, blotched with purple brown. In comparison with the sepals and petals the lip is rather small; it has an obcordate emarginate blade, narrowed toward the base, where it widens out into a small lobe on either side, having a three-toothed crest in the centre. The color is clear, bright yellow, with a forked stain of orange-yellow at the base, in front of the crest. The white column has its "wings" decorated with purple spots.

It must be admitted that, at first sight, the original botanical description of *O. brevifolium* would do very well for what is known to be *O. coronarium*, especially when Lindley adds what would seem to be an emphasizing remark, "flores magintudine et facie Oncidii crispii." By a stretch of imagination the same might be said of *O. coronarium*. But it is important to point out that *O. brevifolium* is described as having leaves often not much longer than two inches, and as carrying its flowers on drooping scapes, while it is well known that the leaves of *O. coronarium* are much longer than two inches, and that its scapes are erect. For ordinary purposes these two particular points should be enough to enable any one to distinguish between the two species, although there are other points of difference in the structure of the flowers.

O. coronarium grows wild in the northern part of the United States of Colombia. It was first discovered by Funck and Schlim in 1847, in the vicinity of Ocana, at altitudes varying from 7,000 to 9,000 feet above the level of the sea, and it is to the latter traveler we are indebted for having first dispatched living plants to Europe—to the nurseries of M. Linden, of Brussels.

Although one of the finest Odontoglossums in cultivation, it is very seldom seen in a good condition. There is always a certain amount of difficulty about its culture, and this being recognized, it is possible that many growers make matters worse by being too careful with it, coddling it in fact, an operation seldom successful. There are some, however, who experience no difficulty in growing this species well, and one of the finest specimens I have seen in flower was grown in the collection of Mr. R. N. Dale, of Bromborough Hall, Cheshire. It was exhibited at a recent meeting of the Royal Horticultural Society, but was first shown on May 1st, 1872, by M. Linden, and obtained a first-class certificate under the erroneous name of *O. brevifolium*.

Owing to what may be called the traveling propensities of the pseudo-bulbs (the production or evolution of which is analogous to that of the common Solomon's Seal), it is not possible to restrain the growth of this plant within the bounds of a pot in the usual way. Some other means must be adopted to suit its peculiarity, and one of the best is to fix the rhizome to a teak raft, having rough peat and sphagnum moss to grow in; the raft may then be stood in a pot filled with large clean crocks, which may be covered over with fresh moss to obliterate the otherwise unsightly appearance. *O. coronarium* will thus thrive in a moderately cool house, with plenty of light and air, and copious supplies of water, with frequent syringings during warm weather and the period of growth.

Isleworth, London, W. *J. Weathers.*

Æschynanthus.

THESE showy epiphytal plants are admirable for baskets in the conservatory. Being natives of India and the Indian islands, they require a high temperature and moist atmosphere. They are generally of a scandent habit and should be allowed to droop over the sides of hanging baskets. A mixture of fibrous peat, sphagnum moss, a little loam and lumps of charcoal makes the proper soil for them, and should have a liberal supply of water when growing, both at the roots and over the foliage. The orange or scarlet flowers are produced in both terminal umbels and from the leaf-axils.

A. cordifolius is a very free-flowering species, with dark green heart-shaped leaves. The flowers are in clusters, deep red striped with black, the inside of tube being orange. The variety is one of the best summer bloomers.

A. speciosus is more erect in growth, and bears very freely large fascicles of erect, long-tubed flowers of rich orange-yellow, with black markings.

A. grandiflorus bears large deep crimson and orange flowers, and *A. Lobbianus* rich scarlet flowers.

A. splendidus is a garden hybrid of very easy cultivation. The flowers remain a long time in perfection. The leaves are long, lanceolate and of a very light green color. The flowers are large, bright scarlet, spotted with black on the edges.

There are many other varieties, but all have the same general characteristics, and they are among the most beautiful summer-flowering stove-plants in cultivation.

Maywood, N. J. *James P. Taplin.*

Dahlias.

THE *Journal of Horticulture* gives, in a late number, some valuable statistics showing the relative positions of the best-known varieties of the Dahlia as revealed by their appearance at exhibitions in England in eight years—*i. e.*, from 1883 to 1890. Here are the first twelve in each section in the order of their rank:

Show Dahlias.—Mrs. Gladstone, pale blush; Harry Keith, rosy purple; W. Rawlings, crimson-purple; J. Cocker, purple; Hon. Mrs. P. Wyndham, pale yellow and rose; Henry Walton, pale yellow and scarlet; R. T. Rawlings, clear yellow; Mrs. W. Slack, blush white and purple; Colonist, chocolate and fawn; Maud Fellowes, pale pink and purple; Goldfinder, yellow and red; Mrs. Langtry, cream and crimson. The premier position has been held by Mrs. Gladstone, which is by far the best of all show Dahlias, five years in succession.

Fancy Dahlias.—Mrs. Saunders, yellow and white; Rev. J. B. M. Camm, yellow and red; Goethe, yellow, red and white; Chorister, fawn and crimson; Duchess of Albany, orange and crimson; Flora Wyatt, orange and red; Henry Eckford, yellow and red; Mrs. N. Halls, scarlet and white; Peacock, maroon and white; G. Barnes, lilac and crimson; M. Campbell, buff and crimson; Hugh Austin, orange and red.

In the following short lists the varieties are arranged according to the total number of times they were staged in competition at the last two exhibitions of the National Dahlia Society:

Pompon.—E. F. Junker, White Aster (Guiding Star), Darkness, Favorite, Gem, Rosalie, Isabel, Golden Gem, Lady Blanche, Grace, Little Duchess, Whisper.

Cactus and Decorative.—Mrs. Hawkins, Empress of India, Panthea, Amphion, Juarezii, Constance, Charming Bride, Cochineal, Henry Patrick, William Darvil, Zulu and Honoria.

Single.—Amos Perry, Miss Henshaw, Duchess of Westminster, Mrs. B. Coninck, W. C. Harvey, Cetewayo, Duchess of Albany, Formosa, Hugo, Marion Hood, Miss Ramsbottom, Miss Roberts.

Hardy Narcissus.

THE Narcissus season is now closing in, and, so far as one can judge at present, has been a complete success. Apart from the newer varieties tried this year for the first time, there are several other points worth recording. It has been fairly tested and proved here that Irish-grown Narcissus are better ripened, and, in consequence, flower better than Holland-grown bulbs. The bulbs received from Ireland were not remarkable for size, but from most of them two flowers, and from many three flowers, were produced, and good flowers, too. This fact may be of use to those who force Narcissus largely, for complaints are common this year of the flowering of bulbs grown in Holland. As to the covering of late-planted bulbs, as heretofore advised, one point should have been emphasized more strongly, which is, that after planting it is absolutely necessary where field-mice abound, as they do here, to allow the frost to penetrate to the depth of two inches in the soil. This will keep the mice above ground, otherwise the Narcissus-bed would be a perfect paradise for them, with the covering of dry leaves to nest in.

One of the best of newer kinds tried this year is *N. bicolor præcox*. This is in flower with the earliest kinds, almost two weeks before *N. bicolor Horsfieldii*, and in shape and color is almost identical except that it is smaller; but one cannot have too many bicolored varieties, especially when they are as good as Grandee or Grandis, which is equal in every respect to

Horsefield's variety, and the one bulb gave us three perfect flowers. The perianth is pure white with a pale yellow trumpet, and the flower is of good substance. I had always thought that Empress and Emperor were tender and hard to keep, but with us they are the most vigorous, and the size and substance of their flowers are unsurpassed. Duchess de Brabant is one of the Eucharis-flowered section and is known as pure white, but there is a tinge of creamy yellow in the flowers, which are two or three on a stem. This is a very pretty variety, dwarf, and useful when cut. Of the Poet's Narcissus the earliest is the variety Angustifolius. It flowered ten days before Ornatus, the well-known early-forcing kind, and is equally as good in its way. The true variety, Pœtarum, is distinct, for, instead of the centre being margined with red, it is wholly of a deep orange-scarlet or saffron. We received a lot of other bulbs under this name which were nothing more than the *N. pœticus*, which is easily distinguished by the coloring of the cup.

Ard Righ, or Irish King, is a very early Trumpet variety, and forces well, and makes a better plant for this purpose than Trumpet Major. Countess of Annesley, also a Trumpet variety, is equal to Golden Spur, and very desirable. It was found in an old Irish garden, as were also many more charming kinds, where they have been hidden for years past, but have been hunted up since the development of what may be considered almost a craze for these flowers. Some of the newer sorts certificated at the London Conference last year command prices which testify to the demand for novelties of this sort among wealthy amateurs. Twenty-five dollars is the modest sum asked for one bulb, and if the flower is as good as described it may be as many years before it will be cheap or common; but this is an exceptional case. Good showy kinds can now be purchased of most dealers in fall, and even the cheapest are good to commence with, and then, again, some of the more expensive sorts are really cheap, they increase so rapidly. Sir Watkin, for instance, is one of the most profitable kinds ever introduced; where one bulb is planted three may be dug the following year, it multiplies so quickly by offsets. The depth at which to plant has been, and is still, a vexed question both here and abroad. Mr. Gerard takes exception to the depth recommended by me, and practiced very successfully in his own locality and in this, but the difference lies entirely in the nature of the soil, which with him is a red clay, while those with which I have had to deal have been of a sandy or gravelly nature, warm and dry in summer, and porous in winter. Had I his soil to deal with it would be necessary, perhaps, to plant differently and to leave the beds bare during summer, but here even the more delicate and even tender kinds do well under the treatment I have described in these columns.

European catalogues often add in their descriptions of Narcissus the dates at which they may be expected to bloom in the open ground. It need hardly be said that this is not of any use to us here, as when spring opens a week of difference there may become something less than a day here, but perhaps if they were grown in pots in cold frames there would be a greater interval between the kinds. Pot-culture, however, is scarcely to be recommended, as even when well grown in pots the plants become so drawn out of all character that it is very difficult to distinguish the varieties. Such was the case at the spring show of the Massachusetts Horticultural Society, and the same may be said of nearly all hardy plants, they lose one of their special charms, their hardiness.

S. Lancaster, Mass. *E. O. Orpet.*

Scilla hyacinthoides, after being grown in gardens some 200 years, would scarcely seem to need an introduction, yet as the Scilla season ends with its blooming in May, perhaps a word as to its value and beauty may cause it to be planted in places where it is now unknown. The white soft bulbs are entirely hardy, and increase rapidly, throwing up in the spring numerous long, narrow, prostrate leaves, and at this season a radical stem furnished with numerous small bell-shaped flowers. In the type these are light blue, but there are also white and rosy forms, both of which are attractive. The flower-stems are some six inches long and useful for cutting.

Trollius Europæus was one of the last hardy plants to bloom in November, and now the same plants are showing their beautiful golden globes. Very satisfactory yellows are their flowers—light yellows to orange in clear fine tones. These Globe-flowers seem of undoubted hardiness, and prefer rather damp places; in such locations they grow vigorously.

Aquilegia flabellata, the dwarf Japanese species, proves the earliest to bloom, leading *A. Sibirica*, and showing flower in April. It is scarcely a foot high and has short-spurred white flowers slightly shaded with violet. The other species and hybrids are rapidly developing and enlivening the borders with their gracefully poised flowers. Either for the border or for naturalizing in wild places there are few more satisfactory and enjoyable flowers than the Columbines, and few plants with a greater range of color and form. Perhaps there are rather too many purples, but on the whole the colors are very attractive. The confirmed hardy plantsman has his tradition that only the true species of Columbines are worth growing. 'Tis true that he is somewhat doubtful as to what may be the genuine type of some species, but he is sternly loyal to the principle. But those who simply enjoy beauty when they find it will be apt to find pleasure in the double and twisted hybrids which spring up through the garden from self-sown seed. The varieties of Columbines are endless since it is very difficult to prevent their crossing. Reliable seeds may be had of some species, however, and it is well to start with a selection of these. A good selection would be, say, *A. cærulea*, *A. chrysantha*, *A. alba grandiflora*, *A. truncata*, *A. glandulosa*, and *A. Canadensis*. It adds to the minor pleasures of the garden to grow the flowers of sentiment, and there seems to be some of this attached to the last-named species, which is our common wood Columbine. I notice that my friends who are old enough or frank enough not to be ashamed of emotion usually pause pensively at this variety, which leads me to infer that in days gone by a great many wild Columbines have been gathered in pleasant company.

Elizabeth, N. J. *J. N. G.*

Begonia semperflorens.—I have been much interested in noticing the hardy character of this Begonia for the past two seasons. On an elevated border, close under the south front of a long piazza in Raleigh, is a row of these Begonias. They are covered in the autumn with rough manure, and in the spring they start up again in full strength. I was at first inclined to think they came from seed, and some may do so, but I find that the fleshy bases of the stems survive. These plants are not tuberous, but the bases of the stems are stout, and are completely protected from our light frosts by the sheltered position in the dry border with the added cover of manure. During each summer the plants grow about two feet high, completely filling the open space between the ground and the floor of the piazza, and they are continually covered with bloom. I have been accustomed to see this Begonia growing as a weed, from seed, about old greenhouses, but had no idea before of its ability to survive out-of-doors.

The Satsuma Orange.—Last spring we planted on an open and exposed hill-top, at the North Carolina Experiment Station, two trees of the Japanese seedless Orange, known as the Satsuma. These small trees are grafted on the *Citrus trifoliata*. One of them was very puny and weak all summer, and we were not surprised to find that it lost its foliage and some wood. The other one did not lose a leaf, though no protection was given it. It is now making a firm new growth, and is in bloom. It seems probable, therefore, that we have here a sweet orange that can be grown a long way beyond the "Orange belt." The lowest temperature noted at the signal station in Raleigh during the past winter was, we believe, twenty-one degrees above zero; but these plants are on an exposed hill-top, fifty feet or more above the city, and must have had several degrees more of frost at times.

Celery-plants.—Celery-plants should be bought in May from those who make a specialty of growing them for sale on a large scale. At thinning time the young plants may be procured for one-third the price asked for them at the regular planting season, and by transplanting them two inches apart each way in a rich border, or, what is better, in a cold frame where a shade can be put over them, fine plants, in the best possible condition, are conveniently at hand when planting time comes. When only a moderate number of plants are needed, it is better to buy them in this way than to raise them from seed.

Raleigh, N. C. *W. F. Massey.*

The Forest.

Redwood Timber.

SOUTH of San Francisco Bay the only Redwood forest of any extent is that of the Santa Cruz Mountains. Compared with the northern belt this forest is small. Two railroads tap it, one piercing it through the centre. A great farming and fruit-growing community is close at hand, while much lumber goes to the cities on San Francisco Bay. With this demand it is a question of no great length of time when this forest will disappear.

North of San Francisco the first great forest is reached at the mouth of Russian River. Here is the southern border of that great Redwood forest which extends, without a break, through Sonoma, Mendocino, Humboldt, and Del Norte Counties, narrowing all the time until it ceases near the Oregon line. On the Russian River were some of the finest Redwoods on the coast. Accurate figures of the yield of Redwood forest per acre are hard to obtain, but here, at Guerneville, Mr. Guerne, the principal mill-owner, cut 24,000,000 feet of Redwood lumber, of first and second quality, from 160 acres, an average actual output of 150,000 board feet per acre. Mr. Guerne paid $2.50 per 1,000 stumpage, or $60,000 for the 160 acres. It is probable that this is as large an amount of redwood as has ever been cut on an equal area. Even at Guerneville, famous as it was for fine timber, there were not over 500 acres of timber approaching this productiveness, while of the Redwood lands remaining uncut now, such quarter sections as will yield 50,000 board feet per acre are considered exceptionally good.

North of the Russian River the Redwood forest widens, reaching its greatest width of twenty-two miles at a point west of Ukiah, Mendocino County. This section is one of very steep mountains and deep cañons, and nearly all of the Redwoods are on the rugged slopes, which even a good mountaineer would consider hard climbing. The river-bottoms or flats are insignificant throughout this region, and a forty-acre piece of level or nearly level land is unusual, and can only be found in narrow strips from which rise the steep, wooded hills. The streams, after a short course, at most forty or fifty miles, flow into the ocean, with deeply cut tidal estuaries. With reasonable accuracy it can be said the entire Redwood belt is included within the basins of these streams. At the mouth of nearly every considerable stream a saw-mill is located. The cutting capacity of the sixteen Mendocino County mills varies from 30,000 to 100,000 feet per day. The mill companies own Redwood lands at different portions of the river-courses. Logging is done at various places during summer, and the logs are rolled into the dry channels to await the winter floods, or, where the tide runs up a river, they are floated directly to the mill. Railroads are also built up the cañons, and make some of the mills independent of high water. These railroads are standard gauge, and from five to fifteen miles in length, and nearly every large mill company has its railroad, which is extended as the timber is cut. Spurs from the main roads are run up lateral cañons, so that the haul by oxen is shortened, and it is all down-hill.

The mills find easy shipping facilities from either a wharf, where the river has no bar, or by chutes, which are, perhaps, peculiar to this high, rock-bound coast. From some bluff a trestle-wharf is thrown to a rock adjacent to deep water, high above the surf. From the end of this wharf an inclined way slants to the deck of the vessel. This slide is upheld by a sort of derrick, and can be lowered to the vessel or raised out of the reach of the waves. The lumber is let down this chute piece by piece, a breaker at the bottom stopping the headway. A line of men stow it away. Passengers and freight are loaded or unloaded by way of these chutes. Steam schooners, of a capacity of 200,000 to 300,000 feet, do most of the carrying trade. On about 100 miles of coast-line belonging to Mendocino County there are twenty-three chutes and ports. In times of extensive railroad-building the Redwood region is the scene of a great railroad-tie industry, and millions are hewn. For this work only the best splitting trees are used, and waste is great. The ties are nearly all cut from the higher ridges and mountains, and hauled by wagon to the coast. Great quantities of the finest timber have thus been cut and half-used. Even in ordinary times no inconsiderable number of ties and posts is cut, and the ridges are cleared far in advance of the operations of the saw-mills.

Northward from Mendocino County the next lumbering centre is at Humboldt Bay, where the output of eight large saw-mills, each cutting from 40,000 to 80,000 a day, is shipped. More of the forest in this region is on flats and lighter slopes, and will average one-third heavier than the Mendocino woods. The last port from which redwood is shipped is Crescent City, near the Oregon line.

The total area of Redwood lands is about 1,450,000 acres, of which five per cent., perhaps, has been cut. The average net yield per acre of redwood under the saw is not easily arrived at, since scaling standing trees will, of course, give gross returns of yield. Such figures are of little practical value, on account of a large percentage of loss by breakage in felling and from unsound trees. This liability to loss is much larger proportionately in very heavy timber, so much so that experts dislike to figure on heavy timber. The most accurate figures I have been able to get are based on estimates made by scaling tree by tree, and rectifying the result by comparison with actual returns from the saw of timber so scaled previously. In other words, not the amount of timber standing on an acre, but the amount which can be actually taken off in merchantable grades. All figures are in board feet. It is to be remembered that, as there is no market for wood or for short lengths, the amount of waste on heavy lands is very large. The Redwood is very brittle, and often a tree shatters into short lengths when felled. By these measurements we find that a very good quality of hill-land will cut 50,000 per acre, with perhaps 35,000 as an all-around average for Redwood lands. Single acres may be scaled which will figure prodigious quantities. In one instance an acre was picked on what is known as the Montgomery tract, near Hot Springs, Mendocino County, which is a narrow creek-flat of perhaps forty acres, and considered the finest small piece in Mendocino County. On the acre selected there were forty-seven trees which would probably cut 1,500,000 feet of sawed lumber.

Not far from here a tree actually cut 49,500 feet of good lumber. At Westport a considerable area of what is considered excellent Redwood, cut 57,000 feet an acre. On Humboldt Bay as high as 250,000 an acre has been cut, but only on limited areas.

Ukiah, Cal. *Carl Purdy.*

Correspondence.

Wild Asparagus.

To the Editor of Garden and Forest:

Sir,—In a recent journey along the shores of Chesapeake Bay I observed that the wild Asparagus which is found growing along the sandy beaches of that region is used quite extensively. The young tops are collected and bunched for sale, and by some are preferred to the cultivated plants, although only the tips are soft enough to be eaten. In his "Field, Forest and Garden Botany," Gray notes that it is "spontaneous about gardens," and in the last edition of his manual it is called "frequent escape from gardens." It grows so abundantly along the western and southern shores of Maryland that it seems to justify the use of the term "naturalized." I observed it also a mile or two inland along the borders of the woods. I find a record of the use of "Sparagus" in "A Perfect Description of Virginia" (1649, p. 4). As a justification for the preference of the wild Asparagus over the cultivated plant, Pomponius, a Roman writer of the second century, says: "Duo genera asparagi, hortense et silvestre, sed incultum gratius est, quod Corrudam."

Framingham, Mass. *E. Lewis Sturtevant.*

Water in "Pot-holes."

To the Editor of Garden and Forest:

Sir,—In your column of notes, page 204, I am quoted as saying that cutting away timber causes more rapid accumulation of water in "pot-holes." What I did say was, that on denuded land there is a more rapid accumulation of water in these hollows. Cutting is not denudation, nor does denudation necessarily follow cutting. In the case observed there had been no cutting within twenty miles.

Washington, D. C. *H. B. Ayres.*

Watering Trees.

To the Editor of Garden and Forest:

Sir,—I am much interested in a large Oak-tree which we moved last autumn. The soil is very dry now, and I wish you would tell me whether the tree should be thoroughly watered and mulched. There seems to be a difference of opinion as to the benefits to be derived from watering at this season of the year.

Ayer, Mass. *E. L.*

[A tree moved last autumn, and therefore with roots which are still working imperfectly, would be greatly benefited, probably, by a thorough watering if the ground is dry, as it is in almost all parts of the country this spring. One thorough watering is better than half a dozen partial ones, however, it must be remembered. The best plan in such cases is to make a dish about the stem of the tree two or three feet wide, by drawing the loam back with a rake, and then fill this basin with water. When the water is all soaked away it can be filled again, and this can be done

two or three times, until the soil in the neighborhood of the tree is thoroughly soaked. Five or six barrels of water would not be too much for a tree fifteen or twenty feet high. After the water has all soaked away the basin should be filled by drawing the soil back, and then the surface of the ground should be thoroughly mulched with a coating of leaves, hay or grass five or six inches thick, and extending out from the trunk several feet. This mulch had best be left about the tree all summer to check evaporation from the ground. A band of straw tied round the trunk will protect it from the sun, and is often beneficial to newly transplanted trees.—Ed.]

On the Names of Some North American Trees.

To the Editor of Garden and Forest:

Sir,—With respect to the Florida and West Indian "Marlberry," which Nuttall described as *Ardisia Pickeringia* ("Sylva," iii., 69, t. 102) in 1854, it appears upon late investigation that a change becomes necessary both in its generic and specific name.

The genus Ardisia, in which this plant has been maintained during the last twenty-five years, was established by Swartz ("Prodromus Flora Indiæ Occidentalis," i., 467, t. 10) in 1797, but this, it seems, must give way to Thunberg's older genus, Bladhia, established in 1781.

The first description of the Marlberry was published by Nuttall, in the *Am. Journ. Sc.* (v., 290), under the name of *Cyrilla paniculata*, in 1822; he next published it as *Pickeringia paniculata* in 1834 (*Journ. Phila. Acad. Sc.*, vii., Pt. 1, 95), and finally described and figured it ("Sylva," iii., 69, t. 102) as *Ardisia Pickeringia* in 1854.

The oldest specific name applied to this plant is therefore *paniculata*, published in 1822; but in calling Professor Sargent's attention to the desirability of resuming this name, he suggested to me the existence of an *Ardisia paniculata* published by Roxburgh ("Hortus Bengalensis," 16) in 1814, which would, of course, preclude the employment of *paniculata* for our species. A suspicion, however, that Roxburgh's name was not founded on a description, led to further investigation and the discovery that no description was published in the "Hortus Bengalensis," therefore making *paniculata* untenable for Roxburgh's plant, and open to use for our Marlberry, as Roxburgh did not properly establish *A. paniculata* until 1824 ("Flora Indica," ii., 270).

Referring our species to its oldest genus under the oldest specific term, the plant becomes *Bladhia paniculata* (Nutt.) (= *Cyrilla paniculata*, Nutt., l. c., 1822; *Pickeringia paniculata*, Nutt., l. c., 1834; *Ardisia Pickeringia*, Nutt., l. c., 1854).

Respecting the author of *Ardisia Pickeringia*, there appears to have been a difference of opinion, some citing Torrey & Gray, and others Nuttall. I believe, however, that Professor Sargent ("Census Cat. For. Trees," 100) was correct in ascribing it to Nuttall (l. c.)

The only author before this who quotes Nuttall for this combination is Cooper (Smithsonian Rep., 1858, 264) though he gives "*A. Pickeringii*, Nutt.," while Nuttall wrote "*A. Pickeringia*"; Cooper may not, however, have intended to change Nuttall's name.

But DeCandolle ("Prodr.," viii., 124), Chapman ("Fl. So. States," 277), Vasey ("Cat. For. Trees," 19), Gray ("Syn. Fl.," ii., l. 65), Hemsley ("Biol. Am. Cent.," ii., 294), all cite Torrey & Gray for *A. Pickeringia*, which is doubtless incorrect, as of Sprengel ("Syst. Veg.," ii., 268), who restored Linnæus' the "Flora N. A." contains, as I take it, no such announcement.

The only reference made to this species in the above work is in a note (i., 256), "*Pickeringia*, Nutt. (*Cyrilla paniculata*, Nutt.) . . . is a species of Ardisia; probably *A. coriacea*, Swartz. . . ." Certainly *A. Pickeringia* could not be properly ascribed to Torrey & Gray on this evidence, and should, therefore, not be so maintained in the synonymy of this plant as a name originating with the above authors.

Persea Carolinensis, Nees.—The synonymy of the Red Bay, a tree which occurs from Virginia to Florida and westward through the Gulf states to Texas, presents some interesting features, aside from the fact that Catesby's specific name, *Carolinensis*, so long maintained, is hardly the one which the plant should now bear.

The first description and figure of this species appears to have been published by Catesby in his "Natural History of Carolina and the Bahama Islands" (i., 63, t. 63), in 1731. But Linnæus, in subsequently studying this plant, seems to have ignored Catesby's name, for he designated it in his "Species Plantarum" (ed. i., 370, 1753) as *Laurus Borbonia*, citing Catesby's name as a synonym, a fact which is of more significance in determining that Linnæus and Catesby described the same plant, than can be drawn from the former's description (l. c.), as this diagnosis gives only in part the characters of the species. The locality given by Linnæus, "Virginia and Carolina," though circumstantial, is additional and legitimate evidence in support of the authenticity of the Linnæan name.

Writers succeeding Linnæus have, nevertheless, chosen to follow and maintain Catesby's name down to the present time, the only exception to the general agreement being in the case name in 1825, referring the plant to its present genus as *Persea Borbonia*. And in the light of present evidence, therefore, it seems advisable that Sprengel should be followed, as there can be no doubt but that the Linnæan name is sufficiently authenticated, and should, therefore, be maintained, in which case *Persea Carolinensis*, Nees, becomes *Persea Borbonia* (Linn.), Spreng.

It should be added, although unknown to me until now, that Professor Sargent had already taken up *Persea Borbonia* for the Red Bay, as he informs me, having changed last year the name in the Jesup collection of American Woods.

It is further of interest to note that the name *Laurus Carolinensis*, founded on Catesby's publication (l. c.) in 1731, and commonly placed in the synonymy of this plant, cannot be longer maintained in this position, as it antedates the Linnæan starting-point for specific names. The reference is, however, of historical interest, and may therefore be properly preserved, though in another connection. *Laurus Carolinensis*, of post-Linnæan synonymy, must take its date from the second edition of Catesby's work, published in 1754.

Recent Publications.

A second edition of the *Catalogue of the Flowering Plants and Cryptogams*, and a list of the vertebrate animals found within about thirty miles of Hanover, New Hampshire, including a few cultivated species, has been issued by Henry G. Jesup, professor of natural history in Dartmouth College, the first edition having appeared in 1882. The region is an interesting one, embracing the mountain peaks Moosilauke and Kearsarge in New Hampshire, and Killington in Vermont. It includes several large sheets of water, and is divided by the Connecticut River. It is, therefore, a fairly representative region of northern New England, and, with the exception of the alpine plants found on the high mountains and the literal plants of the sea-coast, contains a large representation of the New England flora.

"Thirty miles south of Hanover," Mr. Jesup tells us, in his introduction, "in the towns of Charlestown, New Hampshire, and Springfield, Vermont, some trees and shrubs, so common a little further south in both of these states, have already reached their northern limit and begin to disappear from the native woods. The Chestnut and the Shagbark Hickory are no longer abundant. The season is too short for any considerable quantity of fruit to reach perfection, and seedlings are rare. Trees of these two kinds when planted in sheltered localities may attain considerable age and size. A single Chestnut of exceptional size may be seen in Norwich, Vermont, five feet eight inches in diameter, and more than fifty years old, but it was planted where it now stands, and the chestnuts are of little value. An occasional Shagbark Hickory of moderate size may also be met with, though the Pignut Hickory is not infrequent in the woods, and the Bitternut Hickory ascends the Connecticut as far north as Wells River. The Black Birch and the Gray Birch, as well as the Pitch Pine, are rare north of Hanover and not common in its vicinity, while the Sycamore or Buttonwood is nowhere seen in a wild state. To the above may be added, as decidedly rare, the Sassafras, the Spice Bush, the Flowering Dogwood, the Red Cedar and the common Juniper, together with many other trees and shrubs that fifty miles south of Hanover may be common.

"On the other hand, as the traveler advances thirty miles northward from Hanover, another class of arborescent vegetation appears that either is not found at all southward, or at least is not abundant. Here the White Cedar becomes plentiful and very valuable, the Tamarack, or American Larch, fills the swamps, and the White Spruce occasionally appears, while the Black Spruce covers the lower mountain-tops, the Paper Birch adorns the hillsides, the Green Alder is found by

the streams and in the ravines, and the Elder has red berries more commonly than black ones."

The arrangement of genera and species and the nomenclature is that adopted in the latest edition of Gray's "Manual of the Northern States."

Notes.

The first cherries of the season arrived in New York about May 12th. They came from San Jose, California, and were retailed at $1.25 a pound.

The Earl of Gosford, a member of the British House of Lords, has purchased an entire section of land (640 acres) near Bakersfield, Kern County, California, and has begun to plant it with Grape-vines, Peaches and Pears.

A large part of the shore of the picturesque harbor of Sydney, Australia, is already laid out in parks and botanical gardens. Now it is announced that the Government, wisely intent upon preserving as far as possible the beauty of the bay, will take possession of all the islands still unoccupied and devote them to ornamental plantations.

"Perfumes," wrote Heinrich Heine, "are the feelings of flowers; and as the human heart feels most powerful emotions in the night, when it believes itself to be alone and unperceived, so also do the flowers, soft-minded, yet ashamed, appear to wait for concealing darkness, that they may give themselves wholly up to their feelings, and breathe them out in sweet odors."

Part I. of the thirteenth volume of the "Journal of the Royal Horticultural Society" has reached us. It contains papers on the Dahlia, the Grape, on Trees and Shrubs for large towns, on Chinese Primulas, on cultivated Ferns, and other subjects of great and immediate interest to horticulturists, and shows the vitality and usefulness of the Royal Society, which has never done better work than it is doing to-day.

When the votes for a "state flower" were cast by the school-children of New York a year ago the Golden-rod proved the favorite, with the Rose so close a second that another ballot, confined to these two flowers, was thought desirable. This has just been taken in fifty-three public schools; 22,945 children voted for the Rose, and 25,360 for the Golden-rod, which thus becomes the emblem of New York state.

The leaves of *Salvia triloba* are extensively used in the Levant in the preparation of a kind of tea. The plants are simply cut, dried, tied in bundles and sold on the market-place, and are found, ready for use, in every café of Greece, and even in the poorest homes. This "Athenian tea," or, as the Greeks call it, "Phaskomylia tea," is believed to be a sure preventive of colds and fevers, and is therefore universally drunk in winter weather and by sailors at sea.

"In 1873," says a writer in the *Evening Post*, "the government of Assam began to cultivate the India-rubber-tree in the humid forests of Charduar, at the foot of the Himalayas. It was found best to propagate from seedlings, which were planted in the forks of trees, and by 1885 they had reached the ground. The trees were subsequently planted in beds forty feet wide, amid the surrounding forest, which sheltered them. Last year the plantation comprised 1,106 acres, and contained 16,054 healthy plants, besides 84,000 seedlings."

In his "English Flower Garden," Mr. H. A. Bright well says: "One of the greatest ornaments to a garden is a fountain, but many fountains are curiously ineffective. A fountain is most beautiful when it leaps high into the air and you can see it against a background of green foliage. To place a fountain among low flower-beds and then to substitute small fancy jets that take the shape of a cup, or trickle over into a basin of gold-fish, or toy with a gilded ball is to do all that is possible to degrade it. The real charm of a fountain is when you come upon it in some little glassy glade of the 'pleasaunce,' where it seems as though it sought, in the strong rush of its waters, to vie with the tall boles of the forest-trees that surround it."

The *Illustrirte Gartenzeitung* of Vienna says: "White fruits are rather rare in nature, and in this country are represented almost solely by those of *Symphoricarpus racemosus*. Variations into white from the usual red, blue or yellow fruit-colors do, indeed, occur in cherries, plums, raspberries, blackberries, whortleberries, gooseberries, strawberries, tomatoes, privet-berries and other fruits; but they almost always show a tint which is not pure white, but is tinged with the original green, yellow or red. The establishment of L. Van Houtte, Senior, has, however, produced a variety of the common Elder with pure white fruit. The originators say that the plant is vigorous in habit, and bears fruit freely; that this fruit is not only pure white, but translucent like white currants, and that a delicious preserve may be made from it."

According to an account in one of our daily journals, an association of women has been formed in London for the purpose of contracting for the care of city conservatories, window-boxes, balconies and small urban gardens. "It will personally supply and superintend all orders, employing men only for the digging. Once a week one of the lady-gardeners will call to attend to the conservatories, valuable plants in rooms, etc., and leave orders for what is to be done until she comes again. People wishing to close their town homes leave their plants in the charge of the ladies. Swanley Horticultural College is to open a ladies' department, so popular is this work becoming among women, when the women will occupy a separate residence, and devote the days to theoretical and practical work."

The Secretary of the Parisian Chambre Syndicale des Horticulteurs (which may be translated Florists' Board of Trade) recently declared that many of the four hundred gardeners who supply the flower-markets of Paris have been ruined by the exceptional severity of the past winter. Fifty Rose-growers, he declares, have lost about a million francs because they could not house their plants quickly enough on the sudden advent of frost. One hundred and fifty gardeners who make a specialty of hardy flowers, such as Pansies and Gilly-flowers, have lost their entire stock; and the loss of those who furnish pot-plants, or the cut flowers of such plants, is estimated at 800,000 or 900,000 francs. About 6,000 other gardeners, living in the departments of the Seine and of the Seine-and-Oise, have likewise greatly suffered. In general the damage has been much greater than even during the famous winter of 1870-71, for then the excessive cold did not extend to the western and southern parts of the country.

"Variations of flowers," wrote Leigh Hunt, in an essay called *A Flower for your Window*, "are like variations in music, often beautiful as such, but almost always inferior to the theme on which they are founded—the original air. And the rule holds good in beds of flowers, if they be not very large, or in any other small assemblage of them; nay, the largest bed will look well, if of one beautiful color, while the most beautiful varieties may be inharmoniously mixed up. Contrast is a good thing but we should first get a good sense of the thing to be contrasted, and we shall find this preferable to the contrast if we are not rich enough to have both in due measure. We do not, in general, love and honor any one single color enough, and we are instinctively struck with a conviction to this effect when we see it abundantly set forth. The other day we saw a little garden-wall completely covered with Nasturtiums and felt how much more beautiful it was than if anything had been mixed with it, for the leaves, and the light and shade, offer variety enough. The rest is all richness and simplicity united—which is the triumph of an intense perception. Embower a cottage thickly and completely with Roses and nobody would desire the interference of another plant."

The April issue of Hooker's *Icones Plantarum*, being part third of the twenty-second volume, contains figures and descriptions of a number of plants of extraordinary interest, including a new Chinese Rubus; a Magnolia-like tree from Hong-Kong, Mangalietia, the first record that this genus is represented in China; *Eperua Jenmani*, a fine leguminous tree from British Guiana furnishing timber, and from the root a remedy for the toothache; *Ligusticum Sinense*, one of the sources of the Chinese drug known as Kao-pên; *Nyssa Sinensis*, an interesting addition to a genus known before only in North America, where several species occur, and in the Himalaya, where one is known. This Chinese Gum-tree differs from its allies in the pedicellate ovaries. *Dalbergia Hupeana;* this is the T'an-tree of the central provinces of China, and is common in Hupeh "in the flat country, and its wood, being hard and durable, is much used in making rammers for oil-presses, wheel-spokes, tool-handles, and the blocks and pulleys used on the native craft." *Buddleia officinalis*, one of the sources of the Chinese drug known as mêng-hua; it is common about Ichang. *Inula racemosa*, a very fine species from the western Himalaya and China, where it is cultivated as a drug and as a substitute for the root of *Aplotaxis auriculata*, which is so largely imported into China by way of Calcutta and Bombay from Cashmere.

TABLE OF CONTENTS.

The Swamp White Oak.

IN eastern North America there is a peculiar group of Oaks known generally as Chestnut Oaks on account of the fancied resemblance of the leaves of one of their number to those of the Chestnut-tree. They are White Oaks, that is, they belong to the section of the genus in which the fruit matures in one season; and they all have coarsely sinuately-lobed leaves, more or less pubescent and white on the lower surface, and, with one exception, pale, scaly bark. The exception is the Rock Chestnut Oak, which grows on the dry banks of streams and in dry upland forests; on this tree the bark is deeply divided into broad rounded ridges, and is dark-colored like the ordinary bark of Black Oaks. The cup of the fruit of the Chestnut Oak is hemispherical, usually hoary, and encloses nearly one-half of the large oblong acorn, which is sweet and more palatable than the fruit of other American Oaks.

The upland Chestnut Oak was known to Linnæus, who called it *Quercus Prinus;* the elder Michaux, who studied our eastern Oaks conscientiously, and published, or, at least, supplied, the material for an admirable book about them, knew all the Chestnut Oaks. He considered them forms of the Linnæan species, and in all the old works on American trees they are spoken of as varieties of that species. Two of the Chestnut Oaks grow in low, wet situations, near the borders of swamps or pond-holes, and, although they do not grow naturally in swamps, are usually known as Swamp White Oaks. One of these trees belongs to the north, where it is found from Canada to the Potomac and along the mountains as far north as northern Georgia, and from the Atlantic sea-coast to Iowa and Missouri. This is the tree which botanists now generally call *Quercus bicolor;* it is represented or replaced in the south by a larger and finer tree, one of the noblest and most beautiful of the deciduous trees of eastern North America, a second species of Swamp White Oak—the *Quercus Michauxii.* This statement needs, perhaps, some qualification. Extreme forms of the northern, and of the southern, Swamp Oaks are distinct enough, but in the region where the two species mingle—in southern Delaware and in Virginia—it is not so easy to distinguish them, and one appears to pass gradually into the other. These intermediate forms led Dr. Englemann, the most careful student of American Oaks we have ever had, to believe that the two trees should be regarded as varieties of one species. But this is a subject which need not be discussed at this time, our object now being to call attention to the beauty and value of the northern tree as a good subject for care when it is found growing naturally, or for cultivation where proper conditions can be supplied for it.

The Swamp White Oak in its young state, and until it has reached the height of twenty or thirty feet, develops short, rather stout, branches, which grow almost at right angles with the stem, and form a narrow, formally pyramidal head; as the individual grows older the formal habit is generally lost, and an irregularly spreading top is developed, which is broad or narrow, as it has abundant or scanty room in which to enlarge. The lower branches, in its youth at least, are remarkably persistent and generally pendulous on this tree, or intricately contorted toward their extremities. This habit is well shown in the portrait (see page 246) of a tree thirty or forty years old, made in Massachusetts in winter by Dr. William H. Rollins, to whom we are indebted for the privilege of publishing it. The bark of young trees separates into large, thin, brown, papery scales, which remain for a long time on the trunk and branches, and give them a ragged appearance which other young Oaks do not present. The pendulous habit of the branches and this peculiarity of the bark make the Swamp White Oak, as long as it is young, one of the easiest of all our trees to recognize in winter. The bark of large trees is rough, with thick, pale, flaky scales not very unlike those of the White Oak, although usually rather darker-colored.

In summer the Swamp White Oak is easily recognized by the leaves. These are oblong or oblong-ovate, with a narrow wedge-shaped base and are very coarsely crenately-serrate, especially above the middle, where there is often, on each side, a deep sinus; they are six or eight inches long and three or four inches broad, and are smooth and dark green on the upper surface and pale or sometimes nearly white on the lower surface, which is covered usually with fine pubescence. The foliage of no other Oak of the northern states is more beautiful. When the leaves unfold, the upper surface is sometimes pale and sometimes bright red, and the lower surface is thickly coated with white tomentum. The contrast between the colors of the upper and of the lower surfaces of the young leaves makes the Swamp White Oak a delightful object in early May, when the branches are draped with the long catkins of staminate flowers. It is hardly less beautiful in summer, when the wind plays through the foliage and turns to the light first the pale under-surface of the ample leaves and then displays the dark green and glossy covering of their upper surface. In autumn, just before falling, the leaves turn yellowish brown and never assume the brilliant colors put on by many of the Oaks of eastern America. The fruit, which is not produced very abundantly, is borne singly or in pairs on stalks two or three inches long and much longer than the leaf-stems. The upper scales of the cup are pointed and sometimes form a delicate fringe-like margin; the acorn is an inch long, rather obtuse and bright chestnut-brown when ripe. Squirrels and hogs find it to their liking, and a man, if he was very hungry indeed, might get some satisfaction from eating it; it is not as sweet and much less palatable than the acorn of the southern Swamp Oak.

The wood of the Swamp White Oak is perhaps even more valuable than that of the White Oak; it is hard, strong, close-grained, very tough, and is not distinguished from White Oak by timber merchants. The two woods are used for the same purposes.

The Swamp White Oak is a common tree in some parts of the country, especially in eastern New England and in New Jersey, and in some parts of Pennsylvania. It is found usually with the Swamp Maples and the Tupelo, the White Ash and the Shellbark Hickory, and south of New England with the Pin Oak (*Quercus palustris*) and the Liquidambar. It grows occasionally to a great size. Individuals, a hundred feet high, with trunks seven or eight feet in diameter, can be found; such specimens are rare, however, and it is not usual to see this tree more than half this size. The greatest Swamp White Oak of which any record has been preserved is known as "The Wadsworth Oak." It stood on the intervale of the Genesee River in western New York, on the Wadsworth estate, where many large Swamp Oaks still exist. Mr. S. B. Buckley published, many years ago, a note on this tree in the *American Journal of Science and Arts*, from which it appears that in July, 1851, when he visited it, the trunk varied little in size from the ground to the branches, and that it had an average circumference of twenty-seven feet. Its smallest circumference was twenty-four feet. "It was situated in a pasture, and the ground was bare and hard beneath it from the tramping of cattle and visitors. The big tree seems fated soon to die." The prediction, unfortunately, came true, and a few years later this tree, the pride of all the country round, was undermined and washed away by the gradual changing of the bed of the river near whose banks it had stood for centuries.

The Swamp White Oak is rarely planted. It bears transplanting, however, better than most White Oaks, and comparatively large specimens can be moved if care is taken in the operation. It is better, however, as it is in the case of all White Oaks, to plant the acorn or a small seedling where the tree is to grow permanently. Transferred to upland the Swamp White Oak grows rapidly and thriftily, although it is not probable that it will make a very large or long-lived tree, except in deep, moist soil in the neighborhood of streams or swamps. When such positions are available there is no better tree to plant, and when the Swamp White Oak is found growing naturally it will repay the small amount of care and labor required in cutting away any less valuable trees which encroach upon it and interfere with its characteristic development.

The western Arbor-vitæ, of which a portrait was published in these columns a few weeks ago, seems destined to disappear from the face of the earth if the shingles made from the wood of this tree continue to grow in popularity as rapidly as they have in the last two or three years. Nearly a hundred mills devoted exclusively to making shingles from the Red Cedar, as the western Arbor-vitæ is called, have recently been erected in western Oregon, and large quantities of the shingles are manufactured also by hand and by machines attached to saw-mills. It has been found that these shingles are very durable, and that practically the action of the elements alone has little effect on them; and they are now supplanting the Pine shingle of Michigan, the Cypress shingle of the south and the Redwood shingle of California. They are sent all over the United States, the transcontinental traffic companies fostering the industry by advantageous rates; and large numbers, especially those made by hand, are sent to the Hawaiian Islands and to other Pacific ports.

The combined daily product of the fifty shingle-mills controlled by the Northern Pacific Consolidated Shingle Company is said to be 3,500,000 shingles, and probably as many more are made from this wood in Oregon and Washington by individuals and in mills uncontrolled by this company. The supply of this timber is still large, but the region where the western Arbor-vitæ flourishes is not extensive, and it is only a matter of time when the last of these trees will have fallen under the axe of the timber-cutter.

Ivy in an Old French Garden.

THE article recently published in these pages, on the Renaissance Colonnade in the Parc Monceau, may well have recalled to many readers memories of other French parks and gardens where Ivy is most beautifully used. One such picture is especially vivid in my own mind, although it was received in the immediate vicinity of the great cathedral of Chartres, where, one might easily suppose, architectural pictures would crowd out all besides.

When we stand in front of the splendid sculptured porch which furnishes the north transept of the cathedral we have a glimpse off to the left, through a huge ornamental iron gate, of a garden shadowed by lofty graceful trees. Perhaps it is not always possible to pass this barrier, for we were told that the Bishop, who had recently died, was old and cross, and permitted no one to come within sight of the windows of his palace. But when we were at Chartres this unchristian Bishop, fortunately, was dead, and his successor had not yet arrived. So we got into the garden, not, indeed, through the gate of honor, but by a little side entrance at the further end, near the south-east corner of the church. Entering at this point, however, our first view of the quaint, delicious, out-of-the-world spot was all the more delightful.

The garden forms a long narrow rectangle, lying, like the cathedral and the streets beyond it, high above the more eastern portions of the town. At the end where we stood, and all along the eastern side, one looked over a stone parapet far down a massive wall into streets and court-yards, and far above picturesque masses of roofs and a winding little river to the distant hills. Above the other side, to the west, towered the apse of a great chapel which is attached to the end of the cathedral; and at the further end of the garden stretched the white façade of the episcopal palace, with a terrace running in front of it, a few beds of flowers close beneath, and long rows of clipped shrubs in pots. And this was seen between two rows of great ancient trees, whose branches almost met overhead and whose trunks were almost concealed by thick shrubberies, while all the space between them was filled by a quiet expanse of grass. The paths which lead from one end of the garden to the other lie outside these trees and shrubberies, close to the parapet on the one side and close to the chapel on the other. No line of gravel or bed of flowers breaks the harmonious simplicity of the central area. The trees are not planted with formal regularity, though the canopy of their foliage has become uniform and symmetrical; and one almost forgave the selfish isolation of the defunct Bishop, reflecting that, perhaps, had he cared more for company, he would have instructed his gardener to trim up the shrubs which now grew in beautiful luxuriance, trailing their branches on the rather rankly growing grass. It was a picture of the utmost beauty, and if it looked as though no human hand had touched it for many years, this only increased its poetical charm and added that touch of pathos which always seems to befit the neighborhood of a great ancient church.

But what I wanted especially to explain was, that the final finishing touch of beauty was given by the luxuriance of the Ivy which ran riot in almost every part of the garden, yet in its wildest freaks seemed to have been guided by the hand of some non-human artist. It clambered up the trunks of the great trees until it clambered out of sight among their own foliage. It wove each trunk to the stems of the shrubs beneath it, and then it ran out in long festoons and streamers amid the grass until it was impossible to say where the shrubberies ended, where the lawn began. Beautiful, indeed, were the graceful garlands it wove, and beautiful the contrast of their dark shining green with the paler green of the shrubs and the grass. Admiration changed at last to envy, thinking what one would give in an American country home for a growth of Ivy like this, planted, perhaps, a hundred years ago (I should imagine this to be about the age of the garden, as it is not formal in design), and growing since with only shade, dampness and a fertile soil to dictate its course. One felt that such a place as this ought to be seen, to be enjoyed, to be used. And yet, had it always been used and enjoyed, had its most recent owner been something different from a nervous, ecclesiastical recluse, would its pathetic loveliness have so enchanted the eyes of our lucky band of tourists?

New York. *M. G. Van Rensselaer.*

In those vernal seasons of the year when the air is calm and pleasant, it were an injury and a sullenness against Nature not to go out and see her riches, and partake in her rejoicing with heaven and earth.

John Milton.

Native Shrubs of California.—V.

ALTHOUGH the cultivated Cherries, natives of the Old World, thrive better on the Pacific than on the Atlantic slope of our continent, the Atlantic side is richer in native species, for while, between Canada and the Carolinas, as many as seven or eight kinds of wild Cherries are indigenous, an equal extent of Pacific coast territory yields but four or five, and all of these are found within the limits of California. *Cerasus emarginata*, Dougl. (Hook. "Fl. Bor., Am.," i., 169), our best native type of the Cherry genus, is, however, limited in California to the northern counties, and even there fails to attain those tree-like dimensions and that symmetry of outline which it develops in the wooded country of Oregon and Washington. But, whether great or small, the species nowhere degenerates into a scraggy or shapeless bush. Seldom less than fifteen feet high, the branches are ascending, and the general outline of the head is more or less conical. The very finest specimens of this species which I have seen are on one of the streets of Portland, Oregon, where they were planted years ago for shade and ornament. Some of these are about forty feet high, and are so much like the cultivated Cherry-tree in foliage and form that I should perhaps have passed them by as exotic trees had not the ground beneath been strewn with the fallen fruit, which revealed at a glance the native species. The fruits are small for true cherries, of a dark dull red, and intensely bitter. The flowers are borne in umbels, but are small. At Lake Pend d'Oreille, in north-eastern Idaho, where, in a somewhat reduced state, the species is common, I observed that many of the flowers had been bipistillate, and that the drupes were often two to each flower; a circumstance, perhaps, not rare in cultivated Cherries, but which, occurring spontaneously in a wild tree of western America, cannot but suggest a still closer relationship between our western Cherries and their curious relative, the Oso Berry (Nuttallia), in which the drupes are normally from two to five to the flower.

Some years ago Dr. Kellogg, under a misunderstanding, made a synonym for the species, calling it *C. glandulosa*. He had been taught by authority that the following, much more common in California, was the true *C. emarginata:*

Cerasus Californica, Greene ("Fl. Fr.," 50). A mere shrub of unsymmetrical habit, often six or eight feet high, with a very smooth and shining brown and dotted bark; it is entirely distinct from *C. emarginata* in size, habit, and, more particularly, by the characters of its foliage. Its fruit is very small, of a clear and almost translucent bright scarlet, the flesh so keenly bitter—the bitterness so penetrating and permanent in one's organs of taste—that no one is likely to make a second experimental test of its qualities. The bush is common in middle California, among the hills of the coast range and of the Sierra, extending northward beyond Mount Shasta.

Cerasus demissa, Nutt. (Torr. and Gray, "Fl.," i., 411). This, the western Choke Cherry, very nearly allied to the Atlantic coast shrub or tree known as Choke Cherry, is not very prevalent in many parts of California. The acidulous fruit, hanging in somewhat inviting rich red racemes, is astringent when fresh; but cooking dispels this unpleasant quality, and a marmalade, entirely palatable, with a fine cherry flavor, is commonly made from it in most places where it is at all plentiful.

Cerasus ilicifolia, Nutt. (Hook. & Arn. "Bot. Beech.," 340). We seem to have on the American continent only two representatives of the Old World Laurel-cherry group of trees. *C. Caroliniana* is the Atlantic one, *C. ilicifolia* the Pacific. In its distribution, ours, like its eastern analogue, is southern. *C. ilicifolia* does not appear to extend to the northward of San Francisco Bay, and here, at its northern limit, it does not make much of a tree, but is low and shrubby. Its broad, shining, spinose-toothed, evergreen leaves render it useful, as well as ornamental, for hedges, and it has here and there been planted for that purpose. Southward, in the counties of Monterey and San Luis Obispo, it becomes a low, well-rounded tree of compact habit, with a clean trunk, showing a rough very dark bark. The fruit of the species is nearly an inch in diameter, of round outline, but distinctly compressed laterally. The sweet and agreeable pulp is very thin, the stone large, thin and soft for that of a cherry, and the kernel is of so mild a bitter as to be scarcely unpalatable—quite comparable with that of the Bitter Almond. On the island of Santa Cruz, off Santa Barbara, and elsewhere in that archipelago, the species comes out with narrow and perfectly entire foliage. This was at first thought to be specifically distinct from the tree of the mainland, and so like the West Indian *C. occidentalis* that it was so referred. But specimens growing on the grounds of the University, now five years old, from seed of insular trees, up to this time have shown only the notched and Holly-like leaves of the ordinary *C. ilicifolia*. It should therefore, at most, be made only a variety, *integrifolia* (Britton), of *C. ilicifolia*.

University of California. *Edward L. Greene.*

An Oak Scale.

DURING the meeting of the New Jersey State Horticultural Society, Mr. E. P. Beebe, of Elizabeth, New Jersey, brought a small branch of Oak, densely covered with round, clear, golden-yellow scales, and stated that the entire tree was as fully infested. The tree is isolated, in a garden plot in the city itself, and is an old Swamp White Oak. The attack was first noticed during the summer of 1890, but it must have existed some time before. Apparently no other trees in the vicinity are so infested. The scales (see Fig. 43) are either round or a little oval, densely clustered, especially on the smaller twigs, but they do not spare even the older wood. They are from ·04-·08 of an inch (1–2 mm.) in diameter and slightly convex, hard and brittle. Beneath the scale there is a distinct, cup-like depression, extending not only through the bark but indenting the wood itself. I recognized the specimens at once as *Asterodiaspis quercicola*, Bouché, a European species, which Mr. L. O. Howard, of the United States Department of Agriculture, had exhibited at the Toronto meeting of the American Association for the Advancement of Science, from the European Oaks in the Department grounds. In the report of the Department for 1880, Professor Comstock, then United States Entomologist, described the species. According to him, the male scale is oval rather than round, and only about half the size of that of the female. He had not found any male scales, and copied the description from the European authors. In none of the specimens seen by me do I identify a male, and the differences are either less than described, or that sex does not occur very abundantly. Professor Comstock states that the scales are "upon the imported Oaks in the Department of Agriculture Grounds at Washington. The species is not a common one in Europe, but is occasionally quite destructive to an individual tree." I have seen no record of the occurrence of this scale other than at Washington, and its appearance at Elizabeth, on a native species of Oak, is decidedly interesting. I recommended a thorough winter spraying with the kerosene emulsion, one to ten, with the view of destroying whatever of life existed in or under the scales, and I would suggest that a lookout for this pest be kept on ornamental trees. If it be discovered the treatment should be radical. If not too wide-spread, all infested twigs should be cut and burnt. If that be impracticable the trees should be thoroughly sprayed with the kerosene emulsion when clear of leaves. Trees so badly infested as that from which my specimens came will inevitably succumb. The figure gives some idea of the appearance of an infested twig, and most of the specimens showed a greater number of scales than that figured. They are on all sides of the twigs and branches.

Fig. 43.—An Oak Scale.

How We Renewed an Old Place.

VII.—A NEW PERENNIAL GARDEN.

A LITERARY man, who paid his only visit to Scotland in the winter-time, remarked that he realized more fully than ever before how great was the genius of Sir Walter Scott, which had given world-renown for picturesqueness to those low, round, bare, uninteresting hills, the Trossachs. Lacking that genius, I am somewhat dismayed at making my very unimportant little garden the subject of a paper. Our late, cold springs render it rather a dreary object of contemplation even in the month of May, and with only the power of words to help the reader's enjoyment, I shall have to ask indulgence for the meagre record of its very simple charms.

Mrs. Carlyle used to tell a story of an Irish prison that was to be built out of the stones of an old one, while the prisoners were to be kept in the old jail until the new one was com-

pleted. This tale suggests our fashion of constructing a new garden out of the former one, and in our case the prisoners showed a decided preference for the original institution, and were with great difficulty persuaded to leave it. We started out with no very definite plan beyond killing two birds with one stone, always a desirable object when one is short-handed, and the results scarcely merit a place in so eminent a horticultural sheet as this, except to point a moral for the editor, whose text we are proud to be, and to adorn his next account of how well the knowing ones would have managed it. But you shall hear, and we can at least serve as a warning.

While the house at Overlea was building, the carpenters kept their tools in a part of the old dwelling that was still standing, and their constant journeys to and fro, between the knoll and the workshop, wore a narrow winding path, along which we had a flower-bed dug, to put such roots in as we wished to bring with us from the rented place that we were occupying, and also to serve as a home for such plants as we might dig up about the farm. Some sprigs of Box, broken from the arbor, and set in the soil at the edge of the bed, took root and made a rough border, and here, in August, I transplanted Lily-bulbs, and a little later put in such perennials as needed to be set out in the fall.

Between this flower-bed and the street were three rows of straggling old Pear-trees that gave some suggestion of possible fruitfulness, though it seemed likely that they were too old to profit by pruning. They had been famous in their day, and still preserved the remnants of a reputation, though more modern varieties have borne away the palm in newer gardens. But Bartletts and Sheldons and Seckels will never be out of date, and there are others, the very names of which the old settlers have forgotten, which still yield sweet and luscious fruit, when the weather and the insects permit. Half-dead they seemed when we first went to work at them, cutting away the dead branches and scraping their mossy trunks, to the infinite disturbance of the insects that had clustered there for warmth, and we recognized that only strong methods would revive them.

We needed sods for the terraces we were making, and so began by removing the turf around the trees, leaving narrow strips of grass to walk upon. This furnished us with three wide beds, which we fertilized heavily with rich compost and wood-ashes, the surface being tilled with great care, keeping the edge of the spade turned toward the trunk to avoid cutting off the rootlets of the trees. A memory of an old garden in which I had played when a child, where Pear-trees grew among the flowers, induced me to think of utilizing these broad fertile spaces for perennials. The Pear-trees were at that time doubtful as fruit-producers, but they would afford a grateful shelter from the hot sun when we were working among the plants, and their sparse foliage would hardly interfere greatly with the flowers.

In the spring a generous friend sent me a box of hardy plants, which were set out at random, as they came without labels, and many of them were unfamiliar to me. I do not find that they interfere much with the Pear-trees, which, under this steady cultivation, yield more of their fine old-fashioned fruit than we know what to do with, for pears are a drug in this market and can hardly be given away. The Pear-trees certainly do not hinder the growth of the sturdy perennials, which multiply enormously, so that every spring and fall there are boxes full of them to be given away. A nurseryman, who came last year to set some Strawberry-plants, declared that, if properly divided, there were roots enough there to stock an acre.

Such strong, showy plants as the Iris, the Foxglove and the Giant Evening Primrose flourish admirably, while Phlox and Hollyhocks and Columbines and Spiræas encumber the ground.

There is a huge Oriental Poppy that is a gorgeous spectacle, with its rich blue-green velvet robes and its silken headgear of scarlet and black, producing all alone the effect of a procession, as Brett Harte once said of Roscoe Conkling.

Smaller Poppies come up of their own accord, some single, some double, as the fancy takes them, and there is a wild array of Larkspurs and Coreopsis and Sweet Williams all summer. In the spring the variegated Thyme comes up promptly, followed closely by English Daisies and Moss Pinks, and Pansies and Violets, white, blue and yellow. The Giant Solomon's Seal rings its green bells over the heads of the tiny Bellwort; and all summer the Lilies and Pæonies and Spiderworts fight for possession of the ground, while the perennial Peas and Calendulas and Marigolds linger there till the last frost-horn blows.

The collection is not very choice, and, beyond a periodical struggle with the weeds, which try to grow as rampantly as the flowers, it gets not very much attention; but it makes a fine show from the street, and from the veranda which looks down upon it. Any minute effects would be wasted here, and we do not extend its area, which we might readily do, because it already requires more attention than we are willing to spare from the shrubs and trees that we are hurrying along upon the lawn, and which, consequently, take all our best energies, as well as the lion's share of food. In short, the flower-garden takes what it can get—copes more or less successfully with its own weeds, and possibly is more satisfactory than if we took more pains with it, and so were liable to disappointments. It is not at all well adapted to annuals, even Mignonettes and Asters, which are sown every year, for the stronger plants rob them of their proper nutriment; but I have future plans for a parterre in that neighborhood which shall have fitting accommodation for all the sweet old-fashioned kinds of yearly flowers.

Supplemented by the old garden, the new will even now at any season afford a fragrant and showy nosegay, such as our grandmothers liked for a beaupot, and there is always a mass of color under the Pear-trees until late in November, when the cold pinches the very last Calendula. The neighborhood of the salt-water makes this garden cold, and slow to awake in spring; but, on the other hand, it modifies the temperature in the autumn, so that it escapes the early frosts, and, under the shelter of the trees, the flowers last long after those upon the high ground about the house have withered and fallen.

There is a sheltered corner, backed by a mass of Lilacs and Mock Oranges, where I dream of seeing some day a fine clump of Rhododendrons and hardy Azaleas, though I have some doubts about a southern exposure being the very best thing for them; but the decorative effect from the house will be so good that we are disposed to make the attempt.

Hingham, Mass. *M. C. Robbins.*

New or Little Known Plants.

New Orchids.

Mormodes Lawrenceanum, Rolfe.—A fine species of this interesting genus, which was imported from New Granada by Messrs. Linden, L'Horticulture Internationale, Parc Leopold, Brussels, and flowered in that establishment during January last. It is allied to *M. Cartoni*, Hook., but has more acute segments and a markedly pubescent lip. The erect racemes bear numerous flowers, which have the sepals and petals lined with brown, on a paler ground, and the lip light ochre-yellow, with a few light brown spots. It is dedicated to Sir Trevor Lawrence, of Dorking, the possessor of one of the finest collections of Orchids in existence.—*Lindenia*, t. 273.

Zygopetalum Lindeniæ, Rolfe, is a very pretty Zygopetalum, much resembling *Z. rotratum* in habit, but belonging to a different section of the genus. It has large flowers, borne in twos and threes, on an erect raceme, the sepals and petals light rose color, the lip, with many radiating rose-purple lines, on a white ground. The large fleshy crest, which is purple in color, shows that it belongs to the section *Enzygopetalum*. It was discovered by Monsieur Bungeroth in Venezuela, and imported by Messrs. Linden, L'Horticulture Internationale, Brussels.—*Lindenia*, t. 275.

Cattleya × Parthenia, A. Bleu, is a very handsome secondary hybrid, raised from *C.* × *fimbriata*, crossed with the pollen of *C. Mossiæ*, by Monsieur Alfred Bleu, of Paris. The flowers are white, the disc of the lip bright yellow, and the front lobe light rose-purple, both disc and front lobe being veined with deeper purple. Different plants have flowered at various seasons of the year, from April to November. The mother-plant, *C.* × *fimbriata*, was raised from *C. intermedia*, crossed with the pollen of *C. Aclandiæ*, so that three species are involved in the parentage of the present hybrid.—*Lindenia*, t. 276.

Lælia anceps, var. holochila, Rolfe, is a distinct and very remarkable variety, with an entire lip; evidently a peloriate condition of the species. The sepals and petals are lilac, the lip light purple, with a white disc and some yellow at the base. The petals are rather narrow, and the lip elliptical-lanceolate, over two inches long by three-fourths of an inch wide. It was imported by the Liverpool Horticultural Company with *Lælia anceps morada*. There are several plants in existence, all showing the same character, and may all be subdivisions of one original clump.—*Gardeners' Chronicle*, April 4th, p. 426; Garden and Forest, April 15th, pp. 172, 173, fig. 31.

Cattleya × Vedasti, Perrenoud, is a hybrid raised in the collection of M. Perrenoud, of Paris, between *Cattleya Loddigesii* and a form of *Lælia pumila* (to which the name

"*Cattleya Pinelli marginata*" is affixed), the latter being the pollen parent. It flowered for the first time in November, 1889, from seeds sown in 1883. The flower is ten centimetres in diameter across the petals, light rose-purple, flaked with a slightly darker shade, the lip nearly entire, undulate, the front lobe crimson-purple, with a paler margin, the side lobes margined with light rose-purple, and the disc rather pallid with some purple veins.—*Orchidophile*, February, 1891, p. 48, with colored plate.

Kew. *R. A. Rolfe.*

Recent Plant Portraits.

THE *Botanical Magazine* for May contains a figure (t. 7172) of the trunkless *Yucca rupicola*, a native of western Texas, where it was first discovered by Lindheimer, and of northern Mexico as far south and west, at least, as Chihuahua. It is one of a group in which the leaf is margined with minutely horned teeth, and is a showy plant in flower, although, unfortunately, it has not proved hardy in northern gardens. It is interesting to note that it has now flowered in England in the open air—in the garden of Canon Ellacombe, at Bitton.

There is a figure of *Hermannia cristata* (t. 7173), a native of southern Africa, and rather a weedy-looking subject, although it is said to deserve a place in any conservatory, but which, however, is rather botanically curious than horticulturally beautiful. It is interesting in that it differs from all the other species of southern Africa, where the genus is very largely represented, and in approaching an American species, *Hermannia Texana*, in the broad crest of the capsule.

Wahlenbergia undulata appears on t. 7174. This is a widely diffused species from the Transvaal to the Orange Free State and southward to Plettenburg Bay, ascending an elevation of 6,000 feet on the mountains of Natal. Our correspondent, Mr. Watson, who visited southern Africa a few years ago and who brought home seeds with him, speaks of it as "growing in masses in marsh-lands, the stems supporting one another, and the whole forming a beautiful picture, suggestive of a group of Campanulas." It is said to be well adapted for pot culture as a hanging plant, as the branches descend on all sides, with ascending tips loaded with bright blue flowers.

There are figures also of *Pitcairnia Roezlii* (t. 7175), one of a large number of Pitcairnias with red flowers, which resemble one another closely in habit and structure. The species here figured is said to be one of the finest of them all; it is distinguished by distinctly petioled and comparatively broad leaves and long simple racemes of bright scarlet flowers, remaining in perfection for a long time. It is a native of South America.

Cœlogyne Rossiana is figured on t. 7176. This is a native of Burma, and a not very showy species, although, as the editor points out, of considerable botanical interest.

Foreign Correspondence.

London Letter.

L'Horticulture Internationale, Brussels.

THIS powerful nursery company was founded four years ago on the nurseries of Monsieur John Linden, who had built up for himself a great reputation in Ghent, where during the greater part of half a century he occupied himself with the introduction and cultivation of beautiful exotic plants of all kinds. What Veitch, Low and several others were to English, Linden was to Belgian horticulture. But Ghent is provincial, and Monsieur Linden felt that Brussels could afford much greater opportunities for the success of his enterprise. His anticipations have been more than realized, for not only does his "Société Anonyme" include some of the most influential and the richest of Belgian amateurs, but the result of his venture has been to create among the wealthy residents in Brussels, as well as in Belgium generally, a love for Orchids which now bids fair to become at least as far-reaching as it is in England.

The director of the company is Monsieur Lucien Linden, his father retaining control only over the collecting and introducing of new plants. The nursery is very extensive; it is almost entirely devoted to the cultivation of in-door plants, and is planned in such a manner as to afford the best possible conditions for the healthy growth of the plants and at the same time the most enjoyable "show-room" for visitors. From the entrance to the stoke-holes everything in the establishment is in most admirable order, so that whether the visitor is inspecting the gigantic Palms and Tree Ferns in the corridors, the tropical Orchids or the admirably fitted workshop in which packing, cleaning, potting, etc., are performed, he cannot help being struck by the excellent order and cleanliness which prevail everywhere in this well-organized establishment. The nursery is a gigantic drawing-room, for it teems with beautiful objects which may be inspected with perfect ease and enjoyment. In my opinion, this nursery is one of the very best of the many attractions which the beautiful town of Brussels offers to visitors.

So much for L'Horticulture Internationale as an exhibition. The attractions for cultivators of exotic plants are, at least, as great as those of any other nursery known to me. The collection of Orchids is very extensive. All the best garden kinds are grown in enormous numbers and grown wonderfully well. Odontoglossums, Masdevallias, Cattleyas, Lælias, Vandas, Aërides, Dendrobiums—these are represented by thousands of plants, and all so full of vigor that one can scarcely refrain from purchasing. The houses, of which there are about thirty, are all very large, some exceptionally so. They are lightly built, with stages running close to and parallel with the roof-glass; the floor is of fluted tiles, and beneath the stages there are open tanks of soft water. The material used for shading is thin lath-blinds, so constructed as to allow the rays of sunshine to reach the plants directly, but never to shine on any one point long enough to burn. The compost used for almost every one of the Orchids is a mixture of finely chopped sphagnum, and chopped peat formed of the roots of Polypodium, not the Brake Fern commonly used in England. Water is supplied much more liberally than one usually sees, even for Orchids, some of the plants, such as Odontoglossums and Vandas, being liberally syringed overhead several times a day, even in spring. These are the conditions and material, so far as I could discover, which produce such marvelous results in this nursery. There remain still the skill and judgment of the cultivator. Monsieur Linden is his own grower, but he knows the wisdom of having a large staff of permanent assistants. Very few of the men employed by him are what are termed journeymen.

I must not overlook one very important item in the cultural arrangements of Monsieur Linden, namely, the use of tobacco to keep down insect pests, the curse and ruin of the large majority of Orchid collections. Tobacco is an old insecticide, but it is not often applied as Monsieur Linden applies it. In every house, resting upon the hot-water pipes and held in position by means of wire netting, is a layer of the refuse stalks and midribs of tobacco leaves, which, in Belgium, can be obtained at about seven francs the hundred kilos. This is wetted once or twice a day and the vapor which arises is consequently impregnated with nicotine, which permeates the whole atmosphere in the house and is inimical to insects. It does no harm to the most delicate plants, but it keeps down insects so well that Monsieur Linden finds it scarcely ever necessary to clean his plants. In this manner much labor is saved and the plants are kept clean. Moreover, the injury which is the almost inevitable result of scraping and sponging the leaves of delicate Orchids, is altogether avoided. In England tobacco is too expensive to be used in this way, but it would not be difficult to devise some means for obtaining the nicotine cheaply and in such a form as would satisfy the excise authorities. These are small details, perhaps, but upon them a great deal more depends than many growers imagine.

There is a house with about five thousand magnificent plants of *Angræcum sesquipedale*, only a few months imported, but as healthy in foliage and vigorous in root-action as though they had been there for years. Then a huge houseful of *Lælia purpurata*, many of them grand specimens. A large batch of healthy plants of *Saccolabium cœleste*, one of the most beautiful of blue-flowered Orchids, was pointed out as "all that remained" of a very large and successful importation of that very bad traveler. Of Odontoglossums I saw some of the most beautiful species and varieties that it has ever been my privilege to see. Their names were legion, their value, in many cases, almost fabulous; about their exquisite beauty there could be no question. It was abundantly evident from what I saw that Monsieur Linden had "struck a particularly rich vein" of *Odontoglossum crispum*. His recent great success, *Cattleya Warocqueana*, which he insists is the autumn flowering *C. labiata*, is revealed in an astonishing range of richness of variety, both in habit of plant, form of flower and in color. As a garden Orchid it is of the very highest merit, being a vigorous grower, and flowering with great freedom even for a Cattleya. Monsieur Linden pointed to the few plants which remained of the thousands he began with as a proof that Orchid fanciers had discovered the beauty and value of this Cattleya.

A house containing several thousand plants of Dendrobiums from northern Australia, all in splendid health and most of them coming into flower, was pointed to with pride by both

Fig. 44.—A Young Swamp White Oak (*Quercus bicolor*) in Winter.—See page 241.

the veteran Monsieur John Linden and his son, as being likely to reveal some treasures in the way of *D. Phalænopsis*, *D. Goldieana*, etc., before very long. A big batch of *Cattleya Buyssoniana*, another of the new *Coryanthes Bungerothii*, another of *Grammatophyllum Ellisii*, and still another of the new Bornean *Cœlogyne peltasites* followed each other in rapid succession. These may be taken as an example of the richness of the collection which was revealed as we walked through one house after another; they also are evidences of the enterprise of this company in the work of introducing new plants, for in these plants we have new discoveries made by Monsieur Linden's collectors, and under his directions, in Australia, Borneo, Madagascar and South America. At present there are five collectors employed solely in the search for new plants, two others being told off to look after those which are in great demand, such as Odontoglossums and Cattleyas.

Smaller houses contain many rarities such as delight the eye of the connoisseur in Orchids. I noted in them living plants of the beautiful Telepogons, which are certain to rival the best Masdevallias if they can only be induced to stay with us. *Trichoceras muralis*, *Lissochilus giganteus*, *Hæmaria Otleta*, a prettily veined ally of Anæctochilus, *Cattleya Rex*, which Monsieur Linden declares is the most lovely of all Cattleyas, and which has been seen by his collector with fourteen flowers on a spike. *Cattleya Gibezi*, the white variety of *C. superba; Odontoglossum Leopoldii*, one of the most beautiful of recent discoveries. I might go on to enumerate all the best Orchids hitherto described, and add to them nearly fifty new ones as yet undescribed, but here growing under Monsieur Linden's watchful eye, and even then I should not have exhausted the list of interesting Orchids to be seen at this nursery.

Although Orchids are the principal plants, there are many others which are objects of Monsieur Linden's special care. Nepenthes of all kinds are grown in large numbers, a large house being entirely filled with them, so far as roof-space is concerned. Stove plants of the choicest kinds, such as Aroids, Palms, Ferns and many flowering plants, are represented by many beautiful species, a considerable number of them being quite new. Monsieur Linden has decided to pay particular attention to this class of plants, which have lost considerably in popular favor, chiefly because collectors have neglected them for Orchids. He has already secured a large number of new things, which, unless I am very much mistaken, are certain eventually to meet with general favor among lovers of exotic plants. At present I can only refer to them thus vaguely.

By their work in the introduction and distribution of plants alone the Messrs. Linden have won for themselves a reputation of the very highest standing among European horticulturists. Besides this, they have enriched the literature of the garden by their publications, of which *Lindenia* is the most meritorious, the *Illustration Horticole* and the *Orchidophile* being also useful to practical men. Monsieur Lucien Linden has also invented a boiler for heating plant-houses which is likely to become a powerful rival to the best of boilers in use at present. It may be described as a combination tubular and saddle, with an arrangement which insures the exhaustion of all the fire-heat before it leaves the boiler, and the economy of fuel. For large structures, where much piping is necessary, this boiler is likely to become popular.

To those who want to look at all the best Orchids grown, as only few can grow them, I would recommend a visit to Monsieur Linden's establishment. Altogether this nursery is one of the most instructive as well as one of the most delightful to be found in Europe.

London. *Visitor.*

Cultural Department.

The Abuse of Insecticides.

GREAT things are evidently anticipated, all over the country, from the use of insecticidal poisons in Orchards, and upon many of our small-fruit plants. There is also a strong disposition to use mineral poisons as fungicides. I am by no means disposed to make objections to any proper and necessary use even of arsenical preparations, when they are not applied directly to the edible product of our orchards and gardens. I am fully prepared to allow that they may be so used, and that no traceable evils will be noted, perhaps for a long time, if ever. I will admit even, that a small quantity of arsenical spray, falling upon green grass, will not be likely to cause any marked effect upon the health of the animals fed upon either the grass or the hay made from it. It may be true that in many cases nothing short of spectrum analysis will show the presence of arsenic in such food. But, nevertheless, arsenic is a very dangerous substance to introduce into the food of man or beast, even in minute quantities. This is fully proved by the many cases of poisoning from inhabiting rooms papered with arsenical papers. The symptoms of this form of poisoning are so very obscure that even the most skillful diagnosticians may fail to recognize them. On the other hand, I will allow that too much has sometimes been made of the danger arising from this cause. With all reasonable discounts called for by these admissions, hundreds of tons of a most virulent mineral poison in the hands of hundreds of thousands of people, to be freely used in fields, orchards and gardens all over the continent, will incur what in the aggregate must be a danger worthy of serious thought.

As for myself, I have decided that I cannot consent to the use of arsenical sprays in my orchards, either as an insecticide or a fungicide. I have no doubt at all that they can be made effective in the destruction of some of our worst insect pests, especially the codlin moth, the curculio and all leaf-eating species. But there are other effective means within our reach, and without the use of these sprays we may still easily supply, and even overstock the markets with fine fruit in all except such very exceptional seasons as last year. The careful grower should be very cautious in the use of this class of remedies. What will be the effect on consumers when it is widely understood that arsenical sprays are in general use in American orchards?

The codlin moth is rather a benefit than an injury in well-managed orchards. Without them our trees would be overladen, and even with their help, thinning by hand is often imperative. True, the moth makes no discrimination in depositing her eggs, and the worms infest the largest and finest as well as the inferior fruits. But still there is enough for the market, and if all orchards were even fairly well managed there would be a large surplus for export in all but the very worst seasons. As for other insects, like the curculio, which may be met and foiled by simple mechanical means, no other method is needed. Plum-growing is really made more profitable to reasonably active growers by these little beetles, and, without the curculio, plums would soon become too plentiful to be profitable, except in the case of the very finest fruit. In the highest interests of orchard-industry, therefore, I hope it will be seen that the direct application of this substance to fruit-trees, after the formation of the fruit, had better be avoided, at least until its necessity is more fully established.

Newport, Vt. *T. H. Hoskins.*

The Influence of Stock upon Cion.

ABOUT a year ago a large number of experiments in herbaceous grafting were performed by a student under the direction of Professor Bailey, and, among others, a trial was made of grafting a portion of a half-grown Dwarf Champion Tomato upon a similar fruit of the Ignotum variety, from which a corresponding piece had been removed. In habit of growth, as well as in fruit, the Dwarf Champion is very distinct from the Ignotum; the former has thick and short-jointed stems, thick, crumpled, dark green leaves, and the fruit has a distinctly purple tinge; the Ignotum is similar in character to the common red varieties. The two parts of the graft united and grew to maturity, after which the seeds were removed and planted, care being taken to keep the seeds of the two halves, stock and cion, separate.

The results obtained from the seeds of the cion half of the fruit, the Dwarf Champion, were very striking; so surprising, indeed, that it was decided to distrust the accuracy of the records of the experiment until it should be confirmed by further trials. Soon after their appearance above ground the plants from these seeds began to show some of the characteristics of the stock. As the plants developed, this resemblance to the Ignotum increased until at maturity both the plants and the fruit which was produced were indistinguishable from the pure Ignotum variety.

The interesting development of this experiment led to its repetition during the past winter, the work being carried on by means of the Tomato-plants growing in the forcing-houses of the Experiment Station. Of the grafts thus made a part were Ignotum upon Dwarf Champion as a stock, the reciprocal of that mentioned above, and from the seeds of the cion half young plants are now growing which again show a very decided influence from the stock, being plainly intermediate in character of leaf and in habit between the two varieties,

thus confirming to that extent the observations made during last year's experiment. The further developments of the plants and their fruit will be looked for with great interest, since, among the many forms of grafting which have been practiced in the past, few, if any, records are to be found of such a preponderating influence of the stock.

Cornell University. *C. W. Mathews.*

Lima Beans.

THE Bush Lima Bean known as Henderson's, while quite small, is enormously productive and of fine quality. It is remarkable how quickly other varieties of this form of Lima Bean have appeared since the advent of Henderson's. This year Dreer's Bush Lima Bean is placed on the market. The seeds look like the ordinary form of Dreer's Lima Bean, and, if as good as this, will be valuable. Lima Beans have been very uncertain and unproductive in the south, while Dreer's always did well. We have another form of Lima of bush habit. These are larger than Henderson's and larger than the old Sieva or Butter Bean of this section. The seeds are handsomely mottled like the Golden Wax Bean, some of them almost as dark as Scarlet Runners. This is possibly a cross with the latter kind, as the blooms are said to be pink. There are two forms of this Bean, one a climber sent by a North Carolina grower, and the other said to be dwarf, and sent by a Georgia seedsman. Henderson's Bush Lima was also of southern origin, having been raised in Campbell County, Virginia. The prospect is that soon all tastes can be suited with bush varieties, and poles will no longer be needed. One of the greatest advantages of these Bush Limas is the fact that most of them are earlier than the pole sorts, so that the season for this vegetable at the north will be much lengthened.

Raleigh, N. C. *W. F. Massey.*

Spring Garden Notes.

THIS spring has proven the most successful season with us in the cultivation of Irises. A dozen roots of *I. Susiana* were purchased in the fall, and these were planted in deep pans and placed in a cold frame; they were often frozen during the severe winter, but they started to grow, and recently bore eight large flowers. After flowering the foliage dies off rapidly. The pans will then be placed in a frame covered with a sash, where they will receive a thorough drying off. In the fall, when signs of growth are apparent, they will be repotted and treated as before. Any one having a cold frame can grow this plant.

Tulipa cornuta is in flower in the border. Its petals are yellow, striped with red, and are long, very narrow and erect. *Anemone coronaria*, the Saint Bridgid strain, are flowering fairly well in an open border, where they were planted in November last, and covered with dry leaves. When the leaves were removed this spring many had already commenced growing, and since then others have come up. There is no doubt that frame-culture is best for them in Massachusetts, but our frames were all filled when the Anemones came to hand. They were imported direct from Ireland, where the St. Bridgid's strain originated, and where I have had the same strain in bloom in the open border every week of the whole winter. The practice was to sow seeds in the spring for the next winter's flowers; in the moist climate, with very little frost, they were almost evergreen, and flowered abundantly, especially in spring. Anemones require a rich, well-drained soil and early fall planting.

Puschkinia Libanotica.—It is a matter of surprise to me that this desirable plant is not better known. It blooms earlier than the Chionodoxa or Scillas, and, to my mind, is prettier than the Chionodoxa. *P. compacta* is said to differ from the type in having more flowers to a stem. The flowers are like little white bells with a blue stripe down the centre. The Puschkinia is as easily grown and naturalized as the Scilla or Grape Hyacinth. Those who want a showy and easily cultivated spring-flowering plant must not forget the *Mertensia Virginica*. We planted a lot of collected roots last fall which came from Iowa, and they are now vigorous and every one is in flower. The Mertensia should, I think, be planted in the same way as the Oriental Poppy, in patches or clumps, as both die down at midsummer. Annuals may then be planted over them to cover the bare ground. Hardy Cypripediums brought on in pans to flower at this time are a great success, especially *C. spectabile*. We use fourteen-inch pans, with plenty of soil, and these hold six to eight crowns. Many of the stems are bearing two well-colored flowers each. There was a fine exhibit of this plant at the spring show in Boston, by Mr. Jackson Dawson. It is not generally known how easy it is to have an Orchid that will rival any of the exotic Cypripediums in its delicate coloring, or we should not be able to buy good strong collected roots of *C. spectabile* at six cents each. *Cypripedium pubescens* and *C. parviflorum* have also done well, but they do not equal the showier species. All these Cypripediums force well year after year, but as much care must be taken of the plants after the flowering period as before.

Spiræa (*Astilbe*) *Japonica* is a good plant for forcing. It does not seem to be generally known that the variegated variety, besides having leaves variegated with golden yellow, has also spikes of flowers that are much more dense and compact, while equally as graceful as the typical variety. It lasts longer, and is altogether a better plant for room decoration and for cutting purposes. It is easily obtained in the fall from dealers and growers in hardy plants. Home-grown clumps of Astilbe give much better results than imported ones, as the buds that contain the flowers get badly bruised in transit.

S. Lancaster, Mass. *E. O. Orpet.*

Musas.

THIS handsome group includes several species and varieties of value for conservatory decoration where space is ample, and during the summer some of them are also useful for out-door tropical effects, for which their bold leaves make them particularly desirable. When planted outside, however, the Bananas should have a somewhat sheltered position, for when exposed to the full force of the wind the leaves are often split and torn. These plants are gross feeders and enjoy rich soil, and respond to liberal treatment generally. Another point in their favor is, that they are but little subject to insect pests, unless surrounded by infected plants of other species.

The true Banana, *Musa sapientum*, is rather too large a plant to be included in a small collection, but the variegated form of this species, *M. sapientum vittata*, is an extremely handsome one, and is not quite so rampant in growth as the type. This variety is perhaps the most striking member of the genus, the leaves being oblong in form and the ground color bright green, on which are many stripes and blotches of white. The fruit is of little value, but when planted out in a warm house, and at the same time encouraged in growth by a moist atmosphere and plentiful watering at the root, it makes a very effective specimen. The propagation of this form is accomplished by means of suckers, which, in common with most of the members of this genus, it produces in moderate number.

The Chinese Banana, *M. Cavendishii*, is quite dwarf in habit, and has been frequently fruited under glass, for when full-grown it seldom reaches more than eight feet in height, and has often been fruited when about six feet. Its leaves are from three to four feet long and one to two in width, forming a rather compact head of dark green color, and the stem is quite stout in proportion to its length. *M. Cavendishii* is also propagated by means of suckers, the latter being thrown up at the time of fruiting, and frequently before this occurs.

M. coccinea is another highly ornamental species, and was introduced from Cochin China many years ago. This species is of comparatively slender growth, and has bright green leaves about three feet long and six inches wide, the entire height of the plant being from four to six feet. The most striking feature of *M. coccinea* is the flower-cluster, which is terminal and about one foot long, and covered with spathes of bright scarlet, making it the most showy member of the genus in this respect. It may be well grown as a pot plant if it be not convenient to plant it out, by giving it a little extra stimulation in the form of liquid manure from time to time.

The Abyssinian Banana, *M. Ensete*, is now well known as a plant for decorative use, either in-doors or out, and is grown from seeds in quite large quantities in some commercial establishments. This is probably the largest species of this genus, the stem sometimes reaching a height of twenty feet, while the leaves are truly immense. The latter are bright green in color, with a red midrib and stem, and stand out boldly in a semi-erect manner. The fruit of this species is of no value except to furnish seeds, these forming the only means of propagation, as *M. Ensete* does not produce suckers. *M. superba* is also a strong-growing species, and bears some resemblance to the preceding, though possibly more compact in habit, and is a native of India. The two last-mentioned are the best species to use out-of-doors, their leaves being tougher than those of most of the others, though *M. Cavendishii* may also be used in this manner if it has not been grown in a close, warm house just previous to removal outside. *M. zebrina*, also from India, is another handsome foliaged species, the

leaves of which are oblong in shape, and dark green in color, irregularly blotched with bronzy red and purple. The stem of *M. zebrina* is slender, and the plant seldom exceeds ten feet in height. Its peculiar coloring makes it an admirable contrast when grown in company with *M. Sapientum vittata*.

There are some eighteen species in all, but those specially referred to are the most useful for decorative purposes, and are all worthy of more extended cultivation.

Holmesburg, Pa. *W. H. Taplin.*

Gypsophila paniculata is one of the indispensable hardy plants, and seeds of it may now be sown. It should be grown in clumps, and, being furnished with long tap-roots, which make transplanting difficult, it is well to sow seed where the plants are to remain. The seed germinates readily, and plants sometimes show bloom the first season, or, in any case, make strong growth before winter. They are usually reliably hardy, and come into bloom in May and June in many-branched racemes of very small, fine, white flowers. Plants in flower are very pleasing, being covered with a mist of bloom. But it is for bouquets that they are of the greatest value, in their ability to blend and harmonize almost any gathering of seasonable flowers. While a cluster of one variety of flowers with their own foliage, properly arranged, is often the most satisfactory floral effect for vases, there is no reason why a varied collection should not be equally effective. Often, however, one finds, after gathering flowers with good long stems, that they do not seem, for some reason, to "compose" well. In such cases it will be often found that a cluster or two of light, small flowers will give the finishing touch to the arrangement, amalgamating the differing forms into a consistent and graceful group. *Gypsophila paniculata* will give a supply of early flowers, while later the Statices may be grown for the same service. *S. latifolia* is probably the best of the hardy ones, the flowers being very lasting. The little dwarf-growing Baby's Breath (*Gypsophila muralis*) is a dainty little hardy annual, which may be used for the same purpose, and is a beautiful front-border plant, where it will perpetuate itself if the border is undisturbed. The florist in early winter grows Stevia to lighten his bouquets.

Iris pumila alba is a light-colored form of the old purple *Iris pumila*, so common in gardens. Like the type, this plant is very hardy and very dwarf. The color is a faded, uncertain yellow rather than white, resembling in effect somewhat, though lighter in color than *Iris chamæiris*, the latter being very slightly taller.

Elizabeth, N. J. *J. N. G.*

Salsify should not be sown too early. It is a plant of very hardy character and germinates quickly. The result is, when sown so early, growth is checked by the hot weather of midsummer, the lower leaves die and many of the plants run to seed. The roots do not attain their best size and become tough and stringy before they mature. The sowing should be deferred until June, in ground that has been well manured for early radishes, beets, or spring spinach. Here and southward Salsify, sown in August, will make a better crop than if sown in the spring, as it will continue to grow until Christmas. Last summer one of my neighbors was obliged to change his residence about the middle of August. He sowed a plot of Sandwich Island Salsify in his new garden, and the result was the finest Salsify that I saw last year. People here are slowly finding out the value of their long temperate autumns, and I think the time is not far distant when, by later sowing and transplanting after the hot weather is gone, we can grow good fall Cabbage. Early sowing, starving through the long summer heat and drought, has brought about the tall-stemmed Collard, and from this Collard, with proper treatment, we will yet get the Southern Cabbage.

Tuberous Begonias are of special value here, for we find that the tubers are hardy and increase in size and vigor with slight protection. It has long been known that the old *Begonia Evansiana* is hardy almost anywhere with slight protection, but it is gratifying to find that this is also true of the showy and constant blooming sorts of recent introduction.

Amaryllis.—A bed filled with various Amaryllis is a very interesting object. The early blooming Atamasco, which has been making acres of woodland here gay for weeks past, is the earliest one to appear. This variety forms the outer edge, while the centre is filled with exotic species and an imposing clump of Johnsonii. This bed is on a sheltered lawn with no special winter cover, and the perfection of the great masses of Amaryllis gives one a new idea as to the hardiness of these bulbs.

Raleigh, N. C. *W. F. Massey.*

The Forest.

Redwood Timber.—II.

ANY estimates of the value of bodies of Redwood over three hundred acres in extent, which place the amount which can be taken off at over 100,000 feet per acre, are misleading, as even that amount is exceptional, and not to be had except by following water, instead of Government section, lines.

By far the larger part of the Redwood lands have passed from Government to private ownership. In Sonora, Mendocino and Humboldt Counties scarcely any good claims are not titled. By the Timber-land Act citizens could buy 160 acres at $2.50 per acre. A few years ago there was a perfect craze for this class of property, and immense quantities were purchased from the Government. Every one who could get the money took a timber-claim. Men who made a business of it located claims for hundreds. In the course of time the original purchasers have usually sold to mill companies or speculators, who are buying to hold as a long-term investment. Still a very large quantity in the aggregate is owned in tracts of 160 acres by persons who live on their land, selling pickets, trees, tan-bark, etc., and having a small area available for pasture, agriculture and fruit-raising. The Redwood soil produces the best of fruit, especially apples, and many comfortable homes are to be found in the forest.

The holdings of the mill companies range from a thousand acres upward, and are of extra fine selections, which have been bought from time to time. The men who are buying for investment also select the best, carefully inspecting all purchases, and some large buyers have all the forest scaled. Among the largest investment buyers are the "Scotch Syndicate," who have secured a very large area at Humboldt Bay, and several Michigan and Wisconsin companies.

A few figures as to the largest ownerships in Mendocino County may be interesting. The Fort Bragg Company own 70,000 acres; The Navarro Company, 35,000; Big River Company, 32,000; Gualala Company, 18,000. In Humboldt County the Scotch Syndicate is credited with 80,000 acres.

Redwood lands are held at from $5 an acre upward. Outside of exceptional locations, valuable from proximity to a railroad or tide-water, or of extra heavy timber, $5 an acre is a fair price, while claims are held as high as $40 an acre. Of the vast quantity that has changed hands in recent years far the greater portion has brought from $4 to $6 per acre, and any quantity of Redwood lands which will cut from 30,000 to 40,000 feet an acre, and which are within twenty miles of tide-water, can now be purchased at $6 per acre. Indeed, they are cheaper than they were a few years ago, because so much is owned by parties who cannot afford a long-term investment, and who are anxious to realize. If the quantity of land available for the use of the mills were limited, the land would be worth from $70 up, on the basis of usual stumpage, but the vast possessions of the mill companies make them independent, and timber-land on those streams can only be regarded as a long-term investment. The exhaustion of the forests east of the Rockies, in the future, with the great growth in population in California, will doubtless considerably accelerate the rate of cutting. At the present rate of cutting, the forest, if protected from fire, would almost reproduce itself before this growth is cut. The vitality of the Redwood is wonderful. From every stump hundreds of sprouts grow, and with great rapidity. In old clearings quite large trees are to be seen of the new growth.

The forest-fires do little or no injury to any but very small trees, but the seedlings coming up through the leaves, and the sprouts from the stumps, suffer, and although they reappear with great vigor, repeated burning finally destroys the life of the stump, and the Redwood charring grows up a tangle of Ceanothus, known as the "Blue Blossom" (*Ceanothus thyrsiflorus*), and only the blackened stumps testify to the once great forest. If forest-fires were prevented, no forest would be more easily perpetuated. Although the Redwood seeds freely, the number of seedlings to be found in the forest is very small. The Redwood in log is practically indestructible. Fallen trees will lie generations without decaying, and such trees are always cut up and sent to the mill. I have seen logs on which mold had gathered and good-sized trees grown, which were perfectly sound and good for lumber. To fire, as well as decay, these logs are invulnerable if sound. It is only when a tree is shattered in falling, or when a rotten heart gives the fire an entrance, that it can make any serious impression. When logging is done by water, the butt-cuts, which are too heavy to float, are left on the ground for several years to dry out, and, although the ground is burned over several times, are uninjured.

The first saw-mills were built in the redwoods in early days. That at Mendocino City was established in 1850, and has been in continuous operation since, with a present cutting capacity of 60,000 feet a day. This company gives a good illustration of the rate at which cutting progresses. It owns 35,000 acres on Big River, or less than half the water-shed. In its forty years' operations it has cut over less than ten per cent. of its own lands. Most of the large companies have been in operation from twenty to thirty-five years, and several have cut a smaller percentage of their timber than the Mendocino company. On the other hand, all of the timber on some small streams, two to five miles long, has been cut, and the mills moved to new locations. The exceptionally large logs, and the steepness of the slopes, give rise to methods of working peculiar to the Redwood industry. The mills are well equipped, and everything at the mill is utilized for which there is a market. In the woods the waste is large.

Oxen are used altogether in the woods, and logging is summer work. For the wood-roads skids are used, which are either greased or kept wet by water-carriers. From three to five yoke of oxen drag several logs attached by dogs and chains. In a few instances slides, or, as they are called here, chutes, are used. The tidal estuaries are used for dams, and a boom keeps the logs in. Redwood-trees have a bulge at the base, and in cutting large trees a staging is built around the base and the trees cut at ten to twelve feet from the ground. Very narrow, long-bladed axes are used by the woodsmen. The thick bark is peeled off before the logs are hauled. As sawdust cannot be dumped into the streams, it is burned in large furnaces. Logs above seven feet in diameter are blasted.

Ukiah, Cal. *Carl Purdy.*

Correspondence.

Are Plums and Cherries of one Genus?

To the Editor of Garden and Forest:

Sir,—The question is not raised with any view to a full discussion of the subject. If read with due consideration as to the meaning of the word "genus," there will seem little room for discussion at all, for it will readily appear as carrying with it its own negation. Each of the two principal terms of the query, as an English word, is simply and absolutely generic. Each calls to mind a natural group of trees and shrubs, and the two groups are so thoroughly distinct that neither orchardists nor botanists have ever in reality confounded them. No one has said that Cherries are only a sort of Plums, or that the Plums are merely so many species or varieties of Cherries. The qualities of the wood, of the bark and of the fruits of the two are so dissimilar, and their natural constitution, as indicated by their refusal to hybridize with one another, is so different that no man, learned or unlearned, ever thinks of them as congeneric. Nevertheless, some learned botanical theorists, under the disguise of a Latin nomenclature, have pronounced them to be of one genus. Prunus is the Latin equivalent of Plum or Prune, and Cerasus of Cherry, and some authors, dropping Cerasus out of their list of generic names, have named all the Cherry species as species of Prunus. This, in spite of the disguise, may clearly enough be read as a theoretical endeavor to make Cherries over into Plums, but that this is an artificial, not a natural classifying of these well-known trees is attested by the fact already alluded to, that the simple, every-day intelligence of men, whether botanical or unbotanical, has never regarded the two as congeneric. The trees have been under cultivation with nearly all civilized peoples from ages almost prehistoric, and there is yet no dialect of human speech in which they have but one term in use for these two kinds (genera) of trees.

It is not my purpose now to name in order those several distinctive peculiarities upon which many of the most eminent botanists, as well as the common judgment of all unbotanical people, have regarded the Plums and the Cherries as generically distinct. But having read, in a somewhat recent issue of this journal (page 180), that the limiting of the genus *Prunus* to the Plums, and the genus *Pyrus* to the Pears (excluding the Apples as a separate genus, *Malus*), is essentially at variance with the views of "most botanists," it has seemed desirable that a few hints of what may be said on the other side of the question should here be given.

The assertion that most botanists have held Plums and Cherries to be of one genus we judge to have been made without forethought; and only a passing review of leading authors is needed to show it erroneous. Of course we do not in scientific matters decide the merits of an opinion by the number of names of men who, figuring as scientists, have at one time and another subscribed to it. The greater number of botanical authors in every generation are, in so far as their systematizing goes, mere disciples of others. Their own opinions upon the limits of genera have no weight; they have, indeed, no opinions not borrowed. Let us see upon what solid strength of authority one may lean—from what illustrious masters one may have borrowed the opinion when he reiterates it, that the Plums and the Cherries are generically different. The following could hardly be objected to as a fair list of names of the supereminently original men who have figured prominently in the history of plant classification within the last two centuries: Ray, Tournefort, Dillenius, Bœrhaan, Haller, Linnæus, Adanson, Jussieu, Gærtner, Necker, De Candolle, Robert Brown and Salisbury. Only three of these thirteen taught that Plums and Cherries were all of one genus, and they were Linnæus, Gærtner and Brown. And I suppose that any well-read botanist of our time, if asked to name the four greatest of these thirteen, would be likely to select Tournefort, Linnæus, Jussieu and Adanson; and of these Linnæus alone would stand sponsor for the opinion that Cherries are only another sort of Plums. The doctrine originated with him. And if, coming down to our own day, we find in the majority of compiled floras and small hand-books the Linnæan extension of *Prunus* maintained, it is also true that in the most elaborate recent monographs of this family *Prunus* and *Cerasus* are held distinct; and so are *Pyrus* and *Malus*. I need only mention the names of Rœmer, Spach and Decaisne, whose treatises upon these plants, unsurpassed in scholarliness, must be in the hands of all who wish to attain to the fullest understanding of the subject. In America, at least in the western part of it, all our native Cherries were first described—some by Nuttall, others by Sir William Hooker—as species of *Cerasus*, not as sorts of Plums; and Asa Gray, in what is, after all, one of the finest monuments remaining to us of his great ability, the "Flora of North America," conforming to that opinion, which has the support of the most splendid array of great names, retained *Cerasus* for the Cherries and *Prunus* for the Plums, though in more recent works he accepted the unnaturally extended *Prunus* of Linnæus.

But still, everywhere outside the technicalities of the most artificial systematists, it is conceded that Plum and Cherry—*Prunus* and *Cerasus*—are generically distinct. Whether the lines of demarcation between the two will ever be so strongly drawn in the set terminology of botany as to satisfy the requirements of artificial systematists is unimportant. All men, without exception, when speaking in their mother-tongue, and the most weighty authorities upon natural classification in the plant-world, even in their Latin, salute the Plum-trees as one genus, and the Cherry-trees as another.

University of California. *Edward L. Greene.*

Southern Mississippi Floral Notes.

To the Editor of Garden and Forest:

Sir,—To one new to the south the flora of the Gulf shore of Mississippi is full of interest as early in the season as the first of May. The spring flowers have finished blooming, and Orchids are seen in profusion. Even from the car-window it was evident that lower Mississippi must be the home of the Polygalas. Chapman gives twenty-two species in his flora, and the most showy of them are now in full bloom here. The two most conspicuous are *Polygala lutea*, sometimes called "Bachelor's Button," with its orange-yellow flowers in dense spikes, scattered everywhere in the grass-land. More than any other plant, this reminds one of the Pine-barrens of New Jersey, where it abounds later in the year. *P. nana* is less abundant, with beautiful lemon-yellow spikes; the flower-stalks are very short. Among the other Polygalas now in bloom may be mentioned *P. incarnata*, *P. polygama* and *P. Chapmanii*. Everywhere in the grass beneath the tall, scattered, spectral, southern Pine-trees is the showy *Phlox divaricata*, with a tint of pink that at first leads one to take it for *Calopogon pulchellus*. Both of these plants flourish near each other, the latter in low wet places.

The two other Orchids most common in the moist places are *Pogonia divaricata* and its close of kin, *P. ophioglossoides*, each equally abundant and beautiful after its own type. These boggy places are full of the showy and peculiar leaves of the yellow Pitcher-plant (*Sarracenia flava*). It is late for blossoms now, but the variegated foliage makes up for any lack of bloom. Two Sundews frequent the same localities, the *Drosera rotundifolia* being sometimes so abundant as to cover the wet sand with a carpet of sticky red leaves. More striking than any other of these glistening fly-catchers is the *Drosera*

filiformis, which attains more than a foot in height, and bears a single flower an inch in diameter each day through the blooming season. The long slender leaves unroll like a watch-spring, and the inflorescence in like manner turns fast enough to bring the opening bud each morning to the upper side of the wheel.

As we pass to the dry areas again the two species of Star Grass, *Aletris farinosa* and *A. aurea*, are conspicuously abundant. They are about equal in size with their strict tall stalks, bearing numerous scattered blossoms, but one is a pure white, while the other is an attractive yellow. In the thickets there is a tangle of *Schrankia uncinata*. This plant is so sensitive that it closes its leaflets at the slightest touch of its prickly creeping stems. Overhead the *Magnolia fœtida* exhibits its gigantic solitary white blooms in striking contrast with the multitudes of minute Ilex flowers that cover the shrubs below. Perhaps the two most showy red blooms are those of the *Æsculus Pavia* and the more rare *Erythrina herbacea*, only one cluster of which we have thus far seen.

Ocean Springs, Miss. *Byron D. Halsted.*

How Dandelions Escape the Lawn-mower.

To the Editor of Garden and Forest:

Sir,—A day or two after a lawn has been cut with the mower the long, upright stalks of the Dandelion may be seen. The explanation that the stems have been bent down by the machine and left uncut may be true in some cases, but there is a peculiar habit of the plant that is worth noting here. The flower-stalks of this handsome lawn-weed are usually upright until the time of blossoming is past, when they bend outward and downward, and in from three to five days assume what may be called the "scythe-shape," or a double curve, with the head quite close to the turf. Almost any Dandelion-plant, growing unmolested and with several flower-stalks, will show all stages of this downward curving of the stems.

After the depressed stems have remained apparently inactive for from three to five days the period of rapid elongation begins, when they become upright, and the seed-ball is held several inches higher in the air than were the flowers of the same head a week previously. It will be remembered by those who have observed this matter that it is the seed-bearing stalks that quickly appear after the lawn has been mowed. The flowers are first raised for the attention of insects, then comes the reclined repose followed by the second uplifting, that the winds, this time, may bear away the parachute-provided seeds.

Description et Emploi des Eucalyptus Introduits en Europe Principalement en France et en Algerie. Second Mémoire. Charles Naudin. Antibes, 1891, pp. 1–72.

The first memoir published by Monsieur Naudin upon the Eucalyptus cultivated in Europe appeared in 1883. Since that time the veteran French botanist has continued his investigations, and has been able to study a much larger number of species in the garden of the Villa Thuret, over which he presides, and in which he has brought together the largest collection of these trees which has been formed; and in the present paper he arranges fifty-six of them in synoptical tables according to the shape of the leaves, the flowers and the fruit, so that the cultivator of these trees will be able now much more readily than ever before to determine the different species, which have always proved extremely difficult to understand from the fact that many of them appear entirely different in their juvenile and adult states, producing at first leaves of one sort and then later in life leaves of an entirely different shape and character. To overcome this difficulty in the study of the genus Monsieur Naudin has made a special Eucalyptus herbarium, in which are represented all the species cultivated in Europe, by specimens taken at different periods of their growth, and showing all the different stages through which they pass from youth to maturity. In these studies it may be mentioned that Monsieur Naudin has brought to light among the plants cultivated at Antibes no less than thirteen undescribed species, now first made known in this memoir, a fact which shows the value of arboreta and the importance of studying trees in a living state, where different species can be compared with each other and their differences noted.

A few brief extracts from the general considerations which form the first part of this work will be interesting, perhaps, to our readers, especially as different species of Eucalyptus are destined to play, it seems, an important part in the future of California, where many of them have long been successfully grown. "The most interesting things," Monsieur Naudin remarks, "about the genus from the cultural point of view, is the rapidity with which certain species grow, a rapidity which is unequaled by any of our native trees, and the quantity of wood valuable for manufacturing purposes and for fuel which they can produce in a comparatively short time. To this advantage possessed by these trees must be added that of being able to support themselves much farther south than most of our forest-trees of Europe, even to the southern limits of the Algerian Sahara, although the region in which they can be cultivated is extremely restricted on the north. There are certain species, however, natives of Tasmania and of the high mountains of southern Australia, which will succeed beyond the Mediterranean region, and which can be cultivated on the Atlantic coast as far north as Brittany, and even in the southwest of England. In countries with warm and humid climates, especially in equatorial regions at the sea-level, the introduction of the Eucalyptus has so far been a failure. There is reason to believe, however, that there are certain species of the intertropical regions of Australia and of the Maylaysian Islands which might be expected to succeed even in the tropics. More than a hundred species are now known, and it is easy to understand that from this number there is a considerable choice to be made, according to the usages for which they are intended. Most of the species are forest-trees, some reaching in a comparatively short time a colossal size. Their principal value, then, is the production of timber, although the value of their wood for fuel is almost as great—a quality which will be appreciated in countries where the absence or high cost of coal is a serious obstacle to the production of metals or to the use of steam-engines.

"Two species may be distinguished among all the others for the rapidity with which they reach a large size; these are *E. globulus* and *E. Mulleri;* and they grow much more rapidly than any of the native trees of Europe. In twenty years these trees attain to the size and height of an Oak a hundred years old. Other species, without growing as rapidly, are still remarkable for the short time they require in which to grow to a size large enough to produce valuable material. Such species are *E. diversicolor, E. marginata, E. crebra, E. botryoides, E. robusta, E. leucoxylon, E. Gunnii, E. viminalis, E. rudis, E. corynocalix, E. rostrata, E. gomphocephala, E. cornuta, E. amplifolia, E. tereticornis* and *E. polyanthema*. The wood of some of these species is exceedingly heavy, and might be used to advantage for blocks for paving the streets of cities."

"The climate is not all that is necessary to insure the successful cultivation of Eucalyptus. The character of the soil is important. Many species, it is true, are not particular in this respect; others, on the contrary, are apparently very fastidious, and if the soil is not suitable to them they grow badly or soon die outright, either immediately after the seed has germinated or in the course of a year or two afterward. It is difficult to say with our present knowledge what they need, although experience seems to show that granite or sandstone soils suit them, as may be seen on the shores of Provence, where such soils are the most common. It is also necessary that the soil in which they are planted should be well cultivated and freed of other arborescent vegetation. The Eucalyptus cannot bear the neighborhood of other trees, disputing the possession of the ground and depriving them of the light of the sun. When it is attempted to grow them in the shade, they become drawn up and give unsatisfactory results. No Eucalyptus can grow on land impregnated with salt, and they all suffer when planted so near the sea that salt spray reaches their leaves. Bright light and a free circulation of air is indispensable to these trees, two conditions made necessary by the large amount of water evaporated from their leaves, for it is well known that the Eucalypti exhale a large quantity of water drawn from the soil drained by their roots. Certain species, particularly those which grow naturally in the most arid regions subject to long droughts, store water in their roots and in the lower part of their trunks, which are sometimes enlarged into a sort of bulb, and from which they draw the water necessary for their existence during periods of excessive drought. It is useless to hope that arid rocky hills can be covered with forests of the large Eucalyptus, which require for their rapid growth an abundance of soil."
